One acquired cause for which laboratory testing exists is the antiphospholipid syndrome (APS; see below). Inherited causes of thrombophilia are relatively uncommon, although it is essential to recognize their existence by the presence of thrombosis at a young age, a family history of thrombosis, and thrombosis at unusual sites.

Activated protein C resistance

The most common congenital thrombophilia, especially among Caucasians, is activated protein C resistance (APCR), though it may also be acquired. In short, any mechanism that decreases the ability of APC (i.e., PC bound to its cofactor PS) to inactivate FVa and FVIIIa can lead to APCR. This can be diagnosed through the simple use of the addition of APC to a serum sample. In healthy individuals, this should prolong the PTT, as the exogenous APC will block the formation of prothrombinase. In patients with APCR the PTT will not prolong as the exogenous APC will be ineffective. A ratio of the PTT results with and without APC can be used to determine the extent of the effect. This is also known as the "APCR-standard assay" (APCR-S).

A modified APCR (APCR-M) assay is also available, and is based on the PTT clotting time using plasma treated and untreated with APC and with the addition of factor V depleted plasma—this is also expressed as a ratio of the clotting times similar to that of APCR-S. However, the APCR-S assay is affected by anticoagulation therapy, and is less specific and sensitive for factor V Leiden (FVL) than the APCR-M assay. Although the APCR-S assay has higher sensitivity for acquired forms of APCR, such as seen in pregnancy, use of oral contraceptives, and in patients with APS than the APCR-M assay, the APCR-M assay is less influenced by factor deficiencies, oral anticoagulation, and lupus inhibitors.

The most common congenital form of APCR is the FVL mutation, which occurs in approximately 8% of patients of European decent and up to 90% of patients with APCR. The FVL mutation is specifically the G1691A (DNA), or R506Q (amino acid), mutation of the FV gene. This renders it highly resistant to proteolysis by APC leading to prolongation of coagulation as well as spurious activation. Homozygous patients for FVL are up to 18 times more likely than the general population to develop a thrombotic event, though heterozygous patients are only three times more likely. The APCR-M assay is 99.6% sensitive and 99.7% specific for the FVL mutation. In addition to FVL, there are several other FV mutations and FVIII mutations that can lead to APCR, though reports on the penetrance of these mutations are uncertain. Also, there are reports of an increase serum concentration of FV, FVIII, and FIX in acquired APCR patients, though the significance is currently unknown [12].

Prothrombin G20210A

Prothrombin G20210A (PGM) is a polymorphism in the prothrombin (factor II) gene that is associated with an increased risk of VTE. The carrier frequency is approximately 1.5%–3% in Caucasians. Heterozygous individuals for the mutation have approximately a fivefold increased risk of VTE. The mutation, in the 3' untranslated region of the mRNA, does not affect the protein structure of prothrombin, and the amino acid sequence is unchanged. The mechanism of action of this polymorphism is not entirely clear, but it appears to be related to increased plasma concentrations of prothrombin (factor II). Currently, there are no functional assays for PGM,

and the molecular testing methods available are similar to those available for FVL.

Protein C and S deficiency

The anticoagulant PC and its necessary cofactor PS may each be decreased in patients, which leads to a similar clinical picture of FVL in severe cases. However, these deficiencies will appear only as a low PC or PS upon analysis, and will not show positive results in an APCR assay. Congenital deficiencies are quite rare (<1% of the general population), and are almost always heterozygous, as the homozygous form can be fatal in utero. Those that survive may suffer diffuse intravascular thrombosis as well as massive venous thrombosis. In these patients, either PC or PS will be undetectable. This must be treated with oral anticoagulants, PC or PS replacement, or liver transplant, and the last of which is very rare [13].

Acquired deficiencies are much more common, and have a range of causes. As PC and PS are both manufactured by the liver and vitamin K-dependent, liver failure/insufficiency and vitamin K antagonists are both common causes of acquired deficiency. Sepsis has also been shown to cause PS and PC deficiencies, and PS decreases during pregnancy.

Protein C

Testing for PC in plasma is performed using either a clottable or chromogenic assay. In the clot-based PC functional assay, the patient plasma specimen is mixed with a commercial PC-deficient plasma. A PC activator, usually a snake venom derived from *Agkistrodon contortrix* (copperhead snake) is added to the mix. This will convert the endogenous PC to activated APC. When clotting is initiated through a PT- or aPTT-based reaction, the clotting time is proportional to the endogenous functional PC concentration. The higher the PC, the more the FV and FVIII are inactivated and the more the clotting time is prolonged. The clot-based assays provide some advantages: (1) sensitive to Type I (quantitative loss) and Type II (qualitative loss) PC deficiency; and (2) increased sensitivity for most coagulation instruments, regardless of fibrin clot detection methods. Some of the disadvantages include (1) underestimating PC when FVIII is elevated (>250%), PS is low in the test plasma, FVL is present, warfarin antagonism, or vitamin K deficiency; and (2) overestimation of PC if the test plasma contains heparin, DTI's, anti-Xa, lupus inhibitor, or specific factor inhibitors. An alternative functional PC assay is the chromogenic or amidolytic PC assay. In this assay, the endogenous PC is activated through the action of *Agkistrodon* venom, and the APC is detected by its ability to cleave a synthetic substrate with the release of *p*-nitroaniline. This reaction is unaffected by heparin, antiphospholipid antibodies (APAs), anticoagulants, FVIII, and FVL.

Protein S

As indicated above, PS together with APC binds to the phospholipid surface of platelets or other cells, enhancing the enzymatic inactivation of FVa and FVIIIa. Approximately 40% of PS is found free in plasma, and the remaining 60% is bound to complement system protein C4b-binding protein (C4bBP). Different pathological and physiological conditions can alter the ratio of bound to free PS, thus altering the PC/PS inhibitory pathway. For example, studies have shown that during pregnancy, there is a decrease in the level of PS, with values averaging only 60% of those of nonpregnant controls. Also, acquired PS deficiency can be seen, when there is a decrease in synthesis (hepatic disease, vitamin K antagonists), increase in clearance (acute thrombosis, nephrotic syndrome), and hemodilution. Furthermore, genetic deficiencies are classified into Type I or quantitative defect, Type II or qualitative defect, and Type III or increased binding affinity to C4bBP.

In the functional PS assay, patient plasma is mixed with a commercial PS deficient plasma, and an exogenous PC is added. This will cleave FVa and FVIIIa, provided endogenous PS is present. Once again, clotting is initiated through the PT or aPTT, and the clotting time is proportional to the PS concentration. In some of these functional assays, exogenous factor V is added to the reaction mix; if the patient is heterozygous or homozygous for FVL, the reaction will show increased resistance to APC, which will manifest as a falsely decreased PS. Addition of exogenous normal FV will prevent this problem. Furthermore, very high factor VIII concentrations (typically >250%) can also shorten the clotting time, again leading to a falsely decreased S. In some reaction setups, the factor VIII step is bypassed using activated factor Xa to initiate the common pathway. Any effects that prolong clotting times can falsely elevate the PS in these assays, including very high heparin (>1.0 U/mL), direct thrombin inhibitors including the new oral anticoagulants, and APAs. Antigenic assays (for free and total PS antigen) are available and are generally considered to be more reliable.

Antithrombin deficiency

Much like PC or PS deficiency, congenital defects of AT are rare, also at less than 1% prevalence. AT deficiencies are always heterozygous, as homozygous mutations are fatal in utero. Heterozygous AT deficiency can lead to an approximately 15-fold increase in thrombosis risk, similar to that of homozygous FVL. Two types of congenital AT deficiencies are noted. Much as in other disorders, Type I is a quantitative loss of AT, and Type II is a qualitative loss. Type II can be further subcategorized into (1) reactive site mutations (altering AT interaction with factor Xa and thrombin active

sites); (2) heparin binding site mutations (mutations that affect the binding of heparin to AT); and (3) pleiotropic mutations (mutations that affect multiple heparin binding sites and reactive sites).

Acquired AT deficiency is more common. AT is not vitamin K-dependent, but as it is manufactured by the liver, failure or insufficiency will cause a deficiency, as well as disseminated intravascular coagulation (DIC), nephrotic syndrome, and, during the acute period, a venous thrombosis (consumption). In hospital settings, however, a common cause of acquired AT deficiency is the use of high-dose heparin in settings where consumption is occurring, such as in the case of ECMO patients. Activation of AT by thrombotic events, such as passage through extracorporeal tubes and subsequent binding by heparin, results in an increased clearance from the blood and a drop in serum levels. As heparin requires AT to function, this can likewise result in a similar drop in heparin effectiveness. If not adequately monitored, this can result in catastrophic thrombosis, as both AT and heparin cease to function. In cases of heparin use where AT is falling, supplementation with AT infusion is required if crossover to a different anticoagulant is not possible.

AT functional assays are all chromogenic with cleavage of a synthetic substrate by either thrombin or FXa—both formats are available. The reaction takes place in the presence of heparin that is supplied in the reagent. This heparin will bind to the AT from the patient specimen and will inhibit the amidolytic release of the chromogen. Note that these assays can be affected by the new oral anticoagulants. Dabigatran will inhibit the thrombin step, while the direct Xa inhibitors (i.e., rivaroxaban) will inhibit Xa. Both lead to a falsely elevated AT activity. AT antigen assays are performed through immunoassay.

Plasminogen deficiency

Plasminogen is the major regulator of fibrinolysis, and though rare, both qualitative (Type 1) and quantitative (Type 2) deficiencies exist. A deficiency can be suspected in cases where a patient presents with a thrombotic event despite no evidence of a hypercoagulable state such as natural anticoagulant deficiency, or in cases of monitoring for thrombolytic therapy such as anistreplase. Plasminogen can be tested for by either an antigen assay or an activity assay. The antigen assay is an immunoassay, while the activity assay is chromogenic, involving a specific plasmin substrate. A typical algorithm is to test first with activity, and then only test antigen if the activity is low, as normal activity means that a deficiency is not present. Plasminogen is elevated in pregnancy and with the use of oral contraceptives, and is a positive acute phase protein. Plasminogen is synthesized in the liver and thus is sensitive to liver disease, and is also low in newborns up to 6 months of age. Plasminogen can also be lowered temporarily by consumption; therefore DIC, thrombolytic therapy, and other thrombolytic states will show a loss.

Heparin-induced thrombocytopenia

Another relatively rare but hospital-relevant condition is heparin-induced thrombocytopenia (HIT). In around 10% of cases of heparin administration, antibodies are generated against the heparin-PF4 complex. In up to half of these cases (5% of cases of heparin administration), the resulting complex activates platelets, causing severe thrombocytopenia as well as life-threatening thrombosis. This can also occur in cases of LMWH administration, though the incidence is much lower. HIT typically occurs at least 5 days after the start of heparin administration, though it can occur within a day if there was previous exposure to heparin within 100 days prior.

As a result of this possibility, it is recommended that patients on heparin therapy have their platelets monitored serially, starting before therapy initiation. The degree of thrombocytopenia, the onset of thrombocytopenia, occurrences of new thrombi, and other causes of thrombocytopenia can all be used to grade the possibility of HIT through the use of the 4T score, a common tool for clinical assessment (Table 26.3) [14]. In all cases of suspected HIT, heparin therapy should be discontinued and replaced with a nonheparin anticoagulant, as LMWH can also cross-react with anti-PF4-heparin antibodies [15].

Screening for suspected HIT can be performed using an immunoassay against the PH4-heparin complex. The confirmatory and reference method is the serotonin release assay (SRA), which measures serotonin release from patient platelets in the presence of heparin. Patient platelets are mixed with platelets labeled with radioisotope-labeled serotonin, and the release is then monitored in the presence of various levels of heparin In an HIT patient, the labeled platelets will release serotonin in the presence of moderate amounts of heparin (0.1−0.3 IU/mL), but not with high levels (100 IU/mL). Activation of both moderate and high levels of heparin reveals a nonspecific reaction, as high heparin levels will disrupt the causative PF4-heparin complexes. When performed correctly and in the presence of a positive screen and moderate or high T4 score, the SRA is highly specific for HIT [16].

Antiphospholipid syndrome

The most common acquired thrombophilia is APS. As the name implies, these are autoantibodies against phospholipid-binding proteins, such as β_2-glycoprotein 1, known as APAs. These antibodies are frequently referred to as LAs, though they are prothrombotic and less than half of the cases of LAs occur in patients with systemic lupus erythematosus (SLE). However, patients with SLE and other autoimmune diseases are much more likely than

TABLE 26.3 The 4T score.

T category	2 points	1 point	0 points
Thrombocytopenia	Platelet drop ≥50% to a low of ≥20,000/mL	Platelet drop 30%–50% to a low of 10,000 to 19,000/mL	Platelet drop <30% or low of <10,000/mL
Timing of platelet drop	Clear onset 5–10 days after first administration, or within 1 day if previous heparin therapy within the last 30 days	Unclear onset within 5–10 days, clear onset ≥10 days after, or fall within 1 day with previous heparin therapy 30–100 days prior	Platelet count drop <5 days without recent exposure
Thrombosis or other symptoms	New, confirmed thrombosis, skin necrosis, and/or acute systemic reaction postheparin administration	Progressive, recurrent, or suspected thrombosis or nonnecrotizing skin lesions	None
Other causes of thrombocytopenia	None apparent	Possible	Definite

Notes: The 4T score is an effective method of stratifying risk for heparin-induced thrombocytopenia. A low total 4 T score (1–3) has high negative predictive value, and thus the 4 T score is a good rule-out test. Intermediate (4–5) and high (6–8) scores should be followed up with PF4 and SRA testing.

the general population to develop APAs, with 30% to 50% of SLE patients developing APS. When a diagnosis of APS is made in the absence of another autoimmune condition, it is known as primary APS. Otherwise, it is considered secondary APS. Only 8% of cases of primary APS will proceed to develop an additional autoimmune diagnosis.

Laboratory testing of APS is rather diverse, which reflects the diverse nature of the syndrome. APAs are among the most common causes of a prolonged PTT in nonbleeding patients, as the APAs can bind phospholipids intended to trigger the coagulation cascade. This is the genesis of the "anticoagulant" part of the name "LA." This effect is utilized to test for the condition, as this effect can be overcome with the addition of larger amounts of phospholipids, similar to the substrate depletion effect in an immunoassay. A typical screening test is done either as an aPTT reaction with particularly low phospholipid concentration as to enhance the effect of the APA or through the use of dilute Russell viper venom, which is a phospholipid-sensitive venom that activates FX to FXa. In the presence of an APA, these assays will show a prolonged clotting time. This is typically followed by a confirmatory step that involves the addition of much larger quantities of phospholipids. In the case of a true APA, additional phospholipid will overwhelm the inhibitor and the clotting time will "correct." Current guidelines recommend that a ratio is determined by the lab, typically around 1.2, for the clotting time of the screen versus the confirm to call a positive result. Also, a lab may also choose to perform a mixing study to exclude the possibility of a factor deficiency, though the utility of this test varies depending on the specifics of the testing scheme. There are several other functional assays used for LA testing, such as the "silica clot time," which is a particularly LA-sensitive form of the aPTT assay, and aPTT assays using "hexagonal phase lipids," which are insensitive to LAs and thus can be used to "correct" the aPTT in the presence of an LA. Each of these methods has particular sensitivities and specificities for particular forms of LAs, and so each laboratory must determine the best fit for their patient population.

Another method is direct serological testing for antibodies against phospholipid-associated proteins. International guidelines recommend detection of either IgG or IgM antibodies to cardiolipin (aCL) or beta2 glycoprotein I (β2GP1). Elevation in IgA of either aCL or β2GP1 is of unknown clinical significance. APAs are identified by ELISA assays. The specimen from the patient is added to an ELISA well, and if the appropriate antibodies are present, they will bind to the target antigen. The anticardiolipin assay should be β2GP1-dependent. This is achieved by supplementing the reaction with either human or bovine β2GP1 that acts as a binding cofactor. The rationale behind this is that infections may induce transient aCL antibodies and these are typically not dependent on β2GP1. The laboratory definition of APS requires that a significant titer of aCL or β2GP1 persists for at least 12 weeks. International guidelines recommend that antibody titers should be >99th percentile of the population reference range.

While far more specific, a considerable number of APAs are not positive for either of these two proteins, and thus this testing is typically done in concert with the functional testing described above. APS is diagnosed symptomatically; thus the presence of an APA in a nonsymptomatic patient does not confirm a diagnosis. A diagnosis must include both the presence of an APA twice at least 12 weeks apart (as most APAs are transient and not clinically relevant), and accompanied by a patient history of at least one confirmed arterial thrombosis or VTE. It is important to note that several DOACs can cause false

positives on screening tests, most notably apixaban and rivaroxaban. Functional testing on patients currently taking these medications should be interpreted with extreme caution. If possible without high risk, patients should be asked to pause medication before testing to minimize interferences. Also, rivaroxaban has been shown to increase the risk of thrombosis in patients with an APA when compared to warfarin therapy, and any patient at risk for APS should not be treated with rivaroxaban until APS has been ruled out [17]. Heparin can also cause false prolongations on APA screening; however, most reagents include a heparin neutralizer to reduce this effect.

ADAMTS13 deficiency

Deficiency of the ADAMTS13 protein, responsible for cleaving ULVWFs, is linked to the development of a thrombotic microangiopathy termed "thrombotic thrombocytopenic purpura" (TTP), a life-threatening condition that can cause brain damage, stroke, and other thrombotic disorders, and can also lead to hemolytic anemia if untreated. Spurious activation of platelets through ULVWF causes the constant creation of thrombi, resulting in the sequestration and clearance of platelets leading to dangerous thrombocytopenia as well as vascular damage caused by the thrombi themselves.

The deficiency can be either congenital or acquired, though congenital deficiency of ADAMTS13 is very rare and is also known as Upshaw–Schulman syndrome or chronic relapsing TTP. This form of deficiency is only treatable through chronic plasma infusion or exchange from a healthy donor. Acquired ADAMTS13 deficiency is the result of an autoimmune inhibitor, and is also treated with plasmapheresis, though in most cases a sustained response can be achieved in several weeks.

While testing for ADAMTS13 is still relatively uncommon, it can be essential in the diagnosis and proper treatment of TTP. Currently, the standard of care states that therapeutic plasma exchange should be initiated as soon as TTP is seriously considered, given the rapid and destructive effects of TTP. However, testing is essential in confirming the diagnosis and should be performed on blood collected before exchange or infusion is initiated. Testing is functional; therefore both congenital and acquired forms can be tested in the same manner. Testing is typically either done using a fluorescence resonance energy transfer reaction using appropriately labeled peptides matching ADAMTS13's target sequence (between tyrosine 1605 and methionine 1606 of vWF), or through an ELISA assay with an immobilized target sequence and antibodies that recognize only the cleaved sequence.

Thrombophilia testing

A patient presenting with severe VTE, especially in repeated cases, will typically be worked up with a thrombophilia panel depending on the cause of the thrombotic event. If the VTE is a result of a provoked response (e.g., long plane ride and prolonged immobilization) additional workup is typically not performed. However, if the VTE was the result of an unprovoked response, then a thrombophilia workup is warranted. This panel should involve screening tests for APCR and PC and PS deficiencies. AT testing may also be performed, though deficiency should only be suspected in the case of high-dose heparin administration or if other conditions are ruled out.

Even though it is a prothrombotic condition, APS typically presents with a prolonged PTT and is the most common cause of prolonged aPTT without bleeding. A patient presenting with a prolonged PTT and VTE should be immediately tested for the presence of APAs if clinical suspicion is high for APS. When patients are undergoing a thrombophilia workup, anticoagulation therapy should be discontinued for at least 5–7 half-lives of the drug if possible without risk.

Self-assessment questions

1. Choose the correct combination of sheer stress amount, operative platelet binding protein, and operative platelet receptor:
   a. high stress-vWF-GP Ia/IIa, low stress-collagen-GP Ib/IX/V
   b. low stress-vWF-GP Ib/IX/V, high stress-collagen-GP Ia/IIa
   c. high stress-vWF-GP Ib/IX/V, low stress-collagen-GP Ia/IIa
   d. low stress-vWF-GP Ia/IIa, high stress-collagen-GP Ib/IX/V
2. Which platelet feature contains small molecules such as ATP and serotonin?
   a. α granules
   b. Dense granules
   c. OCS
   d. Weibel−Palade bodies
3. Which group of factors is most directly affected by treatment by warfarin?
   a. Vitamin K-dependent factors
   b. Liver-dependent factors
   c. Protease-activated factors
   d. Propagation pathway factors
4. Which protein cross-links fibrin strands?
   a. FX
   b. FXI
   c. FXII
   d. FXIII
5. Which protein's action is potentiated by heparin?
   a. Antithrombin
   b. Protein C
   c. Protein S
   d. Protein Z-dependent protease inhibitor
6. Which laboratory test is used most to monitor warfarin therapy?
   a. aPTT
   b. PT
   c. D-dimer
   d. Fibrinogen
7. Which laboratory test is used most to monitor heparin therapy?
   a. aPTT
   b. PT
   c. D-dimer
   d. Fibrinogen
8. The D-dimer assay has a high negative predictive value for what patient presentation?
   a. High pretest probability of PE
   b. Low pretest probability of PE
   c. High pretest probability MI
   d. Low pretest probability MI
9. A patient presents to their PCP with the complaints of persistent heavy nosebleeds. Their PT and aPTT results are normal, and their provider is on the ball and orders vWF testing. Antigen levels are normal, and ristocetin activity is low. Factor VIII activity is normal. What type is the most likely given these results?
   a. Type 1
   b. Type 1C
   c. Type 2
   d. Type 3
10. What is the most common congenital factor deficiency?
    a. FVII
    b. FVIII
    c. FIX
    d. FX
11. Which platelet disorder results in platelets showing little to no aggregation with all agonists but ristocetin?
    a. Hermasky−Pudlak syndrome
    b. Bernard−Soulier syndrome
    c. Wiskott−Aldrich syndrome
    d. Glanzmann thrombasthenia
12. A patient presents to the ED with a DVT. A PT and aPTT are ordered, and they show an isolated increase in aPTT. What testing should be ordered next?
    a. Antiphospholipid antibody testing
    b. Platelet aggregometry
    c. D-dimer
    d. Serotonin release assay

Chapter 27

Diagnostic body fluid testing

Darci R. Block[1] **and Jonathan R. Genzen**[2]

[1]Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN, United States, [2]Department of Pathology, University of Utah School of Medicine & ARUP Laboratories, Salt Lake City, UT, United States

Learning Objectives

After reviewing this chapter, the reader should be able to:

1. State the regulatory requirements for body fluid validations according to CLIA.
2. Construct a differential diagnosis for pathological accumulations of common body fluids.
3. Cite the most clinically useful tests that aid in establishing or narrowing the differential diagnosis.
4. Interpret cellular, microbiological, and biochemical results for common body fluids examined in the clinical laboratory.

Introduction

Body fluids are routinely collected and sent to the clinical laboratory for analysis as a means to identify the pathological cause for an effusion or transudate. The measurement of biochemical markers in a particular fluid may give diagnostic insights into the pathology of the accumulation or underlying presence of disease. Often, the concentration of a body fluid analyte is compared with a reference interval, a predefined decision limit, or to the concentration of the analyte in blood, to facilitate result interpretation.

Laboratories must perform analytical validations and provide interpretive information for the body fluid tests they routinely perform. This requires a great deal of effort and resources that laboratories need to coordinate and prioritize. Situations where there is limited utility for measuring an analyte in a body fluid include scenarios where diagnostic information may be obtained from measurement of that analyte in blood (or another specimen source that is considered acceptable by the in vitro diagnostic manufacturer) or when the results do not impact patient management or care.

Regulations

The exact analytical validation requirements for a body fluid test may depend on local, state, and/or federal laws, as well as regulation from applicable accreditation agencies. In many jurisdictions, clinical laboratories that choose to test body fluid specimen types that are not specifically referenced in an assay manufacturer's instructions are required to analytically validate measurement in the alternative specimen source. For example, in the United States, the Clinical Laboratory Improvement Amendments of 1988 (CLIA'88) outlines federal regulations regarding establishment of performance specifications for modified Food and Drug Administration (FDA)-cleared assays (and/or assays not currently subject to FDA clearance or approval, e.g., laboratory developed tests), including accuracy, precision, analytical sensitivity, analytical specificity (interfering substances), reportable range, reference intervals, and any other performance characteristics required for test performance [1]. Similar requirements exist in other countries, including International Organization for Standardization (ISO) standards used widely in Europe and other parts of the world. The concerns that these regulations aim to address are due to the potential for matrix-related interferences that may be present in fluids that assay manufacturers do not have data for. Body fluids may have lower concentrations of protein, differences in pH, ionic strength, and viscosity, among other potential attributes that may contribute to an inaccurate analyte measurement. Several resources are now available to provide guidance for laboratories planning analytical validations of body fluid specimens [2,3].

Accuracy, termed more appropriately "trueness," is assessed through a variety of possible experiments to determine whether the test system in question is able to measure the true activity or concentration of a target analyte in a body fluid matrix despite an assay's original intended use in serum, plasma, or urine. There are multiple experiments that may be used to assess trueness in this context, including comparison to a reference method or the combination of calculating analyte recovery upon spiking solutions of standard concentration, mixing samples of high and low analyte concentration, and diluting

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00027-2

samples with an appropriate diluent [2–7]. Precision studies are performed as a means to assess the reproducibility of a method in a body fluid matrix. Experimentally, precision studies can be performed similarly to established approaches for evaluating precision in serum and plasma, choosing analyte concentrations that are near decision limits for the fluid of interest when possible. A detailed description of method validation is included in Chapter 4, Method validation, of this book.

Analytical sensitivity studies are performed to assess the reproducibility of a method at the lowest reportable concentration in a body fluid. Experimentally, sensitivity studies are similar to precision studies but are performed using low concentration specimens. Analytical specificity studies are performed to identify which substances cause interference, the extent of their effect on results, and to establish acceptable limits within which the lab can safely report accurate results. Typically, clinical laboratories adopt the manufacturer's recommended thresholds for interferences such as hemoglobin, lipids, and bilirubin without further study when verifying the performance of an assay on serum, plasma, or urine. Interference spiking studies are often needed when validating body fluid assays; however, there is potential for matrix effects with either the interferent itself or the presence of other substances not typically encountered in blood or urine specimens (e.g., meconium or very high glucose). Additionally, allowable bias and imprecision may be analyte- and fluid-dependent, as medical decision points in body fluids are often different as compared to those implemented for serum and plasma [3,8].

The reportable range represents the range of concentrations that an analyte can be accurately measured within, as well as the maximum reportable concentration with dilution. While reportable range studies in body fluids may be approached in a manner similar to serum and plasma, consideration should be given to choosing and validating appropriate diluents. Reference intervals allow the results of an analyte measurement to be interpreted either in the context of a normal reference population or for a defined population of subjects as a medical decision limit. Body fluids are typically only present in volumes large enough to aspirate for diagnostic purposes in the presence of pathological conditions, thus diminishing the utility of defining reference populations. Medical decision limits are commonly used; however, several challenges for establishing and/or verifying them include the lack of methodological detail from historical studies and the inability to predict the comparability of assays over time. Additionally, most studies do not provide evidence that their method is free of matrix bias [4]. These limitations confer significant difficulty to providing interpretive information or reference intervals with body fluid results. Studies that report the concentration of body fluid analyte in comparison to a corresponding serum or plasma specimen (or as a ratio) circumvent the latter concern. In most jurisdictions, laboratories are required to provide a mechanism to interpret the results for their tests; however, this may be viewed in a variety of formats including a printed/online resource or direct reporting into an appropriate information system.

Laboratories that are initiating or reevaluating their body fluid testing program should be cognizant of all the sources of variation with which they receive their specimens. The manner in which tests are ordered and the manner in which the fluid source is designated can impact the accuracy of information passed to the laboratory. Such workflows should be standardized as much as is practical. The laboratory should ensure that proper collection processes are followed, including use of acceptable collection containers and labeling that follows standard protocols for required content, including two patient identifiers, date and time of collection, and fluid source/anatomic site (if applicable). The preparation for and mode of transportation of specimens from the collection area, as well as the processing steps taken once received, should be conducted in accordance with established analyte stability limits.

Specific body fluids

Cerebrospinal fluid

Cerebrospinal fluid (CSF) is a plasma ultrafiltrate that is modified by both active and passive transports of substances from the systemic circulation into the central nervous system (CNS). CSF is produced primarily by the choroid plexus in the cerebral ventricles. Tight junctions between choroid plexus epithelial cells restrict and regulate the flow of water and solutes from underlying capillaries. The flow of CSF is directed from the lateral ventricles, through the interventricular foramina (foramen of Monro) to the third ventricle. CSF then flows through the cerebral aqueduct to the fourth ventricle, then through the lateral apertures (foramina of Luschka), the medial foramen (foramen of Magendie), or the central canal of the spinal cord. Through these pathways, CSF flows to the outer surfaces of the brain and spinal cord before exiting through arachnoid villi and granulations into dural venous sinuses or into extracranial lymphatics. CSF serves to cushion the brain and spinal cord mechanically during normal and traumatic movement. It serves an important role in nutrient delivery within the CNS as well as helping to remove metabolic waste products.

CSF analysis plays an important role in the diagnosis of many CNS disorders, including infections of the meninges (meningitis) and brain parenchyma (encephalitis). CNS infections can be due to bacteria, mycobacteria, viruses, fungi, or parasites. CSF analysis is also important in the identification of immune-mediated disorders of the CNS,

such as multiple sclerosis, as well as providing supportive evidence for prion disorders such as Creutzfeldt–Jakob Disease (CJD). CSF microscopic examination is also critical for the identification of malignant cells derived from (or metastatic to) the CNS. Along with radiologic investigation [primarily computerized tomography (CT) or magnetic resonance imaging (MRI)], CSF analysis is often conducted in patients who have unexplained mental status changes, fever, headache, meningeal symptoms, and/or suspected cranial nerve abnormalities on physical examination.

Most CSF specimens are obtained through a procedure called lumbar puncture (LP; or spinal tap). In this procedure, patients are placed in a lateral decubitus position while a needle is placed into the subarachnoid space in the lumbar region of the spinal canal. Some LPs are conducted using radiologic and fluoroscopic guidance. CSF specimens (particularly in neurologic intensive care settings) may also be obtained through preexisting ventricular shunts or drains. When the LP procedure causes bleeding into the subarachnoid space, this is called a traumatic tap. Differentiation of traumatic tap from subarachnoid hemorrhage can usually be made based on laboratory findings as discussed later in this section.

Upon successful LP, CSF opening pressure is measured with a manometer. Normal CSF opening pressure in adults is approximately 50–180 mm H_2O, with pressures being lower in young children and slightly higher in obese patients. Abnormal or obstructed CSF flow can lead to accumulation of CSF in the brain (hydrocephalus) and increased intracranial pressure. In patients with elevated CSF opening pressure ($>$200 mm H_2O), only 1–2 mL of CSF should be removed for diagnostic purposes, as collection of additional volume carries an increased risk of potentially fatal cerebral herniation. In these cases, medical intervention to control intracranial pressure is warranted.

After measurement and documentation of opening pressure, CSF is typically collected into three or four consecutively numbered tubes (e.g., tubes 1–4). There are several reasons for collection into multiple tubes. Given the invasiveness of CSF collection, it is imperative that adequate specimen is collected for subsequent diagnostic testing, which may be directed to several different laboratory sections such as chemistry, hematology, microbiology, molecular, and cytology. While laboratories have varying protocols, tubes 1 or 2 are usually reserved for routine chemistry, immunology, and/or esoteric testing, as these assays are less likely to be negatively influenced by traumatic taps. The next tube is often reserved for microbiology (Gram stain, culture, and/or infectious disease molecular testing), while the last tube(s) are often used for hematology, cytology, and/or additional molecular or esoteric testing. Performing cell counts on the final tube decreases the influence of traumatic taps on the CSF white blood cell (WBC) count. Many laboratories will also perform an additional cell count on the first tube, as differences in cell counts between tubes 1 and 4 are indicative of a traumatic tap. In suspected traumatic taps, correction equations can be used to adjust CSF WBC counts for the influence of peripheral blood contamination. Finally, laboratory distribution of CSF should be modified based on a patient's unique clinical circumstances. For example, if the primary purpose of the LP is to evaluate for the possibility of CNS malignancy, specimen volume priority should be directed to hematology and cytology as opposed to chemistry and microbiology.

Normal CSF is clear and relatively colorless in appearance. Yellow or pink coloration is called xanthochromia, which is often indicative of prior bleeding (e.g., subarachnoid hemorrhage) into the CSF. In such cases, red blood cell (RBC) destruction leads to hemoglobin breakdown and accumulation of bilirubin. Yellow coloration, however, may also be evident with systemic hyperbilirubinemia or increased CSF total protein.

CSF cell counts (RBC, WBC, and differential) should be conducted shortly after collection to prevent falsely low results due to cell lysis and/or settling. Cytospin preparations are often used for the differential to improve visualization and identification of cells, given the relatively low cell counts in CSF versus serum. Normal CSF contains $<$5 RBC/μL in both children and adults. Normal adult CSF has $<$5 WBC/μL, while neonatal CSF typically has $<$30 WBC/μL, with progressively decreasing numbers through childhood. These ranges have been based on historical evidence from manual cell counts, typically conducted using a hemocytometer. Recent trends toward automating body fluid cell counting methods, primarily flow cytometry, are forcing many laboratories to evaluate low-end bias and imprecision near assay cutoffs. Establishing method-specific CSF cell count reference ranges using these techniques may challenge the notion of the current, traditionally accepted ranges that permeate the literature and clinical practice.

The WBC differential in normal adult CSF typically shows a lymphocyte predominance (30%–90%), with a moderate percentage of monocytes (15%–50%), and a small number of PMNs (0%–6%). Eosinophils and ependymal cells may be observed, albeit less frequently. The increased WBC count in bacterial meningitis is usually accompanied by a predominance of PMNs, while viral meningitis often shows a lymphocyte predominance. The WBC differential is not specific for bacterial, viral, and fungal meningitis, however, as cell-type predominance can vary between patients and time course of infection. Cytology may be essential when abnormal cells are observed in the differential or when malignancy is suspected.

Normal CSF total protein varies based on age, with adult concentrations typically in the range of 15–45 mg/dL. Neonatal total protein concentrations are typically higher, in the range of 40–120 mg/dL and are higher in

preterm infants. CSF total protein concentrations can increase in the context of infection, inflammation, malignancy, and/or damage to the blood−CSF barrier. Elevations of CSF total protein are particularly common in bacterial and or fungal infections. Normal CSF glucose concentrations are approximately 2/3 the concentration of a corresponding serum specimen, and a normal glucose ratio is often expressed as 0.6 in the literature. CSF reference intervals are also often presented as a range from approximately 50−80 mg/dL. Decreased CSF glucose is frequently observed in bacterial and fungal CNS infections. CSF glucose concentrations may be relatively normal in viral CNS infections.

Gram stain and culture remain essential for the routine diagnosis of bacterial meningitis. The majority of neonatal cases of bacterial meningitis are due to group B *Streptococcus*, *Escherichia coli*, and more rarely *Listeria monocytogenes*. From infancy to young adulthood, the prevalence shifts toward *Neisseria meningitidis*, *Streptococcus pneumoniae*, and *Haemophilus influenzae*. Vaccination against *H. influenzae* type B, however, has decreased the incidence of meningitis caused by this organism. A diagnosis of neurosyphilis (tertiary infection due to the fastidious bacteria *Treponema pallidum*) is supported by a positive CSF Venereal Disease Research Laboratory (VDRL) test result.

Significant advances in molecular techniques have made nucleic acid-based testing (NAT; e.g., PCR) fundamental to the rapid detection of many viral CNS infections. NAT is now the mainstay for diagnosis of commonly observed CNS viral infections such as enteroviruses and members of the herpesviridae family (e.g., HSV-1, HSV-2, CMV, and EBV). Mycobacterial infections may require a combination of culture and/or molecular testing for their detection. Fungal infections may be detected though a combination of culture, direct smears, special preps (e.g., India ink for *Cryptococcus neoformans*), antigen testing, and/or molecular methods.

Testing for CNS production of immunoglobulins plays an important role in the assessment of inflammatory disorders such as multiple sclerosis. CNS inflammatory disorders may be accompanied by the production of immunoglobulins within the brain, spinal cord, or intrathecal space (under the arachnoid membrane). Qualitative assessment of immunoglobulin production with isoelectric focusing, high-resolution gel electrophoresis, and/or immunofixation electrophoresis of paired CSF and serum specimens allows for the detection of oligoclonal bands that are present in the CSF but absent in serum, a finding that is often observed in multiple sclerosis and other CNS inflammatory processes (see Fig. 27.1).

Several calculations can also be used to evaluate the integrity of the blood−CSF barrier as well as intrathecal synthesis of immunoglobulins. Changes in blood−CSF barrier permeability can be assessed through calculation of the Albumin Index (note units):

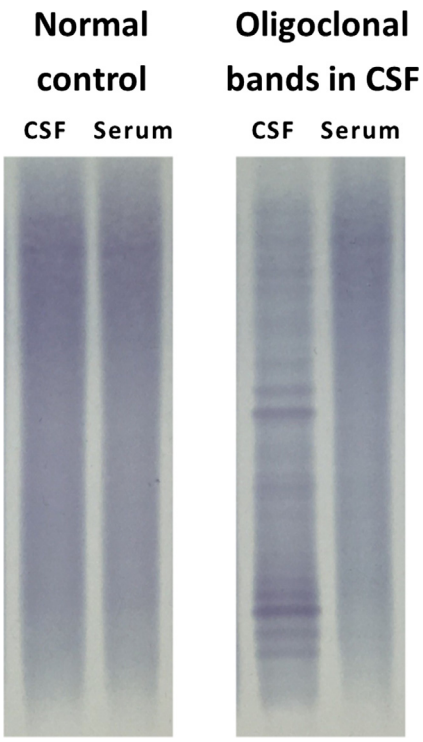

FIGURE 27.1 Cerebrospinal fluid oligoclonal band analysis. Paired cerebrospinal fluid and serum specimens evaluated for the presence of oligoclonal bands using an isoelectric focusing method combined with immunofixation. *Left*: no evidence of oligoclonal bands in cerebrospinal fluid or serum from this normal control. *Right*: oligoclonal bands observed in cerebrospinal fluid, with no matching bands observed in the patient's corresponding serum.

$$\text{Albumin index} = \frac{\text{CSF albumin}\left(\text{mg/dL}\right)}{\text{Serum albumin}\left(\text{mg/dL}\right)} \times 1000$$

Albumin Index results <9 are consistent with an intact blood−CSF barrier, while results >30 are consistent with severe barrier impairment. Intermediate results indicate mild-to-moderate impairment of the blood−CSF barrier. CSF IgG synthesis can be assessed through calculation of the IgG Index (note units):

$$\text{IgG index} = \frac{\text{CSF IgG}\left(\text{mg/dL}\right)}{\text{CSF albumin}\left(\text{mg/dL}\right)} \times \frac{\text{Serum albumin}\left(\text{mg/dL}\right)}{\text{Serum IgG}\left(\text{mg/dL}\right)}$$

IgG Index results <0.7 are considered to be normal. It should be noted that any cause of CSF immunoglobulin synthesis (e.g., inflammatory or infectious) can lead to increased IgG Index results; therefore elevated values are not specific for multiple sclerosis. Additionally, impairment in the blood−CSF barrier can lead to increased CSF IgG and albumin (from the peripheral circulation), and this can also impact the interpretation of IgG Index results. Some

laboratories also calculate CSF IgG Synthesis Rate (note units):

$$\text{IgG synthesis rate} = \left[\left(\text{CSF IgG} - \frac{\text{Serum IgG}}{369}\right) - \left[\left(\text{CSF albumin} - \frac{\text{Serum albumin}}{230}\right) \times \left(0.43 \times \frac{\text{Serum IgG}}{\text{Serum albumin}}\right)\right]\right] \times 5\ \text{dL/day}$$

Units for all proteins in the IgG Synthesis Rate equation are expressed as mg/dL. The equation includes several constants, which are estimates derived from normal populations. For example, "369" is an approximate normal serum:CSF ratio for IgG, "230" is an approximate normal serum:CSF ratio for albumin, "0.43" is a ratio of the molecular weight of albumin to the molecular weight of IgG, and "5" is an estimate of the average daily CSF production in adults (expressed in dL) [9,10].

Identification of CSF leakage is important in the context of nasal drainage (rhinorrhea) or ear drainage (otorrhea) that may be associated with trauma, cranial surgery, or neoplasm. β2-Transferrin is often used as a marker for CSF in these circumstances, as neuraminidase in the CNS removes sialic acid from transferrin to form the desialated (β2) form. Paired testing with a serum specimen, however, is usually performed, as this helps to eliminate the possibility that a patient may have a disorder in which serum transferrin is also hypoglycosylated.

Transmissible spongiform encephalopathies are rare, progressive fatal neurodegenerative disorders caused by abnormally folded proteins known as prions. Prion disorders in humans include CJD, kuru, fatal familial insomnia, and Gerstmann–Sträussler–Scheinker syndrome [11]. These prion diseases involve conformational changes to the protein product of the *PNRP* gene (PrP) [12]. PrP is a cell surface glycoprotein which is present normally in an α-helix-rich conformational state (PrP^C). In prion diseases, PrP^C undergoes a conformational change to form β-sheet-rich isomers known as PrP^{Sc}. PrP^{Sc} is less soluble and has a propensity to form amyloid fibrils. Initiation of conformational changes in PrP^C can occur sporadically, it can be triggered by exposure to PrP^{Sc} from exogenous sources, or alternatively mutations in the *PNRP* gene can also result in a propensity for PrP^C misfolding. While most cases of CJD are sporadic, a minority of cases are associated with inherited mutations. Variant CJD (vCJD) is the human prion disease associated with consumption of meat from cows affected by bovine spongiform encephalopathy ("mad cow disease").

Diagnosis of prion diseases (such as sporadic and variant CJD) is typically supported by clinical, radiologic (MRI), and encephalographic evidence. Biopsy may be considered in certain cases. CSF studies may be supportive and include analytes such as protein 14-3-3, tau, and neuron-specific enolase. Advancements in prion diagnostics include real-time quaking-induced conversion assays for the detection of PrP in CSF [13]. Molecular testing of blood specimens may also be used to detect inherited *PRNP* mutations. Laboratory testing for prion diseases is performed primarily by referral laboratories and prion surveillance centers. This is for both practical logistical reasons (due to the rarity of prion disorders) and the safe handling of potentially infectious tissue specimens. Appropriate handling and disposal are key considerations in laboratory analysis of specimens from patients with suspected prion disease [14]. The World Health Organization has published infection control guidelines that describe the level of infectivity and risk across a variety of tissues and specimen types [15].

Pleural fluid

A small amount of pleural fluid is normally present between the parietal and visceral membranes of the thoracic cavity surrounding the lungs. The parietal membranes line the inner surface of the chest wall, while the visceral membranes line the lungs. Pleural fluid serves as a lubricant between the lungs and inner chest wall during breathing. It is produced under normal conditions by capillary hydrostatic and osmotic pressure from the parietal vasculature. Pleural fluid production is balanced by absorption, predominantly by lymphatic stomata (openings into lymphatic capillaries on mesothelial surfaces) and venous uptake.

Increases in pleural fluid production, as well as decreases in lymphatic absorption, can lead to fluid accumulations known as pleural effusions. These effusions may be unilateral or bilateral depending on their etiology. Some causes for pleural effusions include increased pressure in the lung circulation (e.g., with congestive heart failure or pulmonary emboli), changes in pulmonary vascular permeability that may accompany inflammation or infection, accumulation of pus during infection (empyema), movement of nonpleural fluids (e.g., peritoneal fluid or lymphatic drainage) into the thoracic cavity, hemorrhage, or a variety of disorders, which slow or block the absorption of fluid back into the lymphatic capillaries [16].

Many small pleural effusions may be clinically asymptomatic and detected only during radiologic studies such as chest X-ray, CT, MRI, or ultrasound (US). Pleural effusions may also be suspected based on clinical symptoms or physical examination of the chest using a stethoscope. Patients with symptomatic pleural effusions may report shortness of breath, difficult or painful breathing, or general pulmonary symptoms such as cough [17]. They may also be febrile if an underlying infection is present.

Pleural fluid can be collected through a procedure known as thoracentesis. This may be performed diagnostically (to obtain fluid for cellular, chemical, and/or

microbial analyses) or therapeutically to remove fluid accumulations when clinically indicated. Not all pleural effusions require diagnostic or therapeutic thoracentesis. For example, a bilateral pleural effusion in the context of known congestive heart failure may resolve after initiation of diuretic therapy. Thoracentesis is often conducted using US guidance of the collection needle, as the use of US increases the likelihood of a successful collection and decreases the risk of serious complications such as pneumothorax (collection of air in the pleural cavity) and hemothorax (collection of blood in the pleural cavity) [18]. Immediately after collection, the pleural fluid specimen can be transferred into several different containers to enhance diagnostic testing. For example, transfer of fluid into an ethylenediaminetetraacetic acid (EDTA)-containing blood collection tube can decrease the chance of clotting before cellular analysis. Transfer of fluid into blood culture bottles has been shown to increase the rate of bacterial identification. Additionally, transfer of fluid into a capped, heparinized syringe improves the accuracy of pH determination in the matrix [19]. Care should be taken to avoid cross contamination with collection and transport container additives that may be incompatible with subsequent clinical laboratory testing. Contamination during processing and handling should also be avoided with specimens intended for microbiological and/or molecular analyses.

The most important first step in pleural fluid analysis is to distinguish exudates from transudates. Transudates are fluid accumulations that are caused by differences in hydrostatic and osmotic pressures across otherwise healthy membranes. Exudates are fluid accumulations that may be due to membrane damage, infection, inflammation, or malignancy. The gross appearance of a pleural fluid specimen (e.g., clear, translucent, turbid, bloody, lipemic, or purulent) may provide some initial clues in this differentiation. For example, transudates are often (but not always) relatively clear or translucent. Gross appearance, however, is not diagnostic, and more effective strategies have been developed.

Differentiation of pleural fluid exudates from transudates is usually conducted using Light's criteria or associated parameters (Table 27.1) [24]. Pleural fluid total protein, lactate dehydrogenase (LDH), and albumin—along with corresponding serum measurements—can help to differentiate exudates from transudates. A pleural fluid is typically considered to be an exudate if it has a fluid-to-serum protein ratio of >0.5, a fluid-to-serum LDH ratio of >0.6, or a fluid LDH activity that is >2/3 the upper limit of a normal serum LDH activity [17,24]. Heart failure and diuretic-associated misclassifications by Light's criteria (scenarios where transudates are falsely categorized as exudates) may be correctly categorized as

TABLE 27.1 Differentiation of pleural effusion exudates and transudates.

	Transudate	Exudate
Appearance		
Clarity	Clear	Opaque, lipemic, purulent, and bloody
Color	Pale yellow; straw	Variable
Propensity to clot	Rarely	Sometimes
Light's criteria		
Total protein ratio (fluid/serum)	≤0.5	>0.5
LDH ratio (fluid/serum)	≤0.6	>0.6
LDH activity	≤2/3 upper limit nl serum	>2/3 upper limit nl serum
Prevention of misclassification with heart failure or diuretic use		
Albumin gradient (serum-fluid)	>1.2 g/dL	≤1.2 g/dL
Protein gradient (serum-fluid)	>3.1 g/dL	≤3.1 g/dL
Additional criteria		
Bilirubin ratio (fluid/serum)	≤0.6	>0.6
Cholesterol	≤45 mg/dL	>45 mg/dL
Cholesterol ratio (fluid/serum)	<0.3	≥0.3

Notes: Refer to [16,17], and [19–23].
LDH, Lactate dehydrogenase.

transudates if a serum-to-fluid albumin gradient (serum albumin minus fluid albumin) is >1.2 g/dL or a serum-to-fluid protein gradient (serum protein minus fluid protein) is >3.1 g/dL [20]. Exudates often have a pleural fluid-to-serum bilirubin ratio >0.6, a pleural fluid cholesterol >45 mg/dL, or a pleural fluid-to-serum cholesterol ratio >0.3, although these tests do not typically add diagnostic value significantly beyond Light's criteria and are not recommended for routine testing.

Transudative pleural effusions are most frequently associated with congestive heart failure, where circulatory overload leads to increased osmotic pressure in the lung capillaries. Other causes of transudative effusions include decreased serum albumin (e.g., cirrhosis, nephrotic syndrome, or protein-losing enteropathy), hepatic hydrothorax (where peritoneal fluid crosses the diaphragm with portal hypertension or leak), peritoneal dialysis (PD), collapsed lung (atelectasis), constrictive pericarditis, or rarely urinothorax due to obstruction or trauma [16,17]. Exudative effusions may be caused by a number of mechanisms, some of which include malignancy, pulmonary embolism, parapneumonic effusions (pleural effusions which occur with pneumonia), tuberculosis, rheumatologic and inflammatory disorders, pancreatitis, or chylothorax [16,17].

Gram stain and culture are essential for the assessment of potential bacterial or fungal infection. Cytology should be routinely ordered on pleural fluid specimens to evaluate for potential malignancy. Cell counts, including RBC and WBC counts with WBC differentials can provide supportive evidence for a variety of potential etiologies, in particular lymphocyte and neutrophil predominant effusions. While low pH (<7.2) is not specific for pleural fluid infection, it is one criteria used by clinicians in deciding whether tube drainage will be required for therapeutic management of pleural effusions associated with infection [25]. pH analysis of pleural fluids is typically conducted using blood gas analyzers to provide more accurate and rapid results. Some blood gas analyzers are now FDA-cleared for this particular specimen type. When tuberculosis is suspected, elevated adenosine deaminase (ADA) may also provide supportive evidence of mycobacterial infection. Routine use of tumor markers in pleural fluid specimens is not recommended. Some studies have shown that tumor marker testing (such as CA19-9 and CEA), along with corresponding serum levels, may provide supportive information that could be used along with cytology and other clinical evidence to support the diagnosis of malignant effusion [26]. Current pleural disease guidelines do not support the routine analysis of tumor markers in pleural effusions [27].

Peritoneal fluid/ascites

The peritoneal cavity is the space contained between the peritoneal membranes surrounding the abdomen. A small volume of serous fluid, 25–50 mL, is normally present within this space, lubricating the surfaces and maintaining pliability [28]. The mechanisms of normal fluid filtration out of systemic microvessels follow Starling's equation, which includes liquid conductance (k), vascular permeability of the peritoneal capillaries (s), hydrostatic pressure gradients (**P**) across sinusoidal (ss) and hepatic interstitial (hi) compartments, and colloid oncotic pressure differences (π) attributable primarily to serum albumin concentrations [29,30].

$$\text{Flow} = k\left[(P_{ss} - P_{hi}) - s(\pi_{mv} - \pi_{if})\right]$$

When these forces overwhelm the absorptive capacity within the peritoneum, primarily through drainage via the lymphatic system (maximally 850 mL/day), fluid accumulates [28]. The pathologic accumulation of fluid within the peritoneal cavity is commonly referred to as ascites. The most common cause of ascites is liver cirrhosis resulting from alcohol abuse, viral hepatitis, or tuberculous infection, and causation frequency is location and population dependent. Ascites can be diagnosed by physical examination noting bulging flanks or shifting dullness to percussion and may be aided by abdominal imaging if the volume is relatively small (<500 mL) or the patient is obese.

Paracentesis is a percutaneous procedure whereby a 1- to 4-in. needle is inserted traditionally into the midline between the pubis and umbilicus, to aspirate fluid under US guidance to avoid puncturing major vessels, organs, or the bowel. Today, the lower left quadrant is the preferred location as the prevalence of abdominal obesity increases and more large volume fluid reductions are performed. Up to 60 mL of fluid may be removed for diagnostic purposes in patients presenting with new onset ascites or to evaluate new signs and symptoms concerning for infection in those patients with existing ascites [28]. Alternatively, a larger bore needle may be inserted for therapeutic purposes to drain larger volumes of fluid (>5 L) to relieve symptoms of tense ascites, which may include a grossly distended abdomen, shortness of breath, and early satiety (feeling full after a small meal). There are few reported contraindications to performing paracentesis, even in cirrhotic patients with significant coagulopathies (interquartile range of PT-INR 1.4–2.2) and thrombocytopenia (interquartile range of platelets = 42–56 × 10^3/L) [31]. Patients with clinically evident coagulopathies such as disseminated intravascular coagulation should have paracentesis deferred [32].

The diagnostic approach to peritoneal fluid analysis in patients presenting with ascites involves characterizing the fluid as sterile (i.e., noninfectious), infectious, and/or malignant. The most common cause of ascites is portal hypertension related to cirrhosis, representing approximately 80%

of cases throughout North America and Europe [33]. It is important to consider noncirrhotic causes of ascites in the differential. These include prehepatic etiologies, such as malignancy, pancreatitis, portal vein thrombosis, lymphatic injury or obstruction, bowel perforation, renal failure, and tuberculosis [28]. Posthepatic etiologies include congestive heart failure, constrictive pericarditis, Budd–Chiari syndrome, and veno-occlusive disease [28]. The gross appearance of peritoneal fluid should be noted as it may have diagnostic clues. Ascites due to liver cirrhosis typically has a clear straw-colored appearance. A bloody appearance may indicate traumatic tap (often clots upon standing), malignancy, tuberculosis, pancreatitis, or abdominal trauma [33]. A turbid appearance may indicate the presence of chylomicrons (chylous ascites; which is sometimes associated with malignancy) or neutrophils (pseudochylous ascites) associated with infection.

The recommended screening tests for peritoneal fluids collected for diagnostic purposes received by the clinical laboratory include measurement of a cell count with differential, culture, albumin, and total protein. The serum ascites albumin gradient (SAAG) is the calculated difference between the concentration of albumin in the ascitic fluid and serum, ideally collected within 30 minutes up to 24 hours of each other [34]. SAAG has been shown to correlate directly with measures of portal pressure, and a cutoff of ≥ 1.1 g/dL identifies portal hypertension as the cause of ascites with 97% sensitivity [34]. Cirrhosis is the most common cause of increased portal hypertension but may also be caused by portal vein thrombosis and the posthepatic causes listed above [35].

Spontaneous bacterial peritonitis (SBP) is a frequent and significant complication of cirrhosis affecting 10%–30% of patients with ascites [33]. This infection occurs when intestinal bacteria migrate into the peritoneal cavity as a consequence of the compromised integrity of the GI tract, the type and burden of bacteria present, and any potential reduced immune function of the host. Symptoms vary widely from being completely asymptomatic, presenting with abdominal pain, and in extreme cases accompanied by hepatic encephalopathy.

The primary finding upon cellular analysis of ascitic fluid is elevated polymorphonuclear (PMN) leukocytes or neutrophil count. The recommended cutoff to provisionally diagnose infection and initiate antibiotic therapy is >250 cells/μL [28]. Cultures should be collected for all cases of suspected infection into a culture bottle at the bedside, as this has been demonstrated to maximize the sensitivity of recovering an organism [36]. Leukocyte esterase measured by point of care reagent strips has been studied as a surrogate for cellular analysis for screening purposes or where cellular analysis is not readily available. One diagnostic dilemma encountered in these cases is differentiating spontaneous from secondary bacterial peritonitis. Secondary causes include those that can be surgically corrected such as bowel perforation or loculated abscess in the absence of perforation. The diagnosis of SBP is considered when secondary causes have been ruled out. Runyon observed 100% sensitivity for identifying secondary bacterial peritonitis due to perforation in neutrocytic ascites with or without liver disease when total protein is >1.0 g/dL, LDH is > upper limit of normal for serum, and glucose is <50 mg/dL [28,37]. Nonperforation secondary peritonitis is evident when the PMN count increases from baseline upon repeat paracentesis performed 48 hours after initiating antibiotic therapy [36].

The differentiation of cardiac ascites from cirrhotic ascites is a common clinical conundrum as they are the two most common causes of ascites presenting with elevated SAAG. Heart failure leads to the development of high gradient ascites due to hepatic sinusoidal hypertension. Since the sinusoids are normal and have not been damaged from collagen deposition associated with cirrhosis, protein tends to "leak" more readily into ascites and is associated with higher total protein concentrations with a cutoff >2.5 g/dL used to distinguish it from cirrhotic ascites [33]. Misclassification does occur in milder cases of cirrhotic ascites where synthetic output of the liver is not as significant and in heart failure patients with hypoalbuminemia. It has, therefore, been suggested in limited studies to use serum heart failure biomarkers such as B-type natriuretic peptides in addition to ascitic fluid analysis to screen patients presenting with new onset ascites that could identify heart failure as the cause rather than rely solely on the pattern of elevated SAAG and ascitic fluid total protein [38]. Refer to Chapter 30, Biomarkers of Coronary Artery Disease and Heart Failure, for a complete description of lab testing for heart failure.

SAAG < 1.1 g/dL is not consistent with the presence of portal hypertension and occurs commonly in patients with malignancy-related ascites, tuberculosis infection, nephrotic syndrome, and pancreatitis. Malignancy-related ascites develops as a result of multiple mechanisms including metastatic infiltration of tumor cells through the peritoneum (peritoneal carcinomatosis), liver metastasis, portal or hepatic vein compression, or obstruction within the lymphatic system leading to chylous effusion [39]. Less commonly, the malignant ascites is caused by a primary peritoneal malignancy. More commonly, it is caused by secondary peritoneal carcinomatosis from breast, ovary, endometrium, GI tract, or pancreatic cancers. Hepatocellular carcinoma is a common malignancy of the liver often associated with cirrhosis caused primarily by chronic hepatitis.

The diagnosis of malignant ascites relies on the identification of malignant cells from either cytologic analysis of fluid or tissue biopsy. Cytology suffers from relatively poor sensitivity, as recovery of cells from fluid is often

limited. Therefore biomarkers that can distinguish malignant from nonmalignant ascites are helpful in order to reduce the number of unnecessary biopsies and aid in diagnosis. Numerous tumor markers have been measured in ascitic fluids, including carcinoembryonic antigen (CEA), α-fetoprotein (AFP), cancer antigen (CA) 19-9, CA 125, and CA 15-3, among others. Most studies report decision limits that are derived from differentiating a population with malignant ascites from a population with nonmalignant ascites. These studies report widely varying sensitivities and specificities dependent on which malignancies were included in the study population and whether they are known secretors of that protein, as demonstrated by measurement in serum [40]. The most promising tumor marker for its positive predictive value is CEA, with a pooled sensitivity of 43% (95% CI [38%, 48%]) and specificity 96% (95% CI [93%, 97%]) reported from a meta-analysis of seven studies with cutoffs ranging from 3.5 to 25 ng/mL [41]. These decision limits are comparable to those reported for serum, and just as with any immunoassay, results and decision limits should not be compared between manufacturers due to the lack of harmonization. Elevated cholesterol has been shown to identify malignant ascites with sensitivities and specificities >80% using varying cutoffs between 32 and 70 mg/dL, owing to increased vascular permeability, release from tumor cells, and lymphatic obstruction [4]. The measurement of cholesterol and other tumor markers is probably best limited to circumstances when malignancy is suspected and cytology is negative or indeterminate for best results [33].

Chylous ascites is a rare disorder caused by disruption of the lymphatic system wherein chyle leaks into the abdominal cavity causing a milky-appearing, triglyceride-rich effusion in the peritoneum. The physical appearance can be deceiving as elevated white cell counts may also give a turbid appearance. The most common etiology of chylous ascites in adults is malignancy and cirrhosis, while in children it is congenital lymphatic disorders [42]. Infectious causes such as tuberculosis causing lymphatic obstruction or disruption are more prevalent in developing countries. Triglycerides may be measured to confirm the existence of chylous ascites with a recommended cutoff of >200 mg/dL [43]. Notably, cholesterol measurement does not differentiate chylous from nonchylous effusions and should not be tested for the purpose [44].

Tuberculous ascites is observed in countries with increased prevalence of infection. Acid-fast bacilli (AFB) smears and cultures are used to identify mycobacterial infections. The sensitivity of the smear, however, is quite limited and culture results may take up to several weeks to obtain. The American Association for the Study of Liver Diseases guidelines recommend that only patients at high risk of tuberculous peritonitis (e.g., recent immigration from an endemic area or coinfected with an acquired immunodeficiency syndrome) should be tested, and in such cases, biopsy with mycobacterial culture of tubercles is most efficient. Many studies have been conducted measuring ADA in ascitic fluid with a cutoff >40 U/L giving a pooled sensitivity of 93% (95% CI [89%, 95%]) and specificity 96% (95% CI [94%, 97%]) in a metaanalysis of 16 studies utilizing the Giusti method [45]. The Giusti method involves the colorimetric quantification of ammonia as a colored phenol end product (Berthelot's reaction) from enzymatic conversion of adenosine (substrate) by ADA [46]. This approach is recommended for facilities that may not have biopsy services available or for screening patients to identify those that would benefit most from the procedure.

The measurement of peritoneal glucose is not routinely recommended but may be useful as an adjunct in cases of suspected peritoneal infection. Low glucose concentration is a nonspecific finding, as any process where the localized metabolic activity is increased may result in decreased glucose concentrations. It is recommended to compare the fluid glucose concentration to serum or plasma concentrations for interpretation.

Pancreatic enzyme concentrations two- to threefold greater than corresponding serum concentrations may be highly suggestive of pancreatic ascites though not entirely specific [33]. Measurement of amylase and/or lipase in abdominal fluid may aid in the identification of pancreatic fistulas caused by chronic pancreatitis or formation of a pancreatic fistula following surgery. However, in the setting of a low gradient SAAG and elevated serum enzymes, quantitation of abdominal fluid amylase and/or lipase is unlikely to alter patient management.

Creatinine and/or urea may be elevated in ascitic fluid that is contaminated with urine. Fluid to serum ratios >1 for either creatinine or urea are highly suggestive of bladder rupture or perforation following surgery and trauma or the development of urinary fistula. Such findings will elicit a more focused radiologic examination and surgical intervention to repair.

Choleperitoneum is defined as the presence of bile in the peritoneum, which is an infrequent yet highly treatable cause of ascites observed most commonly as a complication following laparoscopic cholecystectomy or following other surgeries or trauma affecting the biliary tree [47]. Nuclear medicine cholescintigraphy scans are used to diagnose damage to the gallbladder and biliary system but are expensive and time consuming. A fluid that is brown or green highly suggests the presence of bile; however, some bilious fluid has been described as yellow, amber, and orange, and can therefore be easily mistaken as normal. Measurement of the fluid total bilirubin to serum ratio with cutoff >5 has 100% diagnostic accuracy for detecting bile. Detection of bile leaks using the fluid to serum bilirubin ratio following orthotopic

liver transplant is reportedly less accurate owing to possible dilution within the peritoneal cavity due to preexisting ascites, with an optimal cutoff of >3.25 (area under the curve: 0.89, sensitivity 73%, specificity 95%) [48]

Ascitic fluid methods

The accuracy for the measurement of numerous analytes using both chemistry and immunoassay methods have been confirmed in ascitic fluid using the Roche cobas 8000 platform [3,5] and for tumor markers on the Beckman Coulter UniCel DxI 800 platform [7,40]. Older studies have suggested that colorimetric albumin methods should be avoided when measuring SAAG as they are less specific for albumin (demonstrating bias compared to immunochemical methods) with lack of analytical sensitivity in the measurement of low concentrations of albumin [33,49]. Bias has been reported between bromocresol green and purple (BCP) methods in serum owing to BCP having improved specificity for human albumin. This bias was not observed, however, in a small cohort of peritoneal fluids, which caused several SAAG values to be reclassified from high to low gradient when using the BCP method [50]. These findings need to be replicated in a larger cohort; however, they do elucidate a concern laboratories should be aware of.

The gold standard for performing body fluid cell counting is use of a hemocytometer equipped with a manual counting chamber. More recently, automated cell counting analyzers have become available with manufacturer's intended use including quantitation and differentiation of cells in body fluids. Manual methods cannot be completely replaced, however, as automated methods may have limited analytical sensitivity. Use of automated methods may also require manual microscopy to identify abnormal cells flagged by the instrument [51].

The use of leukocyte esterase reagent strips marketed for dipstick urinalysis has been studied as a rapid and simple point of care test for surrogate cellular analysis to expedite identification and treatment of SBP [33]. While studies demonstrate significant correlation to neutrophil count, diagnostic accuracy varies as the reading is semiquantitative, have subjective interpretation, and the cutoffs considered positive need to be established as they vary from manufacturer to manufacturer [52]. It has been suggested that reagent strip methods may be suitable for screening in places where manual or automated cell counting methods are unavailable, such as in developing countries [52].

Dialysate

PD is a type of ambulatory dialysis that can be employed in the home for patients with end-stage kidney disease. The procedure involves infusing 2 L of a hyperosmotic fluid through an abdominal catheter into the peritoneal cavity where the peritoneum acts as an endogenous dialysis membrane to remove metabolic waste molecules and excess body water from circulation [53]. After a prescribed dwell time, the fluid is removed and the process repeated four times within a 24-hour period for the average patient. The advantages of employing PD over hemodialysis (HD) include better quality of life for the patient with fewer hospitalizations and limitations on travel and work life. The frequency of PD versus HD worldwide varies considerably from 81% of all dialysis patients in Hong Kong to <10% in the United States and Germany and is related to reimbursement policies.

PD fluid employs a lactate-buffered glucose solution (1.36%, 2.27%, or 3.86%) as the most common type of osmotic agent, though icodextrin, a glucose polymer, is also available. Laboratory measures of urea (or urea nitrogen), creatinine, glucose or electrolytes in serum, urine, and the PD fluid are commonly requested in the management of PD patients, and the results entered into a software program designed to perform necessary calculations and interpretation of those results [54]. The peritoneal equilibration test (PET) is usually performed 4–6 weeks after initiation of PD with the goal to estimate the rate of small solute transport across the peritoneal membrane and the ultrafiltration capacity, which serves to characterize the patient's membrane transporter characteristics and guide the selection of an appropriate dialysate fluid glucose concentration and dwell time. Faster transport rates are observed when the PD creatinine to serum creatinine ratio after a 4-hour dwell time is largest. Smaller ultrafiltration volumes and slower transport rates are observed when the ratio of PD glucose after 4-hour dwell to PD glucose at baseline is greatest. PD adequacy is determined by collecting samples from a 24-hour dialysate and urine collection to measure urea and calculate Kt/V, where K is clearance of urea, t is dialysis time, and V is the volume of distribution of urea which is approximately equal to the patient's total body water. The result is multiplied by 7 to determine the weekly urea clearance with the goal to maintain weekly Kt/V >1.7. It should be measured at the same time as the PET is conducted and then quarterly or as clinically indicated.

The leading cause of complications for PD patients is peritonitis as a result of infection. The inflamed peritoneum becomes leaky whereby the osmotic gradient dissipates more rapidly and proteins cross more readily necessitating more frequent exchanges to maintain an adequate Kt/V. Antibiotics and/or heparin may be added to the dialysis fluid to treat infection and prevent the formation of fibrin.

Pericardial fluid

The pericardial cavity lies within the thoracic space, surrounding the heart and major vessels. Under normal conditions, 25–35 mL of fluid is present within that space to decrease friction and protect the organ from physical insults [55]. Pericardial effusions develop under pathological conditions when the rate of fluid formation exceeds the rate of removal. Pericardial effusions can be highly variable in presentation and may accompany a variety of pericardial disorders [55]. The onset can be acute (<1 week) to chronic (>3 months), vary in size and distribution, and remain essentially asymptomatic or cause significant hemodynamic instability [56]. The classic symptoms of effusion include shortness of breath, dyspnea on exertion, fever, chills, chest pain, and swelling. Cardiac tamponade is characterized by hypotension and increased pressure within the jugular vein. The physical exam often reveals neck vein distension, diminished heart sounds upon auscultation, and pulsus paradoxus—a phenomenon describing the reduction in radial pulse upon inspiration [56].

Pericardiocentesis is the procedure whereby a few milliliters to several liters of pericardial fluid is removed via percutaneous needle using echocardiographic guidance for diagnostic and/or therapeutic purposes [57]. Laceration or perforation of the myocardium or coronary vessels constitutes the major procedure-related complications, having a reported incidence rate of 1%–1.6% [56]. Pericardial fluid analysis is indicated according to the European Society of Cardiology guidelines in patients with cardiac tamponade, suspicion of infection or neoplasm, and in patients with moderate to large effusions of unknown etiology that have not responded to therapy [58]. Thus the analysis most often centers on the use of Gram stain and culture as well as the identification of malignant cells by cytological evaluations.

The differential diagnosis for pericardial effusion includes infection, connective tissue disease, neoplasm, metabolic causes, and idiopathic etiologies usually assumed to be viral infection [56]. Table 27.2 lists the most commonly reported causes of moderate and large pericardial effusions in several population-based studies. It is notable that in South Africa (and likely other parts of the world where tuberculosis infection is prevalent), infectious causes of pericardial effusion predominate, whereas Western nations report higher prevalence of idiopathic pericarditis, neoplastic, and iatrogenic causes [56]. In 60% of cases in which pericardial effusion is discovered, a known underlying disease exists and often can be treated without a diagnostic

TABLE 27.2 Prevalence and etiology of reported moderate and large pericardial effusions.

Study	Study period	*n* patients	Top three reported causes
United States	1993–2000	441	Iatrogenic 42%[a]
			Postoperative 28%
			Neoplastic 25%
Spain	1990–96	322	Idiopathic 29%
			Iatrogenic 16%
			Neoplastic 13%
France	1998–2002	204	Idiopathic 48%
			Infection 16%
			Neoplastic 15%
South Africa	1995–2001	233	Infection 72%
			Idiopathic 14%
			Neoplastic 9%
China	2007–09	140	Neoplastic 39%
			Infection 29%
			Idiopathic 9%
			Iatrogenic 9%

Notes: Refer to [56] and [60].
[a]*Postoperative causes and cardiac perforation from invasive procedure.*

pericardial fluid workup [56]. Inaccurate classification of pericardial effusions as transudative and exudative when applying classic Light's criteria (see Pleural fluid) has been reported. Therefore there is limited evidence that the measurement of most biochemical and tumor marker analytes in pericardial fluid adds any value to clinical management [61–65].

The most common infectious cause of pericardial effusions are viruses in the United States and Western European populations, whereas tuberculosis is a more frequent cause in developing countries [56]. Viral pericarditis is diagnosed based on clinical symptoms of pericarditis and elevated inflammatory markers, and it is often treated empirically with nonsteroidal antiinflammatory drugs (NSAIDs) or other antiinflammatory therapies. AFB staining and mycobacterium cultures are the mainstay for diagnosis of TB pericarditis; however, testing is limited by sensitivity and turnaround time of result availability. Biomarkers of infection have also been evaluated, and measurement of ADA in pericardial fluids has a reported 88% sensitivity, 83% specificity, and area under the receiver operator curve of 0.9539 using a cutoff >40 U/L by the Giusti method to identify tuberculous pericarditis in populations where the index of tuberculosis infection is sufficiently high [66]. For this reason, ADA measurement is best reserved for regions with moderate to high incidence of TB (approximately 50 cases per 100,000 or more) where the positive predictive value is increased with a lower rate of false positive results [67].

Malignant pericardial effusions are associated most commonly with lung carcinoma [68]. The fluid appears bloody more frequently compared to the serous appearance associated with other etiologies. Cytologic examination for malignant cells is the gold standard for diagnosis. The investigation should be performed on a sufficient volume of sample, at least 60 mL, to adequately rule out the presence of malignant or atypical cells suggestive of malignancy [69]. Dragoescu et al. reported a cohort of 128 specimens analyzed over 6 years in which cytology was 71% sensitive and 100% specific for detecting malignancy compared to pericardial biopsy which was 64% sensitive and 85% specific, although 87% of cases had a pathology-proven history of cancer at presentation [68]. In a separate cohort of patients presenting with large symptomatic malignant effusions with unrecognized cancer, cytology was only 51% sensitive, posing a diagnostic dilemma [70]. In cases of equivocal or suspected false negative cytology results, tumor marker analysis may be considered although such testing has reported limited success [4].

Synovial fluid

Synovial fluid is present in joint cavities and serves a number of important roles in maintaining joint health and mobility. It forms as a plasma ultrafiltrate, with additional components produced from synoviocytes. The synovial membrane lines the inner surface of the joint cavity. Type A synoviocytes are derived from monocytes and serve a phagocytic role in clearing cellular debris from the joint. Type B synoviocytes are fibroblasts that secrete substances, which help to lubricate and maintain the joint as discussed below. Small molecules (such as electrolytes) may filter freely into the synovial fluid, making their concentrations similar to those found in plasma. Size exclusion plays an important role in limiting larger molecules from filtering into the synovial fluid. For example, larger-molecular-weight proteins such as clotting factors typically do not enter the synovial fluid, whereas smaller proteins such as albumin may enter more easily.

Two important substances produced by synoviocytes are hyaluronic acid (HA) and lubricin. HA (or hyaluronan) is a high-molecular-weight polymer of repeating disaccharides (D-glucuronic acid and *N*-acetyl-D-glucosamine). HA increases synovial fluid viscosity, protects the surface of cartilage during stress and impact, and helps to maintain the joint space by influencing water and solute balance. Lubricin (also known as proteoglycan 4; PRG4) promotes joint lubrication and helps to protect articular cartilage. Together, these substances reduce friction and maintain joint health and mobility.

Normal and noninflammatory synovial fluid is typically clear or slightly yellow and somewhat viscous. Synovial fluid that is bloody or brownish in color may be consistent with trauma or recent and/or prior bleeding into the joint space (e.g., hemarthrosis or traumatic tap). In patients with unexplained bloody effusions, the possibility of coagulopathy (e.g., hemophilia) should be included in the differential diagnosis, particularly in pediatric patients. Cloudy, yellowish effusions may be consistent with inflammation and/or infection. Purulence is suggestive of infection, although cloudy-white effusions may also be observed in inflammatory or crystal-induced arthritis. While synovial fluid appearance is often suggestive of a particular etiology, it is not specific for individual diagnoses. Noninflammatory arthritis can be seen with conditions such as osteoarthritis (where protective cartilage is gradually lost from the ends of bone) or trauma. Inflammatory arthritis can have a variety of causes including rheumatoid arthritis, crystal arthritis, systemic lupus erythematosus, and other autoimmune disorders.

Symptoms of joint problems include pain, swelling, stiffness, or decreased range of motion. Septic joints may be accompanied by systemic symptoms such as fever. Joint problems can be localized to individual joints (e.g., knee osteoarthritis), present across many joints (e.g., rheumatoid arthritis), or may spread progressively to nearby joints (e.g., infectious arthritis). The acute versus chronic

nature of symptoms, as well the patient's medical history, often provide clues to underlying etiology.

The technique of synovial fluid collection is called arthrocentesis. Collection should be aseptic to prevent iatrogenic infection of otherwise noninfected joint spaces. Proper approach of the collection needle varies by the location of the joint to be aspirated [71]. Routine analysis of synovial fluid should include Gram stain, culture, crystal analysis, and cell count with WBC differential (to determine the percent of PMN leukocytes; %PMNs), as these tests are effective in helping to support the diagnosis of most inflammatory and noninflammatory diagnoses. Chemical analysis may provide additional information in certain cases. Manual tests (such as the string test for synovial fluid viscosity and the mucin test for clot detection) have limited clinical use.

WBC counts in normal synovial fluid specimens are usually in the range of 0−200 cells/μL. Increased WBC counts are typically seen in noninflammatory (0 to 2,000 cells/μL), inflammatory (2,000 to 100,000 cells/μL), and septic (10,000 to >100,000 cells/μL) joint disorders, although these are only approximate (and obviously overlapping) ranges, which serve as preliminary clues to an underlying category of disorder. Exceptions to these ranges are also quite common. For example, crystal synovitis may be observed with high WBC counts, whereas early septic arthritis may be observed with unexpectedly low WBC counts. Inflammatory causes of arthritis are typically associated with elevated %PMNs (>50%), while septic arthritis may have a %PMN of greater than 75%−90% [72]. Given these overlapping categorizations for WBC and %PMN, the importance of Gram stain and culture in helping to identify infectious etiologies is extremely important.

Crystal analysis should ideally be conducted using polarized microscopy. Polarized filters with a red compensator are used to detect birefringence, the double refraction of light when polarized rays hit certain crystalline materials. Many crystals (such as table salt, NaCl) are not birefringent. Monosodium urate (MSU) crystals, which are typically seen in gout, are needle-shaped in appearance and negatively birefringent. Calcium pyrophosphate dihydrate (CPPD) crystals, typically seen in pseudogout, have a rhomboid shape and are positively birefringent. When the long axis of a crystal is aligned in parallel to the slow wave of the microscope's red compensator, MSU crystals appear yellow while CPPD crystals appear blue. Other crystalline forms that may sometimes be observed in joint fluid include cholesterol, lipids, basic calcium phosphates/hydroxyapatite, calcium oxalate, and even corticosteroids after prior therapeutic injections. Acute attacks of gout and pseudogout are often treated with antiinflammatory medications (such as NSAIDs), colchicine, or corticosteroids. Prophylactic management of gout may include diet modification or medications such as xanthine oxidase inhibitors (e.g., allopurinol), uricosuric agents that increase uric acid excretion into the urine (e.g., probenicid), or enzymes that metabolize uric acid (e.g., uricase).

Early recognition and diagnosis of acute synovitis is essential to initiation of appropriate therapy, to minimize joint damage, and to maintain healthy joint function. Identification of septic arthritis is a primary concern. Common pathogens vary by patient age and underlying medical condition but include *Staphylococcus aureus*, *Streptococcus agalactiae* and *S. pyogenes*, *Neisseria gonorrhoeae*, *H. influenzae*, and more rarely Gram-negative bacteria such as *Pseudomonas aeruginosa*. Clues to disseminated gonococcal infection may include accompanying skin lesions and/or petechia, arthralgia, and arthritis. Risk for septic arthritis are increased in the presence of bacteremia, localized bacterial infections, joint implants, IV drug abuse, or chronic diseases associated with acute or chronic arthritis. Fastidious and atypical organisms may be difficult or impossible to identify by Gram stain or culture. Diagnosis of Lyme arthritis due to *Borrelia burgdorferi* is primarily serological (or molecular) but not conducted on joint fluid.

Chemical analysis of synovial fluids is sometimes ordered as supportive evidence for inflammatory and infectious (versus noninflammatory) causes of arthritis, but in general it is less clinically useful than routine cell count with differential, Gram stain, and culture. In normal synovial fluid, glucose concentrations are similar to those observed in fasting serum. Low synovial fluid glucose has been associated with septic arthritis or inflammation. In normal synovial fluid, total protein concentrations are typically 1/3 of a corresponding plasma specimen. Increased total protein can be observed with inflammation or damage to synovial membranes. Both glucose and protein have inadequate sensitivity and specificity to justify their routine clinical use.

Elevations in synovial fluid LDH have also been associated with both inflammatory and septic arthritis but again provide little benefit over the routine recommended tests. Increased lactate concentrations may also be observed with septic arthritis but are also not considered routine. Serum testing for inflammatory markers, such as rheumatoid factor, erythrocyte sedimentation rate, and C-reactive protein play a role in evaluating systemic inflammatory disease, although they are not considered clinically useful for most synovial fluids. Uric acid measurements may be useful in circumstances where microscopy is not available (or MSU crystals are not observed) but gout arthritis is strongly suspected [73].

Amniotic fluid

Amniotic fluid surrounds and protects a growing fetus within the uterus contained by a membrane known as the

amnion [69]. The volume of fluid contained within the amnion increases from approximately 50 mL present at 12 weeks gestation to approximately 1 L at term. Polyhydramnios is a condition where the volume of amniotic fluid is abnormally increased, while oligohydramnios is a condition of abnormally decreased amniotic fluid volume. The composition of amniotic fluid varies throughout gestation. Early in gestation the amniotic fluid is produced by the amnion and placenta, representing a plasma ultrafiltrate. As gestation progresses, the fetal lungs and kidneys develop and fluid exchange within the amnion gives rise to increasing concentrations of metabolic byproducts including creatinine, urea, and uric acid. These waste products are removed by exchange with maternal serum. Fetal respiratory action develops during the latter weeks of gestation (≥32 weeks) causing fetal pulmonary surfactant molecules to be released into the amniotic fluid.

Amniocentesis is a percutaneous procedure whereby a needle is inserted transabdominally, under continuous US guidance, into an unoccupied area of the amniotic cavity to remove 10−20 mL of amniotic fluid using a syringe [21]. The first drops of fluid are typically wasted as they may contain maternal cells and could be mistaken as mosaicism in cytogenetic studies [74]. The volume of fluid that can be safely removed is approximately 1 mL for each gestational week (e.g., 17 mL at 17 weeks). Diagnostic amniocentesis performed during 14−18 weeks of gestation may be conducted to perform genetic studies if there is suspicion for increased risk of chromosomal abnormalities based on medical history, US examination, or after first or second trimester maternal serum screening. In limited cases where maternal serum screening tests reveal increased risk of open neural tube defects and high-resolution US findings are inconclusive, measurement of AFP and acetylcholinesterase activity in amniotic fluid is recommended. Refer to Chapter 42, Laboratory testing in pregnancy, for a complete description of lab testing for fetal anomalies.

Amniocentesis is performed during 20−42 weeks of gestation to assess fetal distress. Intraamniotic infection or chorioamnionitis is an acute inflammation of the fetal membranes commonly caused by bacterial infection prompting an inflammatory response leading to labor and term or preterm birth [75]. Chorioamnionitis may be symptomatic (clinical) or asymptomatic (histological), occurring most often during prolonged labor or as a consequence of membrane rupture as bacteria have greater opportunity to ascend the lower genital tract to colonize the uterus. Prompt diagnosis and treatment for clinical chorioamnionitis is critical to avoid maternal and fetal morbidity and mortality. The symptoms are not universally agreed upon but include maternal fever and maternal or fetal tachycardia, uterine fundal tenderness, or purulent amniotic fluid. Histopathologic chorioamnionitis occurs when there is microscopic evidence of infection or inflammation of the placenta or chorion which may be accompanied by symptoms of infection or remain asymptomatic and only diagnosed after delivery. Hemolytic disease of the newborn also causes fetal distress due to alloimmunization and Rh incompatibility between mother and fetus. Amniotic fluid may be collected to undergo PCR analysis to genotype an at-risk fetus as well as measure bilirubin to assess the extent of hemolysis and need for intrauterine transfusion.

Historically after week 32, fetal lung maturity (FLM) was evaluated to make decisions to delay an elective delivery while corticosteroids were administered to promote lung development if necessary. Identification of pulmonary surfactants (lamellar bodies, lecithin, sphingomyelin, and phosphatidyl glycerol) in amniotic fluid is supportive evidence that the fetal lungs have sufficiently matured and the risk of developing respiratory distress syndrome is low. However, more recent clinical guidelines favor using gestational age to assess fetal maturity as the assessment of FLM did not improve outcomes and nonmedically indicated late-preterm and early-term deliveries are strongly discouraged due to the increased risk of fetal morbidity and mortality [59]. Laboratories have noted declining volumes of FLM testing in recent years as a likely signal of this trend [76]. Refer to Chapter 42, Laboratory testing in pregnancy, for an overview of FLM.

Therapeutic amniocentesis may be performed in cases of polyhydramnios. The complications associated with amniocentesis include rupture of membranes, fetal injury, infection, and fetal loss. Fetal loss related to amniocentesis typically occurs in the 4 weeks following the procedure at a rate of 1 in 300 to 1 in 500 [77]. Temporary leakage of fluid occurs more frequently (1.7%); however, it is generally associated with normal pregnancy outcomes.

Feces

Feces (also known as stool) is the waste product of digestion. Fecal analysis is typically conducted in the evaluation of diarrheal disease (frequent passage of loose, watery stool), suspected gastrointestinal infection with pathogens (e.g., bacteria, viruses, or parasites), evaluation for malabsorptive or maldigestive disorders, and for the detection of occult blood loss that may be associated with gastrointestinal bleeding or malignancy. Stool examination, as well as testing for fecal occult blood, malignancy, and malabsorptive disorders, is covered in Chapter 32, Gastrointestinal disorders.

Collection of fecal specimens is an unpleasant task for most patients and is often associated with poor compliance. Proper collection includes avoiding contamination with urine and toilet water. Handwashing after collection

is important to prevent pathogen spread. In some cases, multiple stool collections over several days may be required. Preservatives may be recommended or required for some fecal tests (e.g., detection of ova and parasites; O&P) but are incompatible with other analyses such as bacterial culture. Many laboratories have initiated specimen acceptability requirements for some fecal testing. For example, a well-formed stool specimen from an inpatient (hospitalized for several days) may be rejected for routine O&P or bacterial culture, as neither the specimen nor the medical scenario is consistent with ongoing diarrheal disease.

Routine fecal bacterial culture protocols are often designed to detect *Salmonella*, *Shigella*, and *Campylobacter* species. Many laboratories also include processes to detect *E. coli* O157:H7 and Shiga-toxin producing strains of *E. coli*. Bacterial identification may also include *Yersinia*, *Vibrio*, *Aeromonas*, *Plesiomonas*, and *Staphylococcus* species.

Both antigen and NAT have proven to be extremely valuable in fecal analyses. Production of *Clostridium difficile* toxin may be detected by enzyme immunoassay (EIA), PCR, or cell cytotoxicity assays. *E. coli* Shiga-like toxins may also be detected by EIA. *Cryptosporidium* EIA may provide supportive information along with O&P. Stool viral cultures may detect a number of pathogenic viruses, although specific viral antigen testing (e.g., for rotavirus or adenovirus serotypes 40 and 41) provides more rapid turnaround times. Multiplex NAT platforms may reduce the time for identification of bacterial, viral, and parasitic species.

The cause of chronic diarrhea (symptoms lasting >4 weeks) may be investigated using fecal electrolyte and osmolality studies to classify diarrhea as secretory (i.e., epithelial transport-mediated) or osmotic (i.e., due to the presence of poorly absorbed solutes in the GI tract). A Fecal Osmotic Gap is typically calculated as:

$$\text{Fecal osmotic gap} = \text{Fecal osmolality} - 2 \times \left([\text{Na}]_{\text{fecal}} + [\text{K}]_{\text{fecal}}\right)$$

An average fecal osmolality of 290 mOsm/kg is often used in the calculation; alternatively, fecal osmolality may be measured with an osmometer. A low fecal osmotic gap (<50 mOsm/kg) with an elevated fecal sodium is consistent with secretory diarrhea or use of sodium-containing laxatives. A high osmotic gap (>100 mOsm/kg) with a low fecal sodium is typically consistent with osmotic diarrhea. Elevated fecal magnesium concentrations provide evidence for use of magnesium-containing laxatives.

A variety of additional tests have been used to identify inflammatory, digestive, malabsorptive, and even systemic disorders. The detection of fecal leukocytes by stool microscopy is suggestive of GI inflammation or infection. Fecal lactoferrin and fecal calprotectin (substances produced by neutrophils) have both been used to differentiate inflammatory bowel disease (IBD) from irritable bowel syndrome (IBS) or other noninflammatory gastrointestinal disorders. Fecal alpha-1-antitrypsin (A1A) clearance measurements, which compare A1A concentration in 24-hour stool collections to serum, have been used to identify protein-losing enteropathies. Fecal bile acid measurements are essential to the identification of bile acid malabsorption. Increased fecal reducing substances (sugars) are suggestive of disorders in carbohydrate absorption or metabolism. Finally, fecal porphyrin testing is critical to the differentiation of variegate porphyria and hereditary coproporphyria from acute intermittent porphyria.

Self-assessment questions

1. Exudates are fluid accumulations that are most often due to membrane damage, infection, inflammation, or malignancy.
   a. true
   b. false
2. Which of the following laboratory findings provides supportive evidence that a pleural fluid is an exudate:
   a. fluid LDH activity that is $<2/3$ the upper limit of a normal serum LDH activity
   b. fluid-to-serum LDH ratio of <0.6
   c. fluid-to-serum protein ratio of >0.5
   d. serum-to-fluid albumin gradient (serum albumin minus fluid albumin) >1.2 g/dL
   e. serum-to-fluid protein gradient (serum protein minus fluid protein) >3.1 g/dL
3. A SAAG $\geq$ 1.1 g/dL and a total protein >2.5 g/dL is most consistent with which of the following etiologies of the ascites:
   a. cirrhosis
   b. heart failure
   c. malignancy
   d. pancreatitis
   e. tuberculosis
4. The procedure to collect pleural fluid is known as:
   a. amniocentesis
   b. arthrocentesis
   c. paracentesis
   d. pericardiocentesis
   e. thoracentesis
5. The presence of CSF in a nasal fluid specimen can be evaluated by which of the following tests:
   a. alpha-1 antitrypsin
   b. alpha-2 macroglobulin
   c. beta-2 glycoprotein
   d. beta-2 transferrin
   e. beta-2 microglobulin
6. Which of the following fecal tests would be most useful in differentiating IBD from IBS:
   a. fecal calprotectin
   b. fecal fat
   c. fecal *Helicobacter pylori* antigen
   d. fecal porphyrins
   e. fecal reducing substances

Answers

Chapter 28

Lipids and lipoproteins

Leslie J. Donato and Jeffrey W. Meeusen
Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN, United States

Learning objectives

After reviewing this chapter, the reader will be able to:

- Discuss the mechanisms of lipid and lipoprotein production and metabolism.
- Explain the clinical testing methods used in the measurement of lipids and lipoproteins.
- Describe dyslipoproteinemias in terms of laboratory aberrations and clinical manifestations.

Background

In a clinical context, the term "lipids" almost invariably means cholesterol. This focus on a single molecule is due to the extensively studied association between cholesterol and cardiovascular disease (CVD). Despite this attention, cholesterol is not the most prevalent lipid carried in blood plasma nor is it directly pathological. In fact, considerable effort has been made to promulgate the concepts of "good cholesterol" versus "bad cholesterol," which will be discussed further below.

Clinical chemists know that lipids are a class of molecules with poor aqueous solubility. A small number of lipids bind directly with albumin or other globulins; however, most blood lipids are incorporated into lipoproteins. A lipoprotein is a heterogeneous particle composed of proteins and lipids. Solubility is maintained by locating apolipoproteins and polar lipids [e.g., phospholipids, sphingolipids, fatty acids (FAs), and cholesterol] near the outer surface of the particle. Conversely, nonpolar lipids such as triglycerides and cholesteryl esters are carried in the lipoprotein core. The primary role of lipoproteins is to redistribute lipids between organs and tissues via the bloodstream.

Assessment of plasma lipoproteins can be informative in the clinical evaluation of a patient. Abnormal lipoprotein distributions are often indicative of underlying disease, such as liver cholestasis, inborn errors of metabolism, or nutritional imbalances. Furthermore, abnormal plasma concentrations of lipoproteins may have severe consequences, including pancreatitis, neurological deficits, and CVD.

Clinically relevant lipids

Cholesterol is a tetracyclic alcohol that can be produced de novo by all animal cells (Fig. 28.1). Cellular membranes incorporate cholesterol as a structural component, where it provides increased strength without rigidity. Cholesterol is also a precursor for many essential compounds, including vitamin D, bile salts, and hormones.

FAs are carboxylic acids with a variable length hydrocarbon chain. FAs are synthesized via glycolysis and used as a means of energy storage with increased density as compared with glycogen or glucose. The hydrocarbon chain of FAs contains an even number of carbons (typically 4−26) that can be saturated (without double bonds) or unsaturated (with double bonds). FAs are often components of more complex lipids such as triglycerides, cholesteryl esters, and sphingolipids.

Cholesteryl esters are extremely hydrophobic and account for 60%−80% of all plasma cholesterol. Esterification of three FAs with a single glycerol molecule results in the production of a triglyceride molecule, which is the primary energy storage source in animals. Phospholipids are the product of esterification by two FAs and an inorganic phosphate with glycerol. Serine FA esters are precursors for sphingolipids (Fig. 28.1). Nonesterified FAs are also referred to as "free" fatty acids (FFA), and are generated when released from triglycerides and other esters following enzymatic lipolysis.

Lipoprotein metabolism

Apolipoprotein B lipoproteins and triglyceride redistribution

The role of apolipoprotein B (apoB)-lipoproteins is to redistribute triglycerides between tissues. ApoB-lipoproteins begin as triglyceride-enriched lipoproteins (TRLs) synthesized in the liver or intestines. TRLs are converted into smaller lipoproteins in circulating plasma through the enzymatic lipolysis of triglycerides into FFAs (Fig. 28.2).

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00028-4

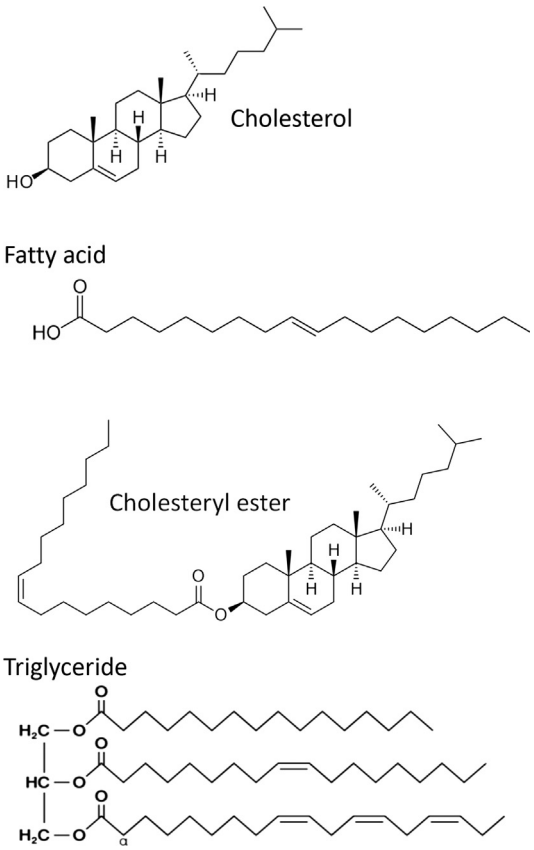

FIGURE 28.1 Common biological lipids.

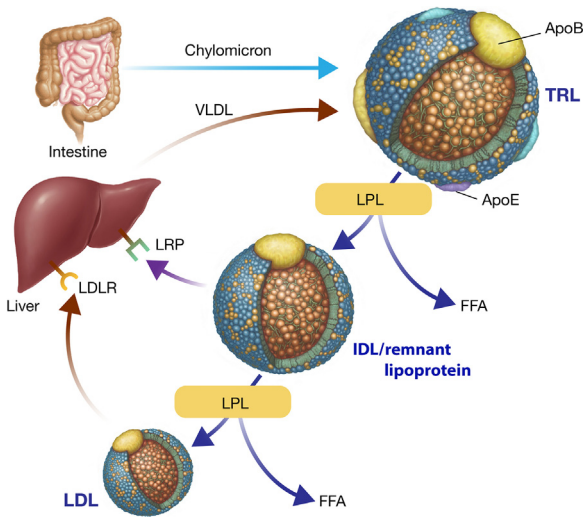

FIGURE 28.2 Apolipoprotein B metabolism. Triglyceride rich lipoproteins are generated by the intestines (chylomicrons: 75−1200-nm diameter) or liver (very-low-density lipoproteins: 30−80-nm diameter). Lipoprotein lipase activity in blood capillaries converts triglycerides in the lipoprotein core into free-fatty acids. The smaller and denser intermediate-density lipoproteins (from very-low-density lipoproteins) or remnant lipoproteins (from chylomicrons) are taken up by the liver via low-density lipoprotein receptors or low-density lipoprotein receptor-related protein. Low-density lipoproteins are apolipoprotein B-lipoproteins produced from very-low-density lipoproteins/intermediate-density lipoproteins and are too small to carry apolipoprotein E so are cleared only via low-density lipoprotein receptor.

ApoB is required for the synthesis of very-low-density lipoproteins (VLDLs)[1] by the liver to start the "intrinsic" lipid metabolism pathway employed for lipids in systemic circulation. A truncated apoB isoform (apoB-48) is synthesized in the intestines during the formation of chylomicrons to initiate the "extrinsic" lipid metabolism pathway from dietary lipids. Both intestinal apoB and hepatic apoB are encoded by a single gene and share a common N-terminal sequence. The shorter apoB-48 protein is produced by RNA editing of the full apoB transcript, resulting in the creation of a stop codon, and early translation termination. In VLDL and chylomicrons, as well as remnant lipoproteins (RLPs), apoB is the primary structural component around which the lipid particle is formed (Fig. 28.2).

In addition to apoB, VLDL and chylomicrons contain apolipoprotein E (apoE), apolipoprotein C-II (apoC-II), and apolipoprotein C-III (apoC-III). ApoE, apoC-II, and apoC-III are exchangeable apolipoproteins, meaning they can be added and removed from the lipoprotein. In this way, any given lipoprotein may contain several copies of apoE, apoC-II, and apoC-III, or none at all. ApoB is unique in that it is a nonexchangeable structural component of the lipoprotein and all apoB-lipoproteins always contain exactly one apoB (Fig. 28.2).

Lipoprotein lipase (LPL) expressed on the capillary endothelium in peripheral tissues converts triglycerides into FFAs. Tissues with a high demand for lipids, such as skeletal muscle and adipose, have increased capillary expression of LPL. The rate of lipolysis is regulated by apoC-II and apoC-III. ApoC-II is an essential cofactor for LPL, while apoC-III is a potent inhibitor of LPL. As LPL converts triglycerides into FFAs, which transfer into the tissues, the lipoprotein becomes smaller and increases in density. VLDL RLPs are referred to as intermediate-density lipoproteins (IDL), while chylomicron remnants are referred to as RLPs.

Hepatic lipases expressed on hepatocytes further reduce triglyceride content and aid in the conversion of TRLs into IDL and RLP. Under normal conditions, IDL and RLP are removed from circulation via two hepatic receptor proteins: the low-density lipoprotein receptor (LDLR) and LDLR-related protein (LRP). Both LDLR and LRP have a high affinity for apoE. Newly synthesized lipoproteins are large, with a diameter of 30−80 nm for VLDL and 75−1200 nm for chylomicrons. This is

1. Lipoprotein nomenclature is based on early studies that fractionated serum lipids by density.

noteworthy because the receptor domain of apoE is masked in large lipoproteins and only becomes available for binding once lipoproteins are reduced in size. This prevents immediate reuptake of newly synthesized lipoproteins by hepatocytes.

ApoB also has some affinity for LDLR, but it is much weaker than apoE. Under normal physiologic conditions, apoE-facilitated clearance is highly efficient and prevents measureable accumulation of IDL or chylomicron remnants. Unfortunately, this clearance may be incomplete. Some lipoproteins lose nearly all triglycerides and all apoE prior to removal from circulation. The result is a low-density lipoprotein (LDL). LDL is rich in cholesterol and contains no apolipoproteins other than apoB. Clearance of LDL relies on the low-affinity interaction between the LDLR and a single apoB ligand per particle (Fig. 28.2); consequently, the in vivo half-life of LDL is significantly longer than other apoB-lipoproteins.

Apolipoprotein A-I lipoproteins and reverse cholesterol transport

Apolipoprotein A-I (apoA1) is the structural protein of high-density lipoproteins (HDLs). In lipid metabolism, the role of apoA1 (and HDL) is to facilitate the removal of excess cholesterol from peripheral tissues. This process is referred to as reverse cholesterol transport (Fig. 28.3). ApoA1 is synthesized by both hepatocytes and enterocytes, as is apoB. However, while apoB-lipoproteins are fully assembled prior to secretion, apoA1 is released directly into circulation. This lipid-poor apoA1 is referred to as nascent HDL (also called preß-HDL, due to its electrophoretic migration pattern).

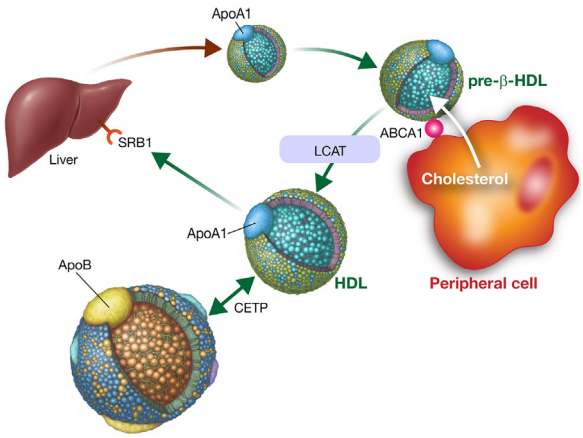

FIGURE 28.3 Reverse cholesterol transport pathway. Lipid-poor Apolipoprotein A-I is secreted by the liver and grows into a pre-ß-high-density lipoprotein as cholesterol from peripheral cells is transferred via adenosine triphosphate binding cassette A1. The pre-ß-high-density lipoprotein is converted into a mature high-density lipoprotein by the activity of lecithin:cholesterol acyltransferase. Cholesterol and triglycerides are exchanged between the mature high-density lipoproteins and the apolipoprotein B-lipoproteins via cholesterol ester transfer protein. High-density lipoprotein is cleared by the liver via scavenger receptor class B, type I receptors.

Nascent HDL interacts with the adenosine triphosphate binding cassette A1 (ABCA1) protein expressed on peripheral cells. ABCA1 facilitates active transport of cellular cholesterol to the nascent HDL. The nascent HDL is converted into a mature HDL via the lecithin: cholesterol acyltransferase (LCAT) enzyme. LCAT is a plasma enzyme that combines cholesterol and FFAs to form cholesteryl esters (Fig. 28.3). The mature HDL particle is larger and more spherical than the disk-shaped nascent HDL. This shape leads to a conformational change exposing the apoA1 binding site-specific for the scavenger receptor class B, type I (SR-BI). SR-BI is expressed on adrenal glands and hepatocytes and facilitates rapid cellular internalization of HDL. Mature HDL can also gain apoE, which enables additional hepatic clearance by LDLR and LRP. Once HDL is removed from circulation, the cholesterol it contained can be converted into hormones, repackaged as VLDL cholesterol, or excreted into the gastrointestinal tract as bile acids.

Neutral lipids (cholesteryl esters and triglycerides) can be shuttled between HDL and apoB-containing particles via the presence of a cholesteryl ester transfer protein (CETP). CETP is found primarily bound to HDL particles and allows for the equimolar exchange of lipids with other lipoproteins. Thus in patients with high LDL cholesterol, the concentration gradient of cholesterol to triglycerides results in a relatively cholesterol-rich HDL fraction (cholesteryl esters go into HDL while triglycerides go out). Conversely, in patients with high triglycerides carried on VLDL, the HDL particles become more triglyceride-rich. Individuals with homozygous mutations in *CETP* with no measurable CETP activity display high HDL-C, low LDL-C, and lower incidence of CVD. However, all attempts to date to create a pharmaceutical agent to inhibit CETP activity have failed to lower CVD risk substantially.

Clinical laboratory lipid measurements

The basic lipid panel

The basic lipid panel consists of three measured values: total cholesterol, HDL cholesterol, and triglycerides. Lipid panel measurements are almost exclusively performed on automated chemistry analyzers in a central laboratory. In addition, some point-of-care methods are also available that, while more expensive to perform, can aid in lipid management in select settings (health fairs, physician office clinics, or pediatric centers), where sending the patient to phlebotomy for central laboratory lipid testing is not ideal.

Total cholesterol

The method used to measure total cholesterol is an enzymatic reaction in which cholesteryl esters are first converted into unesterified cholesterol by cholesteryl ester hydrolase. This free cholesterol is then oxidized by cholesterol oxidase to cholest-4-en-3-one and hydrogen peroxide. Phenol-4-antipyrine and peroxidase then converts the hydrogen peroxide into a quinoneimine dye, which is measured spectrophotometrically (Fig. 28.4).

It is important to note that this assay does not distinguish between the esterified and the unesterified cholesterol. Approximately 60%–80% of cholesterol is esterified with FAs, largely as a result of the enzyme LCAT. The primary or secondary causes of LCAT deficiency (LCATD) can result in erythrocyte abnormalities and dramatically decreased esterification of serum cholesterol. Therefore when abnormalities in the cholesterol esterification process are suspected, a modified version of the cholesterol assay can be utilized, which omits the conversion of esterified cholesterol into free cholesterol to measure only the free cholesterol in circulation. The free cholesterol can then be compared with the total cholesterol in the same sample to determine the percentage of esterified cholesterol. A cholesteryl ester fraction of <20% indicates familial or acquired LCATD and increased risk of kidney, liver, and vascular diseases.

Triglycerides

Clinical laboratory methods to measure triglycerides are also enzymatic assays. Triglycerides are by nature heterogeneous in composition, containing FAs of various carbon-chain length and saturations. To circumvent this heterogeneity, clinical methods take advantage of the fact that all triglycerides include exactly one glycerol molecule. First, lipase is added to convert all triglycerides into free glycerol and FFAs. Then glycerol concentrations are quantified following a secondary reaction with glycerol kinase, glycerolphosphate oxidase, and a chromophore (Fig. 28.4).

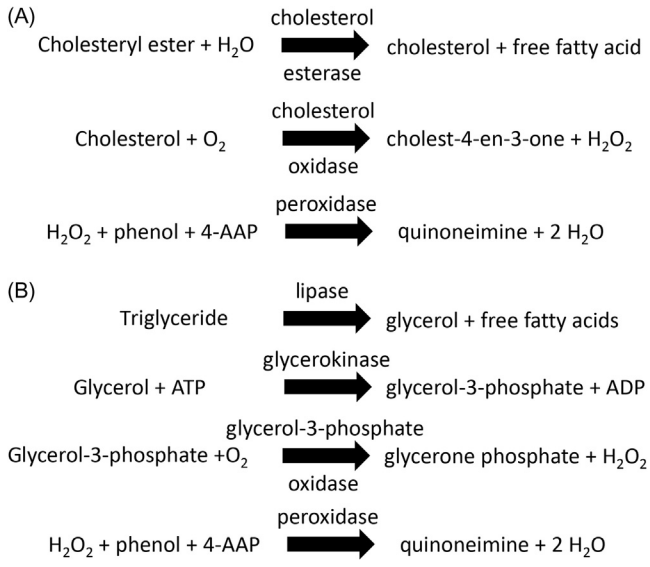

FIGURE 28.4 Enzymatic methods for measuring (A) cholesterol and (B) triglycerides.

The standard triglyceride assay used in most clinical laboratories will measure artificially high triglyceride concentrations (i.e., pseudohypertriglyceridemia) in patients that have abnormally elevated free glycerol. Increased plasma glycerol occurs in chronic alcohol drinkers, patients with glycerol kinase deficiency, or in cases of glycerol contamination of the specimen. If pseudohypertriglyceridemia is suspected, a glycerol-blanked assay can be used in which any free glycerol is first eliminated prior to the hydrolysis of the triglycerides, so that only triglycerides are measured. A comparison of the glycerol-blanked assay with the nonblanked assay can be used to determine the amount of free glycerol in circulation.

High-density lipoprotein cholesterol and nonhigh-density lipoprotein cholesterol

To measure HDL-C, most modern laboratories employ direct homogeneous assays, which utilize masking reagents that selectively interact with non-HDL lipoprotein particles and prevent cholesterol measurement. After masking, the standard enzymatic cholesterol reaction is performed to measure only the cholesterol within the particle of interest. Some reference laboratories and specialty lipid testing centers still employ traditional methodology for HDL-C measurement involving the precipitation of apoB-containing lipoproteins (LDL, IDL, VLDL, and chylomicrons) using a polyanion (such as dextran sulfate or heparin) and a divalent cation (such as calcium or manganese). After the non-HDL particles are precipitated, the cholesterol within the HDL is then measured enzymatically. This technique can still be useful in the cases of hypertriglyceridemia and diabetes where homogeneous methods tend to overestimate actual HDL-C [1–3]. However, new homogeneous methods are reportedly more reliable [4].

The 2001 National Cholesterol Education Program (NCEP) recommendations described a calculated parameter, non-HDL cholesterol, which should be included in basic lipid panels [5]. Non-HDL-cholesterol is calculated from a simple formula [see Eq. (28.i)]:

$$\text{Non-HDL-}C = \text{Total cholesterol} - \text{HDL-}C \qquad (28.\text{i})$$

Non-HDL cholesterol has been shown to predict future cardiovascular events. Non-HDL-C accounts for the cholesterol within all proatherogenic lipoprotein particles (LDL, lipoprotein (a) [Lp(a)], IDL, VLDL, and chylomicron remnants).

Low-density lipoprotein cholesterol

LDL-C is the focus of most lipid interventions and CVD risk assessments [6]. There are a variety of clinical LDL-C methods. We have chosen to focus on the most common clinical methods (estimation and direct homogeneous) and the gold-standard analytical method in this chapter.

Beta-quantification of low-density lipoprotein cholesterol

Beta-quantification is the gold standard method for LDL-C measurement. The assay name originates from early studies showing LDL particles migrate to the "beta" region on lipoprotein electrophoresis (see subsequent section on electrophoresis methods). The contemporary beta-quantification reference method was adopted by the NCEP in 1995 and uses a single ultracentrifugation step at $120{,}000 \times g$ for 16 hours to separate particles at 1.006 g/mL in which chylomicron and VLDL particles will float to the top layer of the sample (Fig. 28.5). The top layer is removed from the bottom layer, which contains LDL, Lp(a), HDL, and IDL [7,8]. Cholesterol is measured in this bottom fraction before it is treated with a divalent cation to precipitate any apoB-containing particles [i.e., LDL, Lp(a), and IDL]. After the precipitation, HDL is the only particle left in solution. Cholesterol is then measured in the HDL fraction. The HDL cholesterol is subtracted from the cholesterol measured in the LDL, Lp(a), HDL, and IDL layer to obtain the cholesterol in LDL (Fig. 28.5).

Prior to standardization to NCEP beta-quantification, LDL-C was classically defined as the measure of all cholesterol with a density between 1.019 and 1.063. Beta-quantification effectively altered the definition to cholesterol from *apoB-containing* lipoproteins with a density ≥ 1.006 mg/dL [8,9]. The amount of cholesterol in IDL or Lp(a) in most subjects is substantially less than the amount of cholesterol in LDL, so they are excluded in the measurement of LDL-C by beta-quantification. However, in the cases of dyslipidemias in which either Lp(a) or IDL is substantially increased, the measured concentration of LDL-C by beta-quantification will be artificially elevated. This inclusion is likely beneficial to the clinical performance of contemporary LDL cholesterol as a biomarker, due to the atherogenic nature of both IDL and Lp(a) [10]. However, it emphasizes the heterogeneity and lack of molecular specificity in the measure of LDL-C.

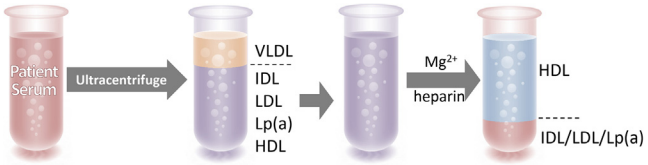

FIGURE 28.5 Beta-quantification. Patient sera is ultracentrifuged and the fraction with density <1.006 is discarded. The cholesterol content in the remaining fraction is measured before and after apolipoprotein B lipoproteins are precipitated.

Estimation of low-density lipoprotein cholesterol

The most commonly used clinical LDL-C method is not a measurement at all, but instead an estimation using the Friedewald equation [11]. In this calculation, the cholesterol within all lipoprotein particles except for LDL is subtracted from the total cholesterol. The main cholesterol-containing particles in a fasting sample are LDL, HDL, and VLDL. Total cholesterol and HDL-C are measured as described above, while VLDL cholesterol is estimated using the calculation: triglycerides (in mg/dL) divided by 5. Thus using the three measurements from a basic lipid panel, the Friedewald equation enables an estimate of the concentration of LDL cholesterol [see Eq. (28.ii)].

$$\text{LDL-}C = [\text{Total cholesterol}] - [\text{HDL-}C] - ([\text{Triglycerides}]/5) \tag{28.ii}$$

It should be recognized that the Friedewald equation was developed in a relatively small number of subjects and intended for research (not clinical) purposes. Nevertheless, estimating the cholesterol within LDL is much easier than measuring by beta-quantification, so the Friedewald equation was ubiquitously adopted by clinical laboratories and reported along with total cholesterol, HDL-C, and triglycerides. In Friedewald's original publication, the authors list three restrictions to the validity of estimated LDL cholesterol: (1) subjects must be fasting; (2) triglycerides must be <400 mg/dL; and (3) patients with a type III hyperlipidemia cannot be assessed [11]. Although the Friedewald estimation was developed for research, without it, LDL cholesterol would not have been incorporated so rapidly into standard clinical care [7].

Estimated LDL cholesterol relies on the assumption that triglycerides are exclusively within VLDL and that the VLDL triglyceride-to-cholesterol ratio is 5:1 (in mg/dL). The fasting requirement eliminates triglyceride contributions from chylomicrons, which typically have a much higher triglyceride-to-cholesterol ratio. The triglyceride limit of 400 mg/dL is meant to reduce inaccuracy of estimated LDL-C caused by the variability in VLDL triglyceride-to-cholesterol ratio at higher triglyceride concentrations. A more contemporary analysis of >1.3 million fasting patient samples with triglycerides <400 mg/dL reported a median VLDL triglyceride-to-cholesterol ratio of 5.2 (IQR 4.7–6.0) [12]. Moreover, the range of VLDL triglyceride-to-cholesterol ratio spanned 0.4–145 and was dependent on triglyceride, total cholesterol, and

HDL-C concentrations. Several studies have confirmed that Friedewald estimated LDL cholesterol is progressively less accurate with increasing triglycerides, with many studies suggesting a limit of 200 mg/dL triglycerides for accurate estimation of LDL-C [13,14]. Estimated LDL-C is also known to be less accurate in conditions associated with altered composition of triglycerides within lipoproteins such as diabetes mellitus [15] and type III hyperlipidemia [16]. In addition, in patients with very low LDL-C concentrations (i.e., below 70 mg/dL), the Friedewald equation tends to underestimate LDL-C [17,18]. These low LDL-C concentrations are becoming increasingly more prevalent as a result of more aggressive lipid-lowering therapies in randomized clinical trials showing increased clinical benefit. Therefore assuming a triglyceride-to-cholesterol ratio of 5:1 to all individuals can result in some inaccurate LDL-C estimations compared with LDL-C measured by beta quantification. However, these clinical scenarios may not be apparent at time of testing, and thus the inaccuracy of estimated LDL-C in these contexts often goes unnoticed.

Several iterations of improved LDL-C estimating equations have been developed, since the Friedewald equation was first proposed. The Martin–Hopkins equation is similar to the Friedewald equation but substitutes a variable in the denominator for estimating the VLDL cholesterol [see Eq. (28.iii)].

$$\text{LDL-}C = [\text{Total cholesterol}] - [\text{HDL-}C] - ([\text{Triglycerides}]/X) \quad (28.\text{iii})$$

The variable X changes according to an empirically derived table that adjusts for triglyceride values up to 400 mg/dL and non-HDL-C between 100 and 220 mg/dL. Using many different VLDL-C factors provides slightly more accurate LDL-C estimations [12], but does not fully correct for the inaccuracies attributable to estimated LDL-C [19]. Nevertheless, some clinical laboratories have acquired licenses to use this proprietary equation.

The empirically defined table on which the Martin–Hopkins equation is based can be mathematically fit using a bivariate quadratic equation with non-HDL-C and triglycerides as inputs. A more generalizable estimate was developed by the National Institutes of Health (NIH) using this approach [see Eq. (28.iv)] [20].

$$\text{LDL-}C = \frac{\text{TC}}{0.948} - \frac{\text{HDL-}C}{0.971} - \left(\frac{\text{Trig}}{8.56} + \frac{\text{Trig} \times \text{non-HDL-}C}{2140} - \frac{\text{Trig}^2}{16,100}\right) - 9.44 \quad (28.\text{iv})$$

The use of continuous variables rather than a delimited table provides the NIH equation superior comparability to measured LDL-C methods at triglyceride concentrations up to 2000 mg/dL and at LDL-C $<$70 mg/dL.

It should be noted that historically all calculated LDL-C was derived using the Friedewald equation. However, given its limitations, some laboratories have implemented other equations when reporting calculated LDL-C, whether it is the Hopkins/Martin equation (which is proprietary and requires a license to use) or the NIH equation. Therefore estimated LDL-C results from different institutions can no longer be assumed to be the same.

Direct homogeneous low-density lipoprotein cholesterol

Direct homogeneous LDL cholesterol assays performed on autoanalyzers are also available and require no special sample preparation or precipitation. Various methods are employed by the different manufacturers, relying on detergents or modified enzymes to isolate selectively and measure only the cholesterol within the LDL particles [21]. These assays are easy to use, cost-effective, and cleared by the US Food and Drug Administration (FDA). However, they suffer from inaccuracies, especially in the cases of dyslipidemias. Bias between 13% and 46% has been reported by various FDA-cleared direct LDL methods [7,22].

Lipoprotein particles of all classes are heterogeneous in size, density, lipid content, and protein composition. When patients have abnormal lipid profiles, the normal distribution of these lipoprotein subclasses is altered. Samples with atypical lipoprotein distributions tend to give inaccurate results when measured by direct LDL-C methods. Various direct LDL-C methods have differing specificities for lipoproteins and measure up to 24% of VLDL cholesterol, 72% of IDL cholesterol, 90% of Lp(a) cholesterol, and even 18% of HDL cholesterol [23,24]. Therefore these assays are only suitable to measure LDL-C in normal patients without dyslipidemia. Laboratorians need to be aware of these limitations and caution clinician colleagues regarding these weaknesses.

Lipoprotein electrophoresis

Lipoprotein electrophoresis is a method that can be used in special cases where dyslipidemias are suspected [25]. In this method, a patient serum is applied to agarose gel and a current is applied allowing for negatively charged lipoproteins to migrate toward the anode. The combination of size and charge of each lipoprotein will determine its migration from the site of sample application. A nonspecific neutral lipid stain such as Sudan Black can then be applied to visualize lipoprotein bands (Fig. 28.6). More specific enzymatic cholesterol staining methods enable quantification by scanning densitometry. In this method, the HDL particles travel the farthest, since they are small and have many negatively charged apolipoproteins and migrate to what is called the “alpha” band. In contrast, LDL does not travel as far as HDL, because it is slightly larger than HDL and has fewer surface proteins.

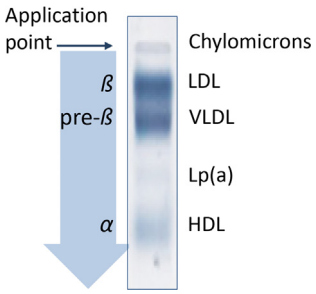

FIGURE 28.6 Lipoprotein electrophoresis. The banding pattern shown is from a serum pool containing chylomicrons, low-density lipoprotein, very-low-density lipoprotein, lipoprotein(a) and high-density lipoprotein.

The position in which LDL resides on electrophoresis is called the "beta" band. VLDL migrates between LDL and HDL in a region called the prebeta band. Even though it is larger than LDL, VLDL has many more surface apolipoproteins, which drives its migration closer to the anode. Patient samples with elevated IDL will often show bridging between the beta and prebeta bands, resulting in a broad beta band. Chylomicrons are so large and neutrally charged that they do not migrate out of the point-of-sample application. Lipoprotein electrophoresis is useful in the cases of suspected dyslipidemia where more traditional lipid testing is inadequate to resolve the diagnosis. It is also the best method to detect the abnormal lipoprotein Lipoprotein X (LpX), a unique lipoprotein found in the cases of cholestasis that reverse migrates (i.e., toward the cathode; see Section "Lipoprotein X").

Apolipoproteins

Other methods can be used to measure directly the amount of apolipoproteins by automated immunoassays on autoanalyzers such as apoB [contained in LDL, Lp(a), IDL, and VLDL], apoA-1 (containing HDL), and apolipoprotein (a) [apo(a); contained in Lp(a)]. All of these methods are becoming more routine, since they are compatible with nearly all central laboratory analyzers as either immunoturbidimetric or immunonephelometric assays.

Apolipoprotein B

ApoB has been proposed by several lipid and cardiology experts as an alternative to LDL cholesterol for the assessment of cardiovascular risk and diagnosis of dyslipidemias [26–28]. Unlike LDL-C, which is confused by the variety of methods with varying specificities and definitions, apoB is a well-characterized protein. A standardized reference material for apoB is available from the World Health Organization in collaboration with the International Federation of Clinical Chemistry [29]. Comparison of 22 different clinical apoB methods found a bias <5% between all methods and 3.6% with imprecision <3.2% [30]. Consequently, apoB methods are significantly more accurate and precise than LDL cholesterol [7].

Apolipoprotein A-I

ApoA1 is useful in the cases of suspected HDL deficiencies. As described above, apoA1 is responsible for reverse cholesterol transport, which reduces atherosclerotic lesions in arteries. Thus the apoB:ApoA1 ratio provides insight into the balance between the atherogenic and antiatherogenic lipoproteins. Several large prospective studies have shown the apoB:apoA1 ratio to be a superior predictor of CVD risk compared with LDL-C [31–33].

Apolipoprotein (a) Apo(a) is the unique apolipoprotein found in Lp(a). Immunoassays that measure Lp(a) utilize antibodies that recognize the apo(a) protein and are useful for the identification of individuals that express high concentrations of this extremely proatherogenic particle. It is especially important in individuals with a strong personal or family history of early CVD events without elevated LDL-C or in individuals where lipid-lowering medications do not reduce their LDL-C sufficiently [remember, the cholesterol within Lp(a) is included in nearly all methods for LDL-C determination; see Section "Lipoprotein (a)"].

Nonfasting lipid assessment

Clinical practice guidelines from major cardiology societies and consensus statements have concluded that nonfasting blood samples are acceptable for routine lipid assessments [34–39]. Fasting samples were historically required for lipid assessment in order to reduce the variability observed in measures of triglycerides (and consequently estimations of LDL-C) [11]. Several lines of evidence support the shift to nonfasting lipid assessment. Data from large groups of patients show that observed triglyceride increases due to nonfasting are clinically negligible in the vast majority of cases. Several large studies have confirmed that nonfasting triglyceride concentrations remain <200 mg/dL in a majority of patients [40–42]. This relatively normal concentration of triglycerides in the nonfasting state contributes to the insignificant impact observed by nonfasting lipid screening and LDL-C estimation [41,43]. The high biological variability of triglycerides is another argument in favor of nonfasting lipid assessment. The average biological variability of *fasting* triglycerides is 20%–30%, and ranges from <5% for persons with low fasting triglycerides (<100 mg/dL) to as large as 75% for persons with elevated fasting triglycerides [44]. Consequently, postprandial increases are often within the noise of typical biological variation [45].

Due to the long history of fasting lipid assessment, it would be prudent to report nonfasting triglycerides and estimated LDL-C unique from fasting samples. In this way, nonfasting triglycerides can have a unique abnormal flag at the recommended 200 mg/dL cut point and an automatically appended comment suggesting repeat testing after an 8−12-hour fast. Due to the novelty of reporting nonfasting Friedewald estimated LDL-C, an appended comment suggesting values may be decreased when triglycerides >200 mg/dL may also be reasonable.

Lipoprotein subfraction methods

Many clinical methods that measure lipoprotein subfractions are available (e.g., nuclear magnetic resonance, vertical gradient ultracentrifugation, ion-mobility, gradient gel electrophoresis, etc.). These methods distinguish between different sizes and densities of LDL and HDL with increased granularity. However, the methods separate by different means (i.e., size, density, and charge), define small, medium, or large by different limits, and measure different lipoprotein components [46]. No medical society has endorsed the use of lipoprotein subfractions. None of the subfraction methods in clinical use have sought FDA clearance for subfractionation of lipids, but rather emphasized their substantial equivalence to traditional lipid measures. The most recent LDL subfractionation method to be cleared by the FDA included an outcome study looking at association between LDL subfraction and CVD in the Atherosclerosis Risk in Communities cohort [47]. In the published report, the authors concede that "small dense LDL-C was not significantly associated with risk for incident coronary heart disease after further adjustment for other lipid risk factors, such as LDL-C, apo B, or total cholesterol."

The lack of independent predictive information for lipoprotein subfractions has been repeatedly cited in many opinion papers and consensus documents [48−50]. The National Lipid Association, the National Academy of Clinical Biochemistry, the American College of Cardiology (ACC), and the American Heart Association (AHA) have all published guidelines specifically recommending *against* the use of lipoprotein subfraction methods for initial clinical assessment or on-treatment management decisions [51−53].

Lipoprotein disorders

Lipid disorders were originally classified by Fredrickson in 1965 into different types (historically termed Fredrickson phenotypes) [54]. The phenotypes were based on patterns of lipoprotein concentrations, as shown by lipoprotein staining on agarose gel electrophoresis. Five of the six classic Fredrickson phenotypes include elevations of triglycerides [55,56]. However, at the time of classification, the underlying disorders were not well characterized. Today, we know that phenotypes can have multiple etiologies from either primary and/or secondary causes, and several lipid diseases do not fit into a Fredrickson phenotype. Both classic phenotypes and other lipoproteinemias are listed in Table 28.1 with their expected laboratory results and major etiologies.

Hyperlipoproteinemias

Exogenous hyperlipemia

The type I Fredrickson phenotype of extremely elevated chylomicrons is associated with extremely elevated plasma triglycerides usually greater than 1000 mg/dL in the fasting state. This rare phenotype, called familial chylomicronemia syndrome (FCS), occurs in 1 in 100,000 to 1 in 1,000,000 individuals and is most commonly caused by the absence of lipoprotein lipase (LPL) activity from the genetic mutations of both LPL alleles. Less commonly, FCS can be caused by mutations in other genes required for proper LPL localization or function, such as the loss of the cofactor apolipoprotein C-II, which is required for LPL activity [57]. LPL is required to hydrolyze triglycerides and distribute FAs to metabolically active tissues; therefore patients with type I hyperlipoproteinemias form no chylomicron remnants; intact chylomicrons stay elevated in systemic circulation, and triglycerides are shuttled to HDL particles via CETP. Triglycerides-rich HDL is rapidly removed from circulation resulting in very low plasma HDL-C concentrations. The loss of remnant lipid flux to the liver results in decreased production of apoB-containing lipoprotein and low plasma VLDL-C and LDL-C concentrations. Chylomicrons are too large to invade the vascular wall so atherosclerosis is not usually a concern.

Depending on dietary fat intake, abdominal pain and pancreatitis are the main clinical consequences of extremely elevated triglycerides via a mechanism that has not been fully elucidated [58]. The resulting hypertriglyceride-induced pancreatitis is more severe with worse outcomes when compared with pancreatitis caused by other etiologies [59]. Children with FCS are identified by extremely elevated triglyceride concentrations or failure to thrive and further clinical sequelae such as eruptive xanthomas, lipemia retinalis, hepatosplenomegaly, or a lifetime risk of acute pancreatitis often manifest by adolescence. Lipid testing reveals a triglyceride-to-cholesterol ratio that is similar to what is found in chylomicrons (>10:1), and lipoprotein lipase activity is decreased. Chylomicrons can also be detected electrophoretically. They are extremely large and do not migrate well in gel electrophoresis systems, so they are visualized as a band at the sample application point. With no

TABLE 28.1 Lipoprotein disorders.

Dyslipidemia	Fredrickson phenotype	Abnormal lipoprotein(s)	Cholesterol (mg/dL)	Triglycerides (mg/dL)	Frequency	Primary disorder(s)
Exogenous hyperlipemia	Type I	↑Chylomicrons	Any	>10,000	1:1,000,000	Lipoprotein lipase deficiency; ApoC-II deficiency
Hypercholesterolemia	Type IIa	↑LDL	>200	<250	1:500	Familial hypercholesterolemia
Combined hyperlipidemia	Type IIb	↑LDL & VLDL	>200	>250	1:100	Familial multiple lipoprotein-type hyperlipidemia
Remnant hyperlipidemia	Type III	↑IDL (a.k.a. ß-VLDL)	Any	Any	1:500	Familial dysbetalipoproteinemia
Endogenous hyperlipemia	Type IV	↑VLDL	Any	>250	1:100	Familial hypertriglyceridemia (mild)
Mixed hyperlipemia	Type V	↑Chylomicrons ↑VLDL	Any	>1000	1:600	Familial hypertriglyceridemia (severe); Familial lipoprotein lipase deficiency
Lipoprotein (a)	–	Lp(a)	Any	Any	1:5	Elevated Lp(a)
Lipoprotein X	–	LpX	>250 LDL-C >200	Any	1:5 among low HDL-C (<10 mg/dL)	Cholestatic liver disease or LCAT deficiency
Hypobetalipoproteinemia	–	↓LDL	<100	<50	1:3000	Familial hypobetalipoproteinemia
Abetalipoproteinemia	–	↓↓ LDL	Undetectable	Undetectable	<1:1,000,000	Microsomal triglyceride transfer protein deficiency
Hypoalphalipoproteinemia	–	↓↓HDL	Any	Any	<1:100	Familial ApoA1 deficiency; ABCA1 deficiency (Tangier Disease); LCAT deficiency

ABCA1, Adenosine triphosphate binding cassette A1; *ApoA1*, apolipoprotein A-I; *ApoC-II*, apolipoprotein C-II; *HDL-C*, high-density lipoprotein cholesterol; *IDL*, intermediate-density lipoproteins; *LCAT*, lecithin: cholesterol acyltransferase; *LDL*, low-density lipoprotein; *LDL-C*, low-density lipoprotein cholesterol; *Lp(a)*, lipoprotein(a); *LpX*, lipoprotein X; *VLDL*, very-low-density lipoproteins.

FDA-approved treatments, patients with FCS must adhere to a stringent diet that is nearly completely devoid of fat. Even with extreme caution toward food intake, triglycerides rarely reduce to normal concentrations in patients with FCS. A homozygous or compound heterozygous genetic variant is sometimes absent and secondary causes of hypertriglyceridemia (high-fat diet, alcohol consumption, metabolic syndrome, type 2 diabetes, hypothyroidism, or certain medications) should be considered.

Familial hypercholesterolemia

Type IIa, Familial hypercholesterolemia (FH), is the only Fredrickson phenotype that does not have elevated plasma triglyceride concentrations. It is an autosomal codominant disorder characterized by elevated cholesterol, which is predominantly found in LDL. FH is further subcategorized as either heterozygous or homozygous, which phenotypically differ in the magnitude of LDL-C increase as well as in resulting risk for developing CVD. Individuals with homozygous FH (hoFH) have significantly higher LDL-C (500−1200 mg/dL) than heterozygotes FH (hetFH), who typically have LDL-C concentrations of 190 mg/dL or greater. Early onset CVD occurs in hetFH individuals in the fifth or sixth decade of life, as compared with childhood in hoFH individuals. Variants in one or both alleles that inactivate either the LDLR or apoB, or mutations that cause a gain of function of proprotein convertase subtilisin/kexin type 9 (PCSK9), can cause FH. The liver requires the action of the LDLR to take up LDL particles from circulation and dispose of the cholesterol contents. apoB is the binding partner for LDLR, so mutations in either apoB or LDLR result in a dramatic increase of LDL cholesterol resulting in FH. PCSK9 functions to remove LDLR from hepatocytes, so gain of function mutations in PCSK9 will cause the FH phenotype. The vast majority of FH cases ($>80\%$) are a result of mutations in LDLR, 5%−10% are from apoB mutations, and $<1\%$ are from PCSK9 gain of function mutations.

The prevalence of heterozygous FH is now estimated to be around 1:250 [60], with some specific populations having a higher prevalence of 1 in 50−67 [61]. Homozygous FH is less common, with a prevalence of 1 in 300,000 [62]. Three groups have developed diagnostic tools to identify individuals with FH (the US MedPed Program, the Simon Broome Register Group in the United Kingdom, and the Dutch Lipid Clinic Network). In general, individuals with FH can be identified by the following criteria: an elevated LDL-C on a standard lipid screen, a family history of hypercholesterolemia and/or early CVD events, personal premature CVD, or the presence of tendon xanthomas. The more the criteria that are met for a patient, the higher the likelihood of FH. Patients with FH will have elevated blood cholesterol starting in childhood. It is now recognized that the lifetime arterial exposure to elevated cholesterol is directly correlated with future risk of developing CVD (similar to the concept of increased lung cancer risk with increased "pack years" of smoking). This means that people with genetic FH have been exposed to high cholesterol from birth and have higher risk of CVD as compared with individuals that may acquire hyperlipidemia later in life from poor diet or lifestyle. Therefore identifying individuals with FH as early in life as possible is important to minimize their risk of future CVD development via early lifestyle and medication therapies.

Combined hyperlipidemia

The Fredrickson-type IIB phenotype is characterized by elevated LDL and VLDL with corresponding elevations in both cholesterol and triglycerides. Also referred to as familial combined hyperlipidemia (FCH or FCHL), the phenotype is caused by hepatic overproduction and/or decreased clearance of apoB-containing lipoproteins (VLDL, IDL, and LDL) and apoB concentrations exceed the 90th percentile of a reference population [63,64]. It is the most prevalent primary dyslipidemia, with a prevalence of 1%−3% in the general population; however, a lack of primary care physician awareness often leads to misdiagnosis. Susceptibility to FCHL is higher in certain ethnic groups such as Hispanics (4.8% prevalence) and is commonly present along with other metabolic diseases such as obesity, insulin resistance, metabolic syndrome, and type 2 diabetes mellitus. Individuals with FCHL have a higher risk of premature coronary artery disease, because both the cholesterol-rich lipoproteins and triglyceride-rich lipoproteins that present in this phenotype can cause atherosclerosis. FCHL is generally considered an oligogenic disease such that genetic diagnosis is not yet possible, but the finding of mixed hyperlipidemia, elevated apoB, and a family history of mixed hyperlipidemia strongly suggests the FCHL phenotype. No specific therapies have been developed for FCHL, so treatment usually aims to control modifiable cardiovascular risk factors such as obesity, smoking, alcohol intake, and cholesterol concentration. In addition, consideration is given to avoid secondary causes of hypertriglyceridemia or implementing pharmacological triglyceride lowering therapies.

Remnant hyperlipidemia

The type III phenotype, or remnant hyperlipoproteinemia, is characterized by elevated remnant particles of triglyceride-rich lipoproteins—namely chylomicron remnants and VLDL remnants. This phenotype is mainly caused from an inability of the liver to clear these remnant particles from circulation [65]. Rarely, individuals

will have a genetic mutation that causes significantly reduced expression of the apoE protein that is required for hepatic clearance of IDL and other RLPs. However, more commonly, these individuals are homozygous for the apoE2 allele that has dramatically decreased affinity for LDLR and LRP (termed familial dysbetalipoproteinemia). The circulating remnants can pick up cholesterol from other lipoproteins such as HDL via lipid exchange mediated by CETP. Therefore accumulated IDL and remnant particles contain both cholesterol and triglycerides, so both are significantly elevated in plasma [66]. In addition to elevated triglycerides and cholesterol concentrations, these patients clinically present with lipid deposits in their skin such as striated palmar xanthomas or tuberous xanthomas. On lipoprotein electrophoresis methods, LDL runs at the β band and VLDL runs at the pre-β band. The abnormal lipoproteins present in type III dysbetalipoproteinemia (IDL and VLDL remnants) migrate between the LDL and VLDL bands in a "broad beta band." These particles are sometimes referred to as β-VLDL particles (i.e., VLDL that migrate in the "beta" band) [67]. Remnant particles are extremely atherogenic, so patients are at high risk for atherosclerosis and CVD. ApoE2 homozygotes are fairly common (~1% prevalence) but dysbetalipoproteinemia occurs in <5% of these individuals, so other contributing factors, possibly a concomitant FCH phenotype, are needed to cause the phenotype.

Endogenous hyperlipemia

Type IV hyperlipoproteinemia is characterized by increased VLDL and triglycerides and affects approximately 1 in 100 individuals. The condition can be genetic and passed down through families as familial hypertriglyceridemia. The condition can be caused by an increased hepatic production of VLDL or from heterozygous LPL deficiency. The majority of cases are caused by multigenetic effects and/or secondary causes of hypertriglyceridemia [68]. Triglyceride concentrations are elevated, but are usually lower (<1000 mg/dL) than that observed in the more severe type I phenotype, because VLDL contains less triglycerides as compared with chylomicrons. However, if high enough, triglycerides can still cause pancreatitis. Total cholesterol and LDL-C concentrations are usually within normal target concentrations. Individuals with this condition tend to have low HDL-C, metabolic syndrome, insulin resistance, and obesity and have precocious atherosclerosis and increased risk of CVD events. Treatment starts with lifestyle modifications such as increasing exercise while lowering carbohydrate and alcohol ingestion. Pharmacological treatments such as prescription omega-3 FAs, fibrates, or niacin can be considered.

Mixed hyperlipemia

Type V hyperlipidemia is characterized by high triglycerides in both chylomicrons and VLDL. This hypertriglyceridemia is either the heterozygous form of the mutations that cause type I FCS (e.g., heterozygous LPL deficiency) or can be polygenic in origin with familial clustering and a prevalence of approximately 1 in 600 individuals. Similar to FCS, patients with polygenic type V hyperlipidemia have extremely elevated triglycerides >1000 mg/dL when triggered by a secondary cause, milky plasma, and a risk of pancreatitis. Since proatherogenic VLDL particles are also increased in this phenotype, these patients are susceptible to increased risk of CVD. In addition, they respond well to triglyceride lowering therapies such as fibrates, niacin, or fish oil.

Distinguishing between the hypertriglyceridemia disorders can be made using advanced lipid testing such as lipoprotein electrophoresis in combination with standard biochemical lipid measurements. A qualitative assessment can also be made visually given that after a sample with high triglycerides is allowed to sit refrigerated overnight. If the sample contains both chylomicrons and VLDL (i.e., a type V), the chylomicrons will float to the top producing a cream-like supernatant, while the elevated VLDL will produce a cloudy lower fraction. If the sample contains only chylomicrons (i.e., a type I), the cream-like supernatant will appear while the lower fraction will be clear. If only VLDL is elevated (i.e., a type IV), the sample will be cloudy throughout and no cream layer will form.

Lipoprotein (a) disorder

Lp(a) (pronounced "lipoprotein little 'a'") is a unique and highly atherogenic lipoprotein particle (Fig. 28.7) [69]. At its core, Lp(a) is an LDL-like particle; however, Lp(a) has a unique feature in that the apoB protein is covalently bound to a unique and highly glycosylated protein called apo(a) (pronounced "apo-little a"). Apo(a) shares sequence homology with, and has likely evolved from, the proenzyme plasminogen. While plasminogen contains five kringle domains (KI−KV) and a protease domain, apo(a) has an inactive protease and does not express the first three kringle domains but does contain 10 subtypes of KIV domain. The second KIV (KIV_2) is present in variable ($n = 1$ to >40) copies. This variability of kringle length is genetically defined and causes the size of the Lp(a) particle to vary greatly with most individuals expressing two different sized apo(a) isoforms, one from each parent. Concentrations of Lp(a) in circulation are primarily determined by the *LPA* gene locus and are not influenced by environment or dietary factors. The half-life of Lp(a) in circulation seems to be longer than LDL,

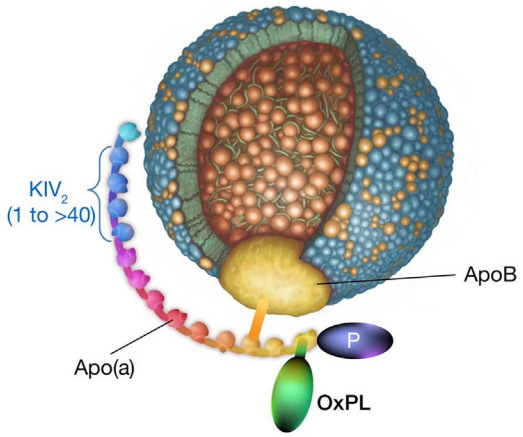

FIGURE 28.7 Lipoprotein(a) is a potently atherogenic lipoprotein. Lipoprotein(a) particles are comprised of an low-density lipoprotein-like core with the apolipoprotein(a) covalently bound to apolipoprotein B by a disulfide bridge. Apolipoprotein(a) contains domains called kringle domains with a variable number of second KIV repeats (shown here as four repeats). Oxidized phospholipids also interact with apolipoprotein (a).

possibly due to apo(a) interference of apoB binding to LDLR for LDL metabolism. In addition, there is an inverse correlation between apo(a) size and Lp(a) concentration likely because the liver can synthesize smaller apo (a) proteins faster than larger ones. The mechanism(s) of Lp(a) metabolism and clearance are not fully elucidated.

Observational studies, prospective population studies, Mendelian randomization studies, and genome-wide association studies have all shown that Lp(a) is highly atherogenic. It contributes to both CVD and calcific aortic valve stenosis [70]. Similar to LDL, Lp(a) particles carry cholesterol and can enter vessel walls, oxidize, and create immunogenic and proinflammatory molecules that promote atherosclerosis. However, apo(a) also contributes to the atherothrombosis via potential plasminogen-like antifibrinolytic effects and interactions with oxidized phospholipids at the KV subunit of apo(a), among others. Given the increased thrombosis at sites of plaque rupture, apo(a) has the potential to cause myocardial infarctions and ischemic stroke. The risk for myocardial infarction, stroke, and peripheral arterial disease associated with Lp (a) expression has been shown in many studies with significant risk starting when Lp(a) measures 30 mg/dL or higher using an automated immunoassay [71]. However, several guidelines, including the most recent 2018 lipid management guidelines by the AHA/ACC and a 2019 position statement by the National Lipid Association, direct physicians to consider intensifying CV risk reduction strategies when Lp(a) is >50 mg/dL. It is estimated that around 20% of the population has elevated Lp(a). However, different ethnic groups display different median Lp(a) concentrations (median/interquartile range: Caucasians: 12/5−32 mg/dL; Hispanics: 19/8−43 mg/dL; Black: 39/19−69 mg/dL) [72]. Whether non-Caucasian should use the same risk cut points as Caucasians is unknown so universal cut points are currently used for test interpretation.

Measuring Lp(a) is not straightforward given that the size of Lp(a) differs depending on the size of the apo(a) isoform(s) expressed in each patient. Commercially available immunoassays may utilize polyclonal antibodies that can cross-react with the KIV_2 region, so clinical laboratories should use assays that are the least susceptible to Lp (a) isoform size [73]. Historically, nearly all studies have used assays that report Lp(a) concentration in mass units of mg/dL. However, the differences in isoform size within the population can lead to inaccurate results when using an assay that is calibrated to mass units. The resulting bias can lead to underestimation of concentration in small Lp(a) isoforms and overestimation in large Lp(a) isoforms; thus there is potential for miscategorizing patients with Lp(a) concentrations near clinically defined cut points. The use of appropriate calibrators using a 5-point calibration scheme and an effort to standardize results to the World Health Organization/International Federation of Clinical Chemistry and Laboratory Medicine International Reference Reagent has helped to minimize the influence of isoform size on measured concentration [73]. Calibrating assays to molar units of nanomoles per liter (nmol/L) alleviates the inaccuracies caused by calibrators of different molecular weights. Indeed, the international reference material is assigned molar concentration units. While some assays are traceable to these reference calibrators, others are not, and results from different commercially available assays are not harmonized. It has been recommended that laboratories cease reporting of Lp(a) in mass units (mg/dL) and instead report in the more accurate units of particle number (nmol/L). However, making this change may be challenging for several reasons. Currently, assay manufacturers may not provide reagents calibrated to particle number or those reagents are not FDA-cleared (an important consideration in the United States) using this calibration scheme. Given that different Lp(a) isoforms have different molecular weights, results from assays calibrated to the traditional mg/dL units cannot be accurately converted into nmol/L after testing. Most clinical studies have reported Lp(a) results in units of mg/dL and most guidelines still use these units, so physician education may be challenging when reporting units are changed. In addition, clinical cut points using particle numbers have not been agreed upon. For example, the 2018 ACC/AHA cholesterol guidelines state that a value of >125 nmol/L (or >50 mg/dL) should be used to consider a patient at higher risk from Lp(a) expression; however, the 2019 National Lipid Association position statement recommends using >100 nmol/L [69].

Testing for Lp(a) is generally recommended when the patients have a personal of family history of premature CVD or if they are at intermediate risk and therapy decisions are uncertain, however some advocate for measuring it once in everyone. Since expression is mainly genetically determined and not affected greatly by lifestyle of pharmaceutical treatment, repeat measurement is not recommended. There is currently no treatment for Lp(a) that specifically targets Lp(a) particles separately from other lipoproteins and concomitantly lowers CV risk. Niacin has been shown to lower Lp(a), but side effects of treatment along with the absence of outcome benefit have led this treatment to fall out of favor. Mipomersen (no longer being produced) and PCSK9 inhibitors have been shown to lower Lp(a), but are only indicated in a very selected patient population. Lipoprotein apheresis removes Lp(a) from circulation and small studies have shown a benefit to outcomes, but this therapy is expensive, time-consuming, and not recommended for most individuals. Interestingly, there is some evidence that statin therapy may moderately increase Lp(a) expression when looking at individual patient Lp(a) values rather than population averages. Correspondingly, while statin therapy lowered the risk for CVD events in patients with elevated Lp(a), the risk lowering was blunted in comparison with individuals with lower Lp(a) [74]. Given the lack of effective targeted treatment for increased Lp(a), physicians will mainly attempt to lower overall CVD risk via intensifying standard cholesterol-lowering strategies. Emerging therapies using antisense oligonucleotide treatment that directly lower apo(a) expression and, correspondingly, Lp(a) concentration may hold significant promise.

Lipoprotein X

LpX is an abnormal vesicle produced during cholestasis and in patients with LCATD. LpX contains bile salts, albumin, a high proportion of unesterified cholesterol, and a phospholipid bilayer. LpX has a similar density to LDL, making LpX cholesterol indistinguishable from LDL-C by beta-quantification, direct homogeneous, and estimated LDL-C methods. Due to this similarity in densities, LpX is often responsible for false-elevations in LDL-C, and LpX should be suspected when unusually rapid elevations in LDL-C are encountered with a low apoB concentration. LpX is an indicator of acute liver dysfunction, which is often a more time-sensitive concern than CVD risk. LpX is not measured via standard lipid or lipoprotein analysis. It is only identified using lipoprotein electrophoresis, where LpX runs in a reversely migrating band. Staining with the standard neutral lipid stain (e.g., Sudan black or similar) is less sensitive for the detection of LpX and should only be used qualitatively. Use of filipin after electrophoresis has been recently developed as a more sensitive and quantitative detection method [75]. It should be noted, however, that LpX is a labile particle and unstable postsample freezing. When LpX is present, LDL-C should not be reported. Patients with LpX will often have dramatically reduced HDL-C concentrations.

Hypolipoproteinemias

While low cholesterol is considered protective against development of CVD, some disorders cause pathologically low concentrations of lipoproteins. Lipid concentrations can be low from secondary effects of conditions such as malnutrition, malabsorption, or chronic liver disease. However, several rare genetic conditions can also result in low concentrations of specific lipoprotein classes.

Hypobetalipoproteinemia

Most clinicians worry about elevated LDL-C; however, in rare cases, individuals can have a condition resulting in extremely low LDL-C (below the 5th percentile of the general population) and reduced apoB [76]. Familial hypobetalipoproteinemia type 1 (or homozygous hypobetalipoproteinemia) results from mutations in both *APOB* genes that produce variably truncated ApoB protein. The consequence is reduced by the synthesis of VLDL particles from the liver with a corresponding reduction in both circulating LDL-C and triglycerides as well as accumulation of neutral lipids in hepatocytes that can cause hepatic steatosis. Familial hypobetalipoproteinemia type 2 (also called familial combined hypolipidemia) is caused by loss of function mutations in both copies of the *ANGPTL3* gene. ANGPTL3 regulates lipolysis, so the loss of its activity results in increased extracellular lipolysis, increased clearance of all lipoproteins, and decreased concentrations of circulating lipids. The extent of cholesterol, triglyceride, and lipoprotein decrease is dependent on the severity of the mutations and the residual functionality of either ApoB or ANGPTL3.

Abetalipoproteinemia

Abetalipoproteinemia is a related condition caused by mutations in the microsomal triglyceride transfer protein, which is required for proper packaging and secretion of apoB-containing lipoproteins. Patients with the most severe mutations of these very low lipid disorders may present early in live with chronic diarrhea and failure to thrive, which is often not recognized as a lipid disorder despite having very low triglycerides, LDL-C, and apoB serum concentrations.

Hypoalphalipoproteinemia

HDL is protective against the damaging effects cholesterol deposition in arteries; individuals with low HDL are more susceptible to developing CVD. There are several etiologies that can result in hypoalphalipoproteinemia with extremely low concentrations (<20 mg/dL) of HDL-C (Table 28.2) [77]. Secondary causes of low HDL include insulin resistance, hypertriglyceridemia, obesity, smoking, liver disease, poor diet, malignancy, and certain prescription medications. The high concentration of paraproteins in patients with immunoproliferative disorders can cause a falsely low result on some homogeneous lipid assays via an interference with the lipoprotein blocking reagents used in those assays.

Familial hypoalphaproteinemia is rare (<1% of the general population) and results from one or more mutations in any of three main proteins required for either the nascent HDL formation or for reverse cholesterol transport. First, homozygous deletion mutations in both alleles for ApoA1 (the primary HDL lipoprotein) result in no reverse cholesterol efflux, very low HDL-C (<5 mg/dL), undetectable ApoA1, and planar xanthomas from cholesterol accumulation. Individuals heterozygous for the ApoA1 deletion have HDL-C and ApoA1 concentrations at approximately 50% of normal, whereas individuals with structural variants of ApoA1 can have variable concentrations of both HDL-C and ApoA1 (depending on the severity of the abnormality). Second, individuals with inactivating mutations in both genes encoding ABCA1 have a condition called Tangier disease (named after the island on which the first two cases were identified). Tangier disease results in low HDL-C and ApoA1 due to rapid clearance of nascent poorly lipidated HDL particles, and patients present with mild corneal opacification, hepatosplenomegaly, and enlarged orange tonsils. Individuals who are partially deficient for this protein have a milder presentation. Third, extremely low HDL-C is observed in individuals with complete LCATD, and the lipoprotein-associated enzyme requires for esterification of free cholesterol [78]. LCAT is synthesized mainly in the liver and is primarily associated with HDL particles, while a smaller proportion associates with apoB-containing particles. The enzyme esterifies free cholesterol at the surface of particles by transferring phosphatidylcholine of lecithin to cholesterol. Once esterified, the cholesterol migrates to the center of the particle and the particle increases in size. Consequently, patients with LCATD have an increased concentration of unesterified cholesterol (usually 60%−80% of plasma cholesterol is esterified in healthy individuals but it is <20% with LCATD) and very small nascent HDL particles that are rapidly cleared from circulation. Patients may also present with corneal opacification, chronic proteinuria, and renal failure. LCATD (or familial LCATD; FLD) is rare with a prevalence of <1:1,000,000. Partial LCATD, called fish eye disease, also results in very low HDL-C and corneal opacity but partial LCAT function is preserved.

Finally, chylomicron retention disease is another congenital disorder that results in little to no postprandial chylomicron formation, low total cholesterol, low HDL-C, and ApoA1 [79]. The causative gene is *SAR1B*, which encodes a GTPase that is required for prechylomicron trafficking from the endoplasmic reticulum to the Golgi within enterocytes of the intestine. The inability to produce chylomicrons results in fat-laden enterocytes, chronic steatorrhea, vomiting, abdominal distension, and delayed infant growth. The decreased HDL-C and ApoA1 is likely secondary from lipid droplet-induced intestinal damage given that approximately half of ApoA1 is synthesized in the intestine. Treatment for this disease is mainly limiting dietary fat intake while providing appropriate nutritional supplements.

TABLE 28.2 Potential causes of extremely low high-density lipoprotein cholesterol (<20 mg/dL).

Primary (monogenic) causes
ApoA1 deficiency
ApoA1 structural mutation
ABCA1 deficiency (Tangier disease)
LCAT deficiency
Secondary causes
Medications (anabolic androgenic steroids, fibrates, and thiazolidinedione in combination with fibrates)
Malignancy
Liver disease
Artifactual causes
Paraproteinemia interference with homogeneous direct lipid assay

ABCA1, Adenosine triphosphate binding cassette A1; *ApoA1*, apolipoprotein A-I; *HDL*, high-density lipoprotein; *LCAT*, lecithin: cholesterol acyltransferase.

Lipids and cardiovascular disease

Atherosclerosis is a disease in which plaque builds up within blood vessels. Atherosclerotic lesions begin when lipoproteins accumulate within arterial intima (Fig. 28.8) [80]. The rate of deposition within the vessel is directly proportional to the concentration of lipoproteins [81,82]. Cholesterol content of lipoproteins is a surrogate for lipoprotein concentration; however, the cholesterol content of

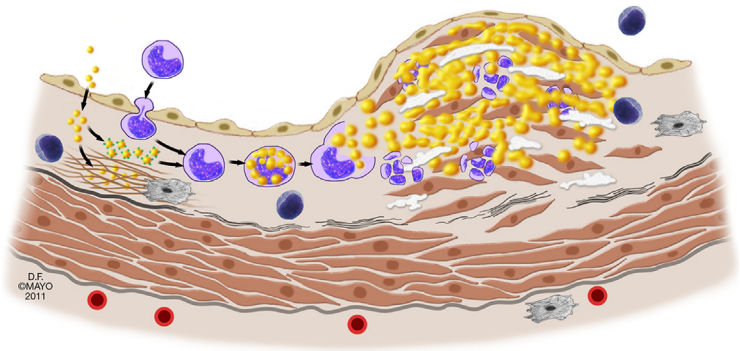

FIGURE 28.8 The role of lipids in atherosclerosis. Atherosclerosis begins when lipoproteins cross the vascular endothelium. Monocytes (turned macrophage) are drawn into the vascular intima to phagocytose the lipids. Macrophages overburdened with lipids become foam cells. Necrotic death of foam cells releases more cytokines, leading to inflammation and anatomical dysfunction of the atherosclerotic lesion.

lipoproteins is highly variable [83]. For these reasons, direct measures of lipoprotein concentrations such as APOB or LDL particle have been shown to give better performance in assessing a patient's risk of a future cardiovascular events compared with risk stratification based on LDL-C alone [33,84–92]. ApoB-lipoproteins are considered atherogenic lipoproteins [10,93]. Slow clearance of IDL and RLP leads to accumulation of LDL in the circulating plasma, which increases the probability of lipoproteins infiltrating the vascular endothelium and becoming trapped within the arterial intima [81,94].

Lipid lowering for treatment of cardiovascular disease

The assembly and secretion of VLDL by hepatocytes (or chylomicrons by enterocytes) is a complex multistep process. ApoB synthesis occurs at a relatively constant rate. Consequently, the rate of lipoprotein formation is a function of triglyceride and cholesterol availability. After implementing lifestyle modifications to lower lipid concentrations, several mechanisms can be pharmacologically targeted to reduce the concentration of circulating cholesterol and corresponding apoB lipoproteins, including inhibition of cholesterol synthesis in hepatocytes (statins), inhibition of cholesterol uptake in the gastro-intestinal system (Ezetimibe or bile acid sequestrants), or modulation of the apoB receptor concentration (PCSK9 inhibitors such as alirocumab or evolocumab).

The most prescribed agents are statins such as simvastatin, lovastatin, atorvastatin, or rosuvastatin. Statins inhibit 3-hydroxy 3-methylglutaryl CoA (HMG-CoA) reductase, the rate-limiting enzyme in human cholesterol synthesis [95]. Metaanalysis based on individual data from randomized clinical trials comparing statin medications to placebo found a mean reduction of 42 mg/dL LDL cholesterol among 175,000 individuals [96]. Modern treatment guidelines recommend statin doses, achieving a 30% or greater reduction in LDL cholesterol for at risk individuals [97]. According to National Health and Nutrition Examination Survey data, a third of U.S. adults ≥ 40 years of age are eligible for guideline-endorsed statin therapy [98,99]. Furthermore, the median LDL cholesterol among eligible adults is 105 mg/dL [100], suggesting that LDL cholesterol values <70 mg/dL will become increasingly common.

Aggressive LDL cholesterol lowering is unarguably beneficial to reducing cardiovascular events; however, it presents two challenges with respect to LDL cholesterol assessment by clinical laboratorians. The first challenge is the pervasive use of estimated LDL cholesterol by the Friedewald equation, which significantly underestimates actual LDL cholesterol at lower concentrations [101–103]. The second issue involves altered cholesterol composition of LDL following statin treatment. Multiple clinical trials have found that statin doses that reduce LDL cholesterol by 50% only reduce apoB by 36% [32,104–107]. These findings suggest that on-treatment subjects have cholesterol-depleted LDL. Since estimated and direct homogeneous LDL-C methods rely on certain assumptions about the relative amounts of triglycerides and cholesterol in lipoprotein fractions, it is reasonable to hypothesize that they would be less accurate in statin-treated subjects. Indeed, multiple studies have shown that on-treatment LDL-C is not significantly linked to the risk of CVD [108].

Clinical practice lipid measurement guidelines

Most laboratory measurements are interpreted in relation to a reference interval defined by the analyte concentration in a healthy reference population. However, interpretations of lipid results are most commonly guideline-driven from population data demonstrating risk of developing future CVD corresponding to various lipid concentrations. Values for desirable, borderline risk, and high risk were defined by the NCEP Adult Treatment Panel III [5], which was last updated in 2004. Additional pediatric and adolescent guidelines have been published for the interpretation of values and suggested screening intervals with an emphasis on early identification of children with FH (Table 28.3) [109].

TABLE 28.3 Basic lipid reference ranges endorsed by the National Cholesterol Education Program.

	Adults (≥18 year)		Pediatrics (<18 year)		
Lipid	**Value**	**Comment**	**Value**		**Comment**
LDL-C					
	<100	Desirable	<110		Acceptable
	100–129	Above desirable	110–129		Borderline high
	130–159	Borderline high	≥130		High
	160–189	High			
	>190	Very high			
Non-HDL-C					
	<130	Desirable	<120		Acceptable
	130–159	Above desirable	120–144		Borderline high
	160–189	Borderline high	≥145		High
	190–219	High			
	>220	Very high			
Total cholesterol					
	<200	Desirable	<170		Acceptable
	200–239	Borderline high	170–199		Borderline high
	>240	High	>200		High
HDL-C					
	<40 (men)	Low	<40		Low
	<50 (women)	Low	40–45		Borderline low
			>45		Acceptable
Triglycerides					
	<150	Normal	0–10 year	10–18 year	
	150–199	Borderline high	<75	<90	Acceptable
	200–499	High	75–99	90–129	Borderline high
	≥500	Very high	>100	>130	High

LDL-C, Low-density lipoprotein cholesterol; *HDL-C,* high-density lipoprotein cholesterol.

It is important to note that the NCEP no longer publishes guidelines and that clinical reference values for lipids are no longer considered therapeutic targets. Recommendations about risk assessment are now published by the AHA and ACC. Evidence from large randomized clinical trials has repeatedly shown that lowering cholesterol lowers risk of CVD, regardless of baseline cholesterol. These findings prompted recommendations that cholesterol lowering medications be prescribed to prevent future CVD based on patient risk factors. The highest dose of statins is recommended for individuals with a history of prior heart disease or LDL-C ≥ 190 mg/dL. Moderate doses are recommended for subjects with LDL-C between 70 and 190 mg/dL and diabetes mellitus or a 10-year risk >7.5% based on the pooled cohort calculation, which accounts for age, sex, race, blood pressure, lipids, and smoking history [6] (http://tools.acc.org/ASCVD-Risk-Estimator-Plus/).

Self-assessment questions

1. Correctly list major lipoproteins in order from largest to smallest:
   a. VLDL, chylomicrons, IDL, HDL, LDL
   b. Chylomicrons, VLDL, IDL, HDL, LDL
   c. VLDL, IDL, chylomicrons, LDL, HDL
   d. Chylomicrons, VLDL, IDL, LDL, HDL
2. What is the calculated non-HDL cholesterol for a patient with the following lipid values: total cholesterol = 226 mg/dL, HDL cholesterol = 37 mg/dL, and triglycerides = 113 mg/dL?
   a. 76 mg/dL
   b. 189 mg/dL
   c. 166 mg/dL
   d. 150 mg/dL
3. Which laboratory measure below is most affected by the patient's fasting status?
   a. Total Cholesterol
   b. HDL Cholesterol
   c. Triglycerides
   d. Apolipoprotein B
4. Explain the rationale behind the requirement of fasting for lipid assessment.
   a. HDL cholesterol decreases changes after a meal
   b. LDL cholesterol decreases after a meal
   c. VLDL triglycerides increase after a meal
   d. Chylomicron triglycerides increase after a meal
5. Statin drugs (lovastatin, simvastatin, pravastatin, etc.) lower cholesterol by:
   a. activating HMG-CoA reductase
   b. activating lipoprotein lipase
   c. inhibiting HMG-CoA reductase
   d. inhibiting lipoprotein lipase
6. You are asked to consult on a case involving a 4-year-old boy who presents with xanthomas on his arms and legs. Laboratory results reveal total cholesterol of 740 mg/dL, an LDL-C of 240 mg/dL, an HDL-C of 52 mg/dL, and a triglyceride of 100 mg/dL. At first glance, you are suspicious of:
   a. FH
   b. lipoprotein lipase deficiency
   c. LCAT deficiency
   d. familial combined hyperlipidemia
7. For a patient who has an elevated Lp(a), the abnormality most likely to be detected by a basic lipid panel is:
   a. elevated VLDL cholesterol
   b. low HDL cholesterol
   c. elevated LDL cholesterol
   d. elevated fasting triglycerides
8. Which analyte is most appropriate to use as a surrogate for the number of LDL particles?
   a. Apolipoprotein A1
   b. Apolipoprotein B
   c. Apolipoprotein CIII
   d. Apolipoprotein E

Answers

1. d
2. b
3. c
4. d
5. c
6. a

8. b

Chapter 29

Pediatric laboratory medicine

Amy L. Pyle-Eilola[1] and Jane Dickerson[2]

[1]*Department of Pathology and Laboratory Medicine, Nationwide Children's Hospital, Columbus, OH, United States,* [2]*Department of Laboratory Medicine, University of Washington Medical Center, Seattle, WA, United States*

Learning objectives

After reviewing this chapter, the reader will be able to:

- Identify three challenges associated with pediatric sample volumes.
- Name the specimen types unique to pediatrics.
- Discuss the role of the clinical laboratory in newborn screening.
- Define the disease states typified by elevated bilirubin concentrations in early childhood.

"Children are not little adults" is a common phrase in the practice of pediatrics, and laboratory medicine is not exempt from issues that pertain primarily to the pediatric population. Handling pediatric specimens presents unique challenges ranging from small blood volumes, sample types, and modes of samples collection, to test validation and establishing reference intervals. Many of these issues affect the day-to-day processes in the clinical laboratory. One of the biggest problems in pediatrics is small sample volume, which affects almost every step in the process from instrument selection all the way to reference intervals and result interpretation.

Blood volume and sample volume requirements

The volume of blood that can be drawn safely per day from an individual is based on the individual's total body blood volume. The small total body blood volume of infants and children limits the amount of blood that can be drawn in this patient population. Current guidelines recommend that no more than 3% of total body volume be drawn per day from infants less than 2 months of age, and no more than 10% of total body volume be drawn per day in healthy children over 2 months of age (Fig. 29.1) [1]. Thus, while 150 mL of blood can be collected from a healthy adult in a day, only 9 mL of blood can be obtained safely from a healthy 7-lb infant. In the pediatric intensive care unit, blood draws for lab testing account for 73% of blood loss, and a single patient typically experiences 7.1 ± 5.3 mL of blood loss per day in the unit [2]. This daily loss closely approaches the recommended total loss for an entire month in a 7-lb infant. Often, to reduce the volume of blood drawn for laboratory testing, the minimum amount of blood necessary for testing is collected in smaller collection devices, rather than filling standard size collection devices.

The minimum volume of blood needed for testing is the sum of volume needed for the actual assay, the volume needed for sample integrity indices, and the instrument dead volume. The instrument dead volume is essentially wasted volume that is required for instrument function and is the volume below which the instrument cannot pipette. The dead volume of the instrument can be quite considerable when compared with the actual assay volume, which is typically very small. For example, an assay may require 30 μL, but the dead volume of the instrument may be 240 μL, bringing the total sample volume to 270 μL. Therefore it is important to be mindful when assessing a manufacturer's claims for sample volume requirements. The dead volume should be validated within the laboratory, as requirements may vary from the manufacturer's specifications. When validating the dead volume, the tube size that will be used most often should be tested. The dead volume may vary considerably between a 10-mL primary tube and a 0.5-mL sample cup. For assays requiring serum and plasma, the volume of whole blood has to be sufficient to provide the necessary volume of serum or plasma.

Hematocrit, or the fraction of red blood cells in the blood, will affect the amount of serum in a whole blood specimen. For example, in a specimen with a high hematocrit, a larger volume of whole blood is required to obtain the desired volume of serum. Neonates and infants have higher hematocrit, with the upper end of the reference interval close to 70%, whereas hematocrit in older

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00029-6

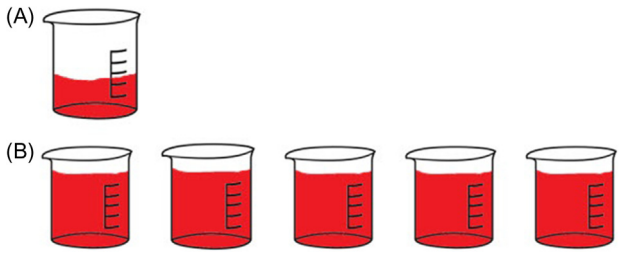

FIGURE 29.1 Illustration of the total blood volume of (A) an 8-lb baby (340 mL) and the total blood volume of (B) a 150-lb adult (~5 L).

children and adults is typically less than 50%. Whole blood assays require less blood overall, since plasma is roughly 40%–60% of a whole blood specimen. This is one reason that assays that require whole blood specimens are preferred for pediatric laboratory testing. Point-of-care systems commonly utilize very small volumes of whole blood and have little to no dead volume requirements, making them attractive options in pediatrics. For example, a whole blood glucose measurement can be obtained from a drop of blood (~10 μL), compared with 80–100 μL for plasma glucose testing in the central lab. However, there are disadvantages to consider with the use of whole blood point-of-care systems; see Chapter 19, Point-of-care testing, for more details.

Challenges associated with small blood volumes

Small blood volumes are prone to particular preanalytical errors. Common errors associated with small volume samples include incorrect blood-to-additive ratios, sample evaporation, hemolysis, and human error during manual specimen processing. Underfilled tubes lead to decreased blood-to-additive ratios, and incorrect ratios can give rise to inaccurate test results, hemolysis, and altered cell morphology. For example, coagulation assays require a specific concentration of anticoagulants, and in cases where sodium citrate tubes are underfilled, the abnormally high concentration of citrate will falsely prolong clotting times. Higher concentrations of additives contribute to other preanalytical problems such as hemolysis and changes to cell morphology. Red blood cells exposed to high concentrations of glycolytic inhibitors, like sodium fluoride, are more likely to hemolyze, and cells exposed to hyperosmolar concentrations of EDTA may shrink and exhibit an artifactual decreased MCV [3].

Evaporation is another major concern for small volume samples given that smaller volumes have a greater surface to total volume ratio. Evaporation of small volume samples can occur during or after sample processing, thus creating large differences in analyte concentrations. The effects of evaporation must be considered when adding on a test to an existing specimen. For example, a sample containing 2.0 mL of separated serum (a typical adult volume) that sits open to the air may show an increase in analyte concentration that is up to 10% higher than the initial measurement after 4 h. By contrast, a sample containing only 0.5 mL under the same conditions may show a 50% increase over the initial analysis. Even frozen samples are prone to evaporation when stored for long periods. To reduce the effects of evaporation, samples should be tightly capped any time they are not actively tested [4,5]. Volatile compounds like ethanol and dissolved gases, such as CO_2, are also significantly impacted by high surface to volume ratios. Total CO_2 (TCO_2) is typically measured in plasma via enzymatic techniques following alkali treatment. Alkali treatment quantitatively converts circulating forms of CO_2 (HCO_3^-, H_2CO_3, and dissolved CO_2) to HCO_3^-, which serves as the limiting substrate for phosphoenolpyruvate carboxykinase. At high surface to volume ratios, extended exposure of a small volume sample (pCO_2 ~40–50 mmHg) to air (pCO_2 ~0.3 mmHg) can rapidly deplete the pool of dissolved CO_2, reducing apparent TCO_2 concentrations. These changes are often incorrectly assumed to reflect metabolic acidosis in the patient, leading to unnecessary repeat testing and further metabolic testing to explain the suspected acidosis.

Small volume samples can be collected in reduced vacuum tubes or in microcollection tubes often referred to as "bullets." These tubes contain lower quantities of additives and are designed for collection of 0.5–1 mL of specimen. The use of these miniature collection tubes poses several obstacles to laboratory workflow, especially for highly automated laboratories. Bullets do not fit most analyzers and automated robotic systems. Standard labels are often too large for bullets and specialized labels, and printers may be required. Laboratories not equipped with such special printers have no choice but to manually enter patient information into the laboratory information system and analyzer. The addition of these manual processes to the workflow can introduce errors, prolong turnaround time, and influence the number of employees needed to manage such specimen types. One potential solution to this problem is to place the bullet into a larger tube that can be barcoded and positioned into the instrument. Some manufacturers make false-bottom tubes that fit on some instrument platforms, but more often, transfer of the sample to a compatible sample cup and relabeling are required prior to analysis. These additional steps introduce more opportunities for error. Measures taken to accommodate small volumes, such as false-bottom tubes, sample cups, or tube within a tube, all require validation prior to implementation into laboratory workflows.

Specimen types and collection

Small volume blood samples are often obtained via capillary blood collection from a finger or heel. Heel-stick collections are commonly performed in infants who are not walking. There are strict guidelines for obtaining heel-stick collections [6]. The heel must be warmed prior to sample collection, as this increases the blood flow to the area and changes the blood composition in the heel to better reflect the composition of arterial blood. The correct lancet length must be utilized. The longer tips result in deeper punctures and more freely flowing blood, but at the risk of puncturing the bone, which can lead to osteomyelitis. Devices with tips no longer than 2.0 mm are recommended for infant heel sticks, and most devices for use in newborns have tip lengths less than 1.0 mm. The heel must be pricked on the lateral or medial plantar surfaces of the heel, and not the back of the heel (Fig. 29.2). The bone is too close to the surface at the back of the heel, and hitting the bone would not only cause pain but also risk for osteomyelitis infections [7]. "Milking" (excessive and repetitive squeezing) the heel must be avoided to reduce sample contamination by tissue factor and to reduce the risk of sample hemolysis. Since exposure of slow flowing capillary blood to disrupted tissue can trigger clot formation, coagulation testing is contraindicated on capillary specimens. Furthermore, dependence on capillary samples may lead to inaccuracy and exaggerated variability. Cholesterol measurement in capillary blood was demonstrated to be positively biased compared with venous blood [8]. A recent study comparing WBC counts, three-part WBC differential, and platelet counts from successive drops of capillary blood reported the average drop-to-drop coefficient of variation was five times higher than obtained with well-mixed venous blood [9].

Urine can be challenging to collect in the pediatric population, especially in infants. Urine should never be collected by squeezing cotton balls, gauze, or diapers into the collection container. If not collected by catheterization, urine can be collected by urine collection bags that have adhesive surfaces and can be placed around the genitals; 24-h collections are best obtained via catheterization.

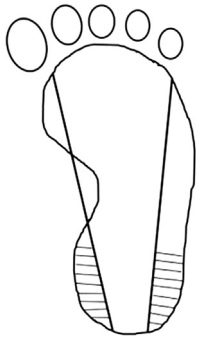

FIGURE 29.2 Capillary blood is safely collected from puncture of the lateral and medial sides of the heel (shaded portions), not the middle of the heel.

Specimen types unique to pediatrics include umbilical cord and meconium. Meconium is the first stool of a newborn infant. It starts to form about the $12^{th}-16^{th}$ week of gestation, and can be used to detect maternal drug use in the last 2–3 months of gestation, depending on the specific drug class. Because it accumulates during gestation, it is more sensitive for investigating long-term maternal drug use than urine, which will only be positive if the mother used drugs within days or weeks of delivery. Meconium can be collected by scraping the specimen from the infant's diaper. Disadvantages to meconium are that it may be passed in utero and therefore not be available to test, and that, when it is available after birth, it is not a homogenous sample and the specimen must be thoroughly mixed, so that all components are equally distributed prior to analysis. The umbilical cord has become more commonly used as an alternative specimen type to meconium, especially in instances where it is not possible to collect meconium, such as after meconium ileus [10]. While the analytical performance is comparable between meconium and umbilical cords, it is important to consider that the distribution of drugs and metabolites in either specimen type is not well understood and discordance has been observed between the two sample types. Most hospitals are not equipped to analyze meconium or umbilical cord tissue; thus these specimens are sent to alternative testing facilities. These specialty reference labs are not standardized in either their test menus (drugs/metabolites they detect) or assay performance. This provides an additional layer of difficulty in interpreting drug testing results in neonates.

Reference intervals in pediatrics

Reference intervals are established by using either parametric or nonparametric analyses and according to guidelines set forth by the Clinical Laboratory Standards Institute. Establishment of new reference intervals requires 120 healthy reference individuals for each partition (e.g., sex and age groups). In practice, it is more common that a lab verifies a previously established reference interval with their test results. Application of adult reference intervals is not always valid in pediatrics; this is true for all areas of laboratory testing including chemistry, hematology, immunology, and coagulation. Establishing appropriate reference ranges remains one of the foremost challenges in pediatric laboratory medicine.

Many available reference intervals for pediatrics were developed decades ago on outdated instrumentation, and many used hospitalized infants and children as reference

individuals [11]. Using healthy reference individuals is important when establishing intervals; however, recruiting healthy individuals less than 18 years of age and especially less than 5 years of age is difficult. The number needed to establish an interval is increased by the need to partition due to dynamic changes that occur during childhood, particularly during infancy and puberty. There are some large-scale initiatives to establish clinical laboratory reference intervals in pediatrics in both Canada and the United States: the Canadian Laboratory Initiative on Pediatric Reference Intervals database and the Children's Health Improvement through Laboratory Diagnostics initiative out of ARUP Laboratories, Salt Lake City, UT, United States [11,12]. In addition, the American Association for Clinical Chemistry has also worked with the US government on several initiatives and is currently advocating for a new nationwide reference interval program [13]. Interpreting results and use of reference intervals also requires attention. Dynamic reference intervals might confound results. For example, immunoreactive trypsinogen (IRT) rises quickly after birth and may lead to false positives on newborn screens if the screening sample is collected several days after birth. In addition, the result must be reviewed in clinical context. A patient who is followed over time may suddenly have normal or abnormal results after a birthday moves them into a new interval partition.

Newborn screening

Every US state and most industrialized countries have regulations in place to test newborns for various metabolic and nonmetabolic conditions, meeting defined criteria established by the World Health Organization. Conceptually, the criteria can be simplified to two main considerations: (1) newborn should benefit from early detection; and (2) the benefit should be balanced by the costs, both financial and risk of harm. With the discovery that mental retardation seen in untreated phenylketonuria (PKU) can be prevented by early dietary restriction of phenylalanine, and that affected patients can be detected by the elevation of phenylalanine in their blood, it became imperative to identify babies with PKU before the onset of developmental delays. This led to the introduction of newborn screening for PKU in 1961 and, subsequently, other conditions were included. Initially, amino acid disorders were tested using bacterial inhibition assays in which bacteria only grew when the concentration of a specific amino acid was elevated, called the Guthrie test. This limited testing to those conditions in which auxotrophic bacteria could identify an accumulating metabolite.

Blood for newborn screening samples is currently collected on a filter paper during the first week of life, ideally between 24−72 h. There are standard guidelines for the collection of newborn screening samples [14]. The filter paper is manufactured to absorb a standard amount of blood. This standardization allows approximation of the concentration of the analyte in plasma based on the volume of blood in the sample of paper used in the test. These approximations are reasonably accurate for term infants without anemia, but the concentrations are less accurate in premature infants with lower hematocrits and infants with polycythemia.

In addition to hematocrit, several other factors can affect the accuracy and specificity of the newborn screening results. These include gestational age, postnatal age, type of infant feeding, and the time of sample collection in relation to feeding. For this reason, the positive predictive value of an abnormal newborn screening may be as high as 1 in 3 or as low as 1 in 500; thus more definitive testing must follow abnormal screening results. Many state programs employ second-tier tests to augment the primary screening result, which improves the specificity and positive predictive value for those conditions. Recently, there has been a push toward redefining analyte cutoff values to be reflective of a disease state, rather than calculated from the central 95% of a "normal" population [15].

Inborn errors of metabolism

With the introduction of tandem mass spectrometry (MS/MS) and other technologies into the clinical diagnostic laboratory, newborn screening has now expanded to include amino acid disorders, organic acidemias, fatty acid and carnitine disorders, congenital adrenal hypoplasia, galactosemia, biotinidase deficiency, as well as hypothyroidism, severe combined immunodeficiency (SCID) disease, and other nonmetabolic conditions. Currently, most screening includes quantitation of selected amino acids and carnitine esters by MS/MS on the same sample.

Organic acidemias can also be detected by MS/MS via accumulation of specific acylcarnitine species (e.g., elevated C3 acylcarnitine may indicate methylmalonic academia or proprionic, and elevated C5 acylcarnitine may be the result of isovaleric acidemia). By using these methods, benign maternal organic acid disorders have been incidentally discovered at a higher rate than expected, including 3-methylcrotonyl CoA carboxylase deficiency and vitamin B12 deficiency [16].

Enzymatic measurement of biotinidase is performed as a semiquantitative test using an artificial substrate [biotinyl-*p*-aminobenzoic acid (pABA)] and colorimetric detection of released pABA. Galactosemia can also be screened for via the enzymatic measurement of galactose-1-phosphate uridyltransferase (GALT) activity, which screens for the most severe form of galactosemia.

Although the aforementioned GALT assay misses galactosemia due to galactokinase (GALK) deficiency and uridine diphosphate-galactose 4′-epimerase deficiencies, these forms of galactosemia are less common than GALT deficiency and, in the case of GALK deficiency, are not associated with risk of systemic illness and death in the first few months of life. However, these other mutations should still be considered in individuals with symptoms of galactosemia. More detailed discussion of many inborn errors of metabolism can be found in Chapter 48, Inborn errors of metabolism and newborn screening.

Cystic fibrosis

Cystic fibrosis (CF) is an autosomal recessive condition caused by mutations in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene that ultimately affects ion transport across cellular membranes in the pancreas, lung, and sweat glands. There is a broad range of phenotypes that complicate diagnosis. Furthermore, over 1500 variants have been reported in the *CFTR* gene, but the functional importance of many of these variants is unclear. The most common mutation, deltaF508 (HGVS nomenclature: p. F508del), accounts for approximately two-thirds of all mutations worldwide. Newborn screening approaches include measurement of IRT and/or mutational analysis of the *CFTR* gene. Guidelines for patient diagnosis and management by the Cystic Fibrosis Foundation rely on a combination of newborn screening results, clinical features, sweat chloride testing, and genetic analysis [17].

Newborns that screen positive for CF need to be confirmed by an alternative method, either sweat chloride testing or molecular testing. Sweat chloride testing involves three parts: (1) sweat stimulation; (2) sweat collection; and (3) sweat analysis. Sweat stimulation is accomplished by introducing a stimulant (pilocarpine) into the sweat glands with a small electrical current (1.5 mA). The stimulation is painless and only takes a few minutes to complete. Sweat is collected most commonly with a disposable plastic sweat collector that is placed on the stimulated skin area, and uses hydrostatic pressure to force the sweat into the collector. The collector contains a soluble blue dye for visual confirmation that sufficient sweat is collected. Paper or gauze methods can also be used for sweat collection. Finally, the chloride in the sweat is determined using coulometric titration on a chloridometer. Sweat chloride concentrations of >60 mEq/L are considered diagnostic of CF. The most common challenges encountered with sweat testing in the newborn population are related to specimen collection (i.e., quantity not sufficient, QNS). Sites that perform this testing are required to monitor their QNS Sufficient rate to identify problems in their training or technique.

Other conditions

Recently, newborn screening for lysosomal storage diseases (LSDs) has been made possible using multiplex enzymatic assays. One tenet of newborn screening is that early treatment improves outcome (i.e., benefits the newborn). Thus the lack of treatment for many LSDs would typically make them unsuitable for newborn screening. In addition, many of these disorders are late onset. However, early diagnosis can allow prenatal testing in future pregnancies and the potential for presymptomatic treatment with enzyme replacement therapy when it becomes available.

In 2010 the Department of Health and Human Services added SCID syndrome to the recommended uniform screening list for all states. This utilizes a unique T-cell receptor excision circle (TREC) assay, which detects T-cell lymphopenia in dried blood spots. Individuals with SCID have low or undetectable TRECs, which are a by-product of the maturation of thymocytes [18]. Most individuals with SCID can be successfully treated with a hematopoietic cell transplantation.

Follow-up

Some conditions are associated with a few common mutations, and DNA testing may be included as a second level of testing for those infants whose primary test result is consistent with the disorder. DNA testing is only definitive if the mutation on both alleles is identified. When DNA testing is not possible or does not identify both mutations, a disorder that is suggested by newborn screening results must be excluded or confirmed by any of the tests used to diagnose the disorder in a symptomatic individual. The American College of Medical Genetics has provided recommendations for clinical and laboratory follow-up for each of the conditions detectable by newborn screening (http://www.acmg.net).

Lead

According to the Centers for Disease Control (CDC), lead poisoning is the most preventable environmental exposure in children, despite the fact that approximately 500,000 children in the United States have an elevated blood lead level. Lead-contaminated dust is the primary source of lead exposure in childhood, and African−American and Hispanic children are at higher risk for exposure than Caucasian children [19]. In overt acute lead poisoning, generally associated with blood lead levels of >70 μg/dL, children may present with the following symptoms: encephalopathy with ataxia, developmental regression, poor coordination, apathy, vomiting, seizures, altered mental state, and/or coma. Physical exam may show diminished deep tendon reflexes, increased intracranial

pressure, facial nerve palsy, and/or papilledema. Milder presentations include nonspecific symptoms such as anorexia, constipation, abdominal pain, irritability, and/or altered behavior. Lower-level, chronic lead exposure (15−70 μg/dL) is associated with slowed reactions and anemia. More subtle symptoms may be missed and wrongly attributed to "normal childhood behavior." These include poor attention span, behavioral problems, and irritability. In addition, these children may present with seizures without encephalopathy, developmental delay, colicky abdominal pain, myalgia, and vomiting [20,21].

The symptoms of lead poisoning in children are nonspecific and are very subtle for blood lead levels of <25 μg/dL. A 2012 report from the CDC on chronic low-level lead exposure reported decrements in intelligence quotient (IQ) and academic achievement at blood lead levels of <10 μg/dL. Studies have shown a decrease of approximately five IQ points for every 10 μg/dL increase in blood lead levels. However, in low-range lead poisoning (1−10 μg/dL), IQ dropped by seven points, suggesting that the rate of IQ loss is greatest at lower levels [22]. Based on these findings, the CDC Advisory Committee recommended that the lowest limit of acceptability for lead be <5 μg/dL [23].

The wide range of symptoms, particularly in children with low-to-mid-level lead exposure, has prompted the American Academy of Pediatrics to recommend regular lead screening for patients deemed at risk for lead exposure [24,25]. In the 1970s and 1980s, patients were screened for elevated lead levels using free erythrocyte protoporphyrin or zinc protoporphyrin testing. Lead interferes with the production of heme, which normally consists of iron and protoporphyrin. Lead inhibits the insertion of iron into protoporphyrin, leading to a buildup of protoporphyrin, which combines nonenzymatically with zinc, to produce the fluorescent compound zinc protoporphyrin. Zinc protoporphyrin can be measured in a drop of blood in specially designed instruments called hematofluorometers. Unfortunately, zinc protoporphyrin does not increase until blood lead levels are ∼25 μg/dL. With findings that lead levels of less than 10 μg/dL can cause decreases in IQ, this test is no longer a viable method for screening patients for lead exposure.

Preferred methods for measurement of lead in blood include graphite furnace atomic absorption, anodic stripping voltammetry, and inductively coupled plasma-mass spectrometry. The capital cost for this testing is high, but the cost per test is low as reagent requirements are minimal. The LeadCare point-of-care instrument, which is based on anodic stripping voltammetry, can perform testing at clinics, and its results are reliable. However, the LeadCare Ultra analyzer has been shown to have a positive bias in low-level samples and a negative bias in high samples compared with inductively coupled plasma-mass spectrometry. Yet, around the cutoff of 5 μg/dL, no significant bias has been noted, and the analyzer is therefore considered suitable as a screening approach [26]. The capital cost for this test is low, but the individual cost is high compared with the other two methods. Another consideration with the use of point-of-care testing for lead measurements is the susceptibility for contamination in capillary collections. Elevated results by point of care need to be confirmed with a venous lead blood test [27].

Treatment

Chelation therapy is indicated in children when blood lead levels are >25 μg/dL. Oral chelation should be used for patients with blood lead levels between 45 and 69 μg/dL, and may be accomplished with succimer, an analog of dimercaprol, a compound that chelates heavy metals. Succimer binds lead, and the resulting water-soluble compound is excreted in the urine. The efficacy of this drug is modest for patients with mild to moderately elevated blood lead levels, and some studies have shown little difference compared with placebo [28]. In general, lead chelation only removes about 1%−2% of total body lead content, as chelators cannot access lead stored in some organs, such as the brain [20].

Since the late 1990s, there has been a national effort to decrease childhood lead poisoning in the United States. This program has consisted of identification of housing that may have lead paint and education of the public and physicians to the dangers of lead poisoning. The removal of lead from gasoline and paint beginning in the mid-1970s has decreased the amount of lead in the environment.

The CDC tracks cases of lead poisoning, and in 1998 reported that, in the United States, approximately 7% of children tested had a confirmed blood lead level of >10 μg/dL. That statistic dropped to <1% by 2011, suggesting that cleanup efforts, public education, and awareness have worked to decrease lead exposure in children.

Transient hyperphosphatasemia

Transient hyperphosphatasemia (TH) is a temporary condition in children under 5 years old, in which serum alkaline phosphatase (ALP) activity is elevated 3−20 times the upper reference range with no clinical indications for the elevation. TH is estimated to occur in 2%−5% of healthy children [29,30]. Patients are usually asymptomatic, with unremarkable history, physical exam and laboratory results. Some patients have had a mild viral condition in the recent past. Isoenzyme analysis is nonspecific, with both bone and liver isoenzymes usually elevated. The hyperphosphatasemia will usually resolve within 1−20 weeks without treatment [29,31]. Although clinically benign, it is important for this condition to be

recognized to prevent undue follow-ups, such as bone scans, liver biopsies, or other workups, to try and identify the cause of the elevation. It is recommended that, in patients under 5 years of age, who have elevations in both bone and liver ALP isoenzymes, and with otherwise normal lab results for liver or bone disease, an isolated elevation in ALP be attributed to TH. In these cases, ALP should be repeated in 4 months to ensure ALP has returned to normal [32].

Potassium and hemolysis

The utility of measuring potassium in pediatrics is similar to that of adult populations. Due to the critical nature of potassium for proper cardiac function and normal physiologic homeostasis, especially of the muscle and nervous systems, it is measured in serum/plasma as part of a basic metabolic panel or may be ordered on its own. For patients at high risk of potassium and other electrolyte imbalances, potassium is followed very closely [33]. Such high-risk patients include those with renal disease, diabetic ketoacidosis, and tumor lysis syndrome following chemotherapy for leukemia. Given the critical nature of this analyte, it is very important that results for potassium be accurate. Since red cells have an intracellular potassium concentration about 20 times higher than plasma, even small degrees of hemolysis can increase the potassium content in a blood sample. In newborns and infants, capillary heel stick is the recommended method of blood collection, and capillary finger stick is often used with older children (see Chapter 1, Preanalytical variation). Although these methods are less painful and invasive than venipuncture, they can cause high rates of hemolysis. Consequently, potassium results (and other hemolysis-affected tests including aspartate aminotransferase, iron, lactate dehydrogenase, haptoglobin, phosphate, and bilirubin) are often inaccurate in pediatrics and must be interpreted carefully [34].

In serum and plasma samples, the degree of hemolysis is easily detected by detecting visually or spectrophotometrically an increase in red-colored hemoglobin. For these sample types, laboratories should have established guidelines to restrict reporting of specific results on hemolyzed samples. Some have proposed the use of correction factors to estimate the true potassium concentration in hemolyzed samples. For example, Mansour et al. derived two correction factors: 0.51 or 0.40 mEq/L increased potassium for every 0.1 g/dL increase in plasma hemoglobin. However, most studies have found such factors to be insufficient for clinical implementation [35]. Potassium may be tested in whole blood using point-of-care instruments. In this situation, hemolysis cannot be identified, and results must be interpreted with caution. It is wise to repeat and verify an unexpected high potassium result from a whole blood sample before making any treatment decisions. Likewise, a normal point-of-care potassium value in a patient who was expected to be hypokalemic should also alert the clinician that hemolysis may have falsely elevated the result [36,37].

Hemolysis and plasma hemoglobin

In addition to using visual means to assess the degree of hemolysis in a plasma or serum sample, plasma hemoglobin can be measured directly with a spectrophotometer using several hemoglobin-specific wavelengths or using chemical reactions to cause a color change, which can also be measured spectrophotometrically [38]. In this way, the amount of hemoglobin in a plasma sample can be quantitated. While this is not routinely used to determine the degree of hemolysis caused by sample collection, it is used to follow hemolysis from a transfusion reaction, or due to mechanical fragmentation of red cells. Extracorporeal membrane oxygenation (ECMO) is a cause of red cell fragmentation and hemolysis seen more commonly in pediatrics than in adult practice. ECMO is an effective means of providing emergency cardiac and pulmonary aid. The process of ECMO requires circulating blood from the patient through a series of pumps, which may mechanically lyse red cells, causing an increase in free circulating hemoglobin, which puts children at risk for renal impairment and death. High plasma hemoglobin may indicate the presence of a clot in the pumps, prompting modification of anticoagulation and maintenance of the ECMO circuit [39].

Lipids

Some degree of cholesterol and lipid testing in children has been recommended for decades, as this may identify early-onset genetic lipid disorders, as well as recognizing obesity-related dyslipidemias. In 2011 the National Heart, Lung, and Blood Institute (NHLBI) published findings from an expert panel, recommending universal cholesterol screening in certain age groups. The goal of this screening was primarily to identify dyslipidemias early in life, to initiate treatment, and ultimately to decrease the risk for developing cardiovascular disease. The screening protocol recommended by the NHLBI is summarized in Fig. 29.3. The guidelines endorse universal screening in the 9–11-year-old and the 17–21-year-old age groups, with screening in other age groups limited to children with certain risk factors [40]. Despite the adoption of these recommendations by the American Association of Pediatrics, this universal screening strategy is not without controversy, particularly due to the low prevalence of disease in that population, and provider adherence to the guidelines has been low [41]. The NHLBI guidelines also published new, pediatric-specific target ranges for lipid testing, which has been more widely adopted by laboratories.

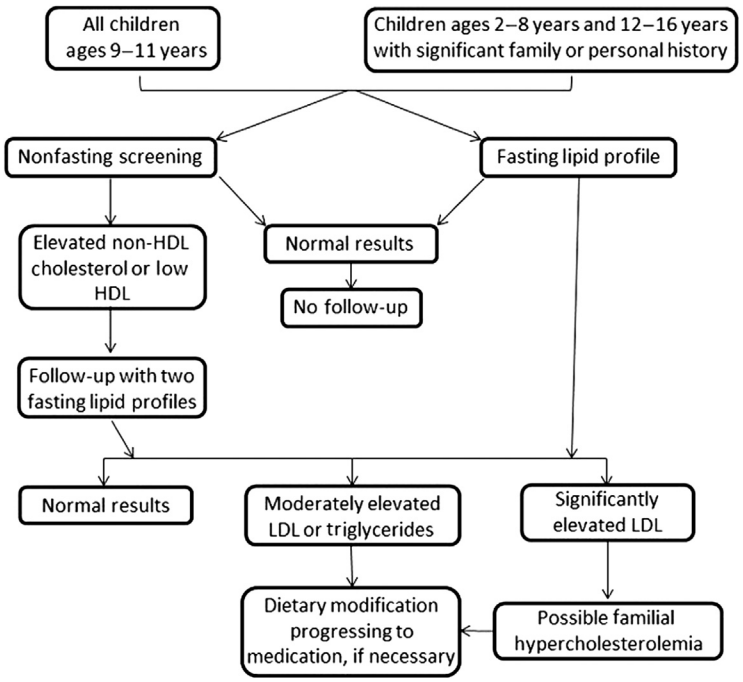

FIGURE 29.3 Algorithm summarizing the guidelines for testing lipids in children.

Bilirubin

Bilirubin is an important analyte in pediatric clinical chemistry. Approximately 60% of neonates admitted to well-baby nurseries in the United States develop hyperbilirubinemia in the first week of life [42]. Normally, bilirubin is conjugated to water-soluble glucuronide moieties, is cleared through renal and biliary mechanisms, and is nontoxic. Unconjugated bilirubin is lipid-soluble and readily crosses cell membranes, including the blood−brain barrier. Accumulation of unconjugated bilirubin in the brain is toxic, and can cause acute bilirubin encephalopathy, which may progress to kernicterus. Kernicterus is chronic and permanent bilirubin-induced brain damage. Neonates are at risk for hyperbilirubinemia, because (1) they produce increased amounts of bilirubin at birth; (2) they have low expression of glucuronosyl transferases, the enzymes responsible for glucuronide conjugation; and (3) they have high rates of red blood cell turnover. Kernicterus is a rare yet completely preventable condition. Unconjugated bilirubinemia is treatable with phototherapy or exchange transfusion in extreme cases. Effective treatment of hyperbilirubinemia relies on appropriate and accurate measurement of bilirubin.

Universally, neonates are screened for hyperbilirubinemia with total bilirubin measurement to assess risk for developing kernicterus [43]. The total bilirubin concentration is compared with the infant's age in hours. Risk assessment for hyperbilirubinemia is based on an age-specific nomogram. The nomogram is not meant to be used in premature infants or infants with significant conditions requiring neonatal intensive care, as the risk of kernicterus is higher at lower bilirubin concentrations [43]. Furthermore, the nomogram was derived from diazo methods for bilirubin and does not necessarily apply across all platforms for bilirubin measurement. As described in a study by Greene et al. [44], instruments with a positive bias for total bilirubin will result in the unnecessary use of phototherapy and those with a negative bias may miss at-risk patients. Harmonization of bilirubin measurement remains a significant challenge in pediatric clinical chemistry.

Transcutaneous bilirubin (TcB) refers to the spectrophotometric measurement of bilirubin through the skin and is measured by a handheld meter. It has become popular in inpatient units and some outpatient clinics, because it is noninvasive, fast, relatively inexpensive, and can successfully identify hyperbilirubinemia in neonates with a variety of skin tones. Hour-specific TcB reference nomograms have been developed for two commercially available, FDA cleared instruments: the BiliCheck (Phillips/Children's Medical Ventures, Monroeville, PA, United States) and JM-103 (Draeger Medical Systems, Telford, PA, Unites States) [16]. Correlation between TcB and total serum bilirubin has been demonstrated with correlation coefficients ranging between 0.71 and 0.93. TcB measurement is dependent on the skin location of the measurement. TcB measurements taken from the heel, back, or thigh do not correlate as well as measurements from the forehead or sternum. Melanin content and dermal thickness also

affect TcB measurements. Bruised, birth-marked, or hairy skin should not be used. Thus appropriate training in the use of this point-of-care instrument is critically important, and vigorous quality assurance is required [43]. TcB is a screening tool; if TcB indicates clinically significant hyperbilirubinemia, this must be confirmed by serum total bilirubin measurements. In addition, TcB only estimates total bilirubin; TcB cannot distinguish between conjugated and unconjugated fractions. Total serum bilirubin remains the gold standard for assessment of neonatal jaundice.

Conditions other than hyperbilirubinemia of the newborn that give rise to bilirubin abnormalities in infancy or childhood include hepatic biliary obstruction and the inherited disorders of bilirubin metabolism: Gilbert, Crigler–Najjar, Rotor, and Dubin–Johnson syndromes (Fig. 29.4). Of the four disorders of bilirubin metabolism, Gilbert syndrome is the most common. Gilbert and Crigler–Najjar syndromes are due to defects in UDP-glucuronosyltransferase (UGT1A1), the enzyme responsible for bilirubin conjugation, and are characterized by unconjugated hyperbilirubinemia. Gilbert syndrome is associated with 10%–35% enzyme activity and mild hyperbilirubinemia (total bilirubin values rarely exceed 6 mg/dL); infants with Gilbert syndrome are treated with phenobarbitone, which induces enzyme activity. There are two types of Crigler–Najjar syndrome. Type 1 is the most severe and is characterized by a near complete lack of UGT1A1 enzyme activity and with severe unconjugated bilirubinemia (>20 mg/dL) in the first few days of life, with no other biochemical evidence of abnormal liver function. Death from neurological sequelae due to kernicterus typically occurs by 18 months in the absence of intensive treatment such as liver transplantation. Type 2 is caused by a partial enzyme deficiency (<10%) and in contrast to Type 1, leads to less severe unconjugated hyperbilirubinemia (6–20 mg/dL). Clinical manifestations may occur if the disease is undetected for many years. Dubin–Johnson syndrome is caused by defects in a transporter gene, *ABCC2* (codes MRP2 protein), resulting in defective excretion of conjugated bilirubin. Biochemically, it is characterized by mixed hyperbilirubinemia. Rotor syndrome presents very similarly to Dubin–Johnson, but the genetic basis for Rotor syndrome is unknown, though there is some evidence that it is the result of defective uptake of unconjugated bilirubin into the hepatocyte [45]. Biliary atresia, caused by hepatic biliary obstruction, is another source of hyperbilirubinemia that presents in the neonatal period. With biliary atresia, hyperbilirubinemia is usually accompanied by elevated liver enzymes.

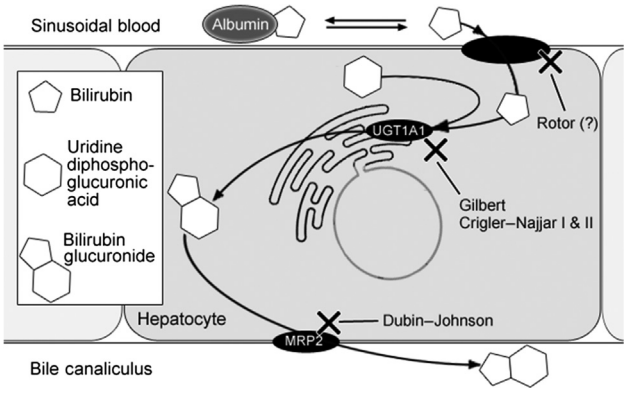

FIGURE 29.4 Disorders of bilirubin transport and conjugation.

Implications for testing in the pediatric population

Laboratory testing in the pediatric population is complicated by the fact that the results can have unintended consequences, ultimately affecting the entire family. This is due to a constellation of three factors: (1) all care providers are mandatory reporters of suspected child abuse; (2) the pediatric population is vulnerable and reliant on others for care and protection; and (3) results reflecting genetically inherited conditions can have important implications for relations, as well as unintended results for adult-onset conditions in the pediatric patient.

For the first two factors, it is important to be aware that care providers are not always able to interpret the lab results with the appropriate filters (e.g., this is a screening test, or has other known limitations). Laboratory testing necessary to diagnose certain inherited conditions may be missed altogether, leading to the wrong conclusion to be drawn (e.g., a urine drug screen may not detect a small but significant pediatric drug exposure, and bruising from bleeding disorders could be mistaken for child abuse). For these reasons, we recommend that pediatric laboratory professionals maintain familiarity with the limitations of lab tests most at risk for misinterpretation and underutilization, and intervene when necessary (e.g., urine drug screens and coagulation workups). Finally, there are guidelines recommending the appropriate approach to genetic screening and testing in children [46]. Guidelines include ensuring appropriate counseling measures for the family before testing is pursued, and deferring predictive genetic testing for adult-onset conditions when medically appropriate.

Transitioning to adult care

The final consideration in pediatric laboratory medicine is the ultimate goal of transitioning patients to adult care. For healthy children, this simple process may require changing primary care providers. For children living with chronic conditions, however, the most successful transitions take place over several years starting at 18 years of age, and ending pediatric care around 22 years old. Chronic conditions

include solid organ and bone marrow transplants, diabetes, and some inherited conditions such as muscular dystrophy and sickle cell disease. These conditions are often lab-intensive, and the transition involves obtaining blood samples at adult collection facilities and analysis, which may take place using different methodologies. Patients with some rare pediatric disorders will continue their care with pediatric specialists, because the disorders are either too rare or the prognosis of such conditions prohibit many of the affected patients from reaching adulthood.

Self-assessment questions

1. A 48-h-old term infant has a serum bilirubin of 12. According to the bilirubin nomogram, this puts the infant in which risk category?
   - **a.** Low risk
   - **b.** High-intermediate risk
   - **c.** High risk
   - **d.** The nomogram cannot be used to predict risk in term infants.
2. Which of the following conditions was the first to be mandated for newborn screening?
   - **a.** Cystic fibrosis
   - **b.** Phenylketonuria
   - **c.** Severe combined immunodeficiency
   - **d.** Kernicterus
3. Which of the following contribute the most to the minimum volume required for an assay?
   - **a.** Patient total blood volume
   - **b.** Analytical volume
   - **c.** Dead volume
   - **d.** The need for duplicate testing
4. A newborn screen is positive for cystic fibrosis. Follow-up sweat chloride testing was resulted as 40 mmol/L. This is interpreted as _____.
   - **a.** Negative for cystic fibrosis
   - **b.** Negative for cystic fibrosis, but positive for pulmonary atresia
   - **c.** Positive for cystic fibrosis
   - **d.** Indeterminate
5. Challenges with establish reference intervals in the pediatric population include _____.
   - **a.** Parental willingness to participate with healthy children
   - **b.** Federal regulations
   - **c.** Changes in analyte concentrations during development
   - **d.** Previously established reference intervals were with outdated methodology.
   - **e.** A, C, and D

Chapter 30

Biomarkers for coronary artery disease and heart failure

Peter A. Kavsak[1,2] and Alan H.B. Wu[3]

[1]Department of Pathology and Molecular Medicine, McMaster University, Hamilton, ON, Canada, [2]Juravinski Hospital and Cancer Centre, Hamilton Health Sciences, Hamilton, ON, Canada, [3]Department of Laboratory Medicine, University of California, San Francisco, San Francisco General Hospital, San Francisco, CA, United States

Learning objectives

At the end of this chapter, the reader will be able to:

- Describe the pathophysiology of acute coronary artery disease and heart failure (HF).
- Compare the diagnostic criteria from the World Health Organization with that of the European Society/American College of Cardiology to that of the Universal Myocardial Infarction definitions, with a focus on high-sensitivity cardiac troponin assays.
- Explain how cardiac troponin and B-type natriuretic peptides have become the standard blood biomarkers for acute coronary syndrome and HF, respectively.
- List novel biomarkers and how they may complement current biomarkers.
- Describe the immunoassay measurement technologies for cardiac biomarkers.

Introduction

Cardiovascular disease (CVD) continues to be an important cause of death throughout the world. In the United States (US), from 2001 to 2011, the death rate due to CVD declined by approximately 30%; however, CVD was still attributed as the cause of death in nearly one-third of all deaths in 2011 [1]. Broken down further into the major cardiovascular conditions/diseases, coronary heart disease caused ~1 in 7 deaths, heart failure (HF) ~1 in 9 deaths, and stroke causing ~1 in 20 deaths in the US [1]. Globally, CVD is the number one cause of death, with both age and population growth acting as contributors to the increased frequency; nearly one-third of deaths globally were attributed to CVD in 2013, with ischemic heart disease and stroke being predominant causes in most countries [2].

Diagnostic tests, in particular blood-based biomarkers, have played an integral role in CVD for over 60 years, especially for the diagnosis of acute myocardial infarction (AMI), where initially the enzymatic activity of serum aspartate aminotransferase (AST) was demonstrated to be increased in patients with AMI [3,4]. Since the turn of the millennium, however, cardiac troponin has taken a prominent role and is considered the most optimal blood-based biomarker to be used in the diagnosis of AMI. Outside of the diagnosis of AMI, cardiac troponin is also used for risk stratification for future adverse cardiac events, and in therapeutic selection such as with platelet inhibitors and acute intervention such as with percutaneous intervention (PCI; an example being balloon angioplasty). The prevalence of HF in the population has increased, with projections in the US suggesting close to a 50% increase in the HF prevalence from 2012 to 2030, resulting in more than 8 million adults living with HF [1]. Fortunately, the blood-based biomarkers B-type natriuretic peptide (BNP) and N-terminal-proBNP (NT-proBNP) are available and may be used for the diagnosis of HF and for the management of patients with HF. Additional/novel biomarkers have been developed and more are being evaluated to aid in the diagnosis, prognosis, and management of the various cardiovascular conditions/diseases, with the development and validation of biomarkers for ischemic heart disease and HF garnering the most attention and effort in this area.

Pathophysiology of acute coronary syndrome and myocardial infarction classification

Coronary artery disease (CAD) usually has a progressive pathophysiology that typically begins with atherosclerosis, the narrowing of coronary arteries by the deposition of

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00030-2

lipid-filled plaques, to vulnerable plaques, and finally to acute coronary syndrome (ACS), a collective term that refers to acute rupture, fissuring, or erosion of vulnerable plaques [5,6]. Fig. 30.1 illustrates the various stages of atherosclerosis. There are no symptoms associated with the initial narrowing of the coronary arteries (stages 2–4). However, with increasing coronary artery stenosis (stage 5), symptoms of chest pain begin first in conjunction with physical exertion (stable angina). These individuals have plaques that are weakened and prone to rupture. The onset of chest pain without exertion signifies the onset of ACS, as seen with the rupture of the coronary artery plaque (stage 6). The release and exposure of the plaque contents ("gruel") to circulating blood cause activation of platelets and formation of a thrombus or distal platelet emboli, which further decreases myocardial blood flow and sets the stage for tissue necrosis. In the historical World Health Organization (WHO, 1979) definition of AMI, a complete artery blockage by the clot was termed a "transmural" AMI, while a subocclusive clot was termed a "subendocardial" infarct. Patients with minimal or no release of biomarkers were termed "unstable angina" [7]. In the latest myocardial infarction (MI) definition, the Fourth Universal Definition of myocardial infarction (2018), the above pathophysiological process would be classified as a spontaneous MI (Type 1 MI), with unstable angina diagnosed if these patients have no biomarker elevation [8].

In addition to elevated biomarkers, patients with Type 1 MI often have electrocardiogram (ECG) changes [8–10]. The ECG finding is important for treatment strategies, and for patients with MI who develop ST elevation in two contiguous leads on the ECG, the MI can be clinically classified as ST elevation MI (STEMI); those MI patients who do not have this ECG finding are classified as non-ST elevation MI (NSTEMI) [9]. Type 1 MI includes processes that involve plaque rupture/erosion with an occlusive thrombus or with a nonocclusive thrombus [8]. In addition to the Type 1 MI classification, the Fourth Universal Definition of MI has further provided additional classification into the other four types of MI: Type 2 MI, Type 3 MI, Type 4 MI, and Type 5 MI.

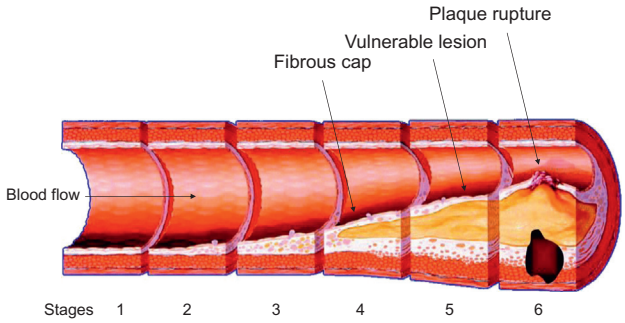

FIGURE 30.1 Pathophysiology of acute coronary syndrome. The initial four stages are not usually accompanied by symptoms. Chest pain upon exertion (stable angina) can occur in stage 5. In stage 6, there is plaque rupture causing clot formation and acute coronary syndrome. *Adapted and used with permission from F.S. Apple, A.H.B. Wu, J. Mair, J. Ravkilde, M. Panteghini, J. Tate, et al., Future biomarkers for detection of ischemia and risk stratification in acute coronary syndrome, Clin. Chem. 51 (2005) 810–24.*

Type 2 MI requires evidence of an imbalance between myocardial oxygen supply and demand, which is not due to an acute coronary atherothrombosis (i.e., not Type 1 MI) [8]. Besides clinical conditions leading to an oxygen supply/demand imbalance alone resulting in Type 2 MI, patients with nonatherosclerotic coronary dissection, vasospasm, or coronary microvascular dysfunction and those with atherosclerosis and oxygen supply/demand imbalance may result in Type 2 MI [8]. Thus context is important, (i.e., Are patients presenting with chest pain or is it secondary to another illness?). Mechanisms that may lead to Type 2 MI include hypotension/shock, severe anemia, respiratory failure, severe bradyarrhythmia, severe hypertension, sustained tachyarrhythmia, drug-induced vasospasm (e.g., amphetamine, cocaine), coronary spasm/microvascular dysfunction, coronary embolism, fixed coronary atherosclerosis, and coronary artery dissection [8]. Accordingly, Type 2 MI represents a challenge, as a condition other than CAD may contribute to the development of MI due to an oxygen supply/demand imbalance that can occur in many hospitalized patients (e.g., noncardiac surgery patients, critically ill patients, etc.) [8–11]. Type 3 MI relates to patients who suffer from cardiac death (i.e., have symptoms suggestive of myocardial ischemia) and die before blood is obtained or before increases in biomarker concentrations are evident or the MI is identified by autopsy [8]. Type 4 MI is subclassified into 4a, 4b, and 4c and all relate to PCI. Specifically, Type 4a is a PCI-related MI (i.e., $\leq$ 48 hours after index procedure), Type 4b is a stent/scaffold thrombosis associated with PCI, and Type 4c is a restenosis associated with PCI [8]. Type 5 MI is a coronary artery bypass grafting (CABG)-related MI (i.e., $\leq$48 hours after index procedure) [8].

Another important physiological process that has a role in the development of CAD and ACS is inflammation. Inflammation stimulates the recruitment of macrophages, monocytes, and foam cells to the shoulder regions of the coronary artery. These inflammatory cells release degradative enzymes such as metalloproteinases, myeloperoxidase, and collagenases that degrade the collagen-rich fibrous cap making plaques vulnerable for rupture and erosion. They may also impair release of nitric oxide, thereby inhibiting vasodilation and further precipitating the vasospasmic etiology of AMI. It should be noted that plaque rupture and erosion do not always occur on the arteries with the highest degree of stenosis. Vulnerable plaques can exist throughout the coronary artery

vasculature. An understanding of the etiologies and the classifications of MI is important for interpreting the results of the current cardiac biomarkers, in the development of new biomarkers and in monitoring and assessing new treatments [12].

Evolving definitions of myocardial infarction with an increasing focus on biomarkers

The criteria for the definition of MI have evolved over the years, in part due to the improvement in detection technologies, in particular biomarkers. In 1979 the WHO determined that two of three criteria were necessary for the diagnosis of AMI [7]. As listed in Table 30.1, these included clinical history, electrocardiographic changes, and changes in serial enzyme results. Serial enzyme results largely referred to as the enzymes creatine kinase (CK), lactate dehydrogenase (LD), and their creatinine kinase-myocardial band isoenzyme (CK-MB) and LD-1 isoenzymes. These criteria were established before the development and implementation of cardiac troponin. Under the WHO criteria, it was possible to diagnose AMI in the absence of an increase in CK-MB or LD-1 enzyme activity. Given that these tests are not as specific and analytic as sensitive as the current cardiac troponin tests, it was possible to have a patient with a mild AMI that had enzyme results that were within that enzyme's reference interval.

The development of immunoassays for CK-MB mass as well as the discovery of cardiac troponin and development of the associated immunoassay tests heralded a new era for laboratory medicine practices for the diagnosis of AMI [4,13]. Importantly, cardiac troponin is a protein (nonenzyme) biomarker that has been shown to be more analytically sensitive and specific than the existing enzyme markers. As a result, in the year 2000, a joint committee of the European Society of Cardiology (ESC)/American College of Cardiology (ACC) redefined the criteria for AMI to be predicated on documenting an increase in cardiac troponin or CK-MB mass (total CK, AST, and LD not recommended) in the context of myocardial ischemia (Table 30.1) [14]. Evidence of ischemia includes clinical history, electrocardiographic changes, angiographic evidence, and anatomic analysis (at autopsy). Therefore unlike the WHO criteria, the ESC/ACC redefinition of AMI was now predicated on an increase of a specific cardiac biomarker measured with immunoassays. Also the ESC/ACC redefinition stated that the 99th percentile upper reference limit (URL) from a healthy population should be used as the cutoff for detecting myocardial necrosis with the cardiac protein biomarkers [14].

With the 2007 Universal Definition, the preferred cardiac biomarker for detecting myocardial necrosis was stated to be cardiac troponin, with CK-MB mass as an alternative assay only if cardiac troponin was not available [15]. The 99th percentile URL was again listed as the cutoff, with an important caveat that "the use of assays that do not have independent validation of optimal precision (coefficient of variation, CV $\leq$ 10%) is not recommended." [15]. One of the important motivating factors for changing to a cardiac troponin standard (besides the myocardial tissue specificity) was the finding that patients who had minor increases in cardiac troponin concentrations were at risk of CVD progression and death, similar to those who had an AMI caused by a totally occlusive clot (i.e., high clinical sensitivity). Therefore these patients should be aggressively managed to reduce morbidity and mortality, and movement to using cardiac troponin as the standard and the 99th percentile URL as the cutoff via the 2000 and 2007 AMI definitions enabled justification of the resources needed. Under these definitions, patients who may have had minor myocardial damage as determined by low cardiac troponin concentrations and were previously diagnosed as unstable angina would now be diagnosed with NSTEMI. The impact of moving from the WHO criteria and high cardiac biomarker cutoffs to the redefinition of MI using cardiac troponin and the 99th percentile URL cutoff is an increase in the number of AMI patients. Importantly though, these newly defined patients are at increased risk of subsequent MI /death as compared with those negative by both the old WHO AMI definition and the 2000/2007 AMI definitions (Fig. 30.2) [16,17]. Roughly, a third more of unstable angina patients were now diagnosed as AMI. Fig. 30.3 is a model that illustrates the impact of the AMI redefinition (post-2000) on the number of AMI cases seen annually in the US. A similar increase is evident worldwide.

With the 2012 Third Universal definition of MI, much has remained the same insofar that the preferred biomarker remains cardiac troponin and the 99th percentile URL is still assigned as the cutoff. Analytically though, the 2012 MI definition has ceded the 10% precision requirement at the 99th percentile URL concentration and allows cardiac troponin assays imprecision up to 20% at this concentration [9]. Also the 2012 MI definition is the first to mention high-sensitivity cardiac troponin (hs-cTn) assays. Before 2012, only Roche Diagnostics' high-sensitivity cardiac troponin T (hs-cTnT) assay was clinically available globally [US Food and Drug Administration (FDA) approval in 2017 with labeling as Troponin T Gen 5 in the US] and no other high-sensitivity cardiac troponin I (hs-cTnI) assays were regulatory approved before 2012 [18]. Accordingly, due to the limited number of studies on hs-cTn assays compared

TABLE 30.1 Comparisons of myocardial infarction definitions using the epidemiological approach: the World Health Organization (1979) versus the clinical approach: European Society of Cardiology/American College of Cardiology (European Society of Cardiology/American College of Cardiology redefinition, 2000, First), Universal (2007, Second), Third Universal (2012), and Fourth Universal (2018) Definitions of Myocardial Infarction.

WHO 1979 definition (two of the following three criteria must be met)
- History is typical if severe and prolonged chest pain is present
- Unequivocal ECG changes, abnormal Q or QS waves, evolving injury lasting longer than 1 day
- Unequivocal serial enzyme changes, or initial rise and subsequent fall of levels. Change must be properly related to the particular enzyme and the delay between onset and sampling

ESC/ACC 2000 redefinition

Typical rise and gradual fall (troponin) or more rapid rise and fall (CK-MB) of biochemical markers of myocardial necrosis with at least one of the following:
- ischemic symptoms
- development of pathologic Q waves
- ECG changes indicative of ischemia (ST segment elevation or depression)
- coronary artery intervention

Pathologic findings of AMI

Universal 2007 definition

Detection of rise and/or fall of cardiac biomarkers (preferably troponin) with at least one value above the 99th percentile of the URL together with evidence of myocardial ischemia with at least one of the following:
- Symptoms of ischemia
- ECG changes indicative of new ischemia
- Development of pathological Q waves in the ECG
- Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality

Criteria for MI Types 3,4, and 5

Pathologic findings of AMI

Third Universal 2012 definition
- Detection of rise and/or fall of cardiac biomarker values (preferably cTn) with at least one value above the 99th percentile upper reference limit (URL) and with at least one of the following:
  - Symptoms of ischemia
  - New or presumed new significant ST-segment-T wave changes or new left bundle branch block
  - Development of pathological Q waves in the ECG
  - Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality
  - Identification of an intracoronary thrombus by angiography or autopsy
- Criteria for MI Types 3,4, and 5

Fourth Universal 2018 definition

The term acute myocardial infarction should be used when there is acute myocardial injury with clinical evidence of acute myocardial ischemia and with detection of a rise and/or fall of cardiac troponin concentrations with at least once concentration above the 99th percentile URL and at least one of the following:
- Symptoms of myocardial ischemia
- New ischemic ECG changes
- Development of pathological Q waves
- Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality in a pattern consistent with an ischemic etiology
- Identification of a coronary thrombus by angiography or autopsy (not for type 2 or 3 MIs)

Postmortem demonstration of acute atherothrombosis in the artery supplying the infarcted myocardium meets criteria for Type 1 MI. Evidence of an imbalance between myocardial oxygen supply and demand unrelated to acute atherothrombosis meets criteria for type 2 MI. Cardiac death in patients with symptoms suggestive of myocardial ischemia and presumed new ischemic ECG changes before cardiac troponin concentrations become available or abnormal meets criteria for type 3 MI.

Criteria for MI Types 4 and 5

Criteria for prior or silent/unrecognized MI: abnormal Q waves; imaging evidence of loss of viable myocardium; and pathoanatomical findings of a prior MI

ACC, American College of Cardiology; *AMI*, acute myocardial infarction; CK, creatine kinase; *cTn*, cardiac troponin; *ECG*, electrocardiogram; *ESC*, European Society of Cardiology; *MI*, myocardial infarction; *URL*, upper reference limit; *WHO*, World Health Organization.

with the sensitive cardiac troponin assays at the time of writing the Third Universal Definition of MI, there was limited text on these assays for use in MI diagnosis. The following was the only statement on hs-cTn assays in the *Biomarker Detection of Myocardial Injury with Necrosis* section of the consensus document: "Sex-dependent values may be recommended for high-sensitivity troponin assays" [9]. A formal definition of hsTn and further

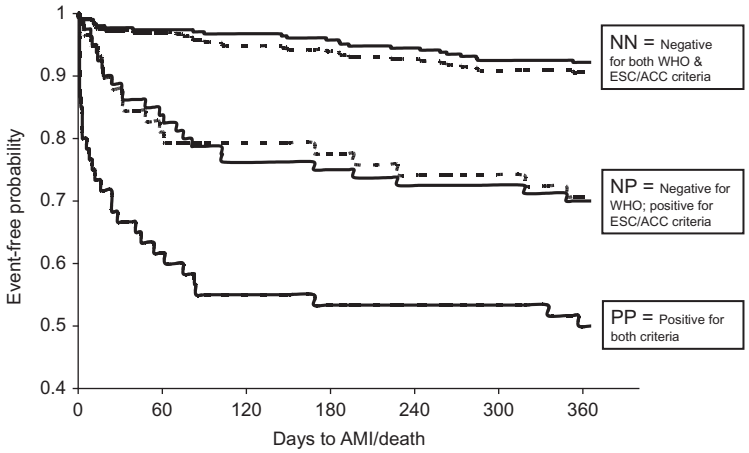

FIGURE 30.2 Kaplan–Meier curves for mortality from all causes and/or subsequent acute myocardial infarction in patients who presented to the emergency department with symptoms suggestive of cardiac ischemia. Among 448 patients stratified by two definitions of acute myocardial infarction, patients were stratified into three groups (NN—negative for both acute myocardial infarction definitions; NP—positive for the European Society of Cardiology/American College of Cardiology acute myocardial infarction definition only; and PP—Positive for both acute myocardial infarction definitions). Solid line indicates use of the 99th percentile cutoff level for cardiac troponin I in the European Society of Cardiology/American College of Cardiology criteria; dotted line indicates use of the 10% cardiovascular cutoff level for cardiac troponin I in the European Society of Cardiology/American College of Cardiology criteria. *From P.A. Kavsak, A.R. MacRae, G.E. Palomaki, A.M. Newman, D.T. Ko, V. Lustig, et al., Health outcomes categorized by current and previous definitions of acute myocardial infarction in an unselected cohort of troponin-naïve emergency department patients. Clin. Chem. 52 (2006) 2028–35 with permission.*

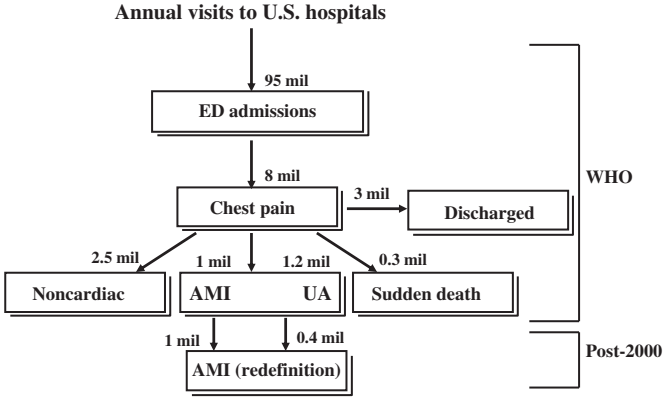

FIGURE 30.3 Emergency department visits for patients with chest pain and the incidence of myocardial infarction under the World Health Organization and the post-2000 redefinition of myocardial infarction (e.g., European Society of Cardiology/American College of Cardiology criteria etc.).

discussion of its utility will be given in the subsequent sections of the chapter.

The Fourth Universal Definition of Myocardial Infarction released in August 2018 has further fleshed out the difference between myocardial injury and MI. Specifically, myocardial injury is identified if the cardiac troponin concentration is above the 99th percentile URL, with acute injury evident if there is a rise and or fall in cardiac troponin concentrations [8]. The term AMI should be used when there is acute myocardial injury with clinical evidence of acute myocardial ischemia [8]. The preferred biomarker of myocardial injury remains cardiac troponin, with hs-cTn assays recommended for routine use. Serial measurements are required to differentiate if the myocardial injury is acute or chronic, with $\leq 20\%$ variation in concentrations indicative of stable elevated levels [8]. The imprecision at the 99th percentile concentration must be $\leq 10\%$ CV for hs-cTn assays, with imprecision between 10% and 20% acceptable at the 99th percentile for the non-hs-cTn assays (i.e., the contemporary assays) [8]. For hs-cTn assays, sex-specific 99th URLs are recommended, despite being "controversy as to whether this approach provides valuable additional information for all hs-cTn assays." [8], according to the ESC 4th Universal Definition of Myocardial Infarction. Finally, the fourth definition still recommends baseline

(0 hour) measurement with a repeated measurement 3−6 hours later, with earlier measurements possible when using hs-cTn assays [8].

Cardiac troponins T and I

Biochemistry

The troponin protein complex binds to tropomyosin and actin of the thin filament and regulates contraction within striated muscle. It consists of three proteins: troponin C (molecular weight ∼ 18 kDa) calcium binding protein; troponin I (molecular weight <30 kDa) protein that inhibits ATPase, and troponin T (molecular weight ≤40 kDa) anchoring protein that binds to tropomyosin. Cardiac troponin T (human cTnT = 298 amino acids) and I (human cTnI = 210 amino acids) isoforms from the heart are structurally distinct from the corresponding skeletal muscle isoforms. Therefore the concentration of cardiac troponin in the patient's blood is not influenced by the presence of most types of skeletal injury, making the test for cardiac troponins T and I highly specific for the heart [19]. Assays for cardiac troponin T and I are also more sensitive than CK-MB, as these subunits have a higher myocardial content (see Table 30.2). The subcellular distribution of cardiac troponin is shown in Fig. 30.4; though this and the release kinetics and forms of cardiac troponin are still an area of active research [20].

TABLE 30.2 Myocardial tissue content of cardiac markers.

Marker	Content
Cardiac troponin T	∼10.8 mg/g wet weight
Cardiac troponin I	∼4.0−6.0 mg/g wet weight
Creatine kinase-MB	∼1.4 mg/g wet weight

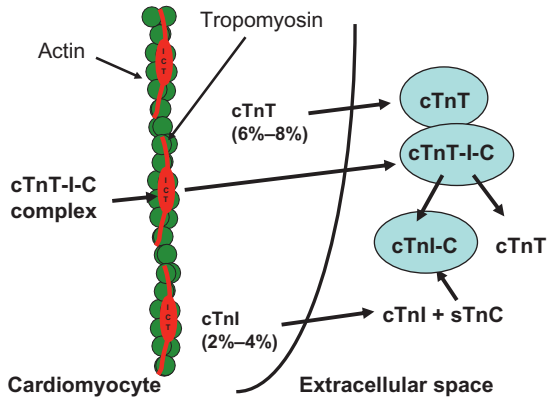

FIGURE 30.4 Subcellular distribution of cardiac troponin within the cardiomyocyte and release into the circulation following injury.

Approximately 6%−8% of cTnT and 2%−4% of cTnI are found free in the cytoplasm. Following irreversible myocardial injury, the cytosolic forms are first to appear in blood (Fig. 30.5A). This is followed by the prolonged release of the ternary complex of cardiac troponin (T−I−C) due to the breakdown of the myofibrils by degradative enzymes. The ternary complex further degrades in blood to the binary I−C complex and free cardiac troponin T, with fragments detected from both troponin T and troponin I; some of this degradation may occur in the necrotic cells from patients with AMI [21−23]. However, there are other mechanisms (i.e., ischemia and reversible injury) that may result in increased concentrations of cardiac troponin [24,25]. Specifically, both cell culture and animal models have demonstrated bleb formation in the presence of anoxia (i.e., bubbles in plasma membrane due to ischemia; see Fig. 30.5B) [24], with a large meta-analysis demonstrating that cardiac troponin (as well as other biomarkers used in the acute care setting, e.g., D-dimer and the natriuretic peptides) can increase after strenuous exercise [25].

Although there are some differences (depending on the manufacturer and assay version used), the clinical performance of cTnT and cTnI overall for aiding in the diagnosis of AMI is similar, and a clinical laboratory would only need to offer one test, not both tests, for this purpose. However, in rare circumstances, measurements of both may be helpful in specific patient conditions and during investigations of possible interferences [26,27]. To this end, for practicality, rather than having more than one cardiac troponin test available in this situation, a clinical laboratory could refer problematic samples to another laboratory running an alternate cardiac troponin assay to aid in the investigation.

Clinical utility of cardiac troponins in acute coronary syndrome

Diagnosis and risk stratification

Cardiac troponin is the most important biomarker for aiding in a diagnosis and for the risk stratification of patients presenting with symptoms suggestive of ACS. However, for an STEMI diagnosis, this can be achieved without laboratory testing, though depending on the time from pain onset and time of blood collection, cardiac troponin concentrations would be elevated in patients presently acute with this condition. Using the 99th percentile URL concentration from a healthy normal population as the decision level for cardiac troponin means that 1% of the healthy population would have a cardiac troponin concentration exceeding this cutoff. Also, until recently, manufacturer assays had a difficult time in achieving the optimal precision at the 99th percentile concentration,

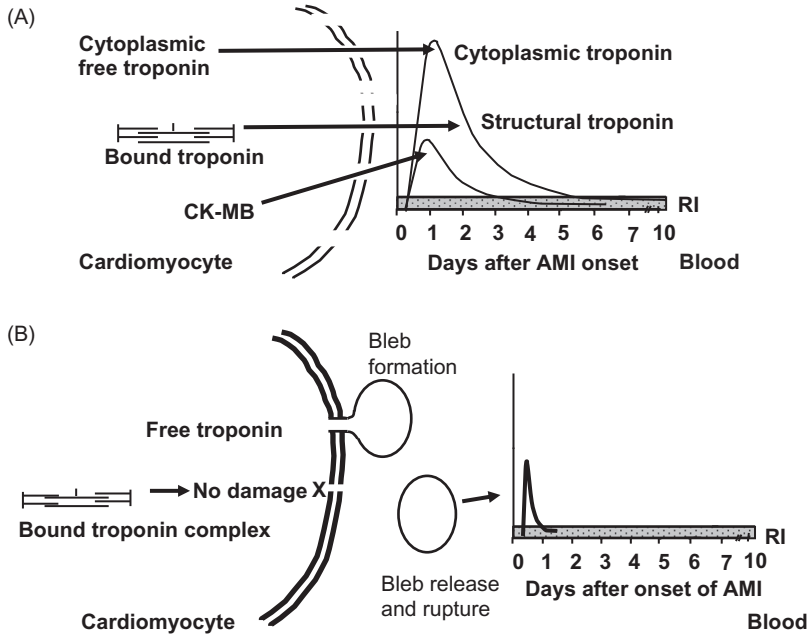

FIGURE 30.5 (A) Irreversible injury release kinetics for cardiac troponin and creatine kinase-MB following myocardial injury with cytosolic cardiac troponin first released followed by structural cardiac troponin into the blood. (B) Reversible injury with cytosolic cardiac troponin release with possible bleb formation. *RI*, Reference interval. *Adapted from P.E. Hickman, J.M. Potter, C. Aroney, G. Koerbin, E. Southcott, A.H. Wu, et al., Cardiac troponin may be released by ischemia alone, without necrosis. Clin. Chim. Acta. 411 (2010) 318–23 with permission.*

causing further analytical and clinical concerns. Accordingly, after the redefinition of MI, there were concerns on the clinical specificity of the test (i.e., the false-positives), which is largely dependent on the cutoff concentration chosen.

Historically, the cutoff concentrations for nonspecific cardiac biomarkers such as CK-MB and myoglobin (both analytes are expressed in skeletal muscle) were established to differentiate unstable angina from AMI. With the clinical implementation of the first generation cTnT and cTnI assays, the National Academy of Clinical Biochemistry (NACB) 1999 recommendation maintained the receiver operating characteristic (ROC) curve cutoff for the diagnosis of AMI [28]. After the 2000 redefinition of MI due to the suboptimal analytical precision at the 99th percentile URL concentration for many of the cardiac troponin assays, the 10% CV concentration cutoff was proposed (i.e., the cardiac troponin concentration with an imprecision of $\leq 10\%$) [29]. This cutoff was selected to minimize the number of false-positive results due to analytical noise and enabled the differentiation of patients with stable versus unstable CAD. Improvements in analytical sensitivity and precision have occurred with the release of the next-generation cardiac troponin assays, whereby the 10% CV concentration level is at or near the 99th percentile URL of a healthy population, with the vast majority of the contemporary, sensitive assays achieving a CV $<20\%$ at the 99th percentile URL concentration [19].

Optimum cutoff concentrations

The use of sensitive cardiac troponin assays with the lower cutoff concentration (i.e., 99th percentile concentration versus the higher WHO ROC curve concentration) enables an earlier detection of AMI and identifies more individuals who are at risk in the short term (i.e., 30 days) for adverse cardiac events. MacRae et al. [30] demonstrated using a sensitive cardiac troponin assay at the 99th percentile with a change in criteria that measurement at least 3 hours after presentation gave equivalent AMI prevalence to samples collected at least 6 hours apart (Fig. 30.6). Melanson et al. [31] also showed that earlier detection of myocardial injury was possible with a sensitive cardiac troponin assay, and estimated that a sensitive cardiac troponin assay will detect injury at least 30 minutes earlier compared with the previous generation cardiac troponin assay. In the risk stratification study of TACTICS (Treat Angina with Aggrastat and Determine Cost of Therapy with an Invasive or Conservative Strategy)–Thrombolysis in Myocardial Infarction (TIMI) 18, Morrow et al. [32] identified 10% more patients who were at risk of future CVD relative to the 10% CV cutoff with standard cardiac troponin assays, without degradation in the hazard ratio. This was followed by another study by Morrow and colleagues, this time using a sensitive contemporary cardiac troponin I assay and the 99th percentile URL. Their findings in more than 4000 ACS patients were that patients with cardiac troponin concentrations between the 99th percentile concentration and the

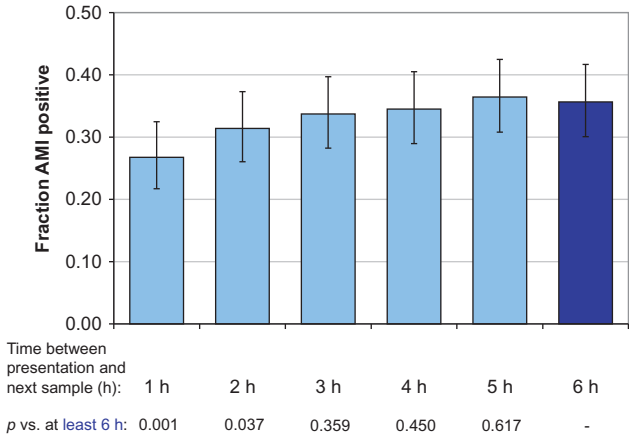

FIGURE 30.6 Effect of the minimum time interval between specimens on acute myocardial infarction positivity. Acute myocardial infarction positivity with progressively shorter minimal intervals between specimens compared with the sample taken at least 6 h after presentation. *From A.R. MacRae, P.A. Palomaki, et al., Assessing the requirement for the 6-hour interval between specimens in the American Heart Association Classification of Myocardial Infarction in Epidemiology and Clinical Research Studies. Clin. Chem. 52 (2006) 812–18 with permission.*

older, higher cardiac troponin cutoff used with the previous generation of assays (i.e., low concentrations above the 99th but below old cutoffs) were at significantly higher risk of death/MI at 30 days (5.0% vs. 2.0%, $P = .001$) and death at 12 months (6.4% vs. 2.4%, $P = .005$) than were patients with cardiac troponin concentrations below the 99th percentile URL [33]. These findings are consistent with other health outcome-based studies and guidelines, demonstrating the benefit of using the 99th percentile URL in patients with ACS symptoms [9,16]. However, even low, detectable, cardiac troponin concentrations below the 99th percentile may provide long-term (i.e., >1 year) risk stratification information for both men and women with ACS symptoms [34] (Fig. 30.7). Future cardiac troponin assays (i.e., the hs-cTn assays) will have even lower limits of detection, coupled with better precision at these low concentrations, which will result in lower and different 99th percentile URLs [19,35].

Lowering the decision limit for a clinical laboratory test may come at the expense of clinical specificity. While cardiac troponin is released following injury to the heart, it is not a specific marker of AMI (which is a clinical diagnosis). There are other conditions and diseases that cause myocardial damage and release of cardiac troponin. Some of these conditions include HF, renal failure, myocarditis, pulmonary embolus, sepsis, and use of drugs that are toxic to the heart (e.g., trastuzumab and doxorubicin) [36,37]. Opponents of the sensitive and hs-cTn assays will argue that lowering the cutoff concentration will result in a higher incidence of abnormal cardiac troponin concentrations in patients without AMI. It is important to emphasize that the diagnosis of AMI in the presence of low-concentration increases in cardiac troponin must be accompanied by other evidence of myocardial ischemia.

In an effort to reduce emergency department (ED) overcrowding, some physicians admitted patients to a coronary care unit on the basis of single positive cardiac troponin test result. This is not in compliance with the previous and current AMI guidelines that have consistently recommended serial testing to document a rise and fall in biomarkers. The use of a change in serial cardiac troponin results can be very helpful to determine if there is an acute cardiac injury (rising pattern), an ongoing release (stable pattern), or resolving damage (falling pattern). Patients with early onset ACS would be expected to have a rising pattern (or falling pattern if the onset of chest pain was distant), but there can be other causes of myocardial injury besides AMI. A patient with an increased cardiac troponin that is unchanging might have a disease that is associated with continual cellular damage. The biological variability is important in properly interpreting serial cardiac troponin results and has been reported for the hs-cTn assays. Based on the analytical and intraindividual coefficients of variances and log transformations, the reference change value (RCV) for cardiac troponin is a rise of about 50% and a fall of about 30%, as reported in one study [38]. Serial values in the short term, which are outside these limits, may imply acute cardiac injury. For sensitive cardiac troponin assays, some studies have derived relative percent change or absolute changes; however, these metrics are dependent on the assay used and the time between the measurements [39,40]. Also it should be stated that the derivation of the 99th percentile URL is specific for each cardiac troponin assay, dependent on how the "healthy population" was selected, and the number of individuals included to obtain a reliable estimate [41–44].

Other biomarkers of acute myocardial infarction

The success and incorporation of cardiac troponin into international guidelines and recommendations for ACS have put into question the need and value of existing biomarkers such as CK-MB, myoglobin, and LD, and other biomarkers of injury such as heart-type fatty acid binding protein (hFABP). While CK-MB has been in use as a cardiac biomarker for over 40 years, its incremental value relative to cardiac troponin has been questioned in the published ESC 4th Universal Definition of Myocardial Infarction [8]. CK and CK-MB with a molecular mass of 84 kDa has a monophasic release pattern from the cytoplasm within the first 12 hours after onset and remains increased for 2–3 days (Fig. 30.5A). While there has

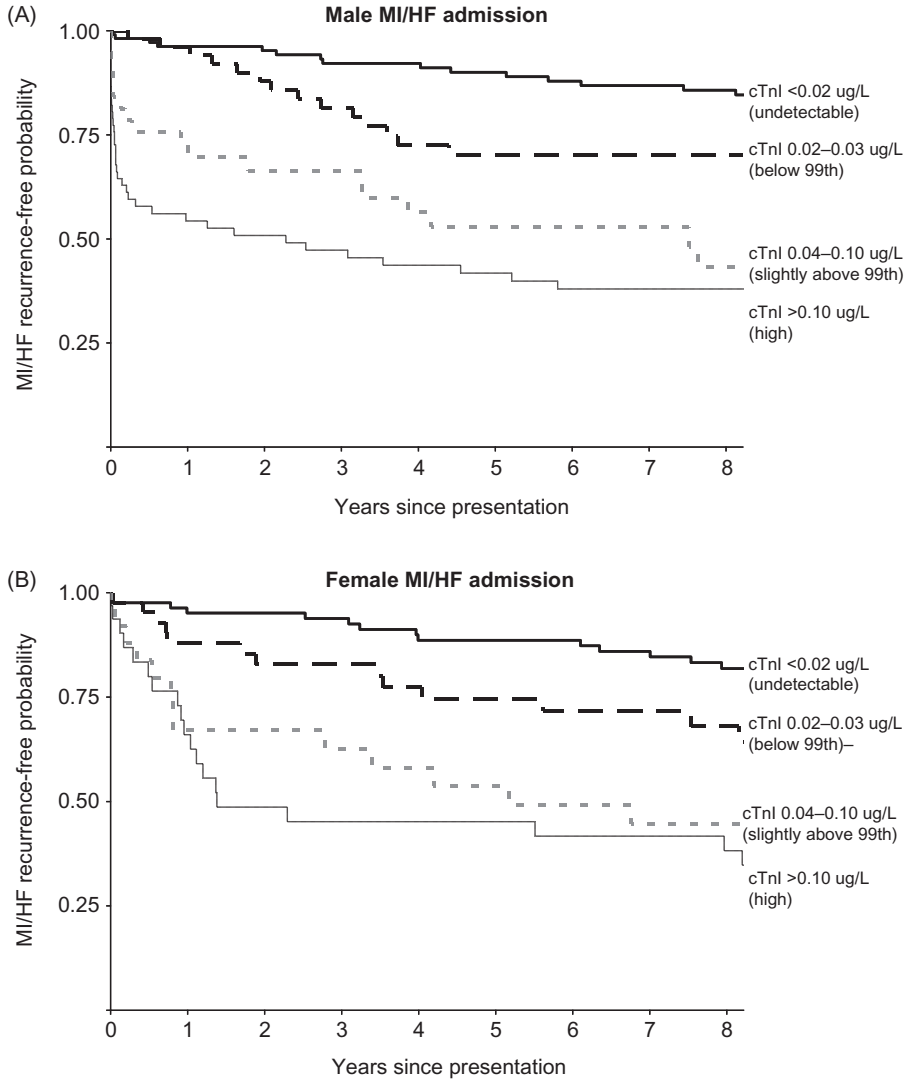

FIGURE 30.7 Kaplan–Meier curves for each sex for myocardial infarction/heart failure readmission endpoint from a population of patients who presented to the emergency department with symptoms suggestive of cardiac ischemia. Kaplan–Meier curves for myocardial infarction/heart failure readmission endpoint among the (A) 265 men and (B) 183 women (event-free survival in women: 82% for not detectable, 64% for low, 45% for intermediate, and 35% for high; event-free survival in men: 85%, 71%, 43%, and 38%, respectively; $P < .001$). *From P.A. Kavsak, A.M. Newman, V. Lustig, A.R. MacRae, G.E. Palomaki, D.T. Ko, et al., Long-term health outcomes associated with detectable troponin I concentrations. Clin. Chem. 53 (2007) 220–27 with permission.*

been some suggestion that CK appears earlier than cardiac troponin, this is clearly not the case when sensitive cardiac troponin cutoff concentrations are used, that is, at the 99th percentile [45]. Cardiac troponin is released earlier and remains increased for longer than CK-MB. Because of its more rapid return to baseline levels, some have suggested that while cardiac troponin is still increased, CK-MB could be used to detect the presence of reinfarction. However, Apple and Murakami [46] have shown that a second cardiac troponin peak can be observed in these patients, even if there is no return to baseline levels. Others have suggested monitoring serial CK-MB measurements for a determination of infarct size. This logic is flawed, as the objective for treating AMI patients is to revascularize as soon as an AMI is diagnosed to salvage jeopardized myocardium, that is, not to wait for a rise and fall to document the extent of injury. Successful reperfusion of a previously occluded coronary artery (as in the case of Type 1 MIs) invalidates the estimates of infarct sizing based on biomarker measurements.

Automated immunoassays for serum myoglobin have been available for the past 20 years as an early marker of AMI. This low-molecular-weight protein (~17 kDa) appears in blood within 6 hours after onset, reliably before CK-MB. The major limitation of myoglobin is the lack of cardiac specificity. Patients with renal failure and skeletal muscle injury will exhibit high myoglobin concentrations. While popular for a few years, the interest in myoglobin has waned as clinical studies have indicated inferior clinical performance as compared with sensitive cardiac troponin assays [45,47,48]. hFABP (encoded by the FABP3 gene) is another small protein that was originally shown to be released from myocardium that underwent ischemia and reperfusion with findings from a meta-analysis, suggesting that the combination of hFABP and sensitive cardiac troponin improved the sensitivity for

AMI as compared with cardiac troponin alone [49]. However, the data on the additive value of hFABP or copeptin (another potential biomarker used for early decision-making in the ED) when combined with hs-cTn assays for early AMI diagnosis are less favorable [50–52]. This is not to say there is no utility of the above biomarkers, as there may be other indications for measuring these biomarkers in different cardiac populations at risk of additional adverse events. One such example is in the setting of cardiac surgery where perioperative measurement of hFABP for predicating acute kidney injury appears to be superior to cardiac troponin in both the pediatric and adult cardiac surgery populations [53–55]. In addition, interferences that may be present in a patient's sample, such as heterophile or autoimmune antibodies to one particular cardiac troponin assay, may necessitate testing with a different cardiac troponin assay or different cardiac biomarkers in these situations or in rare diseases (an example being patients with neuromuscular myopathies and measurable troponin T) [26,27,56,57].

High-sensitivity cardiac troponin assays

The next generation of hs-cTn assays represents another major milestone for cardiac testing. Earlier versions including the sensitive cardiac troponin assays when measured in healthy, nonacutely ill, populations yielded undetectable cardiac troponin concentrations in the majority of individuals. With the advent of hs-cTn assays, now the majority of the healthy, nonacute, populations have measureable concentrations of cardiac troponin, with common consensus indicating that at least 50% of the population must have a measurable concentration with the cardiac troponin assay for it to be deemed a high-sensitivity assay [19,43,58]. However, the most recent laboratory practice recommendation from the Academy of the American Association for Clinical Chemistry (AACC) (previously named NACB) and the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC), published in 2018, proposed that assays unable to detect cardiac troponin at concentrations at or above the limit of detection in at least 50% of healthy men and women be labeled as contemporary assays [44]. This concept is extrapolated from the fact that differences in concentrations between healthy men and women are evident when using hs-cTn assays and in addition to the sex-specific 99th percentiles being reported; those high-sensitivity assays should be able to detect measurable concentrations in both the male and female populations.

Concurrent with this, increase in the analytical sensitivity (approximately 10-fold more analytically sensitive than the sensitive/contemporary cardiac troponin assays) is an improved precision such that concentrations near and below the 99th percentile can be measured with a 10% CV. It should be noted that with this increased analytical performance that there needs to be an increased vigilance to specimen requirements, monitoring the assay and reporting results. For example, matrix differences (i.e., serum versus heparin plasma versus EDTA plasma) may exist (Fig. 30.8) and common interferences and preanalytical handling may affect measurements in one sample type or assay and not others [59–64], as concentrations below the 99th percentile can be measured with studies showing clinical utility in this range. Further, laboratories will also need additional quality control (QC) material and/or procedures in place to monitor hs-cTn assays in the "normal range" to prevent inappropriate drifts in signal at the low end due to instrument performance, reagent lot stability, or new lots of reagent [65,66] (Fig. 30.9). The need for a "normal" concentration QC material when offering hs-cTn testing has been endorsed by the AACC/IFCC expert group, in that their recommendation 1 for hs-cTn assays indicates a QC material above

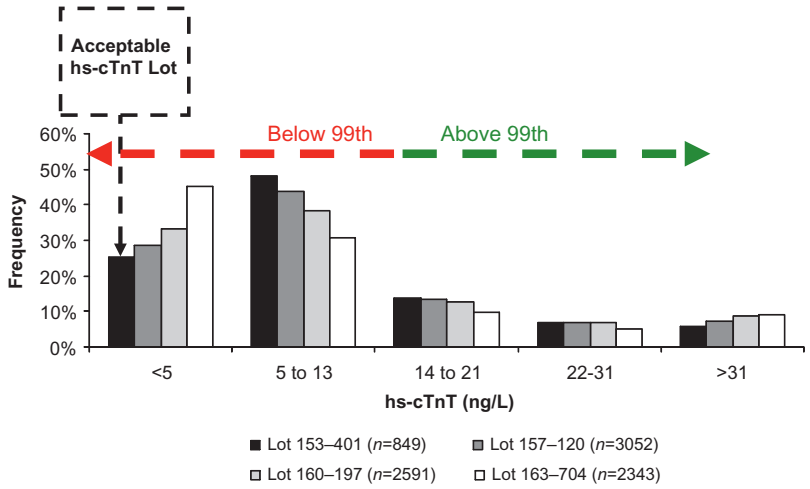

FIGURE 30.9 Distribution of high-sensitivity cardiac troponin T results with one acceptable lot (153401) versus different lots of reagents (March 2010 to September 2012). The percentages of high-sensitivity cardiac troponin T concentrations below the limit of detection (<5 ng/L) were higher in lots 157120 (29%; $P = .032$), 160197 (33%; $P < .001$), and 163704 (45%; $P < .001$), compared with the acceptable lot 153401 (25%). *From P.A. Kavsak, S.A. Hill, M.J. McQueen, P.J. Devereaux, Implications of adjustment of high-sensitivity cardiac troponin T assay. Clin. Chem. 59 (2013) 574–76 with permission.*

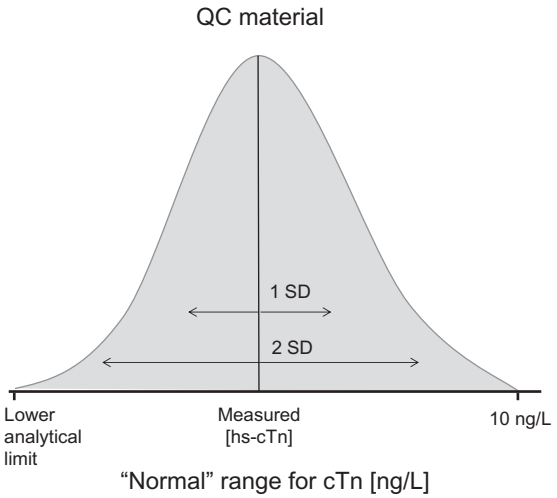

FIGURE 30.10 An illustration demonstrating the utility of measuring a quality control material in the "normal" concentration range for high-sensitivity cardiac troponin assays (i.e., above the lower limit of reporting and below 10 ng/L). The SD value should be ≤0.8 ng/L for high-sensitivity cardiac troponin measurements below 10 ng/L [68].

the limit of detection and below the lowest sex-specific 99th percentile [44]. This is in addition to a QC material near the highest 99th percentile and another QC material at concentrations multiple-fold higher than the 99th percentile to challenge the upper analytical range [44]. Importantly, having a QC material below 10 ng/L (a concentration range that is measurable with high-sensitivity assays), precision goals and total error criteria that have been developed with hs-cTn assays may be utilized [44,67–69] (Fig. 30.10).

Other recommendations by the AACC/IFCC expert group include the validation of the lower limit of reporting, which may be the limit of detection or limit of quantification [44]. Different regulatory bodies may impose or limit concentrations that can be reported with hs-cTn assays [18,44]. Accordingly, standardization and agreement of testing at the low-concentration end may be quite variable [70]. Consensus has also emerged that clinically hs-cTn results should be reported in whole units and in ng/L [8,19,43,44]. This will help avoid confusion among users and may even help in the clinical implementation of hs-cTn assays [44,71]. Another recommendation by the expert group that may help laboratories in offering the most sensitive and precise cardiac troponin assay is the change in turnaround time, where cardiac troponin results should be reported within 60 minutes or less of when a sample is received in the laboratory [44]. This represents a change from previous recommendations that indicate 60 minutes from blood collection, with the rationale being that laboratories can appropriately track, monitor, and control turnaround times when samples are received in the laboratory. In all, the AACC/IFCC expert group has listed 10 recommendations to help laboratories when offering cardiac troponin testing, with a focus on hs-cTn assays [44].

Clinically, hs-cTn assays have advantages over contemporary and sensitive cardiac troponin assays in the early decision-making process in the ED and in the nonacute setting. Specifically, studies have demonstrated that undetectable or very low cardiac troponin concentrations in patients with possible ACS at ED presentation may be ruled out for AMI or earlier serial measurements before the 3–6 hour time frame may be useful for early ED

disposition (i.e., 1- or 2-hour algorithms), though there are important laboratory quality issues and population related aspects that need to be taken into consideration in these approaches [72–77]. Using the published ESC guidelines yields high negative and positive predictive values for AMI, yet the sensitivity of these algorithms may not be sufficient for all physicians and for all patient populations [77–81]. Moreover, despite population reference intervals clearly indicating differences between the 99th percentiles for men and women, a large stepped-wedge, cluster-randomized controlled trial assessing sex-specific 99th percentile cutoffs with one hs-cTn assay found that more patients were identified with myocardial injury than type 1 MI and this did not lead to a reduction in subsequent cardiac events [82]. However, these same authors reported that an hs-cTn assay can identify low-risk patients [82]. This is in agreement with observations obtained in stable, nonacute CVD populations, where hs-cTn assays are able to identify patients at low and high risks for long-term adverse cardiovascular outcomes and death [83–87]. Importantly, data are emerging that treatment decisions based on hs-cTn in the nonacute setting may be beneficial to patient care [87–89]. Accordingly, the use of hs-cTn assays is becoming mainstream, with several hs-cTn assays already approved for clinical use [18,64,69], with more in development [90]. This, therefore, diminishes the need for the contemporary assays and obviates the advantages of other nontroponin biomarkers in the early ED decision-making process as shorter ordering protocols and diagnostic and prognostic evidences have been demonstrated with hs-cTn assays [91].

Pathophysiology of heart failure

HF is a clinical syndrome with patients often presenting with fatigue, shortness of breath, exercise intolerance, and fluid retention; however, as not all patients present with volume overload, the term HF is preferred over congestive heart failure (CHF) [92]. HF is a chronic CVD that occurs when the myocardium is unable to supply oxygen-enriched blood to peripheral tissues to meet metabolic demands and results from impairment of ventricular filling or ejection due to disorders of the myocardium, endocardium, pericardium, heart valves, and great vessels or from other metabolic abnormalities [92]. Risk factors for HF include CAD (and ACS/MI), hypertension, diabetes mellitus, and metabolic syndrome; with the left ventricular ejection fraction (LVEF) an important variable for classification [HF with preserved EF (HFpEF) and HF with reduced EF (HFrEF)] [92]. HFrEF (LVEF $\leq$ 40%), also known as systolic HF, has been most commonly studied with efficacious therapies established in clinical studies, while HFpEF (LVEF $\geq$ 50%) also known as diastolic HF is diagnostically more challenging with limited therapies [92]. The ESC Guidelines have also classified LVEF ranges from 40% to 49% as HF with mid-range EF, as these patients may have different underlying pathophysiology [93]. Typically, HFpEF versus HFrEF patients are older, more commonly female, with greater hypertension, obesity, anemia, atrial fibrillation, and lower natriuretic peptide concentrations [94,95]. In summary, HF is a clinical diagnosis based on history and physical examination, though laboratory tests may be helpful in making this diagnosis.

In HF, the pathophysiological result of reduced systemic blood flow leads to the activation of the renin–aldosterone axis, which causes vasoconstriction, sodium and water retention, and hypertension (Fig. 30.11, right side). In a time of crisis, this axis is necessary to maintain blood pressure and blood flow to vital organs including the brain. Unfortunately, chronic overstimulation of this axis that occurs in HF causes cardiac enlargement and remodeling (Fig. 30.12). A shift in the shape from an elliptical to a spherical geometry makes the heart less efficient in pumping blood out to the body, thereby causing a deficit between blood supply and demand. As a

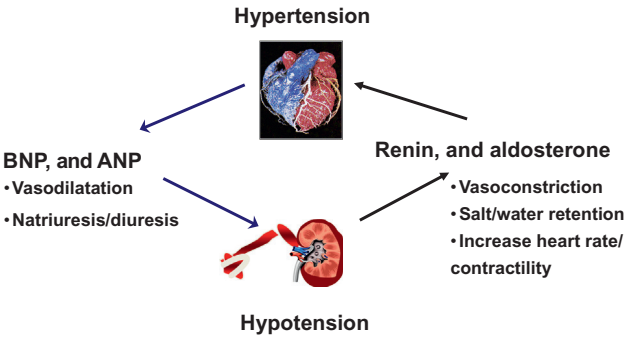

FIGURE 30.11 The hormonal balance between renin–aldosterone and atrial and b-type natriuretic peptide. *ANP*, Atrial natriuretic peptide; *BNP*, B-type natriuretic peptide.

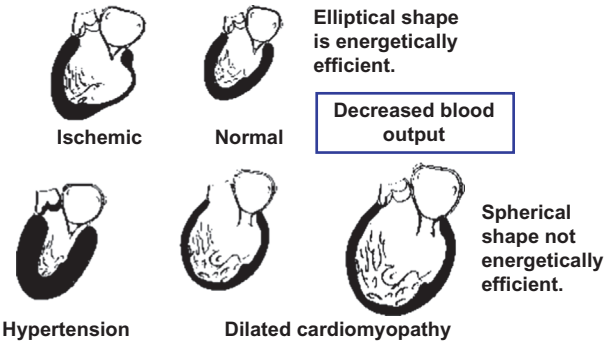

FIGURE 30.12 The chronic overstimulation of the renin–aldosterone axis dilated cardiomyopathy leads to cardiac enlargement and remodeling. The shift from an elliptical to a spherical geometry causes an inefficiency in cardiac output leading to heart failure.

compensatory mechanism, electrolyte imbalance and the stretching of the myocardium caused by cardiomegaly stimulate the release of atrial (ANP) and BNP and are used as biomarkers for this condition. These hormones counteract the renin–aldosterone axis by vasodilation, sodium and water loss, and hypotension (Fig. 30.11, left side). The natriuretic peptides, in various molecular forms, have become important indicators for the diagnosis, staging, and monitoring of HF.

B-type natriuretic peptide and N-terminal-proBNP

Biochemistry

The biochemistry of the natriuretic peptides is complex. ANP has the highest tissue content in the atrium and is stored in cytoplasmic granules and can be quickly released following the acute and transient volume changes. BNP comes from the ventricle and must be upregulated at the genomic level. As HF is most associated with the impaired left ventricular function and sustained volume overload, BNP is more widely used as a clinical biomarker. BNP originates from an inactive precursor protein pre-proBNP (134 amino acids) with the signal peptide (26 amino acids) cleaved to yield the prohormone proBNP (108 amino acids). Upon stimulation, $proBNP_{108}$, a 12-kDa peptide, is cleaved stoichiometrically by the proteases corin and/or furan to BNP_{1-32} (active hormone, ~4 kDa) and the NT-$proBNP_{1-76}$ (inactive peptide, ~8 kDa, see Fig. 30.13) [96]. The half-life of BNP is roughly 20 minutes, and for NT-proBNP, it is between 1 and 2 hours, with NT-proBNP also having higher in vitro stability than BNP. Normal ranges for BNP and NT-proBNP increase from each decade of life, with women having higher levels than men. Obese subjects have lower BNP and NT-proBNP concentrations than lean individuals. In addition to these forms, proBNP itself is released into circulation and is believed to be less biologically active/inactive than mature BNP. The proBNP and the corresponding amino acids contained within NT-proBNP undergo glycosylation. The clinical significance of this posttranslational modification is unknown, though a study has indicated that blood samples treated with deglycosylation enzymes yielded NT-proBNP concentrations that were higher (versus nontreated) when measured with a clinical assay [97]. In addition, intracellular glycosylation on threonine 71 may prevent cleavage of proBNP between the amino acids 76 and 77 by furin and corin [96,98].

Commercial assays are available for BNP and NT-proBNP. Like the different cardiac troponin assays, there are minor differences in the clinical utility of BNP and NT-proBNP. A clinical laboratory will use one test or the other depending on the availability of the commercial testing platform currently in use in that laboratory. It is not fully known at this point whether the clinical utility of proBNP is identical to or provides incremental value to BNP and NT-proBNP.

Clinical utility of B-type natriuretic peptide and N-terminal-proBNP in heart failure

Diagnosis

BNP or NT-proBNP are routinely used for the diagnosis of HF among ED and hospitalized patients. There have been two landmark studies that have examined the clinical utility of BNP for patients who present to an ED with acute dyspnea and shortness of breath. In the multicenter BNP trial, a BNP cutoff of 100 ng/L (pg/mL) produced a clinical sensitivity for HF of 90% and specificity of 76%

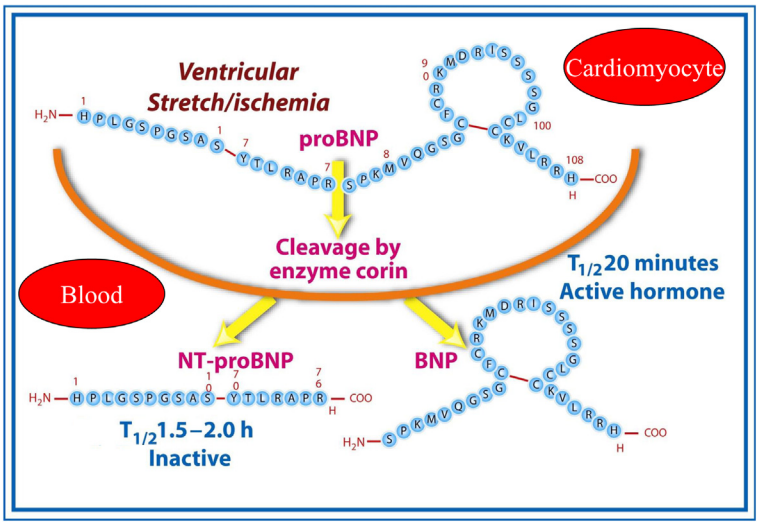

FIGURE 30.13 The processing by corin and subsequent release of proBNP into the circulation as B-type natriuretic peptide (active hormone) and N-terminal-proBNP (inactive peptide).

[99]. From the proBNP Investigation of Dyspnea in the Emergency Department (PRIDE) study, similar clinical performance was observed for NT-proBNP using a cutoff of 450 ng/L for those <50 years, 900 ng/L for those ≥50 years, with an NT-proBNP concentration <300 ng/L optimal for ruling-out acute HF, with a negative predictive value of 99% [100]. Both studies identified a "gray zone" area, as elevations may be caused by non-HF etiologies such as renal failure, hypertension, and pulmonary disease. Thus different concentration ranges have been recommended: (1) for BNP <100 ng/L, HF is unlikely; (2) for BNP concentrations between 100 and 500 ng/L, HF is possible but other diagnoses need to be considered; and (3) with BNP >500 ng/L, HF is very likely. The same concepts apply for the NT-proBNP assay using different cutpoints based on age [95]. To this end, the ICON: Re-evaluation of Acute Diagnostic Cut-Offs in the Emergency Department study has validated the originally proposed age-specific NT-proBNP cutoffs [i.e., age-specific rule-in cutoffs of 450 ng/L (<50 years), 900 ng/L (50−75 years), and 1800 ng/L (>75 years) for the diagnosis of acute HF, and <300 ng/L as the rule-out cutoff to exclude diagnosis of acute HF] in a contemporary cohort of dyspneic patients presenting to EDs in North America [101].

Clinical societies have also endorsed natriuretic peptide testing for the diagnosis of HF in both the acute and ambulatory settings (typically class I recommendation with level of evidence of A) [92,95], with systematic reviews supporting natriuretic peptide testing for ruling-out HF [102]. The 2016 ESC guidelines for the diagnosis and treatment of acute and chronic HF list natriuretic peptide cutoffs in the nonacute setting (BNP <35 ng/L and NT-proBNP <125 ng/L) and in the acute setting (BNP <100 ng/L and NT-proBNP <300 ng/L) [93]. Whereas the 2017 ACC/AHA/HFSA Focused Update of the 2013 ACCF/AHA Guideline for the Management of Heart Failure has not listed specific cutoffs, the update has provided the following Class 1, Level A recommendations for natriuretic peptide testing: (1) in patients presenting with dyspnea, measurement of natriuretic peptide biomarkers is useful to support a diagnosis or exclusion of HF; (2) measurement of BNP or NT-proBNP is useful for establishing prognosis or disease severity in chronic HF; and (3) measurement of baseline levels of natriuretic peptide biomarkers and/or cardiac troponin on admission to the hospital is useful to establish a prognosis in acutely decompensated HF [103]. However, this update has provided natriuretic cutoff information in the following class I recommendation with respect to treatment: in patients with chronic symptomatic HFrEF NYHA class II or III who tolerate an ACE inhibitor or angiotensin receptor blocker (ARB), replacement by an angiotensin receptor-neprilysin inhibitors (ARNI) is recommended to reduce further morbidity and mortality (103, with ARNI effects on BNP versus NT-proBNP concentrations discussed below under the *Monitoring and Management* subsection).

Staging

Assays for BNP/NT-proBNP can also be useful for staging the severity of disease using criteria such as the New York Heart Association Classification (Fig. 30.14) and use of the 6-minute walk test. While a laboratory test is not needed to determine that a patient is in Stage IV (symptoms of shortness of breath at rest), this test is particularly useful for the detection of Stage I HF (asymptomatic patients). This has led some investigators to suggest using the natriuretic peptides for screening asymptomatic individuals. However, Wang et al. [104] reviewed existing studies and concluded that mass screening with echocardiography or the natriuretic peptides was not cost-effective. It may be possible to improve the utility by screening subjects who are at the highest risk for HF. For example, the St Vincent's screening to prevent heart failure randomized trial assessing BNP-based screening and collaborative care on patients with cardiovascular risk factors (i.e., patients at risk for HF) demonstrated benefit with the study approach likely being cost-effective as well [105,106]. Despite some randomized controlled trials in this area, the 2017 ACC/AHA/HFSA Focused Update of the 2013 ACCF/AHA Guidelines have provided a Class IIa (moderate) Level B-R (moderate from one or more RCTs) recommendation for natriuretic peptide testing for the prevention of HF with further studies needed to assess cost-effectiveness, quality of life, and mortality [103].

Monitoring and management

A novel application of the natriuretic peptides is the use of these tests to support therapeutics in HF. There have been numerous studies examining the potential to use

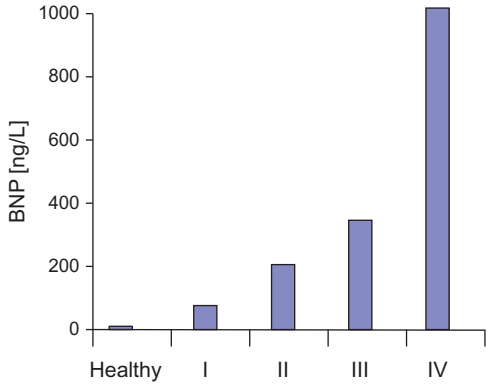

FIGURE 30.14 Correlation of B-type natriuretic peptide concentrations with New York Heart Association classification of heart failure.

serial natriuretic peptide testing to monitor the success of drug therapy such as with diuretics and inhibitors to angiotensin-converting enzyme and angiotensin II. Interpretation of serial results requires knowledge of the biological variation and limits for RCV. Roughly, a 75%−100% increase and a 40%−50% decrease are necessary to determine statistical change in BNP/NT-proBNP concentrations. In patients admitted for decompensated HF, levels of BNP/NT-proBNP can decline by greater than these serial limits. For stable HF outpatients, it is more difficult to produce decreases in natriuretic peptide levels to below these limits. Nevertheless, several prospective trials have attempted to improve HF therapy by increasing anti-HF doses to achieve a target BNP or NT-proBNP concentration. In the STARS-BNP trial (supported by an unrestricted grant from Biosite Inc), patients in the BNP group who had a goal of decreasing BNP to less than 100 ng/L had significantly fewer combined endpoints (unplanned hospital endpoints, death, and hospital stay for HF) than in the group managed without BNP measurements [107]. The NT-proBNP-assisted treatment to lessen serial cardiac readmissions and death study using NT-proBNP showed similar results but only in a subset of younger patients [108], and the findings from the trial of intensified vs. standard medical therapy in elderly patients with congestive heart failure study suggest that NT-proBNP-guided therapy may be more beneficial to HFrEF patients than to HFpEF patients [109]. Therefore from these trials, systematic reviews, and meta-analyses, natriuretic peptide testing-guided therapy showed no benefit in older patients (>75 years) and in HFpEP patients [94,95,102]. Until more studies are reported unequivocally demonstrating clinical benefit to targeting drug therapy to specific BNP or NT-proBNP concentrations, caution is warranted; however, the findings of the Guiding Evidence Based Therapy Using Biomarker Intensified Treatment (GUIDE-IT) trial—Clinical Trial registration: NCT01685840 should be able to assess the effects of a natriuretic peptide testing strategy in high-risk HFrEF patients [110]. Unfortunately, the GUIDE-IT trial in high-risk patients with HFrEF found that a strategy of NT-proBNP-guided therapy was not more effective than a usual care strategy in improving outcomes, with a potential contributing variable to the null findings being the intensive treatment/follow-up in the control arm [111].

Moreover, different beneficial treatments may result in differences between BNP and NT-proBNP concentrations while patients are on these treatments. Specifically, the ARNI [ARB and neprilysin inhibitor, example drug brand name Entresto (sacubitril (neprilysin inhibitor)/valsartan (ARB)] drug class has been shown to be more effective in preventing death, cardiovascular death, and clinical progression of surviving HF patients than angiotensin-converting enzyme inhibition, with the premise that blocking neprilysin (an enzyme that breaks down bradykinin, adrenomedullin, and natriuretic peptides) enhanced the effects of these peptides in HF patients [112]. To this end, HF patients treated with an ARNI may expect an increase in BNP concentrations (action of the drug), while NT-proBNP concentrations may drop representing the beneficial effects of the drug [112]. These important effects of ARNIs on BNP and NT-proBNP concentrations need to be clearly communicated to the health-care team and patients in order to avoid confusion in this setting. To this end, the 2017 ACC expert consensus decision pathway for the optimization of HF treatment has indicated that clinicians need to interpret natriuretic peptides in the context of guideline-directed management and therapy and in the case of ARNI therapy; perhaps, it is more prudent to check only NT-proBNP concentrations [113].

Clinical utility of B-type natriuretic peptide and N-terminal-proBNP in acute coronary syndrome

While BNP and NT-proBNP are considered markers of chronic left ventricular dysfunction, there is considerable evidence that these peptides are released during the initial stages of myocardial ischemia as well. Measurement of the natriuretic peptides in the setting of acute chest pain offers prognostic information for adverse cardiac events, particularly when used in conjunction with other biomarkers. The combination of BNP with cardiac troponin and C-reactive protein (CRP), a marker of acute and chronic inflammation, appears particularly powerful [114]. Fig. 30.15 shows the role of these biomarkers in three cases of MI, which differ in location and etiology. The cardiac troponin concentration is increased in all cases as per the Universal Definition of MI. Fig. 30.15A shows an AMI caused by vasospasm, such as with an acute intoxication with cocaine. As plaque instability and rupture is not the mechanism for AMI, there may not be an inflammatory role for this infarction and CRP may be normal. The natriuretic peptides are increased due to the effect that the myocardial damage has on contractile function. Fig. 30.15B shows an AMI due to plaque rupture occurring at the end of the right coronary artery, near the apex of the heart. Plaque rupture suggested some underlying etiology of inflammation and an increase in CRP. Since this region of the myocardium does not have a major contractile role in pumping out blood, this infarction may not cause a rise in BNP/NT-proBNP. Fig. 30.15C shows an infarct caused by an occlusion of the left anterior descending artery, a key vessel for delivery of blood to the left ventricle. Here, all three blood biomarkers are increased, as there is inflammation and damage to the left regional wall.

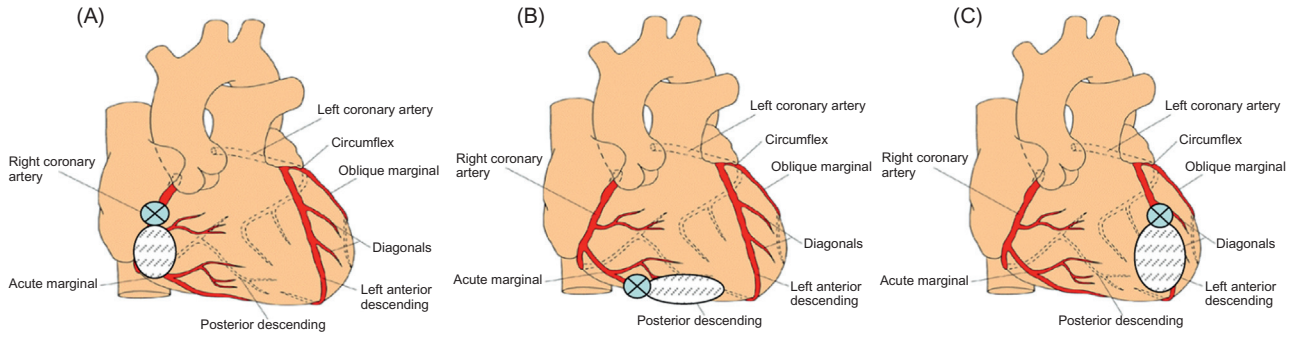

FIGURE 30.15 The combination of natriuretic peptides, cardiac troponin, and C-reactive protein as a multimarker tool for risk assessment in acute coronary disease. The underlying mechanism and location of the infarct could affect which markers are increased and the severity of the increase. See text for details. Site of occlusion. Area of myocardial necrosis. *LAD*, Left anterior descending coronary artery.

TABLE 30.3 Future needs of cardiac biomarkers in acute coronary syndrome and heart failure.

Acute coronary syndrome
- Early detection of myocardial infarction at ED presentation (soon after and ideally even before pain onset)
- Risk stratification for short-term major adverse events (absence of cardiac troponin elevation)
- Differentiation between Type 1 MI and Type 2 MI

Heart failure
- Adds incremental value to natriuretic peptides when results are in the "gray zone" (e.g., renal failure and obesity).
- Improved prediction of cardiovascular morbidity and mortality
- Monitoring and selection of appropriate therapy in both HFrEF and HFpEF patients

ED, Emergency department; *HFpEF*, heart failure with preserved ejection fraction; *HFrEF*, heart failure with reduced ejection fraction; *MI*, myocardial infarction.

Multimarker analysis has potential to play an important role as the clinical cardiac problems and conditions become more complicated (e.g., Type 2 MI and HFpEP). There are additional cardiac conditions that cause elevated natriuretic peptide concentrations besides HF and ACS, with heart muscle disease, valvular heart disease, pericardial disease, atrial fibrillation, myocarditis, toxicity, cardioversion, and cardiac surgery being potential causes [103]. In addition, on the noncardiac side, anemia, renal failure, pulmonary hypertension and disease (i.e., severe pneumonia and obstructive sleep apnea), critical illness, bacteria sepsis, severe burns, and advancing age may also result in elevations [103].

Clinical need for future biomarkers of acute cardiovascular diseases

Table 30.3 lists the future needs for biomarkers within the areas of ACS and HF [115]. In the ED, there is a need to have a cardiac biomarker with high clinical sensitivity and specificity for ACS at the time of patient presentation. For both ACS and HF, better tools are needed to predict morbidity and mortality, particularly if they can be linked to novel therapeutics.

Early acute coronary syndrome diagnosis

Fig. 30.16 shows the classic sequence of biomarker release for cardiac troponin and the natriuretic peptides, biomarkers of myocardial cell injury/necrosis, and ventricular overload/remodeling. None of these biomarkers are reliably increased at or immediately after the onset of symptoms/chest pain, with early rule-out strategies using hs-cTn assays in early presenters also being suboptimal [73,77]. Therefore a laboratory test that can detect the presence of myocardial ischemia, which precedes irreversible damage, would be valuable. Table 30.4 summarizes some of the biomarkers that have been studied for myocardial ischemia (free fatty acids, glycogen phosphorylase BB isoenzyme, ischemia modified albumin, and

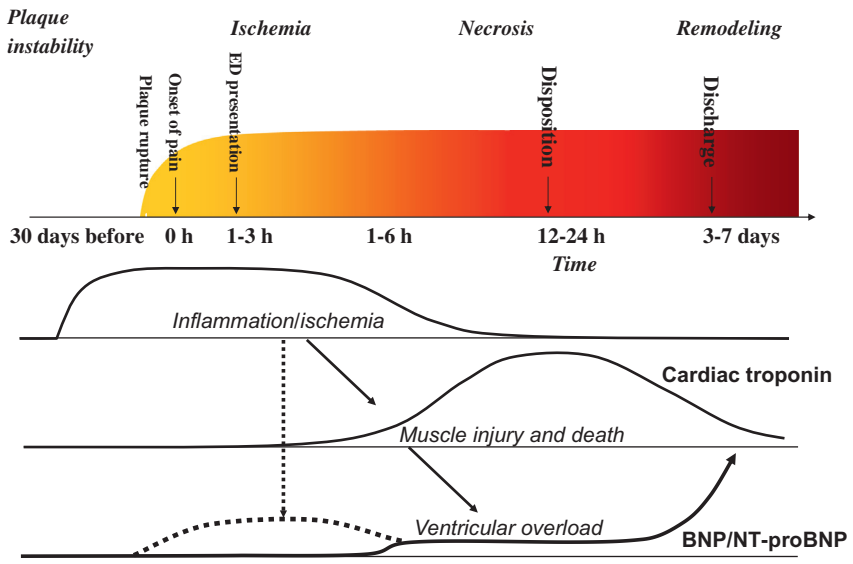

FIGURE 30.16 Timing of current and novel biomarkers in acute coronary syndrome. Cardiac troponin is increased early (in hours) from onset of pain (plaque rupture). B-type natriuretic peptide/N-terminal-proBNP is increased days later with myocardial remodeling. There is also an ischemic release of B-type natriuretic peptide/N-terminal-proBNP. Other blood-based biomarkers are needed to detect the onset of myocardial ischemia and immediately before the onset of Type I myocardial infarction (plaque instability).

TABLE 30.4 Other potential biomarkers of acute coronary syndrome and heart failure.

Marker	Description	Diagnostic role
Acute coronary syndrome		
Free fatty acid	Unbound serum fatty acid	Myocardial ischemia
Glycogen phosphorylase BB	Enzyme in glycogenolysis	Myocardial ischemia
Ischemia modified albumin	N-terminal modification by ischemia	Myocardial ischemia
Plasma choline	Product of phospholipase activation	Myocardial ischemia
Whole blood choline	Product of phospholipase activation	Plaque rupture
Soluble CD40 ligand	Circulating ligand of the CD40 receptor	Plaque rupture
Placental-like growth factor	Vascular endothelial growth factor	Plaque instability
PAPP-A	Metalloproteinase	Plaque instability
Myeloperoxidase	Prooxidant enzyme of leukocytes	Plaque instability
MCP-1	Recruits monocytes into the vasculature	Plaque instability
Copeptin	C-terminal portion of provasopressin	Early rule-out
Heart failure		
ST2	Isoform of IL-1 receptor/fibrosis	Predicator of cardiac death
proAdrenomedullin	Precursor to vasodilative natriuretic peptide	Predictor of cardiac death
proBNP	Precursor to BNP and NT-proBNP	Indicator of impaired natriuretic peptide processing
Galectin-3	β-galactosidase binding lectin/fibrosis	Predictor of cardiac death
GDF-15	TGF-β member/biochemical strain	Predictor of cardiac death

BNP, B-type natriuretic peptide; *GDF*, growth differentiation factor; *MCP-1*, Monocyte chemoattractant protein-1; *NT*, N-terminal; *PAPP-A*, Pregnancy-associated plasma protein A.

plasma choline), and monocyte (whole blood choline) and platelet activation (CD40 ligand) that are indicative of plaque rupture [115]. While these biomarkers are released during the early phases of AMI, the clinical specificity toward cardiac ischemia and thrombosis is not high. Many of the biochemical events that occur within the heart are in common with other organs such as the brain, lungs, intestinal tract, and peripheral tissues. Since cardiac troponin, especially hs-cTn, can be used to rule-out AMI in a few hours after ED presentation, many ED physicians are willing to wait for the more definitive test result rather than to base an early discharge decision on the use of a noncardiac biomarker. This decision is particularly important in the US, as wrongful discharge of a patient with ACS is a frequent cause of malpractice litigation from the ED today. However, large meta-analyses evaluating either hs-cTnT or hs-cTnI alone to rule-out MI via the presentation blood sample using 5 ng/L as the cutoff have yielded very high negative predictive values; however, the sensitivity at this cutoff may not be acceptable to all

physicians [116,117]. Other approaches coupling hs-cTn with other laboratory tests or clinical scores may further improve the sensitivity and rule-out [118,119].

Improved risk stratification for adverse cardiac events

After a patient has been ruled out for ACS in the ED, the next objective is to determine the risk of that patient for developing an adverse cardiac event within the next 30 days, a meaningful time frame for ED physicians. Cardiac troponin is used today to risk stratify patients at high risk. Unfortunately, up to 5% of patients with a negative (below cutoff) cardiac troponin concentration will also suffer AMI or cardiac death, and additional risk stratification tools are needed. A major area of research has been in detecting the presence of plaque vulnerability as in the case of Type 1 MI. Fig. 30.16 shows that such a marker would predict plaque rupture, ischemia, necrosis, and remodeling. Table 30.4 lists some of the tests that have been examined in clinical studies. They are focused on the pathophysiologic events that make plaques vulnerable to rupture, including inflammation (e.g., myeloperoxidase), fibrous cap degradation (pregnancy-associated plasma protein A), angiogenesis (placental-like growth factor, by providing more vascular access to harmful factors), and leukocyte chemotaxis (monocyte chemoattractant protein-1, stimulus to recruit harmful leukocytes to the site of damage). A combination of biomarkers that detect plaque instability, plaque rupture, ischemia, necrosis, and left ventricular dysfunction may be very useful for future diagnoses and risk stratification in ACS. More work will be needed to validate such an approach and to provide commercial tools for the clinical laboratory, such as integrated testing platforms, and test reporting algorithms that are cost-effective. These multivariate decision-making tools must be separately cleared by the US FDA prior to their clinical use. Most importantly, there must be directed therapeutics driven by clinical laboratory tests that can be given to high-risk patients to reduce their short-term CVD risk. This may require a partnership with the pharmaceutical industry to create "companion" diagnostic tests.

Other heart failure biomarkers

While BNP and NT/proBNP are routinely used in the diagnosis and evaluation of HF, their limitations have led some investigators to examine novel biomarkers. ST2 (also known as IL1RL1, DER4, T1 and FIT-1) was originally discovered by mechanically stressing myocytes in cell culture to simulate the progression of HF and use of proteomics to discover the biomarkers that are up- or downregulated. Subsequently, ST2 has been determined to be an isoform of the interleukin-1 receptor, which is secreted into the circulation and binds interleukin-33 [120]. ST2 is less influenced by obesity than BNP or NT-proBNP. Adrenomedullin (ADM) is a natriuretic and vasodilative hormone produced by the heart [121]. The mid-region (MR)-pro-adrenomedullin (proADM) is a more stable precursor peptide to ADM. In the PRIDE and biomarkers in acute heart failure studies, increased concentrations of ST2 and MR-proADM were strong and independent predictors of mortality among HF patients. These results were additive to the value of BNP and NT-proBNP. MR-proADM has a lower biological variation than BNP/NT-proBNP, making this test potentially more useful for therapeutic monitoring [122]. ProBNP is the precursor protein to BNP and NT-proBNP and is released in HF [123]. Preliminary data suggest that this marker may provide insights to patients with impaired natriuretic processing, that is, are unable to produce BNP in severe HF. While it is unlikely that these analytes will replace BNP and/or NT-proBNP in routine practice, the addition of these biomarkers in a multimarker approach may provide incremental clinical value, as they represent different pathophysiological processes. In fact, in addition to ST2, another fibrosis biomarker that has also obtained US FDA approval is galectin-3 [124], with both biomarkers being mentioned in the 2013 ACCF/AHA Guideline for the Management of Heart Failure [92]. Another potential biomarker in this area is growth differentiation factor-15 (GDF-15), a member of the transforming growth factor β cytokine superfamily, which is expressed in the models of MI, pressure overload, and HF [124,125]

Laboratory analysis for cardiac biomarkers

Assays for cardiac troponin and the natriuretic peptides are based on two-site sandwich immunoassays, which are available on automated immunoassay testing platforms and point-of-care-testing-device (though there is a single epitope BNP assay approved in China; see IFCC Committee on Clinical Applications of Cardiac Bio-Markers (C-CB) website that lists tables for cardiac troponin and the natriuretic peptides providing information on assay design and other analytical parameters: http://www.ifcc.org/ifcc-education-division/emd-committees/task-force-on-clinical-applications-of-cardiac-bio-markers-tf-cb/) [90]. Most commercial cardiac troponin assays have undergone a series of improvements to reduce interferences and imprecision and to increase analytical sensitivity, which has also been the case for the hs-cTn assays [126]. The most widely used assays for cardiac troponin T are through Roche Diagnostics, while there are multiple manufacturers of cardiac troponin I assays [19], for an up to date listing see IFCC C-CB

website [90]. Test results differ between and even within manufactures, as manufactures may produce more than one cardiac troponin assay [127]. There is an ongoing effort to standardize/harmonize cardiac troponin testing [128]; however, the differences in antibodies used and methods used in commercial cardiac troponin tests may prohibit complete standardization of results. In fact, there are even differences between the hs-cTn tests as compared with the non-hs-cTn tests from the same manufacturer, as often the assay needs to undergo further optimization to become a high-sensitivity assay (i.e., increase sample volume, antibody reconfiguration, buffers, etc.), so results from one assay to another assay may be divergent [59,129,130]. Point-of-care-testing platforms are also available for testing whole blood and enable a more rapid turnaround time for reporting results and may reduce the length of stay for ED patients with chest pain [131]. Point-of-care-testing devices for cardiac biomarkers are generally not as sensitive or precise as current generation central laboratory equipment, resulting in a reduced ability to detect individuals at risk of adverse events [132,133]. However, advancements are being made for point-of-care hs-cTn testing [134].

Central laboratory and point-of-care-testing devices are also available for BNP and NT-proBNP. Unlike cardiac troponin, low concentrations of these peptides in blood have little clinical significance; therefore, there is not the same need to develop high-sensitivity assays though the ESC guidelines have recommended a BNP cutoff of 35 ng/L in the nonacute setting, indicating that precision is still important at the lower end. There is no standard reference material for BNP or NT-proBNP. Harmonization between assays is not as poor as for cardiac troponin, especially for NT-proBNP. Many of the NT-proBNP assays are licensed from Roche Diagnostics who requires the use of the same calibrators and antibodies and results are similar. Although there are minor differences in BNP assays, most manufacturers have established the same cutoff concentration of 100 ng/L to be used in the acute setting. However, important preanalytical and sample handling issues must be adhered to for BNP measurement, as EDTA plasma is the only suitable matrix for BNP measurement, with BNP more likely to undergo degradation than NT-proBNP [135]. An IFCC laboratory educational report published in 2019 on natriuretic peptide testing with a focus on HF has listed 10 recommendations on the analytical and clinical issues affecting interpretation of the results, with a new proposed target CV $<10\%$ being stated to improve the analytical performance [136].

Conclusions

Cardiac biomarkers continue to play a critical role in the management of patients with CVD. The clinical sensitivity and specificity for cardiac troponin for AMI is among the highest for any clinical laboratory test. The value of natriuretic peptide testing continues to grow from a role in HF diagnosis to prognosis to treatment management decisions. As illustrated in this chapter, there is continued research into new and other biomarkers for heart disease, some cardiac in nature and others not. The biomarkers that can assist in the diagnosis and management of patients with stroke remain elusive with ongoing effort looking into biomarkers that reflect endothelial damage, coagulation/fibrinolysis, and inflammation/growth factors with interest in multimarker panels as well [137]. This will be a much bigger challenge than the myocardial injury due to ischemic processes, as biomarkers evident of brain injury may need to cross the blood−brain barrier, and more analytically, sensitivity assays may be required to detect these products. There is hope here, however, as one only needs to look at the timeline of cardiac biomarkers [4], and in particular cardiac troponin where in 2016 (the previous version of this chapter in the Third Edition) there were no hs-cTn assays approved by the FDA for use in the US. Fast forward, to 2019 (at the time of this chapter revision), there are now many different manufacturers with hs-cTn assay approved for use by the FDA in the US [18,63,90,127,138].

Self-assessment questions

1. Which of the following does not occur as part of the pathophysiological events that lead to Type 2 MI?
   a. Atherosclerosis and oxygen supply/demand imbalance
   b. Plaque rupture
   c. Vasospasm or coronary mircovascular dysfunction
   d. Nonatherosclerotic coronary dissection
   e. Oxygen supply/demand imbalance alone
2. For cardiac biomarkers, what is the difference between the 2012 Third Universal MI definition and the 2018 Fourth Universal MI definitions?
   a. There is no difference.
   b. CK-MB is the preferred biomarker in the 2012 definition.
   c. For hs-cTn assays, the sex-specific 99th URLs are recommended in 2018.
   d. For contemporary cardiac troponin assays, a 20% CV at the 99th percentile concentration is acceptable in both the Third and Fourth definitions.
   e. Type 2 MI classification is only in the 2018 definition.
3. According to the ESC/ACC 2000 redefinition of MI, what is the most appropriate cutoff for cardiac troponin?
   a. The functional sensitivity of the assay (concentration at 20% imprecision)
   b. Concentration that differentiates between unstable angina and AMI
   c. Concentration that differentiates between STEMI and NSTEMI
   d. 99th percentile URL from a healthy population
   e. 10% CV concentration
4. Which of the following best describes the clinical sensitivity and specificity of cardiac markers for AMI?
   a. CK-MB has the highest sensitivity and cardiac troponin the highest specificity
   b. Cardiac troponin has the highest sensitivity and CK-MB the highest specificity
   c. CK-MB has the highest sensitivity and specificity
   d. Myoglobin has the highest sensitivity and troponin the highest specificity
   e. Cardiac troponin has the highest sensitivity and specificity
5. Which of the following statements are not true for MI?
   a. There are no longer STEMIs, only Type 1−5 MIs.
   b. Type 4 MI involves MI due to PCI
   c. Type 5 MI involves MI due to CABG
   d. Type 2 MI is an oxygen supply/demand imbalance
   e. Type 1 MI is due to plaque rupture/erosion
6. What is the correct relationship between BNP and NT-proBNP?
   a. Both are derived from proBNP
   b. NT-proBNP is a metabolite of BNP
   c. BNP is a metabolite of NT-proBNP
   d. Both BNP and NT-proBNP are biologically active
   e. Neither BNP nor NT-proBNP are biologically active
7. Which of the following is false regarding the use of BNP and NT-proBNP?
   a. Very low concentrations can differentiate between HF and pulmonary disease
   b. Used to stage the severity of HF
   c. Predicts who will more likely suffer a cardiac event/death
   d. NT-proBNP is a more stable analyte
   e. Guidelines do not endorse measurement of natriuretic peptides for the diagnosis or exclusion of HF in patients presenting with dyspnea
8. Which of the following factors affect the reference interval for BNP and NT-proBNP?
   a. Age
   b. Body mass index
   c. Biological Sex
   d. All of the above
   e. None of the above
9. Which of the following describes the physiologic roles of BNP?
   a. Vasoconstriction, sodium retention
   b. Sodium retention, fluid wastage
   c. Sodium wastage, vasoconstriction
   d. Vasodilation, water retention
   e. Vasodilation, sodium wastage
10. What makes a cardiac troponin assay a “high-sensitivity” assay?
    a. Manufacturer marketing/labeling
    b. An analytical range up to 100,000 ng/L
    c. The ability to measure cardiac troponin concentrations in at least 50% of the healthy population
    d. The 10% CV concentration at the limit of detection
    e. There is no distinction between hs-cTn and current cardiac troponin assays.

Chapter 31

Laboratory diagnosis of liver disease

Mark A. Marzinke[1] and D. Robert Dufour[2,3]

[1]Departments of Pathology and Medicine, Johns Hopkins University School of Medicine, Baltimore, MD, United States, [2]Department of Pathology (Emeritus), George Washington University, Washington, DC, United States, [3]Department of Pathology (Adjunct), Northwestern University Feinberg School of Medicine, Chicago, IL, United States

Learning objectives

At the end of this chapter, the reader should be able to:

- Identify biomarkers to assess the synthetic, metabolic, and excretory functions of the liver.
- Describe the biochemical pathway of bilirubin, as well as laboratory methods used in the measurements of conjugated and unconjugated bilirubin fractions.
- Interpret traditional patterns of liver-associated enzymes and injury markers in the background of various types of hepatic disease.
- Differentiate the presentation and laboratory abnormalities encountered in acute and chronic liver diseases.
- Discuss the autoantibodies associated with hepatocellular and cholestatic disease states.

Review of normal liver structure and function

Anatomical features

The liver is a large organ located in the right upper quadrant of the abdomen and weighs approximately 1.2−1.5 kg in a healthy adult. The organ has a dual supply of oxygenated blood, with blood supplied from the portal vein and the hepatic artery. Nutrient-rich blood from the gastrointestinal (GI) tract is carried to the liver via the portal vein and comprises 50%−70% of the oxygenated blood reaching the organ. The hepatic artery transports blood from systemic circulation, and accounts for the remaining 30%−50% of oxygenated blood to the liver. Deoxygenated blood from the liver is transported via the hepatic vein, where it is merged with the inferior vena cava flow and is shunted to the right atrium of the heart. The functional anatomical unit of the liver is the acinus, which is part of the hepatic parenchyma that contains portions of the portal vein, hepatic artery, and bile canaliculus.

There are a number of cell types that are located within the organ, and the cellular architecture of the liver denotes many of its associated functions. In addition to porous endothelial sinusoids, which facilitate blood flow into the organ, the liver contains phagocytic Kupffer cells, which remove antigen−antibody complexes and bacteria from blood. Hepatic stellate cells (Ito cells) exist in both quiescent and activated states. In the former, stellate cells store vitamin A in the form of retinol esters (such as retinyl palmitate); when activated, stellate cells synthesize collagen, and increased collagen production can lead to hepatic scarring and cirrhosis. The predominant cell type within the liver is the hepatocyte. Hepatocytes carry out the synthetic and biotransformative processes attributed to the organ. These processes will be discussed later in this chapter. Between adjacent hepatocytes are bile canaliculi, which are small tubular structures which ultimately fuse to form bile ductules, which merge to form intrahepatic bile ducts. The intrahepatic ducts join to make the common hepatic duct. The hepatic duct joins with the cystic duct from the gallbladder to form the common bile duct. These structures facilitate biliary drainage from the liver into the GI system, and are critical for the excretory functions associated with the organ.

Liver functions

The liver performs a number of functions that may be broadly classified as synthetic, excretory, or metabolic in nature. The liver has an extensive reserve capacity; therefore laboratory tests that assess hepatic function are largely insensitive in the identification of liver damage. Further, biomarkers of liver function may also be affected by conditions other than hepatic injury. An overview of analytes and laboratory tests related to laboratory function will be discussed in this section.

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00031-4

Synthesis

The synthetic capacity of the liver is largely dependent on having sufficient nutrients to carry out essential hepatic functions. The synthetic activities carried out by the liver are dependent not only on the number of hepatocytes, but also the amount of nutrient-rich blood that reaches the organ via the portal vein. Therefore synthetic liver functions are impaired not only in the background of liver disease, but also during states of malnutrition, malabsorption, and portal vein obstruction.

Relevant to its role in synthesis, many enzymes required for glucose and glycogen production are expressed in the liver, as are the building blocks and enzymes required for bile acid and cholesterol biosynthesis and lipoprotein production. The liver also serves as the primary site of production of most plasma proteins (except immunoglobulins), including albumin, transthyretin, ceruloplasmin, α_1-antitrypsin, α-fetoprotein (AFP), and several coagulation proteins. Systemic protein concentrations reflect the balance between synthesis and turnover, and serum or plasma protein patterns observed during liver disease are dependent on both the type and duration of injury, as well as disease state severity.

Because each of the aforementioned proteins varies with regards to half-life, changes in serum or plasma protein concentrations may provide information on the duration of an underlying pathology (Table 31.1). For example, toxic or ischemic hepatitis may result in the global destruction of hepatocytes, thereby decreasing circulating concentrations of clotting factors and leading to increased prothrombin time (PT). The same is not the case with albumin, which is exclusively produced in the liver; due to its long half-life (21 days), hypoalbuminemia is more commonly observed in chronic disease states, such as cirrhosis, autoimmune hepatitis (AIH), and alcoholic hepatitis. Additionally, reduced blood flow from the portal vein deprives the liver of raw materials required for protein synthesis, and is typically associated with decreased protein concentrations. However, due to the reserve capacity of the liver, the majority of individuals with acute hepatic injury do not have abnormal serum or plasma protein concentrations.

TABLE 31.1 Half-life estimates for common hepatically synthesized proteins.

Protein	Half-life
Albumin	19–21 days
Ceruloplasmin	4–5 days
Haptoglobin	2 days
Transferrin	7 days
Transthyretin	2 days
Factor VII	6–8 hours

In addition to liver disease, serum or plasma protein concentrations are influenced by a number of nonhepatic factors, including hormones (estrogens increase ceruloplasmin and HDL production, and cortisol increases transthyretin production), cytokines (interleukin-6 increases acute phase response proteins, such as α_1-antitrypsin, haptoglobin, and ceruloplasmin, while decreasing albumin and a number of other proteins), nutrient intake, and protein-wasting states, such as nephrotic syndrome.

High-throughput automated analyzers typically employ photometric methods for protein measurements, including albumin and total protein. Serum dye-binding assays for albumin include reactions based on bromocresol green or bromocresol purple for the production of a complex that may be measured photometrically. Depending on the specimen source and relative abundance of the protein, antibody-based methods that exploit changes in light scattering may also be employed. A discussion on other methods for the quantification and assessment of protein abnormalities, including protein electrophoretic techniques and immunofixation electrophoresis, is covered in Chapter 22: Proteins: analysis and interpretation of serum, urine, and cerebrospinal fluid, of this book.

Excretion

Compounds in the liver may be biotransformed to facilitate excretion of endogenous or exogenous compounds via the biliary or renal routes. To assess the excretory functions of the liver, laboratory tests include measurement of endogenous compounds, such as bilirubin or bile acids. The former is commonly used in the assessment of hepatic function.

Bilirubin is a molecule that results from the degradation of heme, and is predominantly derived from erythrocyte lysis. Upon cellular lysis, hemoglobin is broken down into heme. Heme is metabolized to the hydrophobic compound biliverdin via heme oxygenase; biliverdin is further processed to form the unconjugated bilirubin molecule via biliverdin reductase. Due to the hydrophobic nature of unconjugated bilirubin, it is loosely bound to albumin when released into the bloodstream to facilitate transport to the liver. Unconjugated bilirubin is taken up by the hepatocytes via a receptor-mediated mechanism. Following cellular uptake, unconjugated bilirubin is rapidly solubilized through the addition of two glucuronic acid moieties via the enzyme uridine diphosphate glucuronosyltransferase (UDP-GT). The more soluble conjugated bilirubin is then excreted into the bile ductules for clearance; this is an energy-dependent, highly efficient

process, and in healthy individuals, very little conjugated bilirubin is detected in the bloodstream. Conjugated bilirubin is transported to the intestine via the common bile duct, where it is converted to urobilinogens via anaerobic bacteria. Urobilinogens are then either reabsorbed for further processing via enterohepatic circulation, or further oxidized in the lower GI tract and cleared in the stool.

However, when conjugated bilirubin in the liver is not excreted, monoconjugated bilirubin may become covalently bound to albumin, forming a stable compound termed biliprotein, or δ-bilirubin. With recovery of liver function, conjugated bilirubin is cleared with a half-life of approximately 24 hours; biliprotein follows the trend of albumin, and is associated with an estimated half-life of 3 weeks. As liver disease improves, therefore, conjugated bilirubin will quickly disappear from systemic circulation, while biliprotein remains elevated over a longer time course. The production, transport, and biotransformation of bilirubin are outlined in Fig. 31.1.

Although we define bilirubin as an unconjugated or conjugated molecule, laboratory tests do not typically report concentrations for each bilirubin fraction. Rather, result reporting reflects traditional methods used for bilirubin detection, and readouts are referred to as total, direct, or indirect bilirubin. The most commonly utilized method for bilirubin measurement is through a reaction with diazotized sulfanilic acid (diazo reagent), which was first described by Ehrlich in 1883. In the early 1900s, it was shown that the addition of an accelerant, such as ethanol (Van den Bergh and Muller), methanol (Evelyn and Malloy), or caffeine (Jendrassik and Grof), solubilized unconjugated bilirubin to facilitate an interaction with the aforementioned diazo reagent. The end product that is formed, referred to as azobilirubin, is measured photometrically. These methods facilitate the measurement of all bilirubin fractions (conjugated, unconjugated, and biliprotein), reflecting total bilirubin concentrations.

Conversely, direct bilirubin assays measure bilirubin mono- and diconjugates, as well as the water-soluble biliprotein, through the direct reaction with the diazo reagent in an alkaline environment. Direct measurements do not require the use of an accelerant. The direct bilirubin reaction typically measures 5% of unconjugated bilirubin and 70%−90% of conjugated bilirubin; the fraction of unconjugated bilirubin that reacts directly with the diazo reagent can be increased by use of surfactants, exposure of serum to ultraviolet light, or alterations in the pH of the reaction or specimen. While the aforementioned methods are most commonly employed in measuring bilirubin fractions, other approaches used to determine bilirubin concentrations include HPLC, direct spectrophotometry, and enzymatic methods. Also, simultaneous determination of unconjugated and conjugated bilirubin fractions may be performed via differential spectrophotometry (spectral shift) with the use of a protein separation layer via a two-slide method; this is performed on the Vitros platform and marketed by Ortho Diagnostics. Notably, this method does not detect biliprotein concentrations.

Increases in unconjugated bilirubin concentrations are associated with not only overproduction of bilirubin, but also increased heme breakdown, as seen during hemolysis, rhabdomyolysis, and in the presence of hematomas. Increased unconjugated bilirubin may also result from impaired bilirubin uptake into the hepatocytes, decreased conjugation via UDP-GT, portal hypertension, and severe hepatic injury. Neonates may present with jaundice and

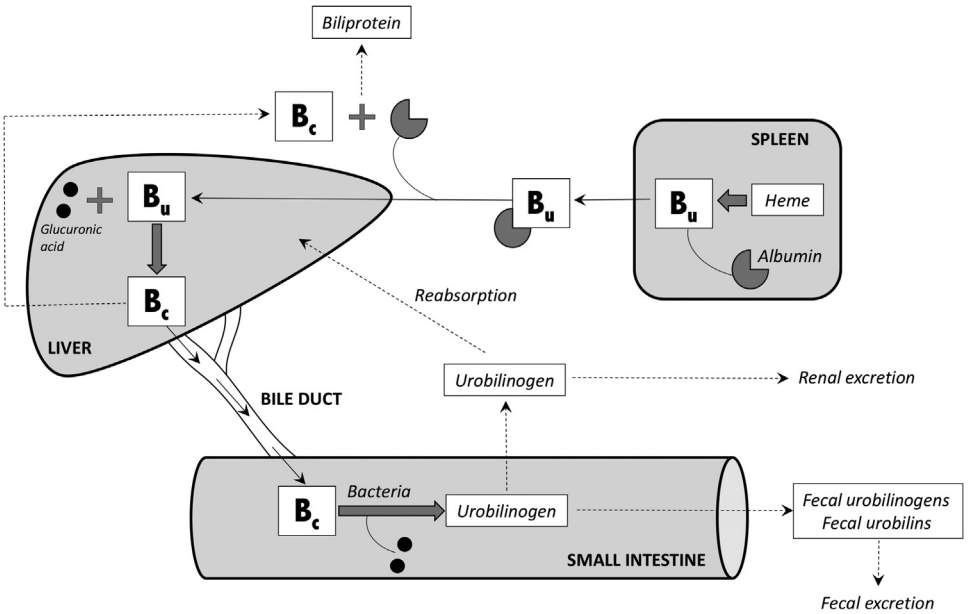

FIGURE 31.1 Bilirubin metabolism. Schematic overview of bilirubin metabolism. B_u: unconjugated bilirubin; B_c: conjugated bilirubin.

increased unconjugated bilirubin concentrations due to decreased conjugation, exposure to drugs that may inhibit bilirubin conjugation, or increased erythrocyte turnover. Neonatal jaundice peaks between 3 days and 2 weeks postpartum. Neonates with sustained jaundice and increased total bilirubin concentrations are treated with phototherapy. Infants are exposed to light at 450 nm to photoisomerize the nonpolar unconjugated bilirubin to produce water-soluble, excretory compounds that may be cleared renally.

There are a number of congenital disorders that can lead to increased concentrations of the unconjugated bilirubin fraction. Crigler–Najjar syndrome is a rare disorder that results from a complete (Type I) or partial (Type II) loss of UDP-GT production. Neonates with Crigler–Najjar Type I present with severe jaundice due to elevated unconjugated bilirubin concentrations in the blood. The hydrophobic, unconjugated bilirubin can cross the blood–brain barrier, resulting in kernicterus, or bilirubin-induced brain damage. Treatment options for infants with Crigler–Najjar syndrome typically involve plasmapheresis or liver transplantation. Less severe disorders that result in increased unconjugated bilirubin concentrations include Lucey–Driscoll syndrome, which is a transient form of familial hyperbilirubinemia, and Gilbert syndrome, a benign form of hyperbilirubinemia associated with mild jaundice.

Conversely, increased conjugated bilirubin concentrations may occur in the background of acute hepatitis, cholestasis, biliary tract obstruction (including biliary atresia), congenital defects, or illnesses that lead to the impairment of bilirubin excretion. Two genetic syndromes that result in increased conjugated bilirubin concentrations are Dubin–Johnson and Rotor syndromes. The former is attributed to an autosomal recessive variant in the canalicular multispecific organic anion transporter gene, resulting in decreased conjugated bilirubin secretion into bile. The clinical presentation varies, but may include mild jaundice or cholestasis; anatomic findings also reveal a hyperpigmented liver due to nonclearance of other pigments, such as lipofuscin. Rotor syndrome is similar in presentation to Dubin–Johnson, but is not associated with liver hyperpigmentation. A summary of hereditary disease states that are associated with increased unconjugated or conjugated bilirubin is presented in Table 31.2.

TABLE 31.2 Increased unconjugated and conjugated bilirubin fractions observed in inherited genetic syndromes.

Syndrome	Unconjugated bilirubin	Conjugated bilirubin
Crigler–Najjar	Elevated	Normal
Dubin–Johnson	Normal	Elevated
Gilbert	Elevated	Normal
Lucey–Driscoll	Elevated	Normal
Rotor	Normal	Elevated

Notes: Increases in unconjugated bilirubin fractions would be observed clinically via increased total bilirubin measurements.

Metabolism

The liver serves as the primary site of metabolism for a number of endogenous and exogenous compounds. The metabolic efficiency of the liver is based not only on the number of hepatocytes, but also on the genetic disposition of metabolizing enzymes. The liver is the primary site of production of a number of metabolizing enzymes, including all of the members of the cytochrome P450 (CYP450) superfamily of enzymes. Many CYP family members are highly polymorphic, resulting in variability in compound metabolism. Since the liver plays a central role in drug metabolism, metabolic tests are useful in assessing hepatic function posttransplantation, as well as in the advanced stages of renal disease.

With regards to endogenous compounds, ammonia metabolism to urea occurs in the liver via the urea cycle. Increased ammonia concentrations (hyperammonemia) can result in hepatic encephalopathy, which is associated with central nervous toxicity and altered mental status; the etiology may be inherited or acquired. Common acquired causes of hyperammonemia include advanced liver and renal disease; increased ammonia concentrations are typical in fulminant hepatitis, Reye's syndrome, and in cirrhotic patients. Additionally, GI bleeding in a cirrhotic patient may lead to increased ammonia production via bacterial metabolism of blood proteins in the colon. However, there is a poor correlation between ammonia concentrations and the severity of hepatic encephalopathy. Ammonia concentrations may also be increased in nonhepatic conditions, including acid–base disorders, infections, or increased protein intake or breakdown. Consequently, ammonia testing is largely nonspecific in assessing the metabolic functions of the liver. Further, ammonia is susceptible to preanalytical factors, such as delayed transportation and separation from red blood cells, as well as prolonged tourniquet use, both of which may falsely elevate ammonia concentrations.

Tests of liver injury

Aforementioned liver function tests are largely insensitive in detecting liver disease because of the reserve capacity of the organ as well as the impact of extrahepatic

pathologies on biomarker concentrations. Therefore markers of liver injury show greater clinical sensitivity and specificity when compared with markers of liver function in identifying hepatic disease. Liver injury markers are helpful both in the recognition and the differential diagnosis of hepatic pathologies, including viral, alcoholic, and toxic hepatitis, as well as biliary tract obstruction and acute liver failure.

The most commonly used biomarkers of hepatic injury or disease are liver-associated enzymes released into systemic circulation. There are a number of mechanisms through which enzymes may be released from a cell into the bloodstream. Enzymes that are associated with various types of liver injury include alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), lactate dehydrogenase (LDH), and gamma-glutamyl transferase (GGT; also known as gamma-glutamyl transpeptidase). Of note, none of these enzymes is expressed exclusively in the liver. A summary of the organ and tissue distribution of each of these enzymes is presented in Table 31.3. Further, within the hepatocyte, the described enzymes differ in terms of their subcellular distribution, as illustrated in Fig. 31.2.

The subcellular localization of these enzymes is an important contributor to the release kinetics of each macromolecule and the clinical correlation with various types of liver injury. Because all cells try to maintain their cellular machinery, macromolecules localized within the cytoplasm are primarily released after irreversible cellular injury. However, membrane-bound enzymes may be released during reversible cellular damage, such as in the background of cholestatic conditions. Induction of enzyme synthesis within cells also increases serum or plasma levels of inducible enzymes, such as GGT. Laboratory assessment of hepatic enzymes typically involves the measurement of enzyme activity as opposed to concentrations; thus enzyme results are reported as units per liter (U/L). The specific patterns of these enzymes in the background of various disease states will be discussed later in this chapter.

TABLE 31.3 Characteristics of liver-associated enzymes.

Enzyme	Tissue/organ sites of expression	Subcellular distribution	Half-life
AST	Liver, heart, muscle, and kidney	Cytoplasm and mitochondria	cAST: 16–18 hours mAST: 10 days
ALT	Liver and kidney	Cytoplasm	40–48 hours
LDH	Liver, heart, RBC, muscle, kidney, and WBC	Cytoplasm	4–6 hours
ALP	Liver, bone, intestine, and placenta	Membrane	24 hours
GGT	Liver, pancreas, kidney, and prostate	Membrane and microsomes	4 days (longer with chronic alcohol abuse)

ALP, Alkaline phosphatase; *ALT*, alanine aminotransferase; *LDH*, lactate dehydrogenase; *AST*, aspartate aminotransferase; *cAST*, cytoplasmic aspartate aminotransferase; *GGT*, gamma-glutamyl transferase (transpeptidase); *mAST*, mitochondrial aspartate aminotransferase; *RBC*, red blood cells; *WBC*, white blood cells.

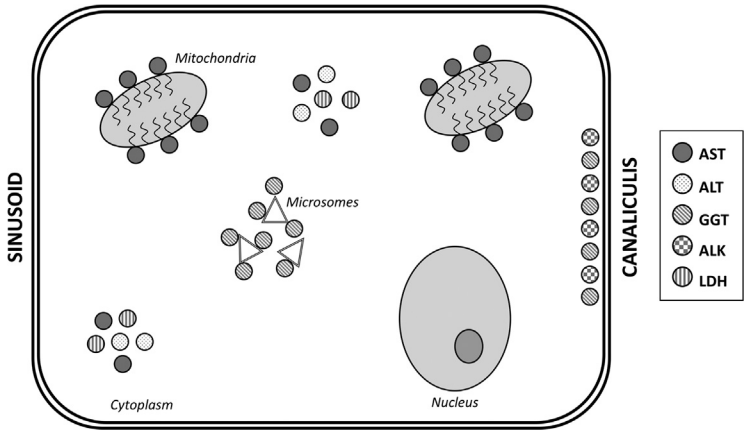

FIGURE 31.2 Subcellular distribution of liver-associated enzymes. The major hepatocyte enzymes have different locations within the cell, which explains the patterns of abnormalities encountered in various forms of liver disease. *ALP*, Alkaline phosphatase; *ALT*, alanine aminotransferase; *AST*, aspartate aminotransferase; *GGT*, gamma-glutamyl transferase; *LDH*, lactate dehydrogenase.

Liver-injury markers

Aspartate aminotransferase

Physiologically, the enzyme AST catalyzes the reversible transfer of an amino group from glutamate to oxaloacetate for the generation of aspartate. Consequently, the enzyme was formerly referred to as serum glutamic-oxaloacetic transaminase. Both AST- and ALT-mediated enzymatic reactions require a pyridoxal phosphate (vitamin B_6) cofactor. Pyridoxine deficiency may occur during states of chronic alcohol abuse, malnutrition, or in the presence of pyridoxine binders. Thus several commercial vendors offer assays that are supplemented with pyridoxal phosphate to ensure sufficient cofactor concentrations. As indicated in Fig. 31.2, the subcellular distribution of AST is in both the hepatocyte cytoplasm as well as within the mitochondria; the cytoplasmic portion is the predominant form of AST released posthepatic injury. Alcohol abuse has been shown to induce the expression and release of mitochondrial AST. However, even in alcoholic liver disease, less than 10%–20% of total AST is the mitochondrial isoenzyme. Notably, the half-lives of the cytoplasmic and mitochondrial AST isoenzymes differ; the half-life of cytoplasmic AST is 16–18 hours, while mitochondrial AST is approximately 10 days. Consequently, in the background of chronic alcohol abuse, AST activity measurements may remain elevated above the upper reference limit of normal for a longer period of time than ALT.

Alanine aminotransferase

The physiological function of ALT is similar to that of AST. ALT catalyzes the reversible transfer of glutamate to pyruvate, generating alanine; historically, ALT was referred to as serum glutamic-pyruvic transaminase. Like AST, ALT is also measured in the clinical laboratory via the determination of enzyme activity, and ALT activity is more sensitive to vitamin B_6 status than AST. ALT is the liver enzyme associated with the fewest other tissue or organ systems, and is primarily located within the cytoplasm of hepatocytes. While it is less abundant in the hepatocyte than AST, it has a longer half-life, estimated to be 40–48 hours. Consequently, following acute liver injury, while AST levels may rise first, ALT activity measurements are elevated above the upper reference limit of normal for a longer period of time. ALT is a key liver-injury marker that is used in the differential diagnosis and monitoring of liver injury or disease. Further, AST/ALT activity ratios can be helpful in the differential diagnosis of hepatic inflammation etiology. This will be discussed in further detail later in this chapter.

Lactate dehydrogenase

As illustrated in Table 31.3, LDH is widely distributed in tissue, with high protein expression in erythrocytes, as well as the heart, liver, muscles, and kidney. Further, there are multiple isoenzymes that exist, which can be resolved electrophoretically. LDH of liver origin has a short half-life of 4–6 hours, and is found at lower levels than other liver-associated enzymes following hepatic damage. While LDH is increased in a number of disease states, including megaloblastic anemia, shock, myocardial or pulmonary infarction, or hemolytic anemia, liver-related causes for LDH activity elevation are primarily toxic or ischemic hepatitis (when patients present soon after onset of injury, allowing detection of the short-lived liver isoenzyme).

Alkaline phosphatase

Although ALP is expressed in a number of tissues, circulating concentrations typically reflect ALP derived from the liver or bone. In the liver, ALP is a membrane-associated enzyme that is released in response to canalicular damage. Damage to the canalicular surface of the hepatocyte may be caused by either drainage obstruction or direct damage to the canaliculi via drugs or viral infections. In response, ALP levels begin to rise within 24–48 hours, and the enzyme has a half-life of 24 hours. ALP is measured by determining enzyme activity; notably, enzymatic activity requires divalent cation cofactors, such as zinc or magnesium. States of clinical zinc deficiency or collection in tubes containing chelating agents (such as EDTA) can result in artificially decreased ALP activity measurement results. While ALP derived from the bone and liver are encoded by the same gene, they are differentially posttranslationally modified and differ with respect to their carbohydrate content. Isoenzymes may be differentiated via heat fractionation, electrophoresis, isoelectric focusing, or antibody-based approaches. With regards to heat fractionation, the lability of various ALP isoenzymes is exploited, as bone ALP is the most heat labile, liver ALP is less so, and another form of ALP, placental ALP, is heat stable. For laboratories that discriminate ALP isoenzymes, an agarose electrophoretic approach is most commonly employed.

Gamma-glutamyl transferase

GGT is a glycoprotein enzyme that is expressed on the canalicular membrane as well as within hepatic microsomes. Similar to ALP, GGT levels will increase in response to canalicular damage. GGT measurements are typically used in conjunction with ALP to assess bile duct obstruction or other forms of ductule damage. GGT activity measurements may also be increased following exposure to microsomal enzyme-inducing drugs, such as ethanol, phenobarbital, phenytoin, and carbamazepine. Regarding ethanol abuse, GGT activity measurements are less likely to be increased in binge drinkers or those consuming less than 2–3 drinks per day, as compared with

chronic, heavy drinkers. Once released into the bloodstream, the half-life of GGT is several days; further, when released from the microsomes in the background of chronic alcohol abuse, GGT levels may be elevated for several weeks.

Other liver biomarkers

In addition to the aforementioned liver-associated enzymes, there are several other biomarkers that can be utilized to assess and monitor liver injury, including hepatic cancers and autoimmune disorders.

Alpha-fetoprotein

AFP is a major plasma protein expressed at high concentrations during fetal development; however, concentrations decrease drastically after birth. When hepatocytes regenerate or proliferate, AFP concentrations may increase. Elevated AFP concentrations may be observed in cirrhotic patients, during a flare-up of chronic hepatitis, or during the recovery phase postacute hepatitis. Additionally, AFP is commonly used as a tumor marker for hepatocellular carcinoma (HCC) or germ cell (nonseminoma) carcinoma. With regards to HCC, AFP may be used as a prognostic indicator of survival as well as in monitoring disease progression. AFP can be further stratified based on protein binding to the lectin *Lens culinaris* agglutinin. One form of AFP, AFP-L3, binds strongly to the aforementioned lectin and is associated with malignant tumors, such as HCC. Consequently, an AFP-L3% test (which is the percentage of AFP that is the L3 isoform) at a cutoff of 10% has shown utility as a tumor marker for HCC.

Des-gamma-carboxy prothrombin

Des-gamma-carboxy prothrombin (DCP), also known as PIVKA-II, is a form of factor II produced in the absence of vitamin K, and is therefore an unmodified form of the protein. In most individuals with liver disease, PIVKA-II is undetectable, but in acute hepatitis and HCC, PIVKA-II concentrations may be increased, often in individuals with minimal or no increase in AFP concentrations. Conversely, PIVKA-II is less commonly elevated in the background of chronic hepatitis or cirrhosis. PIVKA-II is sensitive to vitamin K antagonists, and may be increased in individuals with vitamin K deficiency or on warfarin therapy. In recent years, this biomarker has gained interest as a potential tumor marker for HCC.

Autoantibodies

There are a number of liver diseases that are characterized by the presence of autoantibodies. AIH is a form of chronic hepatitis that is associated with long-term hepatic inflammation and liver damage. While clinical symptoms may be similar to those observed in acute hepatitis, physical findings show a high prevalence of hepatomegaly and jaundice in patients with AIH; ascites is also seen in more severe cases. Most cases of AIH are associated with increased concentrations of immunoglobulins, particularly IgG, as well as the presence of antinuclear antibodies, antismooth muscle antibodies, and antiliver−kidney microsomal type 1 antibodies. Patients with AIH are typically treated with immunosuppressive therapies, such as prednisone and azathioprine. Autoantibodies associated with cholestatic diseases will be discussed later in this chapter.

Assessment of liver disease

Liver diseases are typically stratified as being acute or chronic in their presentation. Etiologies of acute and chronic liver damage will be discussed in this chapter, as well as the role that laboratory testing plays in the differential diagnosis of hepatic injury.

Clinical manifestations of liver disease

There are a number of clinical manifestations that are suggestive of hepatic injury. Jaundice, which is a yellowing of the skin due to excess bilirubin in the bloodstream, is a common manifestation that is typically associated with acute presentations of obstruction of the bile ducts or hepatocyte necrosis. Consequently, urine is dark and stool is light in color. However, children and a percentage of adults with acute hepatitis do not become jaundiced, which may lead to delayed workup of acute liver injury. Jaundice is also a late finding in persons with cirrhosis, In addition to hepatic injury, jaundice may also present in the background of increased intravascular hemolysis, hematomas, rhabdomyolysis, or in previously discussed inborn errors of metabolism. Dysregulation of hemostasis and portal hypertension, which may be caused by cirrhosis and can result in decreased blood flow to the liver, are additional features that may be observed in patients with liver disease. The presence and extent of these manifestations are dependent on the underlying pathology.

Acute liver disease

Acute hepatitis involves injury to the hepatocytes that may be viral/immunological, ischemic, or drug-induced in nature. One common cause of hepatitis, particularly in developing countries, is viral infection, which results in immunological responses, hepatic inflammation, and release of liver-associated enzymes. Ethanol also elicits an immunological response on the liver, resulting in hepatocyte injury. Ischemic or toxic hepatitis can lead to direct

liver damage and hepatocyte necrosis. For example, an acetaminophen overdose can lead to hepatic accumulation of *N*-acetyl-*p*-benzoquinone imine (NAPQI), resulting in cellular death. Ischemic hepatitis may be caused by hepatic hypoperfusion. Of note, ischemic and toxic forms of hepatitis typically impact markers of liver function as well as liver injury. Regardless, all forms of acute hepatitis are associated with irreversible damage to hepatocytes and the subsequent release of biomarkers into systemic circulation. Hepatocyte death may be apoptotic or necrotic in nature; the former being the more common mechanism of cell death.

Clinical presentation and patterns of injury associated with immunologically mediated acute hepatitis

Acute hepatitis that is ethanol-induced or caused by viral infections follows a similar trajectory in terms of clinical presentation. Individuals typically experience an asymptomatic incubation period, followed by a prodromal (early onset) period of nonspecific symptoms, which may include fever, malaise, vomiting, and/or nausea. Viral infections in older children and adults may also result in increased bilirubin concentrations and jaundice, and present with liver tenderness, dark-colored urine, and lightly colored stool. Because liver damage is gradual and prolonged in these disease states, the release of cytoplasmic enzymes shows a gradual increase, reaching a plateau, before demonstrating a gradual decline.

AST and ALT activity measurements of 200 and 300 U/L, respectively, have clinical sensitivity and specificity of 90% in supporting the diagnosis of acute viral hepatitis. These values correlate with approximately five and eight times the upper reference limits of normal, respectively. With viral infections, AST and ALT may reach 10−50 times the upper reference limits of normal throughout the disease course. While AST measurements rise first in viral hepatitis, ALT measurements are typically higher at the time of clinical presentation. This is due to the longer half-life of ALT as compared with AST. Aminotransferase ratios are also useful in the differential diagnosis of acute liver injury, and AST/ALT ratios in viral infections are typically <1 for the aforementioned reasons. In the background of viral hepatitis, ALP activity measurements may also be mildly elevated. Further, increases in aminotransferases typically precede increases in bilirubin concentrations, and may remain elevated for several weeks before gradually decreasing.

Alcoholic hepatitis occurs in only about 10% of those who abuse alcohol; however, some studies indicate that immune responses to acetaldehyde-altered proteins may be involved in the pathogenesis of hepatic injury. There are several laboratory findings that distinguish alcoholic hepatitis from other forms of liver injury. AST and ALT measurements are seldom over 10 times the upper reference limits of normal, and unlike viral hepatitis, AST activity measurements are usually greater than ALT (often more than two-fold higher). Studies have demonstrated that a percentage of AST released during alcoholic hepatitis is mitochondrial AST; *in vitro* studies have demonstrated that alcohol can stimulate the release of the longer half-life mitochondrial AST from the hepatocyte. Additionally, unlike viral hepatitis, alcoholic hepatitis is more commonly associated with increased levels of ALP, and usually GGT. In chronic alcoholics, GGT measurements may be elevated for several weeks; however, there is no correlation between the extent of GGT activity elevation and disease severity.

In cases of jaundice, which may occur due to hepatitis or biliary tract obstruction, conjugated bilirubin predominates, with direct bilirubin accounting for 50%−80% of total bilirubin concentrations. The glucuronidated, water-soluble bilirubin fraction can be renally cleared, resulting in the presence of bilirubin in the urine. Early in hepatitis, biliprotein typically comprises 15%−20% of total bilirubin; with resolution, the percentage increases to approach 100%. The declining presence of bilirubin from urine is a positive sign of recovery posthepatic injury. However, severe liver damage and cellular death can lead to decreased bilirubin conjugation, resulting in increased concentrations of the unconjugated bilirubin fraction. Other liver function tests, including those that assess the synthetic capacity of the liver, are typically within normal reference intervals in the background of viral or alcoholic hepatitis; prolonged PT is a poor prognostic marker with both of these causes of liver injury. Patterns of hepatic function and injury markers in various types of acute hepatitis are summarized in Table 31.4.

Causes of viral acute hepatitis

Hepatitis A

Hepatitis A virus (HAV) is a single-stranded RNA picornavirus that is transmitted via the fecal−oral route, and transmission may occur through the ingestion of contaminated food or water. Previously, hepatitis A was a common cause of hepatic injury in the United States; however, since the licensure of the hepatitis A vaccine in 1995, there has been a marked reduction in the incidence of new infections. However, outbreaks in developing countries, particularly in areas with inadequate water sanitation resources, still remain a public health concern. Postinfection, the virus undergoes an incubation period ranging from 2 to 6 weeks, before the presentation of the aforementioned nonspecific symptoms

TABLE 31.4 Laboratory patterns associated with viral, alcoholic, and toxic/ischemic forms of acute hepatitis.

Feature	Viral	Alcoholic	Toxic/ischemic
% Chronic	Variable	5%–10%	None
% Fatal	<3% (except D)	5%–10%	10%
AST/ALT ratio (at diagnosis)	<1	Usually >2	>1 (transient)
Peak AST (× normal)	10–100	1–10	>100
LDH (× normal)	1–2	1–2	10–40
Peak bilirubin, milligram per deciliter (micromole per liter)	5–20 (85–340)	3–20 (51–340)	Usually <5 (85)
Prothrombin time	Normal	Normal	Usually >15 s

ALT, Alanine aminotransferase; *AST*, aspartate aminotransferase; *LDH*, lactate dehydrogenase.

(including vomiting, nausea, and fatigue). Infected adults typically present with jaundice, but infected children may not exhibit any clinical symptoms. Further, approximately one quarter of individuals are noninfectious at clinical presentation. As demonstrated in Table 31.4, markers of liver function or injury, in particular ALT, may be elevated.

Serologically, the presence of IgM anti-HAV is diagnostic of an acute infection in the proper clinical setting. The IgM form of anti-HAV is typically present at clinical onset of acute hepatitis, and may be detectable via laboratory assays for up to 6 months postinfection. Conversely, total (mostly IgG) antibody concentrations persist following infection or immunization. In the vast majority of cases, hepatocyte inflammation and injury resolve in a matter of weeks; however, if a patient infected with chronic hepatitis C becomes infected with HAV, there is an increased risk for hepatic necrosis and liver failure.

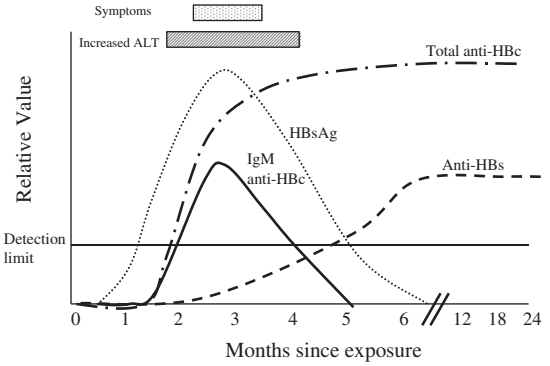

FIGURE 31.3 Clinical course of viral hepatitis B. After a period with no detectable viral antigens, hepatitis B surface antigen appears in the circulation. With the onset of immune response to the virus, liver damage occurs, as manifested by the hatched bar indicating time of elevation of enzymes. After an incubation period, jaundice typically develops (J). Following resolution of the acute damage, jaundice resolves and, eventually, enzymes return to normal, and hepatitis B surface antigen is cleared with appearance of anti-HBs. Antibodies to hepatitis B antigens persist for the life of the patient. *Reproduced with permission from W. Clarke (Ed.), Professional Practice in Clinical Chemistry, second ed., AACC Press, Washington, DC, 2011.*

Hepatitis B

Hepatitis B virus (HBV) is a double-stranded DNA hepadnavirus. Recent estimates indicate that up to one-third of the global population has been infected with hepatitis B, with roughly one-tenth of these cases leading to chronic viral infection. However, as with HAV, the frequency of infection has declined markedly following the implementation of vaccination, although there has been a recent increase in incidence with the current opioid crisis. HBV is transmitted via infected bodily fluids, and routes of contact require sexual contact, mother-to-child (vertical transmission), or blood-based exposures.

The incubation period of the DNA virus ranges from 3 to 6 months, and many of the previously described symptoms may present in an infected individual; 30%–50% of affected individuals will develop jaundice. Further, a small percentage of those infected (<2%) may have significant hepatic injury, resulting in fulminant hepatic failure. Unlike HAV, HBV infection can persist, and an individual may become chronically infected. With a full immune response, following an acute infection, the virus is typically "cleared." However, approximately 2% of immune-competent older children and adults fail to clear the virus and develop chronic HBV; this figure rises to 10%–20% in immunocompromised individuals (including HIV-infected individuals or those using immunosuppressive drugs) and >90% in neonates.

The typical time course of acute HBV infection is illustrated in Fig. 31.3. Both the hepatitis B surface antigen (HBsAg) as well as the hepatitis B core antibody, IgM (anti-HBc, IgM) are expressed during the early stages of an active HBV infection; the HBsAg is

produced at high concentrations by the double-stranded virus, and the anti-HBc, IgM is generated in response to the infection. These biomarkers are detected within the first 6 months of an acute infection. The hepatitis B e antigen (HBeAg) is also a marker of active infection, and detection of this antigen correlates with HBV infectivity when strains produce this antigen (although not all do). The first viral marker of recovery is loss of HBeAg and appearance of anti-HBe. Loss of HBsAg and development of anti-HBs typically take 3–6 months, and is considered evidence of viral clearance; however, low levels of viral DNA usually persist in the liver. Detection of anti-HBs and the total anti-HBc antibodies can indicate a past-infection or immunization (in which case, only anti-HBs will be present). A full discussion of the hepatitis B life-cycle, HBV genotypes, and issues regarding HBV mutations may be found in Chapter 54: Infectious diseases, of this book.

Hepatitis C

Hepatitis C virus (HCV), an RNA flavivirus, causes about 15%–20% of acute viral hepatitis infections in the United States. Intravenous drug use and transfusion of infected blood are routes of infection; however, screening of blood products prior to transfusion has dramatically reduced this route of transmission. As with HBV, there has been a recent rise in incidence correlated with injected opioid use. HCV can also be transmitted from mother to child, but the incidence of this is much lower when compared with HBV. Acute HCV infection has a variable incubation period, with an average period of 6–12 weeks. Elevations in aminotransferases are typically observed in the prodromal incubation period. Similar to HBV, HCV infections may persist. Chronic HCV infections may occur in up to 85% of those infected with the virus; roughly, one-fifth of these individuals may experience cirrhosis, hepatic failure, HCC, or cholangiocarcinoma. Those who are infected through injection drug use may also be infected with HIV and/or HBV. Coinfection can lead to increased hepatic-related morbidity and mortality and can exacerbate viral hepatitis disease progression and liver damage.

With regards to serological testing, IgG antibodies against HCV (anti-HCV) represent the most widely used test to screen for HCV exposure. Currently, second and third generation assays exist (third generation tests can detect HCV antibodies 9 weeks after exposure). Further, the CDC provides recommendations and guidelines, describing signal-to-cutoff ratios for commercial immunoassays. In addition to anti-HCV testing, molecular testing, including HCV RNA analysis, may be used to detect an active infection. Many clinical laboratories now implement reflex quantitative HCV RNA testing, as HCV viral load results can assist in directing treatment.

Hepatitis D

Hepatitis D virus (HDV) is a defective RNA virus that can replicate only in the presence of the HBsAg. It is primarily transmitted via blood. While it is endemic in some parts of the world, it has become less common due to the decline in new cases of HBV infections. In individuals simultaneously infected with both HBV and HDV, acute hepatitis is more severe, and liver failure is more likely. In a person with chronic HBV who subsequently becomes infected with HDV, there may be a flare in disease activity that mimics acute hepatitis. Diagnosis is usually determined through the detection of anti-HDV antibodies, but tests for the HDV antigen and nucleic acid testing may also be used.

Hepatitis E

Hepatitis E virus (HEV) is a single-stranded RNA virus. While not common in developed countries, HEV infections are still endemic in developing and rural areas. HEV is transmitted enterically, and as such, clinical manifestations are similar to HAV. However, HEV can lead to significant hepatic failure and increased mortality during pregnancy. HEV has also been found to cause chronic hepatitis in immunocompromised individuals. Currently, the only commercially available tests for HEV are total and IgM anti-HEV.

Toxic and ischemic hepatitis

Toxic and ischemic hepatitis are associated with abrupt changes in liver function and extensive cell death, resulting in significant elevations in cytoplasmic enzymes as well as changes in liver function tests. Laboratory patterns in comparison with viral and alcoholic hepatitis are summarized in Table 31.4. Toxic hepatitis, as discussed earlier, involves direct damage to the liver, most commonly caused by drugs. The most common cause of toxic hepatitis is an overdose of acetaminophen. Following accumulation of the toxic NAPQI metabolite, cellular necrosis occurs; clotting factors are depleted, leading to increased PT. Further, 24–48-hours postingestion, elevations in AST, ALT, and LDH activities are observed. Enzyme activities may exceed 100 times the upper reference limit of normal. Bilirubin is usually minimally elevated, and may not reach peak concentrations until a few days after peak abnormalities in enzymes or PT occur (Fig. 31.4). Prolonged elevation of PT, which indicates impaired synthetic capacity of the liver, is indicative of a poor prognosis.

From a laboratory perspective, ischemic hepatitis is similar to toxic hepatitis, as both are associated with massive cellular necrosis. Ischemic hepatitis, also known as "shock liver" is the most common cause of acute hepatitis

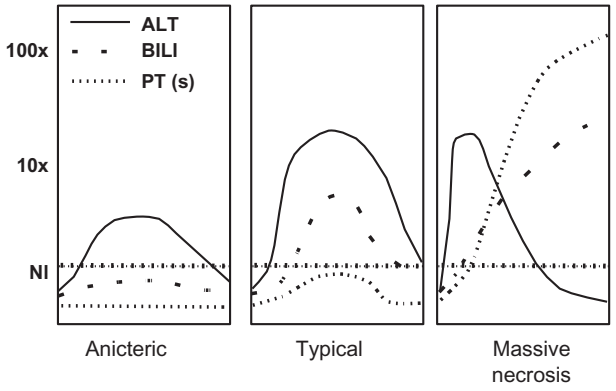

FIGURE 31.4 Results of blood tests in various severity of hepatitis. The patterns of changes in bilirubin (dashed line), alanine aminotransferase (solid line), and prothrombin time (dotted line) are shown for the three major types of hepatitis. In patients with anicteric disease, serum aminotransferases rise slightly, but liver function remains normal. With typical icteric hepatitis, patients have more marked enzyme increases and become jaundiced with increased serum bilirubin; prothrombin time usually remains normal. With massive hepatic necrosis, the loss of all functioning cells causes transaminases to ultimately return to normal limits; however, liver function continues to worsen; transplantation is the only effective treatment. *Reproduced with permission from W. Clarke (Ed.), Professional Practice in Clinical Chemistry, second ed., AACC Press, Washington, DC, 2011.*

in hospitalized patients. It can also occur as a part of the spectrum of hepatic sickle cell crisis or as a consequence of hepatic artery thrombosis in patients with compromised portal circulation. Schematics of ALT, bilirubin, and PT profiles in the background of minimal, nonjaundiced injury, moderate hepatic injury (typically associated with jaundice), and massive cellular necrosis are illustrated in Fig. 31.4.

Biliary tract obstruction

Obstruction is a less common cause of acute jaundice in children and young adults but becomes more prevalent in older individuals. The importance of distinguishing obstructive jaundice from hepatitis is that, while hepatitis is treated conservatively, obstruction is often due to potentially treatable causes that can benefit from immediate intervention. Complete obstruction of both hepatic ducts or extensive intrahepatic obstruction are required to produce obstructive jaundice; the most common causes are gallstones and tumors of the pancreas in adults and congenital biliary atresia in children. With incomplete obstruction, patients often remain asymptomatic and do not present with jaundice.

In the early stages of obstruction, particularly in the background of gallstones, laboratory features are similar to those seen during hepatitis. A comparison between hepatitis and biliary obstruction in terms of laboratory values is summarized in Table 31.5. Initially, increased ductal pressure causes hepatic damage, leading to increased AST and ALT activity measurements. However, as obstruction persists, both increased liver synthesis and bile acid-mediated solubilization of fragments of the canalicular membranes lead to increased release of ALP and GGT. Even with continued obstruction, AST and ALT typically fall, with AST returning to normal within 8–10 days. The degree of elevation in bilirubin and ALP are similar in intrahepatic and extrahepatic causes of obstruction. Bilirubin is mostly direct reacting (50%–80%), similar to the percentage observed in the background of acute hepatitis.

Chronic liver disease

Chronic liver diseases can involve prolonged inflammation or damage to the hepatocytes, as well as longer-term damage, including fibrosis and cirrhosis. In chronic liver diseases, jaundice is either rare or is a late finding, occurring usually after a clinical diagnosis has been made. Common causes of chronic liver disease include persistent viral infections with HBV or HCV, as well as nonalcoholic fatty liver disease (NAFLD), AIH, hemochromatosis, and Wilson's disease. As scarring progresses to cirrhosis, not only are liver injury markers impacted, but synthetic, metabolic, and excretory functions of the liver are affected.

Chronic hepatitis

Chronic hepatitis is the most common cause of chronic liver disease, and is defined as prolonged inflammation and hepatocyte damage typically lasting >6 months; persistent damage can lead to necroinflammation and may or may not be accompanied by hepatic scarring (fibrosis). Individuals with chronic hepatitis may be asymptomatic or present with nonspecific symptoms, such as fatigue or weakness. Chronic hepatitis may be identified by sustained mild elevations of ALT (commonly) or AST activity for 6 months in the absence of other etiologies; elevations in aminotransferase activity average two times the upper reference limit of normal. ALP and GGT activity are typically within reference intervals, as is bilirubin.

Elevated ALT activity measurements correlate more closely with inflammation than fibrosis. Currently, liver biopsies are the standard for the identification of hepatic fibrosis and disease progression. Biomarkers for collagen formation, including laminin, hyaluronate, and collagen fragments, may be observed following fibrosis, but there is weak correlation between biomarker concentrations and disease severity. Increases in aminotransferase activity and compromised synthetic capacity of the liver can be observed during progression to cirrhosis, but these markers alone do not yield sufficient clinical sensitivity for

TABLE 31.5 Differences in presentation, clinical, and laboratory findings between hepatitis and biliary obstruction.

Feature	Hepatitis	Obstruction
Symptoms	Painless jaundice	Jaundice, may be accompanied by pain or silent
% Conjugated bilirubin	50–80	50–80
AST and ALT	>10 times normal (except alcoholic)	<10 times normal (but may transiently increase >10 times)
Alkaline phosphatase	<3 times normal	<3 times normal early and >5–10 times normal later
Bile duct imaging	Normal	Dilated

ALT, Alanine aminotransferase; *AST*, aspartate aminotransferase.

diagnosis. Combinatorial testing assessing liver-injury and proinflammatory markers to predict severity of fibrosis have been patented to predict liver scarring. The FibroTest (referred to in the United States as FibroSure) is a multiplexed panel, including total bilirubin, GGT, haptoglobin, apolipoprotein A_1, α_2-macroglobulin, and demographic information (age and sex) marketed for the diagnosis of fibrosis. Studies comparing the serum biomarker test to liver biopsies demonstrate approximately 25% discordance between the two approaches. Further, when correlations have been performed between aberrant laboratory values and the extent of fibrosis, there is typically a large group of patients who have "indeterminate" results, and the ability of these markers to work in all causes of liver injury has not been demonstrated.

Chronic viral hepatitis

In chronic viral infections, viral markers (HBsAg or HBV DNA, and HCV RNA) are more reliable than liver injury enzymes in the evaluation of chronic hepatitis, as well as downstream initiation and monitoring of therapy. Sustained detection of HBsAg indicates chronic HBV infection. If HBsAg is positive, HBV DNA quantitation is also used to confirm continued replication of virus, and to serve as a baseline value for therapy. Antiviral therapy is commonly used for the treatment of chronic HBV infection, with the goals of suppressing viral propagation and mitigating hepatic injury, which are assessed by decreased HBV DNA levels (with a goal of undetectable HBV DNA) and reduction in ALT activity, respectively. In HBeAg positive individuals, the goal of treatment is to first clear circulating virus from systemic circulation, then clear HBeAg to facilitate the production of anti-HBe. Rarely, individuals will also lose HBsAg and develop anti-HBs. If anti-HBe does develop, treatment should continue for at least 6 months, but treatment may be continued indefinitely if HBV DNA becomes undetectable without loss of HBeAg (or in those individuals who were HBeAg negative before treatment).

Initial assessment of chronic HCV infection includes laboratory testing for anti-HCV. If anti-HCV is positive, HCV RNA quantitation is usually performed to confirm infection. Prior to the initiation of therapy, HCV genotyping is performed to direct treatment modalities and duration. The typical treatment regimen for chronic HCV infection most commonly involves a combination of direct antiviral agents; other drugs (such as ribavirin and ritonavir) may be used depending on HCV genotype. The goal of treatment is the loss of HCV RNA, which persists after treatment is stopped. While most patients are monitored by checking HCV viral loads after 4 weeks on treatment, current treatments are so highly effective that the value of this testing has been questioned. HCV RNA testing is repeated 3–6 months posttreatment. If HCV RNA remains undetectable, the patient is said to have had a sustained virologic response, and there is <1% chance that viremia will recur.

Other causes of chronic hepatitis

NAFLD and nonalcoholic steatohepatitis (NASH) are associated with fat accumulation and hepatic inflammation; both are associated with obesity, diabetes, hypertriglyceridemia, and low HDL-cholesterol concentrations in the absence of significant alcohol use. Laboratory abnormalities are mainly limited to increased aminotransferase activity. While NAFLD is more prevalent than NASH, the latter is more likely to lead to extensive liver scarring and cirrhosis.

AIH, Wilson's disease, Budd–Chiari syndrome, α_1-antitrypsin deficiency, veno-occlusive disease, and hemochromatosis are additional causes of chronic hepatitis and prolonged hepatic injury. AIH is associated not only with increased aminotransferase activity and the presence of previously described autoantibodies, but hypoalbuminemia may also be observed. Wilson's disease, an inherited disorder that leads to copper accumulation in the liver (as well as the brain and tissue), is associated not only with hepatic inflammation and scarring, but in acute

presentations patients may also present with hemolytic anemia and tubular necrosis due to release of excess copper from the liver.

Cirrhosis

Cirrhosis is the end stage of scar formation, usually as a result of chronic hepatitis or chronic bile duct obstruction. Early in the transition to cirrhosis, there are no clinical or laboratory features that allow its recognition. As scarring progresses, protein vein flow decreases, causing portal hypertension. This may become apparent clinically through the development of ascites, bleeding from esophageal varices, or hepatic encephalopathy. Laboratory features that suggest progression to cirrhosis include decreased hepatic proteins, (low albumin and prolonged PT), polyclonal gammopathy (especially with increased IgA, causing $\beta-\gamma$ bridging on serum protein electrophoresis), reversal of AST/ALT ratio to >1, and a fall in platelet count. Increased total bilirubin (mainly indirect reacting) is a later finding in persons with cirrhosis. As liver failure develops, albumin, PT, and creatinine have been found to be of prognostic significance, and are used to calculate the model of end stage liver disease (MELD) score, calculated as:

$$\begin{aligned} &3.8 + \ln \text{bilirubin } (\text{mg/dL}) \\ &\quad + 11.2 \ln \text{International Normalized Ratio} \\ &\quad + 9.6 \ln \text{creatinine } (\text{mg/dL}) \\ &\quad + 6.4 \text{ etiology score} \\ &\quad (0 \text{ if alcohol or obstruction; } 1 \text{ for all other causes}) \end{aligned}$$

which is the major criterion for consideration for liver transplantation. MELD scores of >30 are associated with very high mortality and give preference for liver transplantation.

Chronic cholestatic disorders

Chronic cholestasis is defined by one or more of a constellation of findings, which may include increases in canalicular enzymes (such as ALP), dilated bile ducts on imaging studies, skin itching (pruritus), elevated cholesterol (due to accumulation of lipoprotein X), and deficiency of fat-soluble vitamins. One form of cholestatic disease is primary biliary cholangitis (PBC), which is a disease that causes the inflammation and subsequent destruction of the intrahepatic bile ducts, leading to a buildup of bile in the liver and subsequent hepatic scarring. PBC is typically a progressive disease that can lead to liver failure and require transplantation; it is also associated with an increased risk of HCC. There is higher incidence of PBC in middle-aged women. Clinically, PBC is often associated with other autoimmune diseases, including both hypothyroidism and Sjögren syndrome. Antimitochondrial antibodies, in particular, the anti-M2 isoform, are found with a high prevalence in patients with PBC. The anti-M2 antibodies are directed against the dihydrolipoamide acyltransferase component of the pyruvate decarboxylase complex.

Conversely, primary sclerosing cholangitis (PSC) is an inflammatory disease primarily affecting the extrahepatic bile ducts. Narrowing of the extrahepatic bile ducts results in clinical manifestations of right upper quadrant pain and jaundice; elevated ALP may be observed in individuals with PSC. PSC occurs predominantly in young to middle-aged males, and 80% also have ulcerative colitis. The primary autoantibodies associated with PSC, but not specific to the disease, are antineutrophil cytoplasmic antibodies. PSC disease progression may result in the development of cholangiocarcinoma, thereby worsening PSC-associated morbidity and mortality. Chronic cholestasis may result from mass lesions in the liver (tumors and granulomas as in sarcoidosis), with infiltrative processes in the liver (leukemia and amyloidosis), or with strictures of the bile ducts outside of the liver as well.

Hepatic tumors

HCC is the most common primary liver tumor. Worldwide, it is the fifth most common cause of cancer deaths. Anatomically, the liver is also a common site of metastases. The presence of hepatic tumors (primary or metastatic) may cause bile ductule obstruction, resulting in increased ALP and GGT activity; however, liver function tests may be normal. Chronic viral infections (HBV and HCV), cirrhosis, and NASH are all risk factors for the development of HCC. Approximately 70% of individuals with HCC also exhibit cirrhosis. Disease incidence is three-fold higher in males. Unfortunately, clinical manifestations do not present until late in the disease course. While there is interest in screening high-risk individuals, currently, the tumor marker AFP is used in monitoring disease progression, but not in diagnosis. Other markers such as the L3 variant of AFP and DCP (PIVKA-II) are more specific for HCC, but are not as sensitive as AFP, and are not widely used in the United States.

Self-assessment questions

1. The synthetic functions of the liver are dependent on all of the following EXCEPT:
   a. Number of hepatocytes
   b. Blood flow from the portal vein
   c. Sufficient absorption of nutrients from the gastrointestinal tract
   d. Diameter of intrahepatic bile ducts
   e. Nutritional status
2. Which fraction of bilirubin is found in systemic circulation in a healthy individual?
   a. Conjugated bilirubin
   b. Unconjugated bilirubin
   c. Biliprotein
   d. Equal amounts of conjugated and unconjugated bilirubin
   e. Equal concentrations of biliprotein and unconjugated bilirubin
3. Which method for measuring total bilirubin concentrations uses caffeine as an accelerant?
   a. Evelyn–Malloy
   b. Jendrassik–Grof
   c. Van den Bergh and Muller
   d. Ehrlich
   e. An accelerant is not required for the measurement of total bilirubin concentrations.
4. Which disease is associated with increased unconjugated bilirubin concentrations at birth due to a complete loss of UDP-GT activity?
   a. Crigler–Najjar Type I
   b. Crigler–Najjar Type II
   c. Lucey–Driscoll
   d. Gilbert
   e. Dubin–Johnson
5. ALT requires which molecule as an enzymatic cofactor?
   a. Retinyl palmitate
   b. Zinc
   c. Magnesium
   d. Pyridoxal phosphate
   e. A cofactor is not required for enzymatic activity.
6. Which of the following antibodies is NOT associated with autoimmune hepatitis?
   a. Anti-LKM_1
   b. ASMA
   c. AMA-M2
   d. ANA
   e. All are associated with autoimmune hepatitis.
7. An increase of which of the following enzymes would be expected both in bone and liver diseases:
   a. Alanine aminotransferase
   b. Aspartate aminotransferase
   c. Alkaline phosphatase
   d. Gamma-glutamyl transferase
   e. Lactate dehydrogenase

For the following questions, use the following reference intervals: AST 5–40 IU/L; ALT 4–33 IU/L; alkaline phosphatase 40–130 IU/L; total protein 6.0–8.0 g/dL; albumin 3.7–5.0 g/dL; prothrombin time 12.0–14.3 s.

8. A patient is admitted to the hospital with the following laboratory results: AST 12,500, ALT 7300, alkaline phosphatase 125 (all IU/L), total and direct bilirubin 1.9 and 1.2 mg/dL, respectively, and prothrombin time of 22.0 s. The most likely cause of these abnormalities is:
   a. Alcoholic hepatitis
   b. Acute biliary tract obstruction
   c. Acute viral hepatitis
   d. Cirrhosis
   e. Toxic or ischemic hepatitis
9. A patient is admitted to the hospital with the following laboratory results: AST 280, ALT 95, alkaline phosphatase 85 (all IU/L), total and direct bilirubin 12.9 and 7.2 mg/dL, respectively, and prothrombin time of 12.0 s. The most likely cause of these abnormalities is:
   a. Alcoholic hepatitis
   b. Acute biliary tract obstruction
   c. Acute viral hepatitis
   d. Cirrhosis
   e. Toxic or ischemic hepatitis
10. A patient is admitted to the hospital with the following laboratory results: AST 140, ALT 150, alkaline phosphatase 380 (all IU/L), total and direct bilirubin 3.8 and 2.4 mg/dL, respectively, and prothrombin time of 12.8 s. The most likely cause of these abnormalities is:
    a. Alcoholic hepatitis
    b. Acute biliary tract obstruction
    c. Acute viral hepatitis
    d. Cirrhosis
    e. Toxic or ischemic hepatitis
11. All of the following findings in a person with chronic hepatitis would suggest progression to cirrhosis EXCEPT:
    a. AST/ALT ratio of >1
    b. Albumin of 4.0 g/dL
    c. Serum globulins of 6.5 g/dL
    d. Prothrombin time of 18.3 s
    e. Platelet count of 75,000/mm^3

Chapter 32

Clinical chemistry of the gastrointestinal disorders

David N. Alter

Department of Pathology and Laboratory Medicine, Emory University School of Medicine, Atlanta, GA, United States

Learning objectives

After reviewing this chapter, the reader will be able to:

- Describe the basic structure, function, and physiology of the GIT as it relates to digestion.
- Describe clinical laboratory tests used in the evaluation of gastritis.
- Describe clinical laboratory tests used in the evaluation of malabsorption.
- Describe clinical laboratory tests used in the assessment of GI neuroendocrine tumors.
- Describe clinical laboratory tests used in the evaluation of diarrhea and GI bleeding.

Discussion of gastrointestinal (GI) disease biomarkers requires a simultaneous review of GI tract (GIT) anatomy and physiology. The GIT represents a system of different organs similar in structure but with specific functions; thus markers of disease are specific to the targeted underlying pathology. Consequently, to organize the discussion along those terms, this review will proceed stepwisely through the GIT first in health and then in disease.

Anatomy/physiology

Digestion begins in the oral cavity where chewing facilitates digestion by increasing the surface area as well as stimulating salivary gland release of enzyme-rich saliva. Saliva contains salivary (S-type) amylase for the enzymatic breakdown of complex starches into simpler carbohydrates (e.g., maltose and dextrin) and provides lubrication for food transport through the esophagus (a skeletal and smooth muscle lined tube) into the stomach. The stomach has both mechanical and biochemical digestive functions and is geographically divided into the fundus, body, and antrum; each with different functions and associated cell types (Table 32.1). Relaxed, the stomach has about a volume of 75 mL but can distend to about 1 L when full.

Briefly, all gastric function is initially triggered by the vagal nerve-stimulated release of acetylcholine secondary to the sight, smell, and taste of food. This neural stimulation leads to a stepwise, but integrated, process of mechanical squeezing and distension of the stomach, secretion of histamine and gastrin (from G cells), and release of hydrochloric acid (HCl) (pH 1.5−3) and pepsinogen (I and II). As noted in Table 32.1, gastric cell types are distributed per function, with the protective (foveolar) and stimulatory (enteroendocrine) cells found relatively proximal, while "digestive" (parietal, chief) cells are more distal. Hyperacidity, coupled with the described mechanical processes, encompasses the gastric digestive process, namely, a physicochemical process designed to denature proteins for peptide chain release.

Clinically, gastroesophageal reflux disease [gastric contents reflux into the esophagus (normal pH 7.0)] and peptic ulcer disease (PUD; defects in gastric mucosa secondary to medications or disease exposing unprotected gastric mucosa to acidic conditions) are treated with H2 (histamine) blockers or proton pump inhibitors (PPIs). H2 blockers block histamine stimulation and subsequent parietal cell release of HCl. Conversely, PPIs shut down parietal cell ATPases required to transport actively ("pump") HCl against a millionfold concentration gradient into the gastric lumen. In both of those conditions, the goal is to reduce acid production as both disorders are associated with acid exposure to nongastric mucosa.

From the stomach, a bolus of semidigested food (chyme) enters the small intestine, where digestion continues and the majority of nutrient absorption occurs. The small intestine measures approximately 6−7 m in length by 3 cm in diameter with a surface area of 250 m^2 and is divided up into three geographic and functional segments:

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00032-6

TABLE 32.1 Gastric segments, cell types, and functions.

Segment	Cell type	Secretion	Function
Fundic body antral	Foveolar	Mucous	Mucosal layer for protection against gastric acid
		Pepsinogen II (antrum)	Protein breakdown
	Enteroendocrine	Gastrin and histamine	Stimulates antral motility Stimulates pepsinogen release from chief cells Stimulation of parietal cells to produce hydrochloric acid Stimulates secretion of GI hormones such as secretin, insulin, and ACTH
		Somatostatin	Inhibition of parietal cell gastric acid secretion opposing histamine and gastrin stimulation
Fundic	Parietal	Hydrochloric acid	Digestion
		Intrinsic factor	Vitamin B12 absorption
	Chief	Pepsinogen I	Protein breakdown

the duodenum (25 cm), jejunum (2.5 m), and ileum (3 m) with a gradually narrowing diameter from beginning to end. Digestion physically occurs in the GIT but is dependent on external organs such as the pancreas, liver, and gall bladder for pancreatic enzyme and proenzyme/bile synthesis, storage, and secretion. In the small intestine, chyme is broken down into its smallest components with enzymes (secreted locally and externally) specific for ingested carbohydrates, proteins, and fats. Briefly, carbohydrates are broken by amylase into monosaccharides (dextrose, fructose, and galactose) and oligosaccharides (dextrin and maltotriose). On the other hand, lipids and proteins undergo initial processing steps of emulsification and denaturation, respectively, to make them more digestible by their respective enzymes; lipase, colipase and bile salts; and gastric/pancreatic enzymes, for example, trypsinogen, chymotrypsinogen, and carboxypeptidases. Please refer to Chapter 33, Evaluation of exocrine pancreatic function, for more information on pancreatic enzyme activity and associated laboratory testing. Concomitant with food breakdown is nutrient absorption, which occurs over three phases: (1) luminal processing; (2) mucosal absorption; and (3) transport into circulation.

Duodenum

As chyme enters the small intestine; the pancreas secretes digestive enzymes and proenzymes for the biochemical digestion of digested material to produce amino acids, carbohydrates, and fats. In addition, bicarbonate is produced in pancreatic ductal cells to neutralize gastric acid and optimize enzymatic activity, along with the secretion of vasoactive intestinal peptide and secretin to inhibit gastrin and HCl production. In the duodenal mucosa, enterokinase is released and converts trypsinogen into trypsin. This activates a cascade leading to the conversion of pancreatic proenzymes into active molecules. The duodenum is also the primary site for iron absorption and can actively absorb calcium (when body stores are low).

Jejunum

The jejunum is the primary site of global (carbohydrate, lipid, and protein breakdown products) nutrient absorption (including passive calcium absorption). Absorption occurs at and is facilitated by numerous (20,000 in.^{2}) one to two cell layer thick fingerlike projections on the surface mucosa (villi) via active or passive transport mechanisms. Absorption of lipid breakdown products occurs mostly by passive diffusion or protein-mediated processes. In comparison, absorption of carbohydrate and amino acids or peptides occurs by active or passive transport mechanisms. With respect to amino acids and peptides, there are amino acid transporters as well as distinct di and tripeptide transporters to facilitate absorption.

Ileum

The ileum is similar in function to the jejunum; however, vitamin B12 (VB12) and bile acids are selectively absorbed in this region of the small intestine. Approximately, 80% of what is digested is subsequently absorbed by the small intestine, with an addition of 10% absorbed by the large intestine. The nonabsorbed residua enter the large intestine (colon; approximately 1−2-m long by 7 cm) for water and mineral reabsorption. Approximately, 8−9 L of fluid (oral—2 L, saliva—1.5 L, gastric—2.5 L, bile—0.5 L, and intestinal secretions—1.0 L) are absorbed daily by the gut (with a maximal absorption up to 20 L), and the remaining nonabsorbed material is excreted as feces.

Pathology

Practical biochemical markers for GIT-related disorders are limited in number. In addition, some markers discussed in the literature are either theoretical, minimally used, or historic. Consequently, the focus of this chapter will be on routinely utilized biochemical markers with mention of others as appropriate for comparison.

Oral cavity

There are numerous causes of oral pathology leading to impaired food intake; however, biochemical markers are of limited clinical utility, unless the pathology is associated with an underlying infectious etiology.

Esophagus

Most esophageal disorders are of either a functional (tears, ruptures, strictures, or congenital disorders), inflammatory (esophagitis), or malignant nature. Typically, esophageal disorders do not require routine laboratory-based biomarkers for diagnosis. However, iron deficiency, in combination with anemia, esophageal webs, cheilosis, and glossitis, is associated with *Paterson–Brown–Kelly* or *Plummer–Vinson syndrome*. Although the epidemiology/etiology of Plummer–Vinson syndrome is unclear, its overall incidence has declined. Of note, the Plummer–Vinson syndrome has been identified as a risk factor for the development of squamous cell carcinoma.

Stomach—gastritis

Gastritis (acute and chronic) is a common nonmalignant gastric inflammatory disorder in which there is a disruption of the gastric mucosal layer, allowing normal gastric acidic (pH 1.5–3) milieu to attack the underlying epithelium. The excess gastric acid can result in scarring, ulceration, and perforation. The clinical presentations of acute and chronic gastritis often overlap, and histologic examination is necessary for proper classification. For this discussion, nonatrophic chronic gastritis (superficial gastritis and diffuse antral gastritis) is of importance because of its association with acute *Helicobacter pylori* (*H. pylori*) infection and is typically limited to the antrum.

Clinically, gastritis can be divided into infectious, autoimmune, granulomatous, and unknown etiologies. *H. pylori* infection is the most common infectious cause of gastritis. Prominent noninfectious etiologies include pernicious anemia (PA), autoimmune thyroid disorders, gastric carcinoid tumors, and Crohn's disease (CD) [1]. Biochemically, gastrin and pepsinogen blood concentrations have been proposed in the scientific literature as markers of GI disorders; however, they have limited utility (discussed below).

Stomach—*Helicobacter pylori* infection

H. pylori infection is responsible for the majority of chronic gastritis and may be the most common chronic bacterial infection worldwide. *H. pylori* has elevated prevalence (>80%) in individuals greater than age 50 in resource-limited settings and developing countries. Fecal-oral and oral-oral routes are suspected transmission modalities for *H. pylori* acquisition. Indications for *H. pylori* testing vary, but several recommendations remain consistent across guidelines. Testing is indicated for the following scenarios: (1) low grade mucosal associated lymphoid tissue lymphoma; (2) active PUD or past history of peptic ulcer if cure of *H. pylori* infection has not been documented; and (3) early gastric cancer.

There is no gold standard method for the diagnosis of *H. pylori*; test selection may be influenced by predictive ability, local disease prevalence, clinical presentation, and anticipated course of action. For all nonserologic diagnostic tests, PPIs should be discontinued 1–2 weeks prior to testing and bismuth/antibiotic use should be discontinued up to 4 weeks prior. As will be discussed, urease produced by *H. pylori* is used in diagnosis by its ability to split urea into ammonia (NH_3) and carbon dioxide (CO_2).

Biopsy

Histologic identification of the organism and/or application of tissue to a urea-containing substrate (NH_3 production increases pH triggering a color change) may be performed to determine a *H. pylori* bacterial infection. However, endoscopy is not recommended for diagnosing a *H. pylori* bacterial infection, because it carries risks, has a high cost, and can result in false-negative results due to sampling error or missed organism detection.

Serologic testing

Several kits are available for the detection of *H. pylori* IgG antibodies. Overall, these assays have sensitivities approaching 100%, with specificities ranging from the mid-70s to mid-90s. They are rapid, inexpensive, and widely available for use; however, their appropriate utilization depends on local *H. pylori* prevalence; antibody testing is better suited for high-prevalence disease populations, presumably because of its high negative predictive value. Of note, serologic results can be positive for months to years posttreatment; thus serologic IgG testing does not distinguish between past and previous infections. *H. pylori* IgA and *H. pylori* IgM serologic tests are not widely used in clinical settings. In general, dependent on disease prevalence, diagnosis of *H. pylori* by serology is

rapidly fading due to the aforementioned inability to discriminate between past and current infection [2–5].

Breath/urea breath testing

An active *H. pylori* infection may be detected through measuring urea expiration from breath. From a testing perspective, a patient will ingest a capsule containing ^{13}C-labeled urea. Because *H. pylori* can convert urea into CO_2 and NH_3, radiolabeled $^{13}CO_2$ is produced and can be measured in breath. $^{13}CO_2$ is typically measured using spectrometric (such as infrared spectrometry) analysis. Urea breath testing has a specificity approaching 95% and sensitivity ranging from 88% to 95%. This approach is associated with a low probability of false-negative results, thereby allowing it to be used to document initial infection and treatment success. False-negative results are possible when the patient is being treated with antibiotics, PPIs, and bismuth. A 2–4 week period of nonuse is recommended prior to testing.

Stool testing

Detection of *H. pylori* antigen in stool is similar to the urea breath test in terms of test characteristics, with high sensitivities (>90%) and specificities (>90%), and has improved performance as compared with serologic IgG testing. *H. pylori* antigen testing has increased clinical specificity for a current infection. Thus many clinical laboratory environments have opted to use stool antigen testing to evaluate the presence of an active *H. pylori* infection. From a practical perspective, stool antigen testing is a kit-based ELISA test that is relatively easy to implement at the bench and is recommended as the initial test to use [5].

Stomach—pernicious anemia

PA is a specific form of VB12 deficiency associated with decreases in intrinsic factor (IF) production due to autoimmune destruction of parietal cells. PA is associated with chronic atrophic gastritis, IF autoantibodies, and gastric tumors. Once VB12 deficiency is confirmed via low VB12 and/or high methylmalonic acid (MMA) concentrations (low VB12 inhibits the conversion of methylmalonyl-CoA into succinyl-CoA causing an MMA accumulation), testing for anti-IF antibodies is recommended (sensitivity of 50%–70% with a specificity approaching 100%) [6].

Historically, the Schilling test was used to diagnose PA. However, this test has fallen out of favor, because it utilizes radioactive materials and is technically complicated to accurately perform. The Schilling test consists of successive stages of oral and intramuscular administration of radiolabeled VB12, with subsequent urine collection to determine if absorption is impaired; if results are abnormal, the test may be repeated with the addition of IF to determine if there is an IF-related defect.

Stomach—pepsinogen

Pepsinogen and the ratio of pepsinogen I and pepsinogen II have been discussed in the scientific literature as possible markers of atrophic gastritis and prognostic indicators of gastric cancer; however, metaanalyses of combined studies have revealed low sensitivities and specificities.

Stomach—gastrin

Hypergastrinemia is not a specific disease, but rather a finding with both gastric and nongastric causes. Gastrin elevations occur normally during the digestive process to increase gastric acidity with secretion inhibited by increased acidity (low pH). Gastrin secretion unopposed by gastric pH is considered pathologic. Causes of gastrin secretion relative to gastric pH are listed in Table 32.2. Gastrin elevations may be noted in multiple conditions; however, it is primarily employed as part of the workup for gastrinoma and Zollinger–Ellison syndrome. Both of these are discussed in more detail below.

Small intestine

Malignant tumors of the small intestine are not very common. They account for only 3% of GI malignancies (despite representing 90% of the total GI surface area) and 0.5% of cancers overall. However, in terms of biochemical monitoring of GI disorders, a discussion of two relatively common small intestine related neoplasms, gastrinoma and carcinoid, is required.

TABLE 32.2 Gastrin elevation.

Appropriate—decreased acid production (neutral pH)
Food
Histamine blocker/PPI therapy
H. pylori
Atrophic gastritis
Vagotomy
Inappropriate—increased acid production (low pH)
Gastrinoma/Zollinger–Ellison syndrome
Retained antrum syndrome
Antral G cell hyperplasia
Pyloric (gastric outlet) obstruction
Renal failure

PPI, Proton pump inhibitor.

Small intestine—duodenum—gastrinoma

A gastrinoma is a well-differentiated neuroendocrine tumor (NET) of the duodenum (15%) or pancreas (85%) that causes hypersecretion of gastrin and can lead to Zollinger—Ellison syndrome (gastric acid excess, gastric acid-related gastritis, and diarrhea) [6]. Clinically, gastrinomas are difficult to diagnose due to their nonspecific clinical presentation (abdominal pain and chronic diarrhea). Diagnostic for gastrinoma is the appropriate clinical presentation and a serum gastrin concentration greater than 10 × the upper limit of normal (typically >1000 pg/mL) in the presence of gastric acid pH < 4. Secretin stimulation and calcium infusion dynamic testing may also be used to distinguish gastrinoma from other causes of hypergastrinemia; however, the former is preferred over the latter.

Small intestine—carcinoid

Carcinoid tumors are a general class of well-differentiated NETs with a very low overall incidence (carcinoid tumor: 38/1,000,000) but with characteristic clinical and biochemical presentation (carcinoid syndrome, described below). Carcinoid tumors are predominantly located in the GIT or pulmonary system (55%—30%, respectively). Within the GIT, carcinoid tumors are referred to as NETs and are classified/stratified in terms of clinical characteristics and prognosis by embryonic derivation; foregut (intrathoracic, gastric, and duodenal); midgut (small intestine, appendix, and proximal colon), and hindgut (distal colon and rectum). A description of GIT carcinoid characteristics is described in Table 32.3. In general, these tumors clinically present via their production of vasoactive compounds ("carcinoid syndrome"). Pancreatic carcinoid is very rare and needs to be distinguished from pancreatic endocrine tumors and their respective specific syndromes (e.g., insulinomas, gastrinomas, VIPomas glucagonomas, and somatostatinomas). Prognostically, carcinoid metastatic potential is directly related to size; however, colonic, well-differentiated NETs are more aggressive than any other area of the GIT [7,8].

Small intestine—carcinoid syndrome

Biochemically, carcinoid tumors are characterized by excess serotonin production and release, resulting in the clinical findings associated with the carcinoid syndrome, including flushing, diarrhea, bronchoconstriction, and cardiac valvular lesions (Fig. 32.1). Diagnosis is based on the detection of the serotonin metabolite [5-hydroxyindolacetic acid (5-HIAA)] in a 24-hour urine specimen (sensitivity >90% and specificity 90%). Tryptophan- and serotonin-rich foods, such as banana, pineapple, tomato, plums, eggplant, avocado, kiwi, and nuts, should be

TABLE 32.3 Gastrointestinal carcinoid distribution and characteristics.

Location	GIT incidence	Comments
Stomach (foregut)	7%—9%	• Often incidental identification but can be symptomatic (10% with carcinoid syndrome; pain, anemia, and GI bleeding). • Type 1, 70%—80% with atrophic gastritis and achlorhydria • Type 2, 5% associated with gastrinoma • Type 3, 20% sporadic and the most aggressive are associated with elevated gastrin concentrations • Low DOPA decarboxylase activity, and therefore low 5-HIAA and serotonin levels. Diagnosis is based on 5-HTP levels.
Small intestine (midgut)	38%—45%	• 90% in distal ileum • >60% are metastatic at presentation (regional + distant) • Clinical presentation as carcinoid syndrome (up to 13% of cases) secondary to serotonin release (see discussion). Diagnosis is based on urinary 5-HIAA detection.
Colon (midgut and hindgut)	12%	Lack DOPA decarboxylase, and therefore unable to convert 5-HT into serotonin.
Appendix	16%—18%	Rarely symptomatic and usually incidental detection.
Rectum	20%	Incidental identification can present with rectal bleeding and pain.
Pancreas	Rare	• Large (up to 7 cm) with frequent presentation of carcinoid syndrome (up to 100%) and metastatic spread. • Pancreatic serotonin producing tumors (carcinoid) are an extremely rare subset of pancreatic neuroendocrine tumors.

5-HIAA, 5-hydroxyindolacetic acid; *5-HT*, 5-hydroxytryptophan; *GIT*, gastrointestinal tract.

FIGURE 32.1 Biochemistry of carcinoid syndrome and diagnosis.

avoided up to 24 hours prior to beginning of urine collection to prevent false-positive results. 5-HIAA is most useful for patients with midgut tumors.

Foregut and hindgut-related carcinoid tumors have low to no activity of the rate limiting enzyme [aromatic L-amino acid decarboxylase (DOPA decarboxylase)] responsible for serotonin production; therefore, in these types of tumors, 5-HIAA testing has limited utility. Chromogranin A, a protein stored within neuroendocrine tissues, has been discussed in the literature as an additional biochemical marker of carcinoid tumors, but it has poor test characteristics to be a practical diagnostic tool. A better use of chromogranin A may be as a marker of carcinoid treatment and prognosis.

Small intestine—malabsorption

Clinically, malabsorption symptoms can range from asymptomatic through nonspecific symptoms (anorexia, flatulence, and abdominal distension) to, in severe cases, weight loss, diarrhea, and even death. Malabsorption has both small intestinal and nonsmall intestinal causes; however, in all cases, there is an inability to absorb nutrients. For example, PA and pancreatic enzyme deficiencies are extraintestinal, but result in intestinal malabsorption syndromes.

Small intestine—fat malabsorption

The most common cause of fat malabsorption is due to pancreatic insufficiency or pancreatic enzyme inactivation. Clinically, patients commonly present with steatorrhea; fat malabsorption can be assessed by fecal fat analysis (discussed later in this chapter).

Small intestine—carbohydrate malabsorption

Carbohydrate digestion occurs throughout the GIT starting in the mouth (S-type amylase) and continues utilizing pancreatic (P-type) amylase followed by enzymes located on the "brush border" of the small intestinal surface epithelium (sucrase, lactase, and isomaltase). Enzyme deficiencies from the pancreas, or disorders that reduce functional intestinal epithelium availability at the brush border, may result in decreased serum glucose concentrations as well as the buildup of undigested carbohydrates; the latter can then ferment producing hydrogen gas. Diagnostically, serum concentrations of the target carbohydrate, as well as their subsequent fermentation product, are utilized in assessment of carbohydrate malabsorption.

D-Xylose test

Administration of D-xylose followed by serum or urine measurements of D-xylose is performed to measure proximal small intestine absorptive (not digestive) capacity. If the serum or urine concentrations of D-xylose are lower than expected (indicating that the molecule was not absorbed), a mucosal absorptive defect is suspected. This test is subject to false positives, and may be elevated in patients with renal disease.

Lactose tolerance test

Administration of a measured lactose dose is followed by blood glucose measurements. Glucose is measured as lactose is cleaved by lactase into glucose and galactose and galactose is subsequently converted into glucose in the liver. The absence of elevations in glucose concentrations, in conjunction with clinical symptoms, is diagnostic of carbohydrate malabsorption. However, false-negative results may occur in cases of diabetes (due abnormal carbohydrate metabolism) or in the background of intestinal bacterial overgrowth.

Breath testing

Administration of a measured carbohydrate dose (lactose, fructose, and sucrose) is followed by measurement of hydrogen (H_2) breath levels over a 3-hour period. The pattern of H_2 breath levels at distinct times may be used to evaluate lactose tolerance. A certain pattern of these results is diagnostic of small intestinal bacterial overgrowth (SIBO). Methane testing is also recommended as a small percentage of cases will have nonhydrogen producing bacteria [9–11].

TABLE 32.4 Conditions associated with small intestinal bacterial overgrowth.

Celiac disease
Short bowel syndrome
Chronic pancreatitis
Intestinal fistula
Immunodeficiency
Liver disease
Diabetes mellitus
Scleroderma
Radiation enteritis
Inflammatory bowel disease
Irritable bowel syndrome
Cystic fibrosis

Small intestine—celiac disease

Celiac disease is an autoimmune-mediated intestinal epithelium inflammatory disorder that impairs nutrient absorption. This immune-mediated disorder affects about 1% of the population and is triggered by prolamins (plant-based storage protein) found in wheat (gliadin) and other grains such as barley and rye. Clinically, it manifests as chronic diarrhea, flatulence, abdominal distension/pain, and weight loss. Treatment involves cessation of these foods and is very successful. Testing should be performed after the individual has been on a gluten containing diet as false-positive results can arise, if done otherwise. Serologic testing for antibodies to tissue transglutaminase (TTG; IgA-TTG) has proven to be the optimal serum-based laboratory test in the assessment of celiac disease. Prior to the use and development of TTG serology, antiendomysial antibodies, and antigliadin (IgA and IgG) antibodies had been commonly utilized; however, their test characteristics were not as sensitive or specific as TTG. Low-risk patients with positive serologic testing and high-risk patients regardless of serology should get biopsied. With respect to celiac disease (as well as many others), laboratories should work in concert with local allergists to develop the best protocol for their specific patient population [12,13].

Small intestine—bacterial overgrowth

SIBO syndrome is characterized by an overgrowth of native and/or nonnative bacteria due to poorly absorbed nutrients that result in excessive fermentation and inflammation. Bacterial overgrowth can decrease nutrient absorption, thereby providing a conducive environment for bacterial growth and further exacerbating the underlying condition. Associated disorders are summarized in Table 32.4. Nonspecific clinical and laboratory findings associated with SIBO include abdominal discomfort, bloating, diarrhea, weight loss, macrocytic anemia (VB12 deficiency), increased fecal fat, hypoalbuminemia, and protein deficiency. Confirmation of SIBO requires a combination of laboratory tests, clinical findings, endoscopy, and knowledge of any underlying medical disorders. Breath testing is discussed in the literature and has been occasionally used to help make the diagnosis of SIBO. Breath testing is based on the principle that the overgrown bacteria will cause increased production and expiration of hydrogen gas ($\geq$20 ppm by 90 minutes) or methane [9–11].

Colon

Significant disorders of the large intestine usually present clinically as either diarrhea, bleeding (gross to occult presentation), or a combination of both.

Colon—diarrhea

Definitions vary (i.e., increases in stool by weight, volume, or frequency) but consistent features are persistent liquidity with poorly formed stools. In general, it represents an inability of the large intestine to reabsorb excess water and water-soluble electrolytes passing through the GIT. Diarrhea is broadly classified into two categories: osmotic and secretory; additional causes include inflammatory (colitis-related) and altered motility (vagotomy, sympathectomy, adrenal insufficiency, hyperthyroidism, and irritable bowel syndrome).

Osmotic causes are due to poorly or nonabsorbed substances (e.g., undigestable sugar alcohols, e.g., sorbitol and mannitol) that prevent normal water reabsorption by shifting the osmotic gradient to favor water retention over reabsorption. Osmotic diarrhea should resolve with cessation of the offending agent. In contrast, secretory diarrhea has a multitude of etiologies that include, but are not limited to, bacterial toxins inflammatory bowel disease, lymphocytic colitis and medications.

Diarrheal workup should include routine laboratory testing for blood count, electrolyte, and hepatic and renal function tests to assess patient status and because the differential diagnosis is protean in nature [14,15].

Stool electrolytes

Stool electrolytes are not osmotically active (similar to plasma) and are used to calculate a stool osmotic gap based on the difference between a measured and calculated stool osmolality.

$$\text{Stool Osm gap} = \left(290\left(\text{stool osmolality mOsm/Kg}\right)\right) - 2(\text{Na} + \text{K})\ \text{mOsm/Kg}$$

$<$50 mOsm/Kg) Consistent with secretory type diarrhea

$>$100 mOsm/Kg) Consistent with osmotic type diarrhea

Stool pH values less than 6 are consistent with fermentation and are suggestive of carbohydrate malabsorption. Stool submitted for diarrheal workup, regardless of test, is only useful if liquid stool is submitted. Lastly, stool may be submitted for fecal fat analysis to diagnose steatorrhea. According to the literature and labs that still perform the test, a 24−72-hour (72 preferred) specimen with a specific fat-controlled (100−150-g fat/day) diet during testing is required. In addition, 3 days prior and during the testing period, laxatives and synthetic fat substitutes should be avoided. Expected values are <7-g fat/24 hours (timed specimen) or 0%−19% fat (random collection). A recent discussion has proposed an alternative strategy that depends on stool weight and detection of fat globules [16]. Due to variability in collection and patient preparation, several test utilization campaigns do not endorse using 72-hour quantitative fecal fat testing in the evaluation of lipid malabsorption.

Colon—*Clostridium difficile*-related diarrhea

Any discussion about diarrheal workups would be incomplete without mention of *Clostridium difficile*-related diarrhea and its associated evaluation. *C. difficile* is a Gram-positive spore-forming anaerobic bacterium found in soil and GIT that produces virulent exotoxins (toxin A and toxin B) responsible for colitis and diarrhea. For *C. difficile* infection (CDI) to occur, both the organism and disruption of normal GIT microbial flora are required. As normal flora gets disrupted under conditions, such as, but not limited to, increased age, prolonged hospitalization, prolonged antibiotic use, PPIs, chemotherapy, and chronic kidney disease, conditions become favorable for existing *C. difficile* spores to become "active" by overwhelming normal host defenses releasing their toxins. These interfere with intestinal epithelial integrity, causing an inflammatory mediator release and fluid shift, which lead to inflammation and diarrhea. The prevalence of asymptomatic carriage of *C. difficile* spores is estimated at about 2% in the healthy population, with 30% prevalence in inpatients. However, frequency is dependent on underlying morbidity, antibiotic use, and length of hospitalization.

Diagnosis of *C. difficile* includes diarrhea (three documented episodes per day) in the setting of recent or ongoing antibiotic treatment, especially in hospitalized and/or older individuals. Presumably, episodes of diarrhea in prolonged care (hospital, long-term care facility, nursing home, etc.) should also be investigated for the possibility of *C. difficile* due to contributing comorbidities. Diagnostic modalities are based on either detection of the organism or detection of the toxin. Relevant testing is summarized in Table 32.5. Regardless of method used, the following general principles must be considered: (1) diarrhea must be confirmed; (2) the patient must be symptomatic; and (3) the specimen must be a liquid stool. Assessment of stool liquidity, that is, appropriateness for *C. difficile* evaluation, is accomplished using either the Bristol Stool Form Scale (1−7 with 7 = "liquid or taking the form of a cup") or the Brecher criteria ("if the stick falls, test them all. If the stick stands, the test is banned"). In addition, testing cannot be used to determine "cure," because treated/"cured" (asymptomatic) individuals can continue to shed the organism for up to 6 weeks. Finally, CDI severity stratification includes the use of white blood cell (WBC) count and serum creatinine with increasing values of both (>15,000 and >1.5× baseline, respectively), which are consistent with worsening severity [17−19].

Colon—gastrointestinal bleeding

The differential diagnosis of GIT bleeding is long and can be due to multiple unrelated causes ranging from gingival disease and long distance running through any disorder discussed in this chapter to colonic malignancy. Location/rate/volume of bleed determines how blood appears in stool with presentations varying from gross blood to melena (dark/tarry stools) to not seen at all (occult). If gross blood is observed, identification of blood is usually obvious. However, melena can be a subjective interpretation as charcoal and diet can result in stools with a similar appearance requiring additional testing. Occult refers to "hidden" and fecal occult blood (FOB) indicates blood in the stool that cannot be seen. Evaluation for FOB is performed to assess for unexplained anemia, as a screening test for cancer and in the presence of melena stools. In terms of colon malignancy, occult hemorrhage of the colonic mucosa occurs and increases as precancerous lesions progress to cancerous secondary to an increasing vascularity, cellularity, and impact to the colonic mucosa.

Fecal occult blood testing

Fecal occult blood testing (FOBT) targets either heme or globin components of hemoglobin. Both methods have their pros and cons but globin is gradually replacing the heme method. Detection of the heme component has been around since the 1950s utilizing the ubiquitous plant extract guaiac. Application of the peroxide "developer" in the presence of heme (a peroxidase) will release oxygen, subsequently reacting with alpha-guaiaconic acid impregnated on the card (guiac is extracted from the resin of the hardwood tree *Guaiacum officinale)* to produce a blue-colored product. Operationally, this test is performed by application of stool samples to guaiac pretreated slides followed by two drops of "developer" (hydrogen peroxide solution) and then visual examination of the slide for a

TABLE 32.5 ***Clostridium difficile*** **diagnosis.**

Toxigenic culture	• Reference standard • Isolation of organism from feces followed by confirmation that isolate is toxin producing strain • Time-consuming (24–48 h) and labor-intensive • "Very sensitive"
Cell cytotoxicity assay	• Reference standard • Cell culture-based assay that identifies cytopathic effect of related toxins with confirmatory step to confirm *C. difficile* toxins • Time-consuming (24–48 h) and labor-intensive • Sensitivities 65%—90%
There is some debate in the reviewed literature as to which test TC versus CCA are better reference methods for the detection of *C. difficile*.	
Immunoasssay—GDH	• Metabolic enzyme produced in all strains (toxigenic and nontoxigenic) of *C. difficile* • Up to 46% *C. difficile* strains have been reported to be nontoxigenic • Suitable as a screening test but positive results require confirmation testing • Sensitivities and specificities in the high 1990s • Low-cost kit-based EIA with rapid turnaround time
Immunoassay—toxins (A and B)	• Monoclonal/polyclonal antibodies for detection of toxins A and B • Toxin A can be nontoxigenic, so A and B must be included • Sensitivities ranging from 40% to 99% with specificities ranging 60% to 100% • Low-cost kit-based EIA with rapid turnaround time
There are some kits available on the market, which combine GDH and toxin detection with sensitivities in the 50%–70% range and specificities approaching 100%. However, specimens that are GDH positive and toxin negative should have a confirmatory test performed.	
Molecular—NAAT/PCR	• Molecular detection of either *C. difficile* toxin-related gene sequences to variety of specific methods • Real-time automated molecular technology • Test characteristics are dependent on method/manufacturer utilized with sensitivities ranging from 80% to 100% and specificities approaching 100%

GDH, Glutamate dehydrogenase.

blue color change. Preanalytically, it is important to not apply stool thickly and to confirm that the control circles have properly reacted. The test (FOBT) is subject to dietary false-positive results (upper GI bleeding, animal heme, and vegetable peroxidases) and to false-negative results [antioxidant ingestion such as ascorbic acid (vitamin C)].

Slowly replacing the FOB is the fecal immunochemical test (FIT), which utilizes antibodies specific for the intact hemoglobin molecule. The FIT does not suffer from the false positives and false negatives of the FOBT, but has some limitations itself. Degradation of the globin chain from time/temperature factors can occur (the heme moiety does not) and the test's ability has not been sufficiently evaluated for patients with globin chain disorders. In addition, as the globin chain will be digested, the FIT will not detect the presence of upper GI bleeding. Test characteristics for FOBT and FIT are compared and contrasted in Table 32.6.

No discussion of FIT and FOBT would be complete without mention of stool-based molecular testing being used for colorectal cancer screen. Currently, there is a commercial (Cologuard) test available that assays stool for KRAS mutations, methylation markers, and hemoglobin. For this method, patients collect their stool and send it directly to the company, where it is then analyzed with a proprietary algorithm and methodology. FOBT and FIT have shown that they do detect polyp early and have reduced colorectal cancer mortality. With respect to the molecular test, there appears to be a benefit but data are still limited.

Colon—tumor markers

In terms of colon cancer, carcinoembryonic acid (CEA) is the biochemical (numerous molecular markers are available) tumor marker used in practice. CEA is a glycoprotein associated with cell adhesion produced during fetal development. As well as colorectal cancer, CEA can be elevated in other conditions such as, but not limited to, tobacco smokers, gastritis, inflammatory bowel disease (IBD), liver disease, and chronic obstructive pulmonary disease. The test has a poor sensitivity (46%) and specificity (89%) for diagnosis and is not recommended for screening or diagnosis. However, it may be used to monitor treatment and cancer recurrence [20].

TABLE 32.6 Test characteristics of fecal occult blood testing and fecal immunochemical test.

	FOBT	FIT
Advantages	Point-of-care test that is easy to perform and cards can be sent home for patient application of stool Heme not subject to digestion environmental degradation	Not subject to dietary interference Serial testing not required
Disadvantages	False-positive and false-negative dietary impacts Sensitivity improves with serial testing	Laboratory-based test requiring some manipulation False-negative results possible due to digestion or environmental degradation Will not detect presence of upper GI bleeding
Sensitivity	Single test 24%–40% Serial [3] test 80%–92% Varies by manufacturer and formulation	64%–80% Varies by manufacturer
Specificity		87%–98% Varies by manufacturer

FIT, Fecal immunochemical test; *FOBT*, fecal occult blood testing; *GI*, gastrointestinal.

Colon—inflammatory bowel disease

IBD is delineated into two major types: ulcerative colitis (UC) and CD. UC is characterized by mucosal limited inflammation restricted to the colon, whereas CD appears throughout the GIT and has a transmural inflammatory response. Both diseases clinically present with diarrhea and abdominal pain with diagnosis based on history, clinical presentation, and nonspecific markers of systemic inflammation such as WBC count or C-reactive protein elevation. There are also biochemical markers specific to colonic inflammation, namely, fecal leukocytes, lactoferrin, and calprotectin. All these markers have varying degrees of evidence-based support and have shown greatest utility in ruling out IBD; these tests also have a reported utility for treatment and relapse monitoring.

Fecal leukocyte (WBC) testing has been in use since the 1970s as a tool to diagnose infectious diarrheas especially salmonellosis and shigellosis. The test depends on the infection's ability to spill WBCs into the intestinal lumen; therefore, its diagnostic performance depends on type and severity of infection as well as the ability of the operator to microscopically identify WBCs in stool specimens. Test specificity has been reported to be in the 1970s, with sensitivities ranging from 30% to 80% depending on study reviewed. Better than identification of WBCs has been the development of immunoassays for WBC (neutrophil)-associated constituents, namely, lactoferrin (iron binding protein from neutrophil secondary granules) and calprotectin (calcium–zinc binding protein neutrophilic cytosolic protein). For the detection of inflammatory disorders especially IBD, both have reported sensitivities in the 1990s with specificities approaching 100%. Neither can be used to distinguish UC from CD, but they can monitor treatment and relapse as needed. Unfortunately, both will be also be present in most intestinal inflammatory disorders. In addition, neither is useful in distinguishing *C. difficile*-related diarrhea from other etiologies. To differentiate biochemically between CD and US, two serologic markers are currently being used: antisaccaromyces cervisiae antibodies (ASCA) and perinuclear antineutrophil cytoplasmic antibodies (pANCA). In short, various combinations of ASCA and pANCA positivity and negativity have sensitivities in the 1950s to 1960s and specificities in the high 1980s and 1990s [21–23].

GI CHEMISTRY—Self-assessment questions

1. The most cost-efficient, reliable test for *H. pylori* is:
   - **a.** Culture
   - **b.** *H. pylori* PCR
   - **c.** *H. pylori* stool antigen
   - **d.** Serum antibody to *H. pylori*
   - **e.** Urea breath test
2. In a patient with signs and symptoms of malabsorption, the best initial test to document malabsorption is:
   - **a.** Carotene in serum with the patient on usual diet
   - **b.** D-Xylose test
   - **c.** Fecal fat excretion
   - **d.** Lactose tolerance test
   - **e.** Schilling test
3. Which of the following tests is considered the best test for diagnosis of celiac disease?
   - **a.** Antibody to gliadin
   - **b.** Antibody to tissue transglutaminase
   - **c.** D-Xylose test
   - **d.** Fecal fat excretion
   - **e.** Lactose tolerance test
4. Which of the following is considered a biomarker for inflammatory bowel disease (IBD)?
   - **a.** Gliadin
   - **b.** Neutrophil cytoplasmic antigens
   - **c.** Nuclear antigens
   - **d.** Calprotectin
   - **e.** C-reactive protein
5. Which of the following can be a contributing factor to *C. difficile*-related diarrhea?
   - **a.** Prolonged antibiotic use
   - **b.** Chronic use of proton pump inhibitor drugs (PPIs)
   - **c.** Use of probiotic supplements
   - **d.** A and B
   - **e.** B and C
6. Currently, screening for colorectal cancer is usually done by means of:
   - **a.** Colonoscopy yearly
   - **b.** Fecal DNA tests yearly
   - **c.** Fecal occult blood tests yearly
   - **d.** Fecal occult blood tests yearly, followed by colonoscopy or sigmoidoscopy if abnormal
   - **e.** X-ray examination of the abdomen

Chapter 33

Evaluation of exocrine pancreatic function

Steven W. Cotten

Department of Pathology and Laboratory Medicine, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States

Learning objectives

After reviewing this chapter, the reader should be able to:

1. State the physiological actions of the pancreas.
2. Differentiate endocrine and exocrine pancreatic function.
3. List the enzymes secreted by the pancreas and their functions.
4. State the methodology used in assays for enzyme determination in the clinical lab.
5. Describe the expected biochemical profile for relevant pancreatic disorders.
6. Recognize the laboratory's role in validating off-label use of FDA-cleared assays for pancreatic function evaluation.

Anatomy and physiology of the pancreas

The pancreas is an organ 12−15 cm in length located along the posterior wall of the abdominal cavity. The organ's shape consists of a "head," nestled in the duodenal curve that extends from the stomach, and a "tail" extending left toward the spleen (Fig. 33.1). The head of the pancreas is connected to the duodenal loop via the hepatopancreatic ampulla (also known as the ampulla of Vater). The union of the bile duct and pancreatic duct creates the hepatopancreatic ampulla, and the release of bile and pancreatic juice into the duodenal loop is controlled by the Sphincter of Oddi. The pancreas is one of just two organs having both endocrine and exocrine functions, with the other being the liver. Endocrine glands secrete hormones directly into the circulation, while exocrine glands secrete compounds to epithelial cells via a series of ducts.

The endocrine functions of the pancreas are largely related to glucose homeostasis and carbohydrate metabolism. The cells forming the Islets of Langerhans in the pancreas are responsible for the synthesis and secretion of insulin, glucagon, pancreatic polypeptide, and somatostatin. (Table 33.1) The endocrine functions of the pancreas and carbohydrate metabolism are covered in Chapter 34: Carbohydrate disorders. In certain rare cancers, endocrine cells of the pancreas can also produce other peptides, such as gastrin (Zollinger−Ellison syndrome) and vasointestinal peptide (Verner Morrison syndrome).

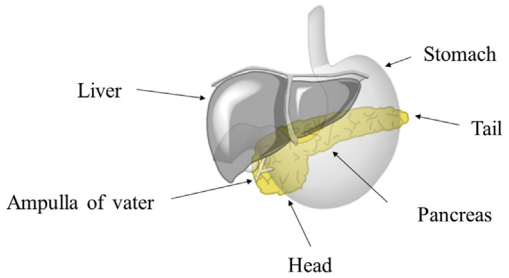

FIGURE 33.1 Anatomy of the pancreas.

The exocrine functions of the pancreas relate to the secretion of enzymes or factors that control the degradation of proteins, lipids, and polysaccharides in the duodenum and gastrointestinal tract. These enzymes include amylase, lipase, trypsin, chymotrypsin, carboxypeptidase, elastase, and phospholipase A2 (Table 33.2). These enzymes, in concert with bile salts, allow for the breakdown, emulsification, and reabsorption of sugars, amino acids, and lipids. Impaired enzyme production or secretion by the pancreas results in maldigestion and malabsorption of these breakdown products.

Laboratory measurement of pancreatic enzymes

Amylase

α-Amylase (EC 3.2.1.1), also known as 1,4-α-D-glucan glucanohydrolase, catalyzes the hydrolysis of 1,4-α-glucosidic linkages between adjacent glucose residues within complex carbohydrates. Amylase is present in several organs and tissues with the highest concentration in the salivary glands. In addition to salivary glands and the pancreas, amylase activity has been detected in semen, testes, ovaries, fallopian tubes, striated muscle, lungs, and

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00033-8

TABLE 33.1 Endocrine pancreatic secretions.

Hormone	Expression	Biological role
Insulin	β-cells	Reduces blood glucose
Glucagon	α-cells	Increases blood glucose
Pancreatic polypeptide	F-cells	Regulates endocrine and exocrine pancreatic secretions and acts as an antagonist to cholecystokinin
Somatostatin	δ-cells	Inhibits insulin and glucagon release
Gastrin	Zollinger–Ellison syndrome	Increases gastric acid, pepsinogen, secretin, and intrinsic factor
Vasointestinal peptide	Verner Morrison syndrome	Stimulates bicarbonate secretion and inhibits gastrin stimulated gastric acid secretion

TABLE 33.2 Exocrine pancreatic secretions.

Enzyme	Substrate
Amylase	1,4-α-glucosidic linkages in polysaccharides
Lipase	Glycerol esters of long-chain fatty acids
Trypsin (1 and 2)	Peptide bonds formed by the carboxyl groups of Lys or Arg with other amino acids
Chymotrypsin (1 and 2)	Peptide bonds involving carboxyl groups of Trp, Leu, Tyr, or Phe, with preference for the aromatic residues
Carboxypeptidase (A and B)	C-terminal peptide and proteins
Elastase-1	Carboxyendopeptidase that catalyzes hydrolysis of native elastin, with a special affinity for the carboxyl group of Ala, Val, and Leu
Phospholipase A-2	Phospholipids

adipose tissue. The salivary glands produce amylase (S-type) encoded by the *AMY1* gene that initiates the breakdown of starch in the mouth and esophagus. Salivary amylase content varies, but, on average, may account for up to 66% of circulating plasma amylase [1]. Genomic analysis has revealed a correlation between low copy number of *AMY1* genes and a predisposition to obesity [2,3].

The pancreas produces amylase (P-type) encoded by the *AMY2A* and *AMY2B* genes, and the enzyme is secreted into the duodenum via the pancreatic duct system. The primary physiological role of pancreatic amylase is to facilitate the breakdown of polysaccharides present in the chyme in the duodenum. Pancreatic amylase does not show a significant difference in reference intervals between males and females during development. Both sexes show a slight increase during development, with upper ranges for pancreatic amylase activity starting at approximately 28 U/L and moving toward 44 U/L by age 17 [4].

Macroamylase refers to a circulating complex of amylase and immunoglobulins (usually IgA, followed by IgG) [5]. The combined molecular weight of amylase ($\sim$62 kDa) and immunoglobulins (360-kDa IgA dimer) prevents clearance by the kidneys, resulting in accumulation of macroamylase molecules in the plasma. Most cases of macroamylasemia are idiopathic and have little clinical significance. Amylase measurements usually reveal elevated amylase activity in the absence of acute pancreatitis. In the cases of suspected macroamylasemia, polyethylene glycol (PEG) precipitation or gel filtration chromatography may be performed [6]. For PEG precipitation, the sample is treated with a PEG solution that precipitates large antibody complexes. The solution is then centrifuged to pellet any insoluble proteins and the supernatant is measured for remnant amylase activity. If macroamylase molecules were present, the residual activity of amylase should be decreased. The cutoff used for

TABLE 33.3 Amylase and lipase substrates used in common automated chemistry platforms.

Instrument platform	Amylase substrate	Lipase substrate
Beckman coulter AU	CNP-G_3	1,2-Diglyceride

determination is dependent upon the specific procedure used [5–8].

Determination of total amylase activity

Most methods for amylase measurement involve the assessment of enzyme activity rather than total amylase protein concentrations. Conventional assessment by the clinical laboratory measures both salivary and pancreatic amylase activities in the specimen. The majority of modern methods use defined substrates that generate colorimetric products upon digestion by amylase enzymes (Table 33.3). The unique reactivity of amylase toward each individual substrate imparts different specificities for each assay. This can impact reference intervals and interassay comparisons. The International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) published recommendations for standardization of amylase activity measurements at 30°C in 1999 and at 37°C in 2006 [9,10]. An earlier published recommendation for amylase measurement used the substrate 2-chloro-4-nitrophenyl-α-D-maltotrioside (CNP-G_3) (Fig. 33.2).

In the original IFCC method, amylase catalyzes the cleavage of the CNP-G_3 substrate liberating 2-chloro-4 nitrophenol (CNP), resulting in an absorbance change that is monitored at 410 nm. The release of CNP can be either from the original CNP-G_3 substrate or from the intermediate product CNP-G_2. No auxiliary enzymes are required for the reaction. The most recent IFCC recommendation uses the substrate 4,6-ethylidene-4-nitrophenyl-α-(1→4)-$_D$-maltoheptaoside (ethylidene-4NP-G_7). In this reaction, the substrate is protected with the ethylidene group on the nonreducing end of the oligosaccharide. The moiety improves the stability of the substrate by preventing slow hydrolysis from α-glucosidase, an auxiliary reagent. The reaction works in a similar fashion to the CNP-G_3 substrate by measuring the liberation of 4-nitrophenol that is measured via a color change at 410 nm. Using assays traceable to the most current IFCC method, serum reference intervals for adults are reported to be 31–107 U/L. Notable differences between the substrates used in the aforementioned methods are readily observed on proficiency testing participant summaries between peer groups. Samples near the upper limit of the reference interval of 107 U/L show variation between 87 and 134 U/L across all peer groups.

Commutable reference material for α-amylase

External quality assessment and multilaboratory studies have demonstrated wide interlaboratory variation of the catalytic measurement of α-amylase in serum samples. Currently, there are two primary reference measurement procedures (PRMPs) for amylase that occupy the highest position in the traceability chain. These methods use certified reference material (CRM) IRMM/IFCC-456 that consists of purified pancreatic amylase protein in an artificial matrix. As the supply of IRMM/IFCC-456 material diminishes, a new CRM is sought that may also offer commutability for calibration of routine methods. Recently five candidate reference materials were evaluated for commutability for α-amylase using clinical and laboratory standards institute (CLSI) EP30-A and the bias method recommended by the IFCC Working Group on Commutability [11]. Four of the five candidate reference materials contained amylase purified from human pancreatic tissue, and the other candidate reference material contained recombinant amylase. Three of the four candidate reference materials containing purified amylase materials were stabilized in buffer and one of four was stabilized in human serum. Two candidate reference materials containing purified amylase from human tissue showed acceptable commutability with Biosystems, Roche, and Siemens amylase assays. Differences in commutable acceptability were observed depending upon the statistical method (CLSI or IFCC) chosen; the IFCC

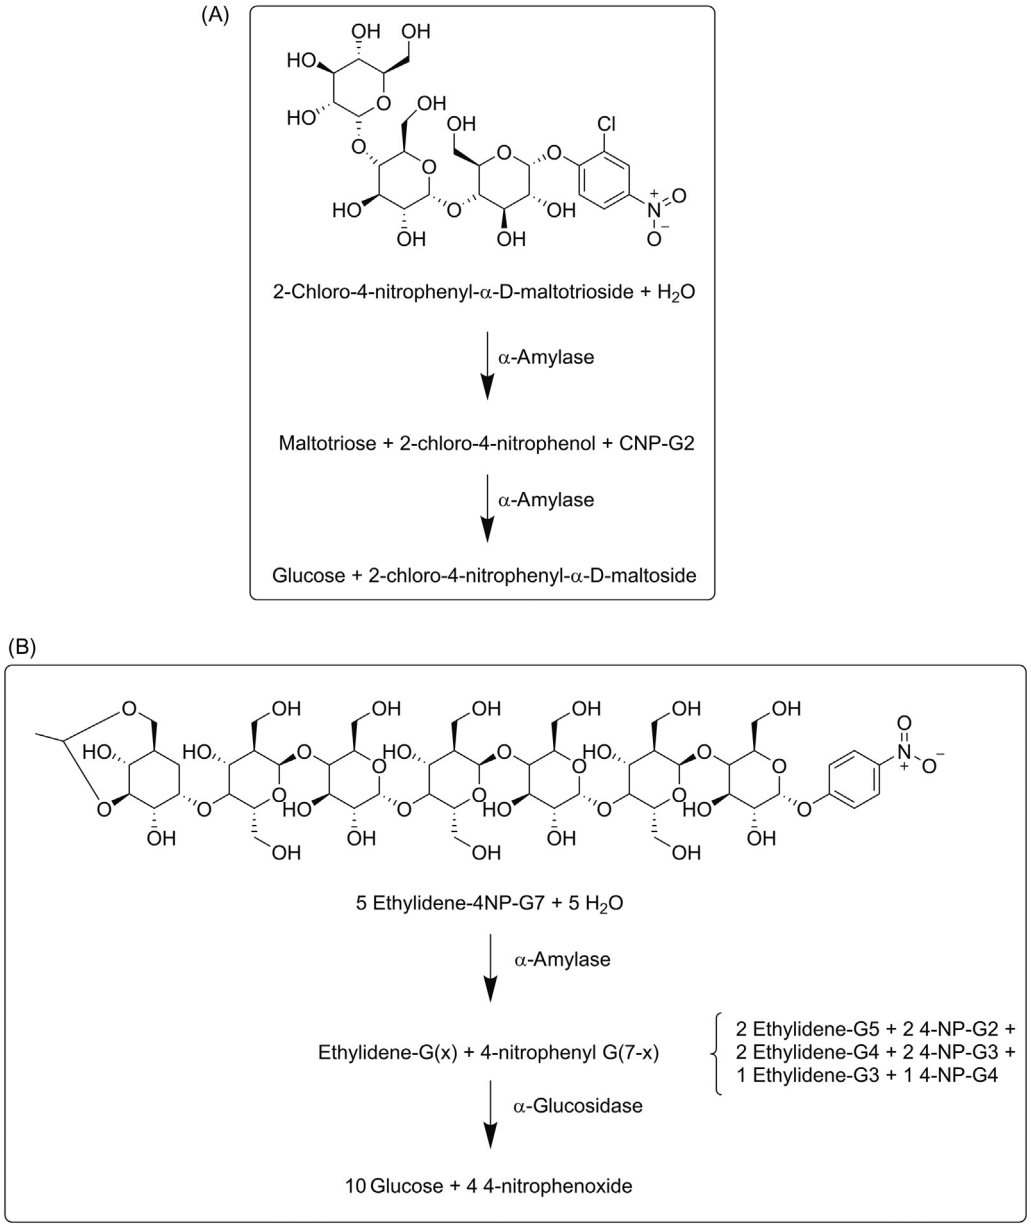

FIGURE 33.2 Two distinct substrates used for amylase activity measurement. (A) Chloronitrophenol coupled to three glucose molecules. (B) Ethylidene 4-nitrophenol coupled to seven glucose molecules.

method employs a more stringent benchmark for agreement. The evaluation of a candidate reference material shows that commutability is achievable for routine methods in an artificial matrix, but further work is required to generate a universal reference material across all amylase methods and substrates.

Determination of pancreatic-specific amylase activity

Total amylase measurement has limited specificity due to the contributions of both pancreatic and salivary amylase. The exclusive measurement of pancreatic amylase provides improved diagnostic accuracy for the identification of patients with suspected acute pancreatitis. Specific measurement of pancreatic amylase activity involves the use of two monoclonal antibodies that bind and inhibit the salivary amylase enzyme in vitro. After incubation of patient sera with these immunoinhibitory antibodies, the uninhibited pancreatic amylase can be measured using the substrates described earlier. Using pancreatic-specific amylase reagent, the IFCC reference interval has been reported for adults as 13−53 U/L [10]. Prior to immunoinhibition for specific measurement of pancreatic amylase

activity, amylase isoenzymes were separated using electrophoresis [12,13]. The type of matrix used for separation (cellulose acetate, agarose, or polyacrylamide) substantially impacted the degree of protein resolution. In addition to the separation of pancreatic and salivary amylase, other posttranslational modifications, such as glycosylation or deamination, could be observed in the form of three bands in both the P- and S-type amylase migration windows.

Lipase

Lipases (EC 3.1.1.3) refer to a class of enzymes that catalyze the hydrolysis of the glycerol esters present in long-chain fatty acids (triglycerides) into β-monoglyceride and two free fatty acids (Fig. 33.3). Several types of lipases have been identified, such as lipoprotein lipase, hepatic lipase, and pancreatic lipase. Pancreatic lipase shows selectivity for long-chain fatty acids, while other ancillary lipases, such as lipoprotein lipase and hepatic lipase, are more specific for short-chain fatty acids. The concentration of pancreatic lipase is approximately 9000 times greater in the pancreas as compared to other tissues. Complete enzyme activity is achieved only when the enzyme is present in an emulsion, usually facilitated by bile salts, such as sodium deoxycholate, and in the presence of the cofactor colipase. The bile salts promote and stabilize the emulsion of the long-chain fatty acid substrates for pancreatic lipase. Colipase binds to pancreatic lipase resulting in a conformational change of the complex that increases the binding affinity and catalytic activity of the enzyme. In addition, the presence of colipase and bile salts in the reaction mixture mitigates lipoprotein lipase activity in vitro, which increases the analytical specificity of lipase assays. All major diagnostic manufacturers have lipase reagent formulations supplemented with colipase and at least one bile acid, which may be listed as a surfactant or stabilizer in the product insert.

Determination of lipase activity

Currently there is no established consensus for a pancreatic lipase reference method [14]. Modern methods for lipase measurement utilize a variety of synthetic substrates whose breakdown products are measured. The most common substrate utilized by automated chemistry instruments is 1,2-o-dilauryl-rac-glycero-3-glutaric acid-(6'-methylresorufin) ester (DGGMR; see Table 33.3) Under basic conditions, pancreatic lipase, in concert with colipase and bile salts, cleaves the conjugated glutamic acid and phenoxazine dye from the triglyceride (Fig. 33.4). Base-mediated separation of glutaric acid from the phenoxazine liberates the dye and results in a color change that is measured at 560 nm. The measured rate of color change is proportional to the amount of lipase present in the sample. Using this substrate, reference intervals for lipase in a normal adult population are approximately 15−51 U/L, but may vary slightly based on specific population and study design.

Several diglyceride substrates have also been employed for lipase measurement due to their superior solubility [15,16]. However it has been suggested that these methods may be more prone to interferences from nonpancreatic lipase enzymes. Recently a new substrate, 1,2-dioleoylglycerol (DODG), has been reported and proposed as another candidate reference method for lipase [15]. Several modifications have been interrogated to improve the selectivity toward pancreatic lipase, including changing bile salts from sodium deoxycholate to a combination of sodium taurodeoxycholate and sodium glycodeoxycholate, a reduction in the measurement pH from 8.15 to 7.0, and an increase in temperature from 37°C to 43°C. The IFCC and Japanese Society of Clinical Chemistry (JSCC) are both actively working toward defining a reference method and reference material; however, pancreatic lipase remains one of the only enzymes that is not yet standardized in the clinical laboratory [17].

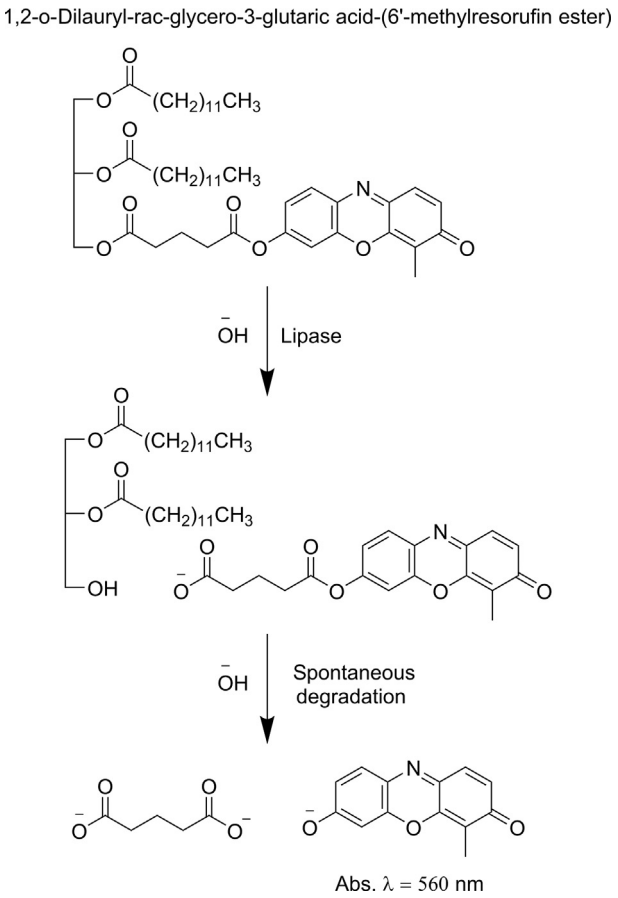

FIGURE 33.4 The enzymatic reaction scheme for the measurement of lipase activity using the substrate 1,2-o-dilauryl-rac-glycero-3-glutaric acid-(6'-methylresorufin) ester.

Trypsin

Trypsin (EC 3.4.21.4) is a serine protease enzyme produced by the pancreas that cleaves carboxyl groups present on lysine and arginine. Three isoforms (trypsin 1, 2, and 3) are synthesized and stored in the pancreas as inactive trypsinogens. Upon stimulation by cholecystokinin, the pancreas releases inactive trypsinogens into the intestine where they are activated by enterokinase via proteolytic cleavage. Protease inhibitors, such as α-1-antitrypsin (A1AT) and β-2-microglobulin (B2M), bind activated trypsin that may enter the circulation as a means to protect plasma proteins. The measurement of trypsin complexed to an inhibitor (immunoreactive trypsin) has limited clinical utility for patients with acute pancreatitis [18]. Immunoreactive trypsinogen (IRT) measurement is used extensively in newborn screening programs for cystic fibrosis, but is not diagnostic for the disease [19].

Chymotrypsin

Chymotrypsin (EC 3.4.21.1) is another serine protease produced by the pancreas that hydrolyzes the peptide bonds of tryptophan, leucine, tyrosine, and phenylalanine. Two forms of chymotrypsin (1 and 2) are synthesized by the pancreas as inactive chymotrypsinogens. Once released into the intestinal tract, the precursor enzymes are converted to chymotrypsin through proteolytic cleavage by trypsin. Chymotrypsin is more resistant to degradation than trypsin and therefore can be measured in the feces. Measurement of chymotrypsin in stool has been one method to assess adequate exocrine pancreatic function and may be useful in detecting compliance with exogenous pancreatic enzyme supplementation. Issues related to collection and analysis of fecal chymotrypsin have led to the development of alternative approaches to assess adequate pancreatic function. Collection and analysis of secretin-stimulated duodenal fluid provide a direct assessment of pancreatic function and are discussed later in this chapter.

Elastase-1

Elastase (EC 3.4.21.36) is a serine protease produced by the pancreas that catalyzes cleavage of carboxyl groups present on small hydrophobic amino acids, such as glycine, alanine, and valine. Its primary role is the breakdown of elastin, a protein that imparts elasticity to connective tissue. There are up to eight genes that encode elastase or elastase-like enzymes, four of which are classified as chymotrypsin-like. Neutrophil elastase breaks down the outer membrane of *E. coli* and other Gram-negative bacteria. Measurement of fecal elastase-1 can be used to indirectly assess exocrine pancreatic sufficiency [20]. Currently, there are two reagents commercially available for measurement of elastase with varying specificities (Table 33.4) [21]. One reagent is a monoclonal antibody against pancreatic elastase-1 and the second assay contains two polyclonal antisera mixtures against elastase. Both assays measure total elastase content, not enzyme activity. Based on their low specificities, neither reagent is recommended as a broad screening test [22]. Comparison of the two elastase reagents reveals that they detect different epitopes and the polyclonal elastase reagent reacts with nonhuman elastase. This lack of specificity of the polyclonal reagent for human elastase becomes problematic in patients with chronic pancreatitis (CP) that are receiving porcine enzyme supplements [21]. Low false positive stool elastase results can occur with small bowel bacterial overgrowth and watery stool.

Quantitative fecal fat

The measurement of fecal fat is used as another indirect measurement of pancreatic insufficiency. Conventional measurement requires the patient to be on a standard diet containing 8−12 g of fat daily for five days prior to collection of the last 72 hour stool sample. The sample is

homogenized and fatty acids are extracted; extracts are commonly measured gravimetrically. However, this original method showed poor interlaboratory agreement and was both challenging for the patient and the laboratory [23]. Three subsequent methods have been reported that seek to better harmonize results and simplify analysis. The first method uses midinfrared spectroscopy following a liquid extraction with petroleum ether or chloroform. The assay is reported to have acceptable interassay and intraassay precision with %CVs <10 [24]. The second and third methods use ^{13}C-NMR or ^{1}H-NMR spectroscopy to measure the natural abundance of either ^{13}C or ^{1}H in fatty acids [24,25]. Several improvements to these NMR methods have been published that obviate the need for homogenization, lyophilization, or extraction of the sample, thus making NMR methods more suitable for high-throughput analysis with minimal sample processing. These methods dramatically reduce sample preparation and analysis time from hours to minutes [25].

The clinical utility of fecal fat analysis from timed stool collections has been questioned extensively with many compelling arguments against its use [26,27]. Proper collection requires the patient to adhere to a moderate to high-fat diet for several days, which may be difficult for patients experiencing diarrhea. Poor analytical performance has been documented by the absence of internal quality controls and external quality assessment between laboratories. Clinical specificity toward true fat malabsorption is low and the test results do not identify the cause of possible malabsorption. For these reasons, many laboratories restrict the use of fecal fat analysis in favor of alternative assessment of malabsorption [27].

CA 19-9

CA 19-9, also known as the Sialyl-Lewis^{A} antigen, is a tetrasaccharide carbohydrate originally described in 1979 [28]. The monoclonal antibody (1116 NC 19-9) was characterized from a human colorectal carcinoma cell line and the antigen was subsequently defined as a siaylated lacto-*N*-fucopentase II oligosaccharide. CA 19-9 is synthesized by normal epithelial tissue in the pancreas, biliary ducts, colon, endometrium, and salivary glands. A small amount of CA 19-9 can be found in plasma present on large circulating mucin glycoprotein complexes. Plasma levels of CA 19-9 rise with the progression of neoplastic diseases, such as pancreatic and colorectal cancer. The automation of tumor marker analysis has greatly decreased imprecision for CA 19-9 laboratory assays, but comparison of CA 19-9 results across multiple platforms reveals large discordant values. Method comparison using Passing−Bablok analysis generates slopes ranging from 1.0−2.0 and correlation coefficients from 0.85−0.98 for five commercially available reagents [29]. The observed lack of harmonization reinforces the need to use a single assay for serial monitoring of patients.

Disorders of the pancreas

Exocrine pancreatic insufficiency

Exocrine pancreatic insufficiency refers to the inability of the pancreas to produce the digestive enzymes required for the proper breakdown of fats, sugars, and proteins. This condition can arise from most pancreatic diseases, including acute pancreatitis, chronic pancreatitis (CP), pancreatic cancer, and cystic fibrosis. It has been estimated that malabsorption only occurs after 90% of pancreatic enzyme output has been lost [30]. Clinical presentation includes abdominal bloating and cramping, loose malodorous stools, fat-soluble vitamin deficiencies, and weight loss. Laboratory evaluation of exocrine pancreatic insufficiency can be indirect through measurement of excreted enzymes and fecal fat analysis or direct measurement of collected duodenal fluid after secretin stimulation of the pancreas. Direct measurements are suitable for detecting mild to severe insufficiency, while indirect methods are only considered suitable for the detection of moderate to severe cases.

Despite its limitations, 72-hour fecal fat analysis is currently considered the "gold standard" for indirect laboratory evaluation of exocrine pancreatic insufficiency; however, fecal elastase-1 and fecal chymotrypsin testing have also been used [31]. A comparison of quantitative fecal fat analysis and elastase-1 demonstrated that

elastase-1 (at a cutoff of 200 μg/g) predicts fat malabsorption only in patients who have not undergone partial surgical resection of the pancreas [32].

Several studies have published discordant clinical sensitivities of fecal elastase-1 to detect pancreatic insufficiency based on the specific reagent used (monoclonal or polyclonal antibody-based method). One study ($n = 127$) using the monoclonal antibody reported sensitivity and specificity for severe insufficiency reported as 100% and 55%, respectively, at a cutoff of 200-μg/g stool [22]. A subsequent study ($n = 45$) comparing the monoclonal reagent with a polyclonal reagent calculated sensitivities and specificities of 68.9% and 77%, and 76% and 77%, for the monoclonal and polyclonal reagents, respectively [21].

Direct assessment of pancreatic insufficiency

Direct pancreatic function tests involve hormonal stimulation of the pancreas through IV administration of secretin, cholecystokinin, or both [31]. The resulting duodenal secretions from the pancreas are collected and analyzed for bicarbonate, pH, and lipase. Contemporary procedures collect specimens through the accessory channel of an endoscope while the patient is sedated. Bicarbonate values >80 mmol/L observed 60 min after stimulation suggest normal duct-cell function [33,34]. Lipase measurements evaluate acinar-cell function, and pH measurements are used to monitor possible contamination from gastric fluid.

Collection of duodenal fluid may be recommended as a standard practice for direct assessment of pancreatic insufficiency by gastroenterologists; however, the analysis of this fluid creates challenges for the laboratory. Duodenal fluid is typically not FDA-approved for bicarbonate, pH, or lipase measurements, and their analyses represent off-label reagent use. This effectively classifies these assays as laboratory developed tests (LDTs) and clinical laboratories should perform the appropriate validations prior to analysis. Several publications have evaluated the performance of automated chemistry analyzers for total CO_2 or bicarbonate analysis from duodenal fluid with the back titration reference method [35–37].

Acute pancreatitis

Acute pancreatitis refers to the transient inflammation of the pancreas. Pancreatitis occurs when digestive enzymes of the exocrine pancreas spill into the parenchyma and upon activation by trypsin, autodigest pancreatic tissue. Clinical presentation is limited to nonspecific symptoms, such as abdominal pain, fever, nausea, and tachycardia. The most common causes of acute pancreatitis are gallstones (40%–70%) followed by alcohol abuse (25%–35%) [38]. Pancreatitis from gallstones usually resolves when the stone is removed or is passed spontaneously. Other minor causes of acute pancreatitis may include medications [6-mercaptopurine, azathioprine, and DDI (2',3'-dideoxyinosine)], hypertriglyceridemia (>1000 mg/dL), trauma, autoimmune diseases, genetic factors, and pancreatobiliary tumors.

Diagnosis of acute pancreatitis

Guidelines from the American College of Gastroenterology for the diagnosis of acute pancreatitis require two of the three following features: abdominal pain, elevated serum lipase, or amylase >3x the upper reference interval, and characteristic findings of pancreatitis on computed tomography (CT) scan [39]. Elevation of amylase and lipase peaks within the first 24 hours. Amylase can remain elevated for 72–96 hours, while lipase can remain elevated for 7–14 days. The kinetic differences between amylase and lipase can be attributed to different serum half-lives. Lipase has a reported half-life of 6.9–13.7 hours, which is longer than that of amylase [40–42]. The prolonged half-life is attributed to filtration of lipase by the kidneys and almost completes resorption by the proximal tubules. The extent of either enzyme elevation does not directly correlate with disease severity. Lipase is the preferred enzyme due to its extended elevation but an elevation in either enzyme fulfills criteria for diagnosis. Amylase has decreased sensitivity and specificity due to its possible normalization after 24 hours and nonspecific elevation in pregnancy, renal failure, and esophageal perforation.

Assessment of disease severity

Up to eight scoring systems have been proposed to stratify severity of acute pancreatitis in the clinical setting [39]. Each scoring system evaluates a slightly different clinical question, such as organ failure, diagnosis of severe acute pancreatitis, mortality, admission to an ICU, likelihood of readmission, or diagnosis of mild acute pancreatitis.

Chronic pancreatitis

CP refers to the progressive chronic inflammation, scarring, and irreversible fibrotic damage to the pancreas that result in loss of endocrine and exocrine pancreatic function [43]. Clinical presentation includes abdominal pain, steatorrhea, pancreatic calcifications, and diabetes. This can be caused by recurring episodes of acute pancreatitis or slow subclinical damage that occurs over many years (as seen in cystic fibrosis). The etiology of CP can be classified using the TIGAR-O system: toxic metabolite (alcohol, tobacco, hypercalcemia, hyperlipidemia, chronic

renal failure, medications, and toxins), idiopathic (early onset, late onset, and tropical), genetic (*PRSS1, CFTR*, and *SPINK1*), autoimmune (isolated, syndromic), recurrent and severe (post necrotic, vascular/ischemic, post irradiation), and obstructive [pancreas divisum, sphincter of Oddi disorders, duct obstruction (tumor), and posttraumatic pancreatic duct scars] [44].

The incidence of CP is estimated to be 4−12 per 100,000 individuals per year [44]. The incidence is higher in men than women by a factor of 1.5−3. Smoking and alcohol are both independent risk factors, and, concomitantly, they are multiplicative in the risk for the development of CP. Alcohol is the single most common risk factor and accounts for 44%−65% of CP cases. A threshold of four to five alcoholic drinks per day clearly increases the likelihood of developing CP. The prevalence of pancreatitis for alcoholics is three to six times greater than that for nondrinkers. Tobacco use (<1 pack per day) increases the risk of CP 2.4-fold; this risk increases to 3.3-fold when tobacco use increases to >1 pack per day. Smoking cessation decreases the risk of developing CP by 50% and reduces the risk of pancreatic calcifications in active disease.

Diagnosis of chronic pancreatitis

Recently, the American Pancreatic Association (APA) proposed a diagnostic algorithm for the diagnosis of CP (Fig. 33.5) [44]. The algorithm integrates both direct and indirect pancreatic function tests as well as imaging modalities, such as CT, magnetic resonance imaging (MRI), and endoscopic ultrasound. Clinical signs of CP, including history, physical exams, and existing laboratory data, initiate the workup. Fecal elastase measurement is suggested if not already performed. Fecal fat may be performed, but due to its cumbersome collection, challenging laboratory analysis, and patient dietary restrictions, its utility is diminished. Both elastase and fecal fat are moderately sensitive for the detection of pancreatic insufficiency in established CP, but may not detect or differentiate mild or early disease. These indirect tests are followed up by CT scans evaluating calcifications or atrophy. If inconclusive, then MRI imaging followed by endoscopy ultrasound is recommended. Inconclusive MRI or endoscopy may be followed by direct analysis of pancreatic function (secretin stimulation pancreatic function tests). If bicarbonate values do not meet criteria for diagnosis (<80 mmol/L at 60 min) or are inconclusive, the last remaining diagnostic test is endoscopic retrograde cholangiopancreatography (ERCP). This imaging modality, which requires contrast dye administration, should be reserved only for patients with whom direct pancreatic functions tests are equivocal.

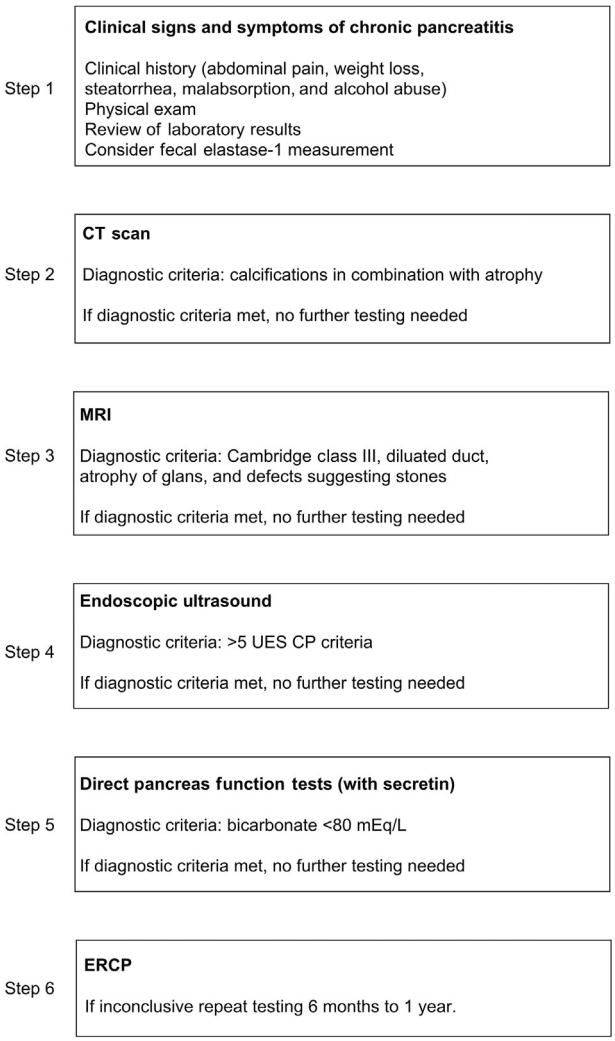

FIGURE 33.5 Diagnostic algorithm for the diagnosis of CP.

Pancreatic cancer

Pancreatic cancer is one of the most lethal cancers due to the typical late-stage diagnosis of the disease. Approximately 90% of those diagnosed with pancreatic cancer die from the disease within 5 years [45]. Smoking, long-standing diabetes, heredity factors, CP, and obesity are large contributing risk factors for the development of pancreatic cancer. Approximately 60%−70% of pancreatic tumors are located at the head of the pancreas. Early detection and surgical resection can increase 5-year survival to 20%−30% [46]. Currently, there is no effective screening tool for asymptomatic patients or early stage disease.

Imaging modalities, such as CT, MRI, and endoscopy ultrasound, are the primary diagnostic resources for pancreatic cancer. CA 19-9 is the only marker that may be used in symptomatic patients. A review of the performance of CA 19-9 has a reported median sensitivity of

79% (70%–90%) and median specificity of 82% (68%–91%) [47]. There are several limitations to the use of CA 19-9 as a biomarker for pancreatic cancer that contribute to its low sensitivity and specificity. Of note, 5%–10% of Caucasians cannot synthesize the CA 19-9 epitope due to a deficiency in fucosyltransferase [48]. Thus negative results will be obtained in these patients, even in the presence of advanced disease. Transient CA 19-9 elevations may occur in nonmalignant disorders, such as inflammation, obstructive jaundice, CP or acute pancreatitis, liver cirrhosis, and cholangitis. The frequency of obstructive jaundice in hepatobiliary disease (50%), acute pancreatitis (75%), and CP (20%) diminishes the specificity of CA 19-9. Additionally, other unrelated conditions, such as heart failure, Hashimoto's thyroiditis, rheumatoid arthritis, and diverticulitis, have all been reported to elevate CA 19-9.

If CA 19-9 is found to be elevated in the setting of pancreatic cancer confirmed by imaging studies, it may be useful in staging/prognosis and assessment of chemotherapy response [48]. The degree of elevation of CA 19-9 can be used to stratify patient survival. Both preoperative and postoperative measurements have been suggested to be predictive of patient survival and resectability of the tumor. Several studies have also demonstrated that serial measurements of CA 19-9 during the course of chemotherapy correlate with disease progression. Results suggest that changes in measurements over time correspond to tumor growth as well as overall survival [49–53].

Pancreatic cyst fluid analysis

Pancreatic cysts are detected in approximately 1%–3% of patients who undergo abdominal imaging for an unrelated condition [54]. These cysts can be classified into inflammatory cysts (pseudocysts), cystic neoplasms, and true cysts. The correct classification of the type of cyst greatly impacts treatment with the clinical goal being the identification and resection of cysts that may progress to invasive carcinomas. In addition to imaging, fine needle aspiration (FNA) followed by biochemical analysis of the cyst fluid and cytology can help differentiate the type of cyst. The analysis of cyst fluid for glycoproteins, such as CA 19-9, CA 125, CA 15-3, and CA 72-4, seeks to classify mucinous from nonmucinous neoplasms. Cyst fluid CA 19-9 values >50,000 U/mL have a reported sensitivity of 86% and specificity of 85% in distinguishing cystadenocarcinomas from other cystic lesions [55]. Cyst fluid CEA measurement has been shown to be the most accurate method to differentiate mucinous from nonmucinous lesions. Accuracy of cyst fluid CEA is 79% compared with endoscopy ultrasound (51%) and cytology (59%) using a cutoff of 192 ng/mL [56].

In addition to the measurement of tumor markers, biochemical analysis of enzymes is sometimes requested on cyst fluid. Several studies have come to different conclusions about the sensitivity of these enzymes in the classification of cyst pathology or differentiation of malignancy [56,57]. Amylase measurement is suggested to have the highest specificity for differentiation of malignant cysts from nonmalignant or indeterminate lesions based on cytology. Amylase measurements were found to be lower in patients with malignancy as compared to nonmalignant lesions, with mean measurements of 55.9 U/L (malignant) versus 78.8 U/L (indeterminate) and 101.1 U/L (nonmalignant). Lipase measurements were found to be similar across all three groups, limiting its clinical utility. Laboratories should be mindful that the analysis of tumor markers in cyst fluid are laboratory developed tests and require additional validation. The viscous nature of cyst fluid and limited volumes available can be challenging on automated chemistry analyzers. Conservation of cyst fluid is imperative if both biochemical and cytological analyses are requested.

Conclusion

The endocrine and exocrine functions of the pancreas are key regulators in carbohydrate and nutritional metabolism whose dysfunction can contribute to a range of pathologies. Laboratory analysis of exocrine pancreatic function comprises a wide variety of analytes and specimen types. Many of these less common specimen types, such as stool, duodenal fluid, and pancreatic cyst fluid, have additional preanalytical and analytical considerations for proper handling and interpretation. Furthermore, analysis of routine enzymatic analytes and tumor makers in serum may be complicated due to the lack of assay harmonization and poor clinical specificity. For these reasons, it is crucial for the laboratory to play a significant role in the stewardship, education, and research for diagnostic testing related to exocrine pancreatic function.

Self-assessment questions

1. What is the biochemical action of α-amylase?
   - **a.** Breaks down triglycerides into glycerol and fatty acids
   - **b.** Degrades proteins at the N-terminal end
   - **c.** Degrades carbohydrates at the α-1,4 linkage
   - **d.** Degrades carbohydrates at the α-1,6 linkage
2. What is the biochemical action of lipase?
   - **a.** Hydrolyzes the glycerol esters present in long-chain fatty acids into β-monoglyceride and two free fatty acids
   - **b.** Breaks down starches into triglycerides
   - **c.** Breaks down triglycerides into glucose and fructose
   - **d.** Hydrolyzes peptide bonds formed by the carboxyl groups of Lys or Arg with other amino acids
3. Which of the following does not add specificity to lipase measurements?
   - **a.** The presence of colipase
   - **b.** The presence of bile salts
   - **c.** Reaction conditions in an emulsion
   - **d.** The concentration of substrate
4. Measurement of pancreatic-specific amylase activity is achieved through ____.
   - **a.** addition of antipancreatic amylase antibodies to determine salivary activity
   - **b.** use of antisalivary amylase antibodies in a sandwich immunoassay format
   - **c.** addition of antisalivary amylase antibodies to inhibit this isoenzyme activity
   - **d.** use of a pancreatic-amylase specific substrate that cannot be hydrolyzed by salivary amylase
5. The conventional standard method for indirect determination of exocrine pancreatic insufficiency is ____.
   - **a.** quantitative fecal fat
   - **b.** elastase-1
   - **c.** chymotrypsin
   - **d.** trypsin
6. Which of the following is the most common cause of chronic pancreatitis?
   - **a.** Pancreatic cancer
   - **b.** Alcohol abuse
   - **c.** Genetic mutation
   - **d.** α_1-Antitrypsin deficiency
7. What laboratory test(s) should be used to diagnose acute pancreatitis?
   - **a.** Lipase 2x the upper limit of normal in serum
   - **b.** Amylase 2x the upper limit of normal in serum
   - **c.** Lipase or Amylase 3x the upper limit of normal in serum
   - **d.** Lipase 3x the upper limit of normal urine.
8. What is not a limitation of CA 19-9 as marker for pancreatic cancer?
   - **a.** Reactivity with other related cancer antigen markers
   - **b.** Elevations in heart failure and Hashimotos thyroiditis.
   - **c.** Transient elevations from inflammation, obstructive jaundice or liver cirrhosis
   - **d.** A deficiency in fucosyltransferase in 5%−10% of Caucasians
9. What is the primary analyte used for direct assessment of exocrine pancreatic function after secretin stimulation?
   - **a.** Phospholipase A2
   - **b.** IRT
   - **c.** Bicarbonate
   - **d.** Gastrin
10. Pancreatic cyst fluid CEA analysis ____.
    - **a.** should not be performed by laboratories
    - **b.** is FDA approved by most manufacturers of CEA reagents
    - **c.** is not FDA approved and requires validation by clinical laboratories
    - **d.** is not considered an LDT

Chapter 34

Carbohydrate disorders

William E. Winter[1], **J. Peter R. Pelletier**[2], **and Neil S. Harris**[3]

[1]Department of Pathology and Pediatrics, University of Florida, Gainesville, FL, United States, [2]Department of Pathology and Anesthesia, University of Florida, Gainesville, FL, United States, [3]Department of Pathology, University of Florida, Gainesville, FL, United States

Learning objectives

After reviewing this chapter, the reader will be able to:

- Identify the salient features of hypoglycemia in the clinical history of a patient.
- Differentiate type 1 diabetes, type 2 diabetes, other specific types of diabetes, and gestational diabetes.
- Diagnose diabetes using clinical and laboratory methods.
- Recommend laboratory testing to assess long-term glycemic control.
- Understand the relationship between insulin sensitivity and the metabolic syndrome.
- Diagnose inborn errors of metabolism that cause hyper- or hypoglycemia (including galactosemia).

Introduction

Disorders of carbohydrate metabolism can be grouped into those that involve glucose (i.e., hypo- and hyperglycemia) and the far less common disorders that involve nonglucose carbohydrates (e.g., galactose and fructose). Disorders that involve carbohydrate digestion or malabsorption (e.g., lactose intolerance) will be discussed in detail in Chapter 31, Laboratory diagnosis of liver disease, of this book.

Glucose measurements

The most common laboratory approaches for glucose measurement are the hexokinase and glucose oxidase (GO) enzymatic methods. Point-of-care (POC) devices commonly utilize the GO or glucose dehydrogenase (GDH) methods.

In the hexokinase method, glucose is phosphorylated to glucose-6-phosphate by hexokinase, with ATP providing the phosphate group. Glucose-6-phosphate dehydrogenase then catalyzes the oxidization of glucose-6-phosphate to 6-phosphogluconate with the reduction of nicotinamide-adenine dinucleotide phosphate or nicotinamide-adenine dinucleotide (NAD^+) to nicotinamide adenine dinucleotide + hydrogen (NADH). Fructose is also detected by this method; however, plasma fructose concentrations are typically low and not clinically significant.

The hexokinase reaction is summarized below:

$$\text{Glucose} + \text{ATP} \xrightarrow{\text{hexokinase}} \text{glucose-6-phosphate} + \text{ADP}$$
$$\text{Glucose-6-phosphate} + \text{NAD}^+ \xrightarrow{\text{G6PD}} \text{6-phosphogluconate} + \text{NADH} + \text{H}^+$$

Various drugs, hemolysis, hyperbilirubinemia, and triglyceride concentrations ≥ 500 mg/dL can interfere with the assay. Hemolysis produces a negative bias, whereas hyperbilirubinemia and hypertriglyceridemia cause positive biases in the glucose measurement. Serum blanking may be useful in minimizing some interferences.

The GO method selectively and specifically measures glucose via the oxidization of glucose to gluconic acid and production of hydrogen peroxide (H_2O_2) as a by-product. Catalyzed by peroxidase, H_2O_2 reacts with o-dianisidine to form the chromogenic product oxidized o-dianisidine, which is measured spectrophotometrically at 540 nm. By inhibiting the peroxidase reaction, increased concentrations of ascorbic acid, bilirubin, uric acid, and glutathione can result in falsely low glucose measurements. The GO reaction is depicted below:

$$\text{Glucose} + \text{O}_2 \xrightarrow{\text{glucose oxidase}} \text{gluconic acid} + \text{H}_2\text{O}_2$$
$$o\text{-Dianisidine} + \text{H}_2\text{O}_2 \xrightarrow{\text{peroxidase}} \text{oxidized } o\text{-dianisidine} + \text{H}_2\text{O}$$

In POC testing (POCT), GO methods using ferrocene are affected by ambient oxygen tension. Thus when using a ferrocene-based secondary reaction, hypoxemia or laboratory testing at elevations >5000 feet can produce falsely elevated glucose measurements, whereas hyperoxemia produces falsely low glucose concentrations.

$$\text{Glucose} + \text{FAD}^+ \xrightarrow{\text{GO}} \text{gluconolactone} + \text{FAD}$$
$$\text{FAD} + \text{ferrocene}^+ \dashrightarrow \text{ferrocene} + \text{FAD}^+$$
$$\text{ferrocene} \dashrightarrow \text{ferrocene}^+ + e\text{-(electrochemical detection)}$$

An electrode measures oxygen consumption in the GO−oxygen electrode method. A polarographic oxygen

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00034-X

electrode assesses the rate of oxygen consumption. H_2O_2 is degraded by reacting with ethanol in a reaction catalyzed by catalase or by reacting with iodine catalyzed by molybdate (depicted below):

$$H_2O_2 + C_2H_5OH — \text{catalase} \rightarrow CH_3CHO + 2\ H_2O$$
$$H_2O_2 + H^+ + I^- — \text{molybdate} \rightarrow I_2 + 2\ H_2O$$

Whole blood cannot be used in these analyses, because living cells consume oxygen. Since GO is specific for beta-D-glucose, mutarotase is typically included as a reagent to accelerate the interconversion of alpha-D- and beta-D-glucose. In the absence of mutarotase, reaction time must be prolonged to allow for spontaneous interconversion. In the absence of mutarotase and an extended reaction time, glucose levels will be underestimated.

GDH catalyzes the formation of glucono-delta-lactone and NADH, the latter of which is measured spectrophotometrically. Like the GO method, mutarotase can be used to accelerate the reaction. This assay is highly specific for glucose and shows high correlation with the hexokinase assay. The GDH reaction is depicted below:

$$\text{Glucose} + NAD^+ — \text{glucose dehydrogenase} \rightarrow D\text{-glucono-delta-lactone} + NADH + H^+$$

Used in POCT, the glucose dehydrogenase pyrroloquinoline-quinone (GDH-PQQ)-based glucose monitoring systems are not specific for glucose and can detect maltose, xylose, or galactose [1,2]. Because of this significant limitation, this methodology is not recommended in POCT devices especially in the hospital setting. Maltose, a glucose disaccharide, is employed as an osmolality regulator or stabilizing agent in various biological preparations. Xylose and galactose are used in some diagnostic tests and are present in some dietary supplements, herbs, and foods. Such positive interferences in the GDH-PQQ assay can lead to an overestimation in glucose concentrations [3]. Subsequent administration of insulin based on GHD-PQQ measured glucose levels has resulted in hypoglycemia and even death. Icodextrin, which is present in some peritoneal dialysis solutions, is converted into maltose and can, therefore, also produce a positive interference in the measurement of glucose.

$$\text{Glucose} + PQQ — GDH \text{ -- } > \text{gluconic acid} + PQQH_2$$
$$PQQH2 + \text{ferricyanide ----- } > PQQ + \text{ferrocyanide}$$
$$\text{ferrocyanide ----- } > \text{ferricyanide} + e\text{-(electrochemical detection)}$$

Common specimen sources for glucose measurement

Differences in reference intervals exist among capillary blood, serum or plasma, and whole blood glucose levels. Because the water content of whole blood is lower than serum or plasma, whole blood glucose concentrations are lower than serum or plasma values. Serum or plasma glucose concentrations are ~15% higher than those of whole blood. Blood gas analyzers take this into account by normalizing to a correction factor, but individuals with very high or very low hematocrits can have aberrant results. Because serum or plasma glucose concentrations are independent of hematocrit, these fluids are preferable for analysis over whole blood. Because of the improved stability of sodium fluoride (NaF)-treated plasma as compared with serum, plasma is often the preferred specimen type when prepared from a tube containing NaF [4]. A 2015 report recommended a tube containing NaF, potassium oxalate, citrate, and EDTA for maintaining glucose stability [5].

Capillary blood is comparable with arterial blood with regard to glucose concentrations. Arterial blood glucose is 2–3 mg/dL higher than venous blood glucose in the fasting state. After a glucose load, glucose concentrations may be ~15% higher in capillary blood than in venous blood, presumably because tissues clear glucose after a meal. In emergency, operating room (OR), or intensive care unit (ICU) settings where patients may suffer from hypotension or hypoperfusion, capillary glucose measurements from finger sticks, or the forearm are not recommended. This is because the capillary glucose level may not immediately reflect the plasma glucose level (e.g., there can be an approximate 15-minute delay with forearm measurements) and the measured capillary glucose may be reduced compared with the circulating plasma glucose level. From a regulatory point of view, POCT devices used in critical care settings (e.g., ICUs or ORs) must be Food and Drug Administration (FDA)-approved for use in critical care settings. This being said, there is no universal definition of what a critical care setting is; it is the responsibility of the hospital to define "critical care." Nevertheless, POCT devices approved for critical glucose testing are available (CLIA-waived HemoCue Glucose 201 Systems, Brea, CA; and CLIA-waived Nova Stat Strip, Waltham, MA). In a study from France involving critically ill patients, POC glucose measurements were validated by measuring glucose in arterial samples split between the POCT device and the core laboratory [6]. This could serve as a model for validating glucose measurements in critically ill patients.

Whereas urine glucose measurements are part of the routine urinalysis, urine glucose testing does not play a major role in the diagnosis or management of diabetes. Urine ketone testing (e.g., Acetest) is important to detect inadequate insulinization and impending ketoacidosis. When diabetic patients are ill with nausea, vomiting, or diarrhea, or have a blood glucose level greater than 200–240 mg/dL, urine ketones should be checked. Trace ketones can be treated by increasing the patient's oral

fluid intake. Urine ketones that are 1 + or greater may require additional acute insulin administrations (e.g., ~10% of the total daily dose of insulin). It is best that individually packaged sodium nitroprusside urine test strips be used, as test strips exposed to air degrade and lose their reactivity to ketones. There are reports where diabetic ketoacidosis (DKA) was missed, because the sodium nitroprusside strip had degraded causing a false-negative result [7]. Ketonemia with an unequivocally elevated plasma beta-hydroxybutyrate (BHB) concentration supports the diagnosis of DKA as opposed to hyperglycemic hyperosmolar state (HHS).

In addition, continuous subcutaneous glucose measurement systems are available and their use is increasing. In these systems, a GO-coated electrode is typically placed in the subcutaneous space for 3 or more days; glucose measurements may be obtained as frequently as every 10 seconds, reporting an average glucose (AG) concentration every 5 minutes. The meter reports these results in real time and stores the results for graphical interpretation or wireless transmission to a subcutaneous insulin pump (i.e., an "artificial closed-loop pancreas" system). Closed-loop systems linking an insulin-infusion pump and continuous subcutaneous glucose measurement are currently under intense study and reduce the frequency of hypoglycemia while also reducing hemoglobin A1c levels. In September 2016, the FDA approved Medtronic's MiniMed 670 G System as the first hybrid closed-loop system for patients with type 1 diabetes (T1DM).

Hypoglycemia

Clinical presentation of hypoglycemia

Clinically, hypoglycemia presents with neuroglycopenia and/or adrenergic symptoms and signs. With insufficient supply of glucose to the brain, impaired mentation, sleepiness, irritability, drowsiness, seizures, or coma may develop. Death can follow in cases of severe and/or prolonged hypoglycemia. The normal adrenergic response to hypoglycemia is the release of epinephrine from the adrenal medulla. The rise in epinephrine can lead to increased anxiety, sweating, tachycardia, and raised blood pressure. However, individuals who suffer from repeated bouts of hypoglycemia may not display such dramatic symptoms.

The diagnosis of hypoglycemia is based on three criteria: (1) identification of a low blood glucose as defined above; (2) symptoms compatible with hypoglycemia; and (3) resolution of symptoms with the administration of glucose. Biochemical hypoglycemia is generally defined as a plasma glucose of 45 mg/dL or less. Note that there is a "gray" zone of decreased blood glucose between 45 and 70 mg/dL. From a 2015 study in neonates, when plasma glucose concentrations were maintained at ≥47 mg/dL, neurodevelopmental outcomes at 2 years were normal [8]. The 2019 American Diabetes Association recommendations describe glucose concentrations between 54 and 69 mg/dL as "level 1" hypoglycemia, glucose concentrations below 54 mg/dL as "level 2" hypoglycemia, and "level 3" hypoglycemia is defined as "a severe event characterized by altered mental and/or physical status requiring assistance" [9].

Artifactual hypoglycemia must be excluded prior to proceeding to an extensive patient workup. Glucose will decline at a rate of approximately 2%−3% per hour once a sample is obtained, due to continued glycolytic activity within red blood cells. Even when collected in tubes containing the NaF additive, glucose will decline in the first hour until glycolysis is fully inhibited. The delayed effect of NaF is due to the inhibitory effect of fluoride on the penultimate step of glycolysis; fluoride inhibition of the enolase enzyme prevents the production of phosphoenolpyruvate (PEP), thereby disrupting the glycolysis cascade. Moreover, extreme leukocytosis (e.g., some cases of leukemia) can lower glucose after the sample is drawn, as the white blood cells will metabolize glucose. Activated white cells (as occurs in sepsis) will metabolize glucose at an increased rate. If whole blood glucose or capillary glucose is measured, polycythemia can produce artifactual hypoglycemia, because the plasma content of blood (e.g., "plasma crit") is reduced in polycythemic states.

Hypoglycemia can be classified as fasting or postprandial. Postprandial hypoglycemia (sometimes referred to as "reactive" hypoglycemia) can be a true occurrence in the setting of "dumping" syndromes that might follow gastric bypass. In these patients, if there is disordered gastrointestinal tract motility and a carbohydrate-rich meal rapidly delivered to the small intestine, there can be an initial, rapid rise in blood glucose possibly into the hyperglycemic range. In response to this acute hyperglycemia, there may be increased release of insulin producing transient hyperinsulinism, leading to a "reactive" hypoglycemia. This condition can be treated by limiting simple carbohydrate intake, decreasing the amount of carbohydrates eaten at any one time, and increasing the frequency of smaller meals. Five-hour oral glucose tolerance tests (OGTTs) should not be performed in search of "reactive hypoglycemia" [10−12]. Five-hour OGTTs can transiently display plasma glucose levels less than 40 mg/dL at 2 hours or later in otherwise healthy individuals. However, this "transient biochemical hypoglycemia" correlates poorly with symptoms of hypoglycemia. Many such patients are women with irregular eating habits, including skipped meals.

Fasting hypoglycemia can be a very serious medical condition that requires rapid and appropriate evaluation and treatment. Fasting hypoglycemia develops most commonly in the morning following an overnight fast, after skipped meals, and following rigorous physical activity.

Hypoglycemia can be elicited in the controlled environment of the hospital by fasting an individual for up to 72 hours. Failure to develop hypoglycemia after a 72-hour-monitored fast excludes medically important fasting hypoglycemia.

Fasting in the hospital setting for up to 72 hours may be needed to prove that fasting hypoglycemia is indeed present. During the fast, the subject is given nothing by mouth except glucose-free electrolyte solutions. Fasting is observed in inpatients in order to carefully record symptoms and signs of hypoglycemia while taking laboratory measurements of glucose-related metabolism and treating low blood glucose with intravenous (IV) glucose and/or glucagon should hypoglycemia occur. If hypoglycemia does occur during the fast, glucagon can be injected to observe the rise in glucose postinjection. An excessive rise in glucose following the injection of glucagon (e.g., the increase in glucose is $\geq 30-40$ mg/dL within ~ 45 minutes) supports the diagnosis of hyperinsulinism.

At baseline, plasma glucose is determined. Because hypoglycemic symptoms can become attenuated in some individuals affected with chronic and recurrent hypoglycemia, the blood glucose must be measured regularly (e.g., every 4 hours) at the POC and by the central laboratory. Urine samples are tested for ketones throughout the fast, as ketonuria is a normal response to fasting. Once the plasma glucose declines to below 60 mg/dL, venous blood draws can be increased to every 2 hours. The fast is continued until (1) symptoms of hypoglycemia are present; (2) the venous glucose is persistently <45 mg/dL (e.g., for at least 30 minutes); or (3) 72 hours have passed without either hypoglycemia or hypoglycemic symptoms developing. Once symptoms of hypoglycemia occur or the plasma glucose declines below 45 mg/dL, blood should be obtained for clinical studies listed below:

Test	Comment
Plasma glucose	Measured to diagnose hypoglycemia
Insulin	Measured to rule out hyperinsulinism (if elevated, measure C-peptide)
βHB and urine ketones	Assessment of ketosis
Optional measurements at the time of acute hypoglycemia	
Arterial blood gases	Measured to assess acid/base balance; acidosis is common in many disorders that cause hypoglycemia
Na^+, K^+, HCO_3^-, Cl^-, and urine pH	Measured to assess acid/base balance and anion gap; acidosis is common in many disorders that cause hypoglycemia
Drug screen/ethanol	Performed to rule out intoxication; ethanol can cause hypoglycemia
Cortisol	Measure when other causes are excluded
Growth hormone	Measure when other causes are excluded
Branched-chain amino acids	Assists in documenting the biochemical effects of hyperinsulinism; rarely needed
Lactic acid	Assessment for lactic acidosis and gluconeogenic defects
Free fatty acids	Assists in documenting the biochemical effects of hyperinsulinism or suspected fatty acid oxidation disorders
Urine dicarboxylic acids	Measured when an aminoacidopathy or fatty acid oxidation disorders are suspected

Mechanisms and causes of hypoglycemia

The product of pancreatic islet beta cells, insulin is an anabolic hormone that stimulates glucose uptake into skeletal muscle, adipose tissue, and hepatocytes. Insulin is initially synthesized as preproinsulin. Upon entry into the rough endoplasmic reticulum (RER), the presequence is cleaved and remains in the cytoplasm. Secretory granules then bud off from the RER. Within the secretory granule, proinsulin is cleaved into insulin plus C-peptide (C = connecting) by prohormone convertases Pc1/3 and Pc2, and carboxypeptidase E. For every molecule of insulin secreted by the beta cell into the portal system, one molecule of C-peptide will also be secreted. During passage through the liver, more insulin is removed than C-peptide so that the molar ratio of insulin to C-peptide in the systemic circulation is less than 1.

The effect of insulin is to lower plasma glucose concentrations. Within the liver, insulin stimulates glycolysis sparing fat for storage as triglyceride in adipose tissue. As well as the suppression of gluconeogenesis by insulin, amino acids are spared and are then available for protein synthesis. Hepatic glycogen synthesis is stimulated by insulin resulting in glucose being stored as glycogen. Once glycogen stores are filled, glucose is converted into triglyceride for further energy storage in adipose tissue.

Insulin rises in response to glucose absorption from the gastrointestinal tract. As plasma glucose concentrations rise, glucagon, the product of pancreatic islet alpha cells is suppressed. In the fasting state, insulin concentrations decline and glucagon concentrations rise. Low insulin concentrations and high glucagon concentrations stimulate gluconeogenesis, glycogenolysis, and lipolysis. Low insulin concentrations reduce glucose uptake by skeletal muscle, adipose tissue, and hepatocytes, whereas increased gluconeogenesis and glycogenolysis increase hepatic glucose output. Low insulin levels permit adipose tissue lipolysis, supplying fatty acids to the liver for ketogenesis. The resulting ketone bodies BHB and acetoacetate serve as alternative fuel sources sparing glucose.

Primary disorders of glucagon deficiency [13] and excess [14] are rare. Insulin excess is one of the most

severe and life-threatening causes of hypoglycemia. Deficient insulin action underlies most forms of diabetes.

Hypoglycemia occurs when glucose utilization exceeds glucose provision by the liver. The causes of hypoglycemia can be excess glucose demand (e.g., sepsis) or deficient hepatic supply of glucose (e.g., gluconeogenic defects or liver failure). Hyperinsulinism affects both processes: hyperinsulin causes increased glucose demand as tissue uptake of glucose is accelerated (e.g., skeletal muscle, adipose tissue, and the liver) and glucose production and release by the liver is suppressed.

Laboratory evaluation of hypoglycemia

The causes of fasting low blood glucose can be divided into hyperinsulinemic hypoglycemia and nonhyperinsulinemic hypoglycemia. The measurement of insulin at the time of hypoglycemia can help differentiate between these two causes. If the insulin-to-glucose ratio is ≥ 0.3 [(uIU/mL)/(mg/dL)], hyperinsulinemia is considered to be present. Some experts state that insulin should not be measurable in the plasma in the setting of hypoglycemia not due to hyperinsulinism.

The reference interval for fasting insulin alone should not be used to define hyperinsulinemia, because, in the cases of severe hypoglycemia, an insulin concentration within the normal range would still be excessive. Furthermore, because insulin suppresses ketosis, the absence of urine ketones in the face of hypoglycemia may also be suggestive of hyperinsulinemia. Absent urine ketones may also be reflective of defective ketogenesis, which is observed in fatty acid oxidation disorders (FAODs) in infants and children. Increased insulin concentrations will also inhibit elevations in free fatty acid (FFA) and alanine concentrations that would otherwise normally occur in a fasted state or hypoglycemic state in the absence of hyperinsulinism.

The sources of excess insulin can be endogenous or exogenous and the measurement of C-peptide can help differentiate these conditions. In the setting of hyperinsulinemic hypoglycemia, if the C-peptide is very low or undetectable, the source of insulin is likely to be exogenous, because injected insulin lacks C-peptide. If there has been repeated exposure to exogenous insulin, the subject may have developed insulin antibodies (IA).

A relative excess of exogenous insulin is a common occurrence in insulin-treated diabetic patients who skip meals, skip snacks before exercise, or exercise excessively.

In testing for exogenous insulin in insulin-naive patients (e.g., patients not previously treated with exogenous insulin), the clinical laboratorian must be aware of whether or not their insulin assay will detect the various forms of recombinant-DNA produced insulins that include intentional amino acid substitutions, an altered amino acid sequence, or the addition of myristic acid to insulin. The very rapid acting insulin analogues are lys-Pro (Humalog), aspart (Novolog) and glulisine (Apidra), while the long acting insulin analogues are glargine (Lantus) and determir (Levemer). Newer insulins continue to come to the market including insulin lispro (Admelog from Sanofi approved in December 2017) and insulin aspart (Fiasp from Novo Nordisk approved in September 2017), which includes L-arginine as a formula-stabilizing amino acid and niacinamide (vitamin B3), which speeds subcutaneous absorption.

Measuring insulin in insulin-treated patients is challenging, because most patients treated with exogenous insulin (regardless of the type of insulin, including human insulin) develop IA [15,16]. IA are found in $\sim$80% to $\sim$100% of insulin-treated patients [17–19]. IA develop after as little as 14 days of exogenous insulin treatment. IA usually increase total insulin levels, because IA act as binding proteins and both bound insulin and free insulin are measured by insulin immunoassays. Therefore total insulin measurements in IA-positive patients may not reflect free (and bioactive) insulin concentrations. However, free insulin assays are not standardized. Therefore there is no analytically robust method for measuring insulin in insulin-treated patients. Such measurements are usually misleading and may lead to diagnostic errors.

Most cases of hypoglycemia in insulin-treated patients are the result of accidental or intentional overtreatment with exogenous insulin. Unfortunately, a patient may need to be hospitalized and denied any access to insulin (other than as administered by the staff) to prove that hypoglycemia does not occur spontaneously. Consultation with psychiatry should be considered for possible Munchausen syndrome or Munchausen by-proxy syndrome. Many cases of "brittle diabetes" where glycemic control is very poor result from noncompliance with the administration of insulin. Again, hospitalization with insulin administered by staff may be required to prove that a person's diabetes can be controlled with standard doses of insulin.

When the insulin and C-peptide levels are both elevated, the source of excess insulin is endogenous. Endogenous hyperinsulinemia results from the ingestion of a medication that can stimulate pancreatic beta cells to secrete insulin (e.g., sulfonylureas or meglitinides), a beta cell tumor (i.e., insulinoma), beta-cell hyperplasia (e.g., nesidioblastosis in neonates), or an inborn error of metabolism producing neonatal hyperinsulinism. Hyperinsulinemia and hypoglycemia can be transient in neonates.

In the initial evaluation of "hyperinsulinemic-elevated C-peptide" hypoglycemia, sulfonylurea or meglitinide ingestion must be excluded by history and urine toxicology testing. Similar to the problem with detecting insulin analogues, later generation sulfonylureas may not be detected with older screening methods for sulfonylureas. Therefore the specificity of urine sulfonylurea testing

must be known to the clinician and the laboratorian to ensure that false-negative results are not reported.

If drug-induced hyperinsulinemia is excluded, the patient's evaluation will focus on the circumstances of hypoglycemia. Infants of diabetic mothers (IDMs) commonly display hypoglycemia after birth if the mother's diabetes was not well-controlled. Exposure to a hyperglycemic in utero environment elicits fetal hyperinsulinemia. When the umblilical cord is clamped following birth, glucose supply to the infant is abruptly curtailed yet hyperinsulinemia persists for some days or longer causing hypoglycemia. Sick premature infants, asphyxiated infants, and infants suffering from erythroblastosis fetalis may exhibit hypoglycemia from hyperinsulinemia. The pancreas of infants requiring partial pancreatecomy for persistent, severe hypoglycemia may demonstrate beta-cell hyperplasia that is histologically termed "nesidioblastosis." This is a histologic description and is not a diagnosis unto itself.

In an infant born of a nondiabetic mother who clinically presents with symptoms of hypoglycemia, familial hyperinsulinemia should be considered as a cause of neonatal persistent hyperinsulinemic hypoglycemia [20]. Several autosomal recessive inborn errors causing hyperinsulinemia have been reported involving: (1) beta-cell inwardly rectifier subunit of the potassium channel ($K_{ir}6.2$); (2) sulfonylurea receptor-1 (SUR1; which is part of the aforementioned $K_{ir}6.2$ potassium channel); (3) beta-cell glucokinase; and (4) glutamate dehydrogenase. These defects can be understood by examining the normal pathway of insulin secretion.

Insulin release from pancreatic beta cells involves: (1) initial glucose sensing; (2) ATP generation; (3) coupling energy production to calcium entry into the beta cell; and (4) insulin release (Fig. 34.1). Extracellular glucose enters pancreatic beta cells via the facilitative glucose transporter-2. Once inside the beta cell, glucose is phosphorylated by glucokinase, which is a specialized high-K_m hexokinase with limited expression. The enzyme is expressed in hepatocytes, beta cells, and intestinal mucosal cells. The rate of energy generation (e.g., ATP production/unit time) by the beta cell via glycolysis and the Krebs cycle is dependent on the rate of formation of glucose-6-phosphate. At higher plasma glucose concentrations (with higher interstitial glucose levels), the rate of formation of glucose-6-phosphate is greater, leading to increased insulin release (Fig. 34.2). ATP generated within the beta cell then binds to SUR1, which regulates the inwardly rectifier potassium channel $K_{ir}6.2$. Closure of this K^+ channel depolarizes the beta cell. With depolarization, calcium channels open, thereby increasing intracellular calcium that triggers insulin release as insulin-containing granules fuse with the plasma membrane. These granules also contain amylin, which is released together with insulin (and C-peptide).

If SUR1 is active in the absence of ATP, hyperinsulinemia results. Likewise, if $K_{ir}6.2$ closes in the absence of SUR1 stimulation, hyperinsulinemia ensues. Excessive glucokinase activity leads to hyperinsulinemia via an excessive rate of production of glucose-6-phosphate. Gain of function mutations in glutamate dehydrogenase

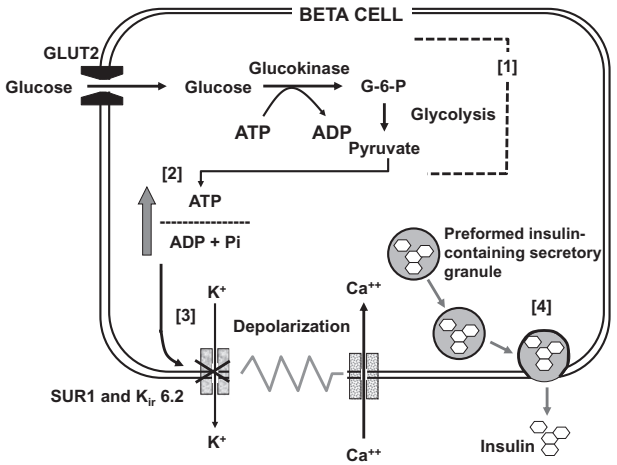

FIGURE 34.1 Insulin release is dependent on the interstitial glucose concentration. Interstitial and plasma glucose are in equilibrium and are essentially equal in concentration. Glucose enters the beta cell via glucose transporter-2. Once inside the beta cell, glucose is phosphorylated to glucose-6-phosphate as catalyzed by glucokinase, a special high Km hexokinase. Glucose-6-phosphate is converted into two pyruvate molecules that enter the mitochondrion where they undergo the Kreb citric acid cycle followed by oxidative phosphorylation and the production of ATP. An increase in the ratio of ATP to adenine dinucleotide phosphate plus Pi (inorganic phosphate) allows ATP to bind to the sulfonylurea receptor 1 closing the potassium channel ($K_{ir}6.2$). The entry of potassium into the beta cell causes beta-cell depolarization. A calcium channel opens leading to a rise in cytoplasmic calcium, which triggers insulin exocytosis.

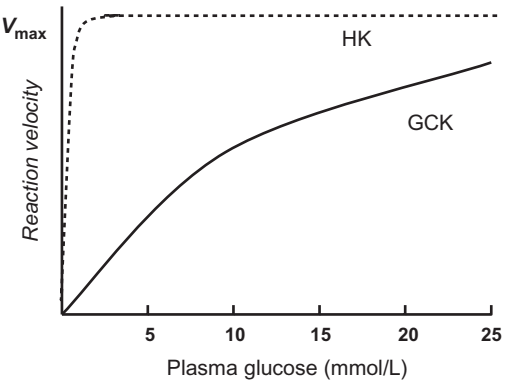

FIGURE 34.2 The high K_m glucokinase displays a rising reaction velocity in the formation of glucose-6-phosphate as interstitial glucose levels rise. A physiologic range for FPG is roughly 3.9 mmol/L (70 mg/dL) to 5.5 mmol/L (99 mg/dL). At higher glucose levels, the rate of formation of glucose-6-phosphate is increased (solid line), producing ATP at a higher rate causing greater degrees of insulin release. This is the basis for calling glucokinase the "glucose sensor" of the beta cell. Usually hexokinases display a maximum reaction velocity (V_{max}) at low glucose concentrations (*dotted line*).

produce excessive ATP production and subsequent hyperinsulinemia. Because of liver dysfunction, infants with glutamate dehydrogenase mutations can also exhibit hyperammonemia, which is a clinically useful finding in the evaluation of infants with congenital hyperinsulinism.

Insulinomas are relatively uncommon, and are diagnosed in only 1 in 1 million people per year [21]. However, the diagnosis may be difficult to establish. Some patients with proven insulinomas have had symptoms for up to 20 years. The diagnosis is based on the identification of a mass (or masses) within the pancreas using a variety of radiologic procedures, demonstration of hyperinsulinemia in a venous blood vessel draining the mass, resolution of symptoms after removal of the tumor, and immunohistological confirmation that the tumor contains insulin. Occasionally, tumors clinically suspected of secreting insulin do not stain vigorously. This may reflect recent discharge of insulin from the tumor. Although not a routine laboratory test, proinsulin levels can be disproportionally elevated in individuals with insulinomas. Proinsulin measurements are recommended by the Endocrine Society [22]; however, the basis for the recommendation is expert opinion.

Insulinomas are sometimes multifocal and not commonly malignant ($\sim$10% of all insulinomas are malignant). Malignancy in individual patients is demonstrated by the finding of metastases, for example, to the liver or regional lymph nodes. Multifocal insulinomas suggest a familial cancer syndrome such as multiple endocrine neoplasia (MEN) type 1 [23]. MEN type 1 is manifested as tumors of the pituitary, parathyroid, and pancreatic islets (the 3 "Ps"). The most common pituitary tumor is a prolactinoma. The most common pancreatic tumor is a gastrinoma. MEN type 1 is inherited as an autosomal dominant condition that results from a loss-of-function mutation in a tumor suppressor gene (menin; location: chromosome 11q13). Although localized to the nucleus, the specific function of menin remains controversial. Menin may link transcription factors and chromatin-modifying enzymes such as the histone H3K4 methyltransferase complexes (MLL1 and MLL2) [24].

If insulin concentrations are not inappropriately elevated in the setting of documented hypoglycemia, initially, a search for drugs other than sulfonylureas should be pursued. Ethanol is the most likely cause of hypoglycemia in the absence of increased insulin concentrations [25]. With the conversion of NAD^+ to NADH during ethanol oxidation, there is reduced availability of NAD^+ for the conversion of lactate to pyruvate and glutamate to alpha-keto glutarate. This results in impaired gluconeogenesis and possible hypoglycemia with fasting. Children are particularly sensitive to ethanol-induced hypoglycemia because of an increased brain-to-liver ratio (i.e., glucose consumption versus glucose production) and lower muscle mass (than adults), providing lower amounts of gluconeogenic amino acids with fasting (e.g., alanine). Other drugs causing hypoglycemia include acetaminophen via its toxic effect on the liver and propranolol, which blocks epinephrine action. Epinephrine is one of two counter regulatory hormones that protect us from acute hypoglycemia. The other hormone is glucagon. Growth hormone (GH) and cortisol provide longer-term protection from hypoglycemia by providing alternative energy sources via increased FFA production and causing insulin resistance. Cortisol also stimulates the synthesis of gluconeogenic enzymes.

Assuming that the toxicology and ethanol screens are negative, cortisol should indeed be measured. A discussion on cortisol deficiency and testing can be found in Chapter 41, Disorders of the adrenal cortex and medulla. In children, in the absence of hypocortisolism, growth hormone deficiency should next be sought (see Chapter 39: Disorders of the anterior and posterior pituitary). Deficiencies of glucagon and epinephrine essentially only occur in the setting of diabetes mellitus of 5 or more years of duration. Deficiencies of these key counter regulatory hormones may reflect some form of autonomic neuropathy. In the absence of diabetes, the rarity of epinephrine and glucagon deficiency indicates that both hormones are essential for survival.

Having excluded drugs and hormone deficiencies as causes of hypoglycemia, if not already studied, liver and renal function should be investigated using standard laboratory profiles. Any severe liver disease can cause fasting hypoglycemia, because during fasting, the liver is the single major source of circulating glucose. Renal disease is a rare cause of hypoglycemia. The kidneys have about 10% of the gluconeogenic capacity of the liver.

Hypoglycemic conditions in children

Unexplained hypoglycemia in children under age 5 should elicit a search for inborn errors of metabolism assuming other causes of hypoglycemia have been excluded.

The clinical onset of hereditary fructose intolerance occurs with the introduction of table sugar (sucrose; glucose plus fructose) into the infant's diet (Fig. 34.3). This usually occurs at nearly 6 months of age. The presentation of hereditary fructose intolerance includes vomiting postingestion of sucrose, failure to thrive, liver dysfunction,

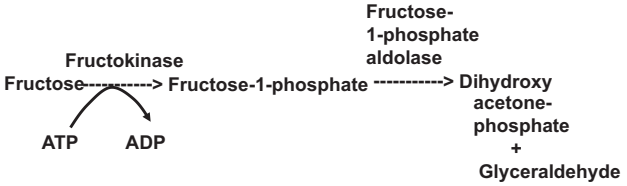

FIGURE 34.3 Benign fructosuria results from a deficiency of fructokinase. Hereditary fructose intolerance results from a deficiency of fructose-1-phosphate aldolase.

and consequent hypoglycemia. The diagnosis of hereditary fructose intolerance is made via fructose-1-phosphate-aldolase enzyme activity; chromatographic detection of fructose in urine can also support a diagnosis of fructose intolerance. Removing fructose and sucrose from the diet is the recommended treatment for hereditary fructose intolerance. Even with this dietary intervention, some children with a severe form of the disease may develop serious liver disease. Benign (essential) fructosuria results from a deficiency of fructokinase (Fig. 34.3). Fructose, sucrose, and sorbitol ingestion leads to persistent and excessive increases in blood fructose concentrations. About 10%–20% of these ingested sugars are excreted in the urine.

A cause of hypoglycemia believed to be due to substrate limitation is termed "ketotic hypoglycemia" [26]. Thin children (more commonly boys) of low birth weight between ages 18 months and 5 years who fast and develop hypoglycemia and ketosis without an identifiable inborn error are categorized as having "ketotic hypoglycemia." Insulin concentrations are appropriately suppressed in these individuals. This condition is a diagnosis of exclusion, although low alanine levels have been observed in conjunction with the hypoglycemic episode [27]. Lactate and pyruvate concentrations are within normal reference intervals. Ketotic hypoglycemia usually resolves spontaneously by 8–9 years of age.

If the liver is enlarged (with or without splenomegaly), a glycogen storage disease (GSD) should be considered [28]. Lactate and pyruvate are important measurements when considering gluconeogenic defects. GSD type 0 (zero), I (Fig. 34.4), III (Fig. 34.5), and VI (Fig. 34.6) may all present with hypoglycemia. GSD 0a is a deficiency of liver glycogen synthase encoded by the *GYS2* gene on chromosome 12p12.2 [29]. Glycogen synthase normally transfers glucose from uridine diphosphate (UDP)-glucose to glycogen's terminal branch. This disorder does not cause hepatomegaly, because excess glycogen is not produced. In the absence of increased glycogen production, fasting ketotic hypoglycemia results. Clinically, there may be muscle abnormalities, but intellectual development is usually normal. Reduced bone mineral density and short stature are also common in affected children.

In GSD type I (Von Gierke disease), glucose cannot be released from the liver, and similar to most other forms

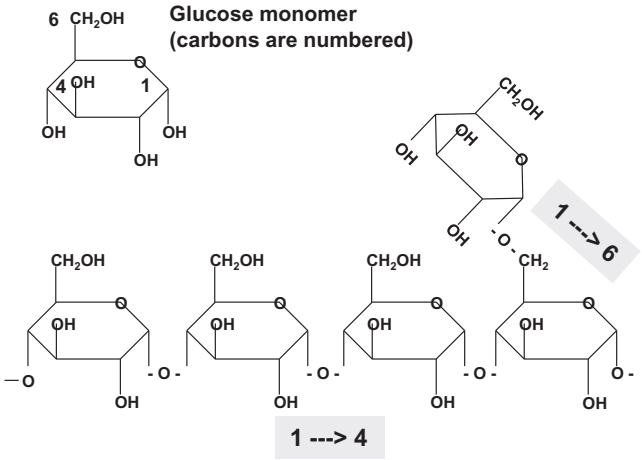

FIGURE 34.5 Glycogen storage disease type III results from a deficiency of the debrancher enzyme: amylo-[1 -> 6]-glucosidase. "1 --- > 6" depicted 1–6 branched linkages, whereas "1 --- > 4" depicts 1–4 linear linkages.

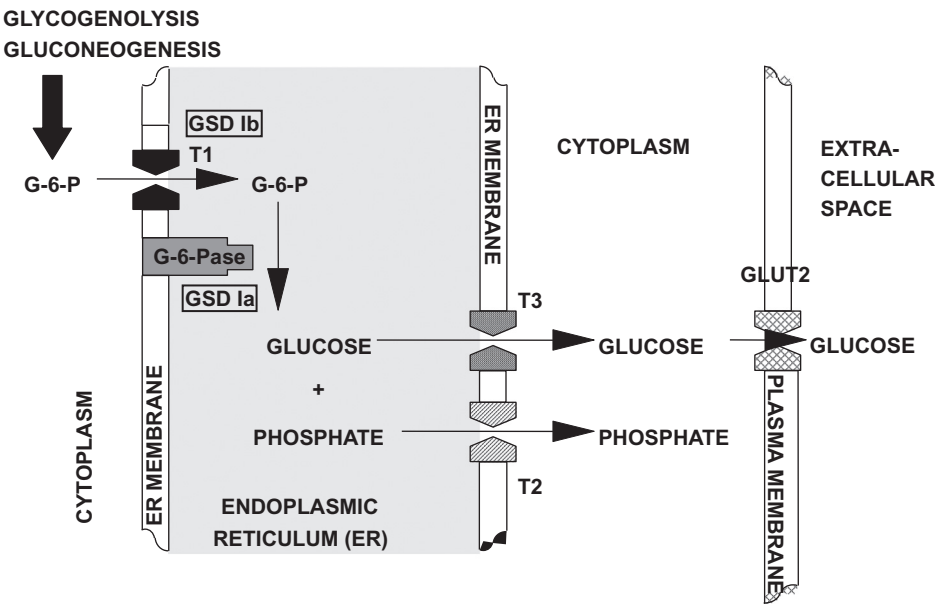

FIGURE 34.4 Glycogen storage disease types Ia and Ib are depicted. In the hepatocyte during fasting, glucose-6-phosphate results from glycogenolysis and glucoenogenesis. T1 transports glucose-6-phosphate into the endoplasmic reticulum, where glucose-6-phosphatase cleaves glucose-6-phosphate to glucose plus phosphate. T3 transports glucose into the cytoplasm, whereas T2 transports phosphate into the cytoplasm. Glucose passively leaves the hepatocyte via glucose transporter-2. *G-6-P*, Glucose-6-phosphate; *G-6-Pase*, glucose-6-phosphatase; *GLUT*, glucose transporter.

of GSD, hepatomegaly results [30]. Impaired gluconeogenesis causes hypoglycemia with fasting. There are two confirmed types of GSD type I: GSD Ia—glucose-6-phosphatase deficiency (the most common form of GSD I; the *G6PC* gene)—and GSD Ib—T1 transporter deficiency (the *SLC37A4* gene); notably, neutropenia is commonly present in the latter deficiency. With an interruption in the Cori cycle resulting from impaired gluconeogenesis in GSD type I, lactate concentrations rise, causing an anion-gap acidosis. Hypoglycemia and acidosis appear to be responsible for impaired growth in children with untreated or undertreated GSD type I. Because uric acid and lactate compete for urinary excretion via the same transporter system, hyperuricemia can result, causing gout. Since pancreatic beta cells are functioning normally, hypoglycemia suppresses release of insulin. This can lead to ketosis, elevated FFA levels, and hyperlipidemia. GSD type I is treated through nasogastric infusions of starch to prevent GSD I-related hypoglycemia [31].

GSD type I is just one type of defect that can lead to impaired gluconeogenesis. Other enzyme defects that interfere with normal gluconeogenesis include deficiencies of fructose-1,6-bisphosphatase, PEP carboxykinase, and pyruvate carboxylase (Fig. 34.7). All of these conditions can produce lactic acidosis because of impairment of the Cori cycle, thereby preventing lactate-to-glucose recycling.

GSD type III results from a deficiency of the debrancher enzyme amylo-[1 -> 6]-glucosidase. The liver and skeletal muscle are affected. GSD type VI is the consequence of phosphorylase or phosphorylase kinase deficiency. Phosphorylated phosphorylase (i.e., phosphorylase a) liberates glucose-1-phosphate residues from glycogen. Active phosphorylase kinase phosphorylates phosphorylase b to phosphorylase a.

In the setting of hypoglycemia if: (1) ketones are absent; (2) insulin is suppressed; and (3) FFA concentrations are elevated, the search for an FAOD should be undertaken. The differential diagnosis includes systemic carnitine deficiency, carnitine palmityl transferase deficiency, acyl-CoA dehydrogenase deficiency, medium chain acyl-CoA dehydrogenase deficiency, glutaric aciduria type II (multiple acyl-CoA dehydrogenase deficiencies), and hydroxymethylglutaryl coenzyme A lyase deficiency. Hypoglycemia develops in such FAODs, because ketones normally provide an

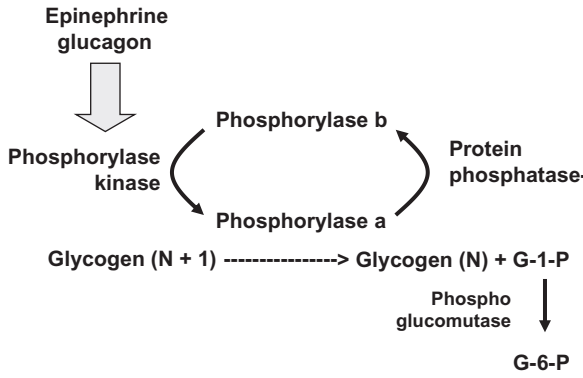

FIGURE 34.6 Glycogen storage disease type VI results from a deficiency of phosphorylase or phosphorylase kinase. The normal actions of epinephrine and glucagon are to activate phosphorylase kinase converting phosphorylase b into phosphorylase a Phosphorylase a cleaves one glucose-1-phosphate unit from glycogen. Phosphoglucomutase converts glucose-1-phosphate into glucose-6-phosphate. Protein phosphatase-1 converts phosphorylase a into phosphorylase b. *G-1-P*, Glucose-1-phosphate; *G-6-P*, glucose-6-phosphate.

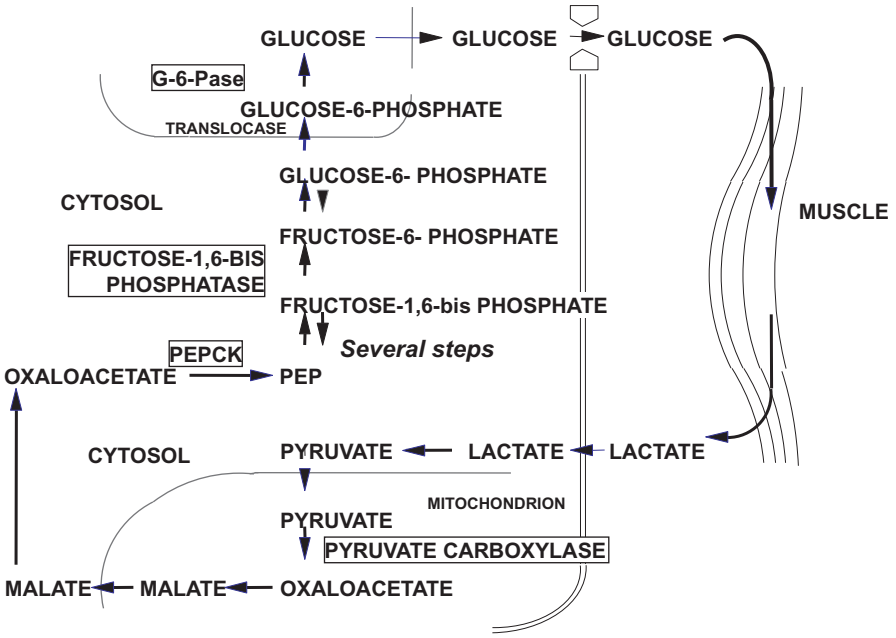

FIGURE 34.7 Gluconeogenesis is outlined. The key (irreversible) gluconeogenic enzymes are pyruvate carboxylase, phosphoenolpyruvate carboxykinase, fructose-1,6-bisphosphatase, and glucose-6-phosphatase.

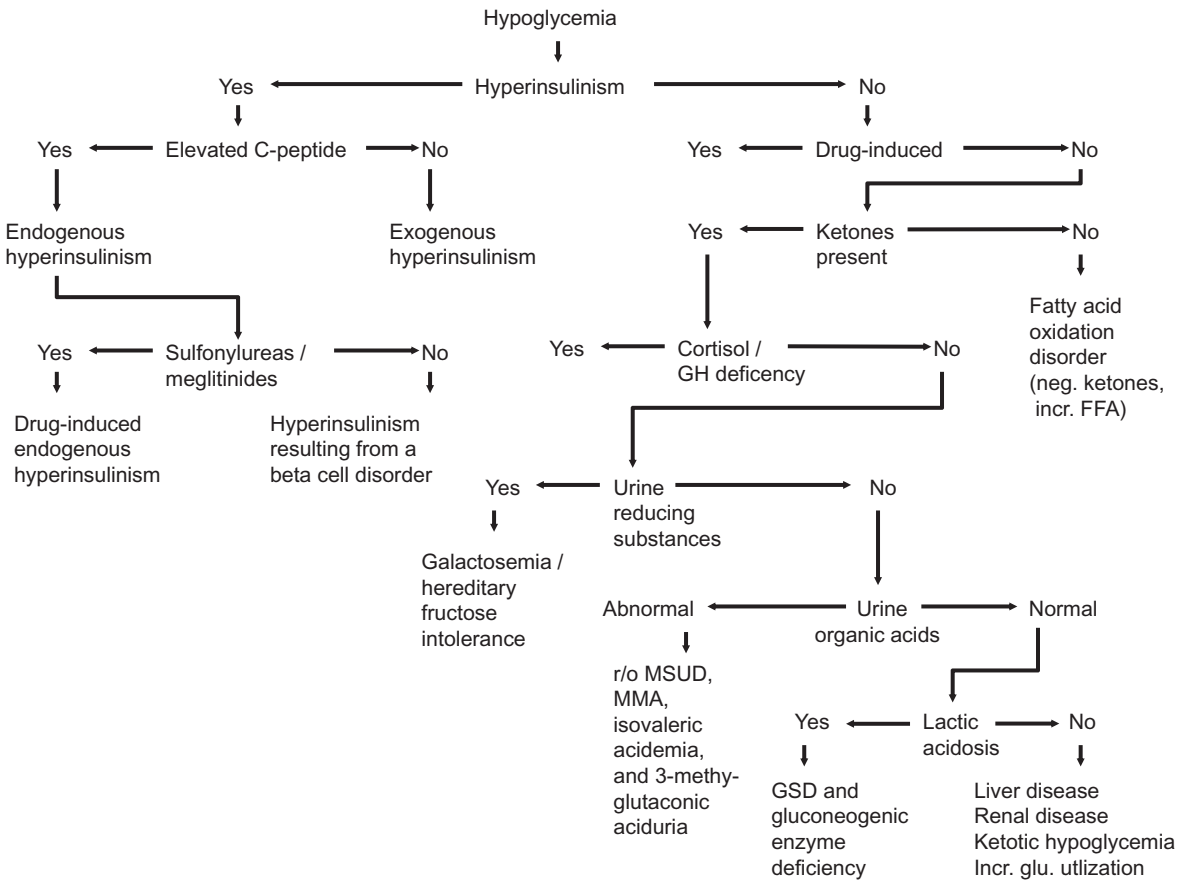

FIGURE 34.8 Overview of a reasonable approach to the evaluation of hypoglycemia. *FFA*, Free fatty acids, *GH*, growth hormone, *glu.*, glucose; *GSD*, glycogen storage disease; *incr.*, increased; *MMA*, methylmalonic aciduria; *MSUD*, maple syrup urine disease; *Neg.*, negative.

alternative energy source during times of fasting. Without these alternative energy sources, the body is more dependent on glucose for its fasting energy needs, thereby increasing the likelihood of hypoglycemia in infants and children. Screening for FAODs via mass spectrometric techniques has become routine in the United States [32]. Amino acidopathies can produce hypoglycemia, likely via impairment of hepatic function. Such amino acid disorders that can lead to hypoglycemia include methylmalonic aciduria, maple syrup urine disease, isovaleric acidemia, 3-methyl-glutaconic aciduria, and tyrosinemia type I. Specific testing for FAODs, amino acidopathies, and disorders of organic acids is beyond the scope of this chapter. Such investigations can encompass measurements of plasma amino acids, urine organic acids, ketones, lactic acid, carnitine, and FFAs.

Fig. 34.8 provides an overview of a reasonable approach to the evaluation of hypoglycemia. Testing is influenced by the age of the patient. Inborn errors of metabolism would likely not be part of the differential diagnosis of hypoglycemia in teenagers or adults. Even though liver and renal disease are listed at the terminal branch of the nonhyperinsulinemic hypoglycemia decision tree, in reality, liver function and renal function would be some of the earliest tests performed. "Increased glucose utilization" refers to conditions such as hypoglycemia occurring in children with cyanotic heart disease and hypoglycemia occurring in the setting of sepsis.

Hyperglycemia

Chronic hyperglycemia with the development of long-term complications constitutes the clinical description of diabetes mellitus. In Greek, diabetes means "siphon" referring to the polyuria that diabetic subjects suffer from. Mellitus in Greek means "sweet."

The complications of diabetes are classified as macrovascular, microvascular, neuropathic, and perinatal in cases of diabetes in pregnancy. Macrovascular disease manifests as premature and severe coronary, carotid, and/or peripheral vascular atherosclerosis. Retinopathy and nephropathy are the primary microvascular concerns associated with diabetes. Neuropathies can affect a single cranial nerve (i.e., mononeuropathies) or, more commonly, peripheral nerves (i.e., polyneuropathies). Polyneuropathies are expressed as sensory-motor deficits, painful neuropathies, or paresthesias (a "pins-and-needles" sensation). Autonomic neuropathies

can produce impotence, hypotension upon arising to the standing position, loss of beat-to-beat variation, gastroparesis (decreased intestinal motility), or "diabetic" diarrhea. Diabetes in pregnancy is discussed below in the section on "Gestational diabetes mellitus." Presently, four major categories of diabetes are recognized: T1DM, type 2 diabetes (T2DM), other specific types of diabetes, and gestational diabetes mellitus (GDM) [33].

Pathophysiologically, decreased insulin action of any cause leads to hyperglycemia. Insulin action is the product of the plasma insulin concentrations and the insulin sensitivity of target tissues. Insulin receptor variants rarely arise; thus insulin resistance is almost always a postreceptor aberration. When plasma glucose concentrations exceed 150−180 mg/dL, the renal threshold for glucose reabsorption by the renal tubules is exceeded and glycosuria develops. This is manifested as polyuria (increased urination) that results from an osmotic diuresis. Children may suffer from enuresis (bed wetting), while both adults and children can experience nocturia (urinating at night). Polydipsia (increased drinking) is a physiologic response to increased urinary fluid loss. Glycosuria can cause urinary sodium, potassium, magnesium, bicarbonate, and phosphate wasting. Hyperglycemia associated with plasma glucose concentrations ≥250 mg/dL also impairs normal neutrophil function, thereby producing an acquired defect in the innate immune system and increased risk of bacterial and fungal infections. Poor wound healing is typical in individuals with poorly controlled diabetes. This can result from impaired microvascular circulation, dehydration, acidosis, and/or neutrophil impairment.

Type 1 diabetes

T1DM results from autoimmune destruction of the pancreatic beta cells [34]. Seventy-five percent of patients develop T1DM prior to 18 years of age. While patients are usually lean at the time of onset, because the endemic frequency of obesity has reached epidemic proportions, obesity should not exclude the diagnosis of T1DM. Up to 15% of persons with T1DM will have a similarly affected first-degree relative. Northern Europeans and Caucasian North Americans are most commonly affected. The highest prevalence of T1DM is in Finland, where ~1 in 100 people are affected with T1DM. T1DM is rare in Asia. The frequency of T1DM in Japan is ~1 in 10,000 (a rate one−one hundredth of that observed in Finland).

At onset, one or more islet autoantibodies can be found in ≥95% of T1DM individuals [35]. The most common islet autoantibodies at onset are islet cell cytoplasmic autoantibodies (ICA) and glutamic acid decarboxylase autoantibodies (GADA). Each autoantibody is present in 70%−80% of new-onset patients. Insulinoma-associated-2 autoantibodies and zinc transporter 8 (ZnT8A) autoantibodies are slightly less common at onset (~60%). Insulin autoantibodies (IAA) are detected in ~50% of children at T1DM onset; however, IAA are uncommon in adults. The GADA, IA-2, IAA, and ZnT8A are measured by immunoassay, whereas ICAs are measured by indirect immunofluorescence. In the case of IAA, assays do not discriminate IAA from IA that are developed as a consequence of exposure to exogenous animal or human insulin. Therefore IAA should be measured within 14 days of the initiation of insulin therapy. After that time, IA can emerge in insulin-treated patients.

From a genetic point of view, the alleles human leukocyte antigen (HLA)-DR3, HLA-DR4, HLA-DQB1*0201, and HLA-DQB1*0302 are increased in frequency in T1DM subjects compared with the general population. These alleles are genetic variants of various class II major histocompatibility complex protein chains. Heterozygosity for HLA-DR3 and HLA-DR4 increases the risk of developing T1DM by a factor of 12. However, the absolute risk of T1DM is still "relatively" low as only 1 in 40 such heterozygotes develop T1DM. The alleles HLA-DR2 and HLA-DQB1*0602 are far less common in T1DM individuals than in controls, and therefore these alleles are considered to be protective of T1DM. Only 1 in 5000 people with T1DM carry an HLA-DR2 allele. The second most important gene locus for T1DM is the insulin gene (e.g., the variable number of tandem repeats region 5' of the insulin gene). More than 10 other genes or loci have been implicated as influencing the development of T1DM [36]. Such other loci include protein tyrosine phosphatase, nonreceptor type 22, cytotoxic T-lymphocyte-associated protein 4, and the IL-2 receptor alpha chain. At the present time, genetic testing is predominantly a research tool.

A slowly progressive variant of T1DM seen in adults that initially presents as "noninsulin dependent diabetes," where GADA or ZnT8A are positive, is termed "latent autoimmune diabetes of adulthood (LADA)" [37]. Subjects who present with a "noninsulin dependent diabetes" phenotype that carries HLA-DR3 or DR4 are likely to express an islet autoantibody (most commonly GADA or ZnT8A) and are more likely to become insulin requiring compared with DR3/DR4-negative T2DM subjects.

With poor diabetic control and consequent unrestrained gluconeogenesis in T1DM, weight loss occurs as protein is metabolized to glucose. Weight loss also results from accelerated conversion of fat into ketone bodies because of severe insulin deficiency. Polyphagia (increased eating) can be a response to weight loss. Weight loss despite increased caloric intake is characteristic of untreated T1DM. With severe insulin deficiency, ketosis is not restrained leading to an anion gap acidosis [38]. Massive hyperglycemia also results with the plasma glucose concentrations regularly exceeding 500 mg/dL. Hyperosmolarity then ensues. Early on, ketosis is evident in the finding of urinary ketones (e.g., the urine

Acetest is positive). As the plasma concentration of ketones rises (i.e., increased beta-hydroxybutyric acid and acetoacetic acid), nausea with vomiting results. Fluid loss from polyuria compounded by decreased fluid intake because of nausea and vomiting and extreme ketosis can precipitate the clinical syndrome of DKA. As fluid depletion becomes more severe, lactic acidosis from hypovolemia and impaired microvascular tissue perfusion can supervene.

Untreated DKA results in a worsening cycle of hypovolemia, acidosis, impaired perfusion, declining cardiac output, impaired mentation, coma, and death. Children can develop cerebral edema and die of foraminal herniation, where displacement of the cerebellar tonsils through the foramen magnum compresses the brain stem. DKA is treated through the administration of IV fluids and an insulin infusion that halts ketosis, corrects acidosis, and lowers plasma glucose. The etiology of cerebral edema in children is controversial [39]. However, excessive fluid administration in children should be avoided. A recent study reported: "Neither the rate of administration nor the sodium chloride content of intravenous fluids significantly influenced neurologic outcomes in children with diabetic ketoacidosis" [40].

The diagnosis of T1DM is based on the findings of severe hyperglycemia, polyuria, and polydipsia and supported by a history of polyphagia, weight loss, and ketosis. Excluding obese adolescent African Americans, where DKA can occur in the setting of untreated T2DM, DKA is pathognomonic of T1DM. At diagnosis, 30% of children with T1DM still present with DKA. If the diagnosis of T1DM is in doubt, for example, a suspected case of LADA, islet autoantibody testing should be ordered. DKA in children has a mortality of $\sim$0.5%. In adults, 10%−15% of patients with DKA will succumb because of the frequent coexistence of serious disorders of the heart, lung, liver, and/or kidney.

Measurements of BHB can be helpful in diagnosing ketoacidosis. Clinicians will usually follow BHB concentrations during the treatment of DKA. Successful treatment of DKA includes a reduction in BHB concentrations into the reference interval. Despite our enthusiasm for BHB measurements, DKA can be managed successfully without such measurements [41]. Crushed "Acetest" tables should not be used to titrate blood ketones. This nitroprusside reaction is not specific for ketones. In addition, Acetest tables are no longer manufactured.

Type 2 diabetes

Approximately 95% or more of non-GDM diabetes cases are accounted for by T1DM or T2DM. Furthermore, T2DM is 9−10 times as common as T1DM. T2DM results from a combination of insulin resistance and relative insulinopenia. T2DM is not autoimmune in etiology and affected patients are negative for islet autoantibodies (including IAA). Islet autoantibodies in persons with clinically diagnosed T2DM indicate that such individuals actually have a slowly progressive form of T1DM termed "LADA." Insulin resistance is most commonly a consequence of obesity. Until recently, T2DM was observed almost exclusively in people over age 40. However, with the epidemic of childhood and young adult obesity, T2DM can now be observed well before age 40. Women are affected more often than men predominantly because of their higher rates of obesity and lower lean body mass. A family history of T2DM is very common in affected individuals. T2DM is two or more times as common in minorities (e.g., African American, Hispanic American, Asian American, Native American, and Pacific Islander) as in Caucasians. The onset of T2DM can be very subtle. In the absence of screening programs for T2DM, up to 15% of adults with T2DM display microvascular complications at onset suggesting that dysglycemia (e.g., an abnormal glucose level) has been present for long periods of time prior to the formal clinical diagnosis of T2DM.

An unusual complication of T2DM is the development of HHS (once termed: hyperosmolar, hyperglycemic, nonketotic coma) [42]. In this condition, often under stress, severe hyperglycemia develops in a patient with T2DM. Ultimately plasma glucose levels can exceed 1000 mg/dL. There is sufficient insulin produced to avoid ketosis, yet coma develops from dehydration and hyperosmolarity. Because of severe polyuria from massive glycosuria, circulating blood volume becomes depleted. When renal blood flow declines sufficiently, urine output does begin to decline. However, this decline in urine output now only further worsens the patient's hyperglycemia as less glucose is cleared through the kidney due to glycosuria. HHS is treated by gradual rehydration and an insulin infusion to reduce the plasma glucose level. HHS has been recognized as a cause of death in obese African Americans (particularly males) at the onset of T2DM [43].

Other specific types of diabetes

Other specific types of diabetes encompass eight major subcategories: (1) genetic defects in beta-cell function (e.g., insulinopathies, hyperproinsulinemias, maturity-onset diabetes of youth, and mitochondrial diabetes) [44]; (2) genetic defects in insulin action (e.g., lipodystrophy and insulin receptor mutations observed in Rabson−Mendenhall syndrome and leprechaunism syndrome); (3) diseases of the exocrine pancreas (e.g., chronic pancreatitis, cystic fibrosis, and hemochromatosis); (4) endocrinopathies (e.g., acromegaly, Cushing syndrome, and pheochromocytoma); (5) drug- or chemical-induced diabetes (e.g., glucocorticoids, growth hormone, and pentamidine); (6) infections (e.g., congenital rubella,

meningitis, and sepsis); (7) uncommon forms of immune-mediated diabetes [e.g., type B insulin resistance (insulin receptor autoantibody-mediated)]; and (8) other genetic syndromes associated with diabetes [e.g., type A insulin resistance, myotonic dystrophy, and Down, Klinefelter, Turner, Prader-Willi, Lawrence−Moon−Biedle, Werner, Cockayne and Wolfram (diabetes insipidus−diabetes mellitus−optic atrophy−deafness) syndromes].

Genetic defects in beta cell function account for the neonatal diabetes syndromes [45]. The neonatal diabetes syndromes can result from chromosome 6q24 imprinting anomalies, K_{ATP} channel mutations involving Kir6.2 (*KCNJ11*) or SUR1 (*ABCC8*), transcription factor mutations [e.g, HNF-1alpha (MODY3); IPF-1 (MODY4); FoxP3 (the IPEX syndrome), PTF1A, GLIS3, and HNF-1beta (MODY5)], enzyme loss-of-function mutations (e.g., glucokinase and eukaryotic translation initiation factor 2-alpha kinase 3), and insulin gene mutations.

Gestational diabetes mellitus

GDM is diabetes that is diagnosed during pregnancy [46,47]. The consequences to the fetus can be significant. Maternal hyperglycemia produces fetal hyperglycemia with consequent fetal hyperinsulinemia. As described above, such IDMs are at risk for neonatal hypoglycemia when, following delivery, clamping and cutting of the umbilical cord abruptly terminate the hyperglycemic state yet hyperinsulinemia continues. IDMs are physically large, which can lead to mechanical problems with delivery (dystocia) that may necessitate caesarian section. However, IDMs are biochemically less mature than age-matched control infants. IDMs suffer higher rates of hypocalcemia, hyperbilirubinemia, and respiratory distress syndrome. Because of the rising prevalence of T2DM in women of reproductive age, diabetes screening early in pregnancy is necessary to detect undiagnosed diabetes that existed prior to pregnancy. The biochemical diagnosis of GDM will be discussed below.

If diabetes is present prior to the pregnancy and the mother's glycemic control in the first trimester is not optimal, there is a threefold increased risk of the fetus suffering a birth defect. While ~3% of all infants have a recognizable birth defect, ~10% of IDMs whose mother was not in good glycemic control exhibit a birth defect. Excellent maternal diabetic control preceding conception and continuing during the pregnancy reduces the risk of birth defects to the level seen in the general population.

Diagnosis of diabetes mellitus

In patients with classical symptoms of diabetes including DKA, HHS, or polyuria and polydipsia, the demonstration of unequivocal hyperglycemia (e.g., a random plasma glucose level of 200 mg/dL or greater) on a single occasion meets the diagnostic definition of diabetes. Other markers of hyperglycemia include: (1) a fasting plasma glucose (FPG) of 126 mg/dL or greater; (2) a 2-hour glucose result of 200 mg/dL or greater during an oral glucose tolerance test (OGTT); or (3) a hemoglobin A1c result of 6.5% or greater. However, in persons presenting with DKA, HHS, or acute symptoms, most physicians would order a random plasma glucose measurement as opposed to ordering an FPG, an OGTT, or a hemoglobin A1c.

Excluding such classical symptoms, the diagnosis of diabetes rests upon the recognition of hyperglycemia on two different occasions. Hyperglycemia is defined as follows: (1) an FPG level of 126 mg/dL or greater; (2) as part of an OGTT, a 2-hour plasma glucose level of 200 mg/dL or greater; or (3) a hemoglobin A1c level of 6.5% or greater. Any combination of hyperglycemic criteria is adequate to diagnose diabetes; however, it is preferred that the same test be repeated on different days (e.g., if the FPG was elevated initially, the second test should be an FPG measurement). In the 2020 American Diabetes Association (ADA) clinical practice recommendations, 2 glucose abnormalities on a single day were added as an option in diagnosing diabetes. Therefore the following abnormalities identified on a single day can diagnose diabetes: (1) elevated FPG and elevated hemoglobin A1c, (2) elevated 2-hour plasma glucose during the OGTT and elevated hemoglobin A1c, or (3) elevated FPG and elevated 2-hour plasma glucose during the OGTT.

Blood for plasma glucose measurement is preferably placed in a gray top tube, because within 1 hour, NaF inhibition of glycolysis is complete. If blood is placed in a red top tube for serum glucose measurement or in a green top tube for plasma glucose measurement, the glucose concentration will decline by at least 2%−3% per hour. This is problem can be minimized if the sample can be rapidly centrifuged and the plasma or serum separated (note: for serum, blood should be allowed to clot for ~10 minutes prior to centrifugation). With delayed sample delivery to the laboratory, a substantial decline in the glucose concentration can be observed potentially leading to the missed diagnosis of diabetes. If a gel separator tube is used, once the sample is spun, the plasma or serum above the gel will be stable for up to 18 hours at 24°C and stable for up to 36 hours at 4°C [48].

Oral glucose tolerance test

In nonpregnant women, men, and children, the 2-hour, 2-time point OGTT is carried out following an overnight fast of 8−14 hours. A baseline (zero time) plasma glucose level is drawn and then a 75-g oral glucose load is

administered. Time zero is when the subject begins to drink the glucose beverage. The subject should finish drinking the beverage in 5 minutes or less. However, it is recommended that the glucose beverage should not be drunk rapidly, as this can induce nausea or even vomiting (especially in pregnant women). The concentration of glucose in the beverage should not exceed 25 g/100 mL. Children are administered 1.75 g/kg to a maximum dose of 75 g of glucose. At time 2 hours, a second plasma glucose level is obtained. During the test, the subject should remain sedentary. Other than water on the morning of the test, the subject should take no food, medications, or caffeine and should not smoke. The patient should be in their usual state of health, at a stable weight, and on their usual diet. The subject should not be acutely ill and should not have been recently hospitalized as this could cause a transient abnormality of glucose tolerance and a falsely abnormal OGTT. To prepare for the OGTT, for ~3 days prior to testing, the subject should ingest a minimum of 150 g of carbohydrate per day.

Whereas insulin resistance and hyperinsulinism are the characteristics of T2DM, there is no recommendation from the ADA that insulin or C-peptide be measured in the diagnosis of any form of diabetes. Furthermore, hyperinsulinemia may not persist in long-standing T2DM as progressive beta-cell failure can occur. Only when insulin or C-peptide levels are very high (e.g., T2DM) or extremely low (e.g., T1DM) might they be of diagnostic value. In comparing patients with T1DM and T2DM, there is considerable overlap in the distributions of insulin and C-peptide levels. Because the measurement of insulin and C-peptide may lack diagnostic value, insulin or C-peptide should not be measured as a routine part of the OGTT. In addition, while there is reference interval data for fasting insulin levels, there is little data on "normal" insulin responses to oral glucose.

The normal 2-hour plasma glucose during an OGTT is less than 140 mg/dL. The OGTT has no validated utility in the management of diabetes. The cutoffs defining normal and hyperglycemia are summarized below.

Time	Normal cutoffs		Hyperglycemia cutoffs	
	mg/dL	(mmol/L)	mg/dL	(mmol/L)
0	<100	<5.6	≥126	(≥7)
2	<140	<7.8	≥200	(≥11.1)

The American Diabetes Association and various other professional societies [i.e., American Association for Clinical Chemistry (AACC)] now recommend hemoglobin (Hb) A1c measurements for screening and the diagnosis of diabetes. Hyperglycemia is present when the Hb A1c is 6.5% or greater.

Prediabetes

In the absence of hyperglycemia, an FPG level of 100 mg/dL to 125 mg/dL identifies "impaired fasting glucose (IFG)." Similarly, concerning the OGTT, a 2-hour plasma glucose of 140−199 mg/dL identifies "impaired glucose tolerance (IGT)." Hb A1c values between 5.7% and 6.4% also indicate an increased risk of developing diabetes. Collectively, these carbohydrate abnormalities are termed "prediabetes." Note however that prediabetes is not a diagnosis or a disease. Prediabetes is a descriptive term. While IFG dates from 1997, IGT is a term that has been used for over 40 years.

The significance of IFG, IGT, and Hb A1c's of 5.7%−6.4% is that affected individuals have a 25%−50% chance of progressing to T2DM unless the individual changes their lifestyle to lower their caloric intake, exercise, and lose weight. Certain medications such as metformin have also been shown to decrease the rate of progression to T2DM. However, diet and exercise are twice as successful as metformin at reducing progression to T2DM [49,50].

Diagnosis of gestational diabetes mellitus

The term GDM is now restricted to diabetes, which is first diagnosed in the second or third trimesters of pregnancy. Diabetes diagnosed in the first trimester of pregnancy most likely represents preexisting or newly developed T2DM recognizing that T1DM will rarely present during pregnancy. Pregnant women with marked obesity, a previous personal history of GDM, glycosuria, or a strong family history of diabetes should be tested for diabetes as soon as it is feasible [33]. If diabetes is not diagnosed previously or is not diagnosed in the first trimester, all women should be tested for GDM between 24 and 28 weeks using one of two possible approaches.

In the one-step approach to GDM screening, between 24 and 28 weeks gestation, a fasting, 2-hour, 75-g OGTT is carried out. GDM is diagnosed when any one of the plasma glucose cutoff levels is met or exceeded:

Time	Cutoffs	
	mg/dL	(mmol/L)
0	92	(5.1)
1	180	(10.0)
2	153	(8.5)

In the two-step approach, between 24 and 28 weeks gestation, a nonfasting, 1-hour, 50-g OGTT is carried out. If the glucose is equal to or greater than 140 mg/dL, then the fasting, 3-hour, 100-g OGTT is performed. Using a cutoff of 130 or 135 mg/dL during the 1-hour, 50-g OGTT as a trigger for the 3-hours OGTT increases sensitivity for the diagnosis of GDM.

During the fasting, 3-hour, 100-g OGTT, glucose is determined at times 0, 1, 2, and 3 hours. If the plasma glucose concentrations meet or exceed the following cutoffs at 2 or more time points, GDM is diagnosed. Either the Carpenter/Coustan cutoffs or the National Diabetes Data Group (NDDG) cutoffs can be used.

	Cutoffs			
	Carpenter/Coustan criteria		NDDG criteria	
Time	mg/dL	(mmol/L)	mg/dL	(mmol/L)
0	95	(5.3)	105	(5.8)
1	180	(10.0)	190	(10.6)
2	155	(8.6)	165	(9.2)
3	140	(7.8)	145	(8.0)

Screening for type 2 diabetes in adults and children

The ADA recommends that all adults aged 45 and above be screened for diabetes every 3 years with an FPG measurement or Hb A1c measurement [51] [note: guidelines from the American College of Obstetricians and Gynecologists (ACOG) were not available to this author as one must be an ACOG member to access their guidelines]. According to the ADA, an OGTT is an acceptable alternative test for diabetes screening, but the OGTT should not be used routinely. If there is a high index of suspicion for T2DM but the FPG or Hb A1c is not clearly elevated, the physician can elect to order an OGTT on the patient.

If an adult patient is overweight [i.e., the body-mass index (BMI) is 25 kg/M^2 or greater] and has one or more risk factors for T2DM, screening should begin prior to age 45 and/or be performed more frequently. Risk factors for T2DM include a positive family history of diabetes in a first degree relative, habitual physical inactivity, being a member of a minority group, previously identified IFG, IGT or Hb A1c of 5.7%−6.4%, history of GDM or having a baby weighing more than 9 lbs, hypertension (≥140/90 mmHg), hypertriglyceridemia (triglycerides ≥ 250 mg/dL), low HDL-cholesterol (HDL-C ≤ 35 mg/dL), or a history of vascular disease or polycystic ovarian syndrome. The American College of Clinical Endocrinology (ACCE) recommends that screening of high-risk subjects be initiated at age 30.

The ADA recommends that screening for diabetes be considered in overweight children who also have two other risk factors for diabetes such as (1) a family history of T2DM; (2) minority group ethnicity; and (3) signs of or conditions associated with insulin resistance such as hypertension, dyslipidemia, acanthosis nigricans, or polycystic ovarian syndrome. Overweight in children is defined as a BMI >85th percentile for age, weight for height >85th percentile, or weight >120% of ideal for height. The preferred screening test for diabetes in children is an FPG. Hb A1c screening for diabetes is not as sensitive in children as in adults [52]. Such children should be retested at 2-year intervals beginning at age 10 or earlier if puberty develops before age 10.

Special aspects of blood glucose testing

Self-monitoring of blood glucose (SMBG) is a vital part of diabetic care in insulin-treated patients. There is increasing data to support the use of SMBG in noninsulin-treated patients who treat their diabetes intensively [53]. Initially developed for use in clinical problem solving, the continuous glucose monitoring system is FDA-approved for routine use. Furthermore, hardware and software for closed-loop subcutaneous insulin infusions controlled according to frequent subcutaneous glucose measurements (i.e., an "artificial" pancreas) are FDA-approved for adults and children aged 7 years and above [54].

Postprandial glucose (PPG) measurements may improve outcome in pregnancy [55]. Otherwise, there are a few circumstances where PPG measurements may theoretically be helpful: (1) in patients with diabetes whose preprandial glucose levels are within the target range yet their Hb A1c levels are above target; (2) when using a drug that primarily affects the PPG level to titrate drug dose; and (3) recognition of hypoglycemia following exercise or nutritional changes. The 2019 ADA guidelines state: "... it is reasonable for postprandial testing to be recommended for individuals who have premeal glucose values within target but have A1C values above target." [and] "Postprandial glucose may be targeted if A1C goals are not met despite reaching preprandial glucose goals. Postprandial glucose measurements should be made 1−2 h after the beginning of the meal, generally peak levels in patients with diabetes" [56]. For nonpregnant adults with diabetes, the preprandial capillary plasma glucose recommendation is 80−130 mg/dL (4.4−7.2 mmol/L), whereas the peak postprandial capillary plasma glucose recommendation is <180 mg/dL* (10.0 mmol/L).

Transient hyperglycemia

An area of interest is the potential value of preventing stress-induced hyperglycemia in the setting of the ICU. Initial data from a single-institution pulmonary ICU demonstrated that improved clinical outcomes were observed in the critically ill, nondiabetic patients whose glucose was maintained within narrow limits (e.g., 80−120 mg/dL) using an IV insulin infusion [57]. Following this

report, several studies also illustrated clinical benefit resulting from "tight glycemic control" (TGC). However, the value of TGC has become controversial as additional studies showed no benefit and higher rates of hypoglycemia. A metanalysis concluded that TGC is not supported by the available data [58].

Maintenance of near normoglycemia may be beneficial to the management of the patient's fluid and electrolyte balance and to assuring optimal granulocyte function, because hyperglycemia impairs granulocyte function. The ADA has provided guidelines for inpatient management of hyperglycemia [59]. The reader is referred to this resource.

Long-term glycemic monitoring in diabetes

Glycated hemoglobin measurements

The nonenzymatic glycation of proteins is a generalized phenomenon that occurs in both diabetic and nondiabetic individuals. However, because of higher plasma glucose concentrations, glycated proteins are in higher concentration in diabetic than in nondiabetic individuals. Hemoglobin can be glycated by glucose and nonglucose sugars. Glycated hemoglobin [a.k.a, hemoglobin A1 (Hb A1)] takes three major forms: Hb A1a, Hb A1b, and Hb A1c. In Hb A1c, the N-terminal valine of the beta chain is glycated with glucose. Hb A1c represents the major glycated hemoglobin species being ~85% of Hb A1. The chemistry responsible for the formation of Hb A1c is illustrated in Fig. 34.9.

Hb A1c measurements correlate with the average plasma glucose level over the preceding 2−3 months. Glycemia over the month immediately prior to Hb A1c testing has a disproportionately larger effect on the Hb A1c measurement and is responsible for ~40% of the glycated hemoglobin concentration. The Hb A1c concentration is proportional to the extent to which blood glucose is elevated and the duration of time over which the glucose is elevated. Elevated Hb A1c predicts an increased risk of microvascular and neuropathic complications, whereas reductions in Hb A1c predict reduced risks of such complications. This is true in both T1DM, as shown in the Diabetes Control and Complications Trial (DCCT) [60], and T2DM, as demonstrated in the United Kingdom Prospective Diabetes Study [61]. Therefore the measurement of Hb A1c has become the standard of practice for the assessment of glycemic control.

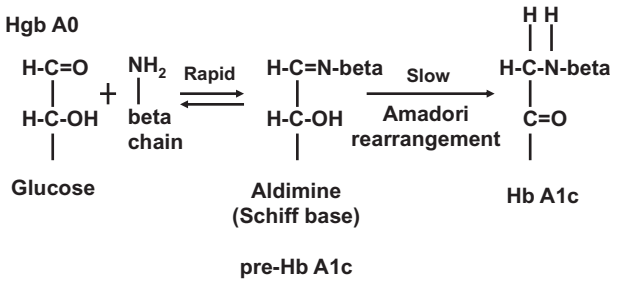

FIGURE 34.9 A rapid and reversible dehydration occurs between glucose and the N-terminus of the hemoglobin beta chain that yields an aldimine (Schiff base). This product can be termed "pre-Hb A1c." Via an Amadori rearrangement, Hb A1c is slowly and irreversibly formed.

The ADA's goal for diabetic patients is an Hb A1c of less than 7%. The 2018 guidelines state: "Providers might reasonably suggest more stringent A1C goals (such as <6.5% [48 mmol/mol]) for selected individual patients if this can be achieved without significant hypoglycemia or other adverse effects of treatment (i.e., polypharmacy)" [56]. ACCE recommends a target Hb A1c of <6.5%. Hb A1c should be measured at a minimum interval of every 6 months in patients whose Hb A1c is less than 7%. Otherwise, Hb A1c should be measured quarterly as an assessment of glycemic control.

Hb A1c can be measured using high-performance liquid chromatography (HPLC) (ion exchange or boronate affinity), gel electrophoresis, capillary electrophoresis (CE), enzymology, or, most commonly, immunoassay. At least two companies in the United States sell commercial HPLC systems designed for the measurement of Hb A1c in central laboratories [e.g., Tosoh Biosciences (South San Francisco, CA) and BioRad (Hercules, CA)]. Sebia (Lisses, France) markets a CE system for Hb A1c measurement. There are analytical and biological limitations associated with all technologies. For example, in some HPLC systems, if a patient's HbF exceeds ~15%−20%, Hb A1c cannot be accurately reported. Further, if an abnormal Hb coelutes with Hb A1c, such as Hb Raleigh, Hb Hope, Hb N-Baltimore, or Hb Franklin Park, Hb A1c cannot be accurately measured [62]. Hb A1c can be measured at the POC using manual chromatography systems or using immunoassays (e.g., A1cNow or DCA2000). The DCA2000 is a popular immunoassay POC instrument that many diabetes clinics use to measure rapidly Hb A1c in their clinic patients. Reporting Hb A1c at the time of the patient's visit has been shown to improve their clinical outcome [63].

To measure Hb A1c, a patient must have Hb A: patients lacking Hb A (e.g., Hb SS, Hb CC, or Hb SC) cannot produce Hb A1c by glycation. In addition, if erythrocyte half-life is shortened (e.g., because of hemolysis), the Hb A1c measurement may be falsely low. On the other hand, if erythrocyte half-life is elevated (e.g., because of splenectomy), Hb A1c concentrations may be increased. Recent data where Hb A1c was measured by HPLC indicated a negative Hb A1c bias of 0.3% comparing persons with sickle cell trait to controls [64]. This would result in the underdiagnosis of either prediabetes or diabetes in persons with sickle cell trait if Hb A1c were measured by HPLC. Iron deficiency raises Hb A1c on average by 1.5% producing a positive bias in Hb A1c measurements [65]. This may be because of an altered rate of glycation [66].

The original reference method for the measurement of Hb A1c was HPLC as used in the DCCT study. In the early 1990s the National Glycohemoglobin Standardization Program (NGSP) was established to develop rigorous analytic performance standards and calibrators that would standardize Hb A1c measurements throughout the United States and other areas of the world that participated in the NGSP program [67]. The NGSP used the DCCT HPLC method as its reference method for measuring Hb A1c. It was determined early on that the best way to standardize Hb A1c measurements was for manufacturers to standardize their methods using procedures and calibrator materials from the NGSP. Commercial methods that meet specific standards of precision and accuracy are declared "NGSP-certified." Individual laboratories can also apply for certification based on their analytical performance. The NGSP has progressively set more stringent precision and accuracy goals for manufacturers and laboratories that have driven improvements in assay performance.

The present reference method for Hb A1c calibration was developed by the International Federation of Clinical Chemists (IFCC) [68]. In this method, N-terminal hexapeptides are cleaved from the beta chains of hemoglobin by the action of the protease endoproteinase Glu-C. These hexapeptides are purified by reverse-phase HPLC into glycated and nonglycated hexapeptide pools. The hexapeptides are then quantified by mass spectroscopy or CE with UV detection. Calibrators are created from these materials with the Hb A1c expressed as the ratio of the glycated hexapeptide to the nonglycated hexapeptide.

For a large group of patient samples when the IFCC method was compared with the NGSP DCCT HPLC method, the NGSP method was shown to display a positive bias of $\sim$1.5%−2.0% [69]. It was subsequently decided that the IFCC method would be employed to produce calibrators used by the NGSP, manufacturers, and laboratories. However, the calibrator values would be recalculated to DCCT method results so that there was no bias from previous DCCT HPLC method results. Thus the IFCC method produced "DCCT-aligned" calibrators. The IFCC A1c method units are mmol/mole (i.e., mmol of Hb A1c per mole of Hb). In short, use of the IFCC reference method affected manufacturers and reference laboratories but did not affect the actual reporting of percent Hb A1c. In regions of the world where Hb A1c are reported based solely on the IFCC method (without reference to the HPLC HbA1c method), HbA1c is reported, as noted above, in the units of mmol/mole.

During these discussions among professional associations from North America, Europe, other parts of the world, and the NGSP, the question arose as to the relationship of Hb A1c to a patient's AG. Patients are sometimes more familiar with the concept of glucose measurements than Hb A1c measurements. This may be especially true for patients who perform SMBG. Researchers wondered how estimated average glucose (eAG) correlated with Hb A1c and if eAG should be reported together with the Hb A1c result. A 1987 publication from the DCCT [70] had shown that for every 30 mg/dL rise in the mean plasma glucose, the Hb A1c increased by $\sim$1% and that eAG and Hb A1c were linearly correlated ($R^2 = 0.64$).

In 2008 a major paper from the A1c-Derived Average Glucose Study Group [71] was published showing an even stronger correlation between Hb A1c and eAG. In their study of over 500 people with T1DM, T2DM, and normal controls, 90% of the eAG fell within $\pm$15% of the predicted estimate based on the following equation: AG mg/dL = 28.7 × A1c − 46.7. R^2 was 0.84 and the P value was <.0001. There was no effect of age, sex, diabetes type, race, ethnicity, or smoking status on this correlation. Based on this strong linear correlation, the ADA and the AACC recommend that eAG be reported along with the Hb A1c result. Below is a comparison of Hb A1c and the eAGs from the 2008 study and the 1987 DCCT study.

	2008	1987
HbA1c (%)	eAG (mg/dL)	eAG (mg/dL)
5	97	100
6	126	135
7	154	170
8	183	205
9	212	240
10	240	275
11	269	310
12	298	345

A previous controversy was the use of Hb A1c for diabetes screening and diagnosis [72]. This was resolved in 2010 as noted in the present recommendations. Advantages of Hb A1c measurement are that it can be determined regardless of the time of the day, Hb A1c is stable, and Hb A1c is relatively standardized from one laboratory to the next as a benefit of NPSG's efforts to standardize Hb A1c assays. Hb A1c is more reproducible than FPG measurements and Hb A1c is much more reproducible than 2-hour OGTT glucose values. This being said, Hb A1c testing is the least clinically sensitive of the three methods for the detection of diabetes: the 2-hour plasma glucose on OGTT testing is most sensitive (and most difficult to obtain) following by FPG measurements. In practical terms, the best way (most sensitive way) to detect hyperglycemia is the 2-hour OGTT. However, the 2-hour OGTT is the most invasive and difficult test to perform. The next best method of detecting hyperglycemia is the measurement of FPG. HbA1c measurements are the least sensitive tests for the detection of hyperglycemia; however, measuring HbA1c is the most convenient test for patients, because fasting is not required.

Glycated serum protein measurements

Proteins other than hemoglobin will become glycated in patients with diabetes. Because the major serum protein is albumin, the "glycated serum protein" test predominantly assesses the concentration of glycated albumin. The addition of glucose to albumin forms a 5-membered ring with a structure similar to fructose. This is why glycated serum albumin is usually referred to as "fructosamine." Because the half-life of albumin is ~10 days, fructosamine measurements reflect 2–3 weeks of glycemic control. Besides its use in patients that lack Hb A, fructosamine measurements may be sought during pregnancy when a shorter term integrated assessment of glycemia is required. This does not exclude also measuring Hb A1c every 2–3 months during pregnancy. During pregnancy, there may be a negative bias in Hb A1c measurements due to the development of anemia.

Future therapies for type 1 diabetes

In T1DM, there may be opportunities to apply immunotherapy to mitigate autoimmune beta cell destruction. Therefore several studies are underway developing therapies to preserve C-peptide secretion in new-onset T1DM patients, as well as prevent T1DM. These efforts have focused on suppressing or altering the immune response using putative autoantigens, drugs, or monoclonal antibodies. Efforts at impairing T cell proliferation [i.e., mycophenolate mofetil plus an anti-CD25 monoclonal antibody (daclizumab)] [73], producing tolerance with glutamic acid decarboxylase-alum [74] or insulin [75] and suppressing inflammation with an anti-IL-1 monoclonal antibody (canakinumab) or an anti-IL-1R monoclonal antibody (anakinra) [76], were not beneficial. However, B cell inhibition with an anti-CD20 monoclonal antibody (rituximab) [77] and impaired T cell activation with CTLA-4-Ig (abatacept) [78] were beneficial to preserving C-peptide secretion in new-onset T1DM individuals. Studies using anti-CD3 monoclonal antibodies, such as otelixizumab, have produced beneficial results in some studies whereas least one study showed no benefit [79–81]. Another monoclonal antibody, teplizumab (a humanized monoclonal antibody IgG1κ directed against CD3), in multiple studies showed preservation of beta-cell function compared with placebo [82–86].

Metabolic syndrome

Metabolic syndrome is a collection of disorders that are caused by, or highly associated with, insulin resistance. Insulin resistance has been strongly linked to central obesity, especially, and visceral obesity [87]. A combination of elevated FFA levels delivered to the liver from the intestine and omentum, cytokines (e.g., tumor necrosis factor-alpha in skeletal muscle), disordered adipokine secretion (e.g., a deficiency of adiponectin), and possible excess cortisol levels (from the adipose-tissue conversion of cortisol precursors to cortisol) produce insulin resistance in skeletal muscle, adipose tissue, and the liver. Fatty infiltration of skeletal muscle, liver, and the beta cells is well-recognized pathologies in this condition. Consequent to decreased insulin action, the beta cells attempt to compensate initially producing hyperinsulinemia. The combination of insulin resistance and/or hyperinsulinemia is associated with the common features of the metabolic syndrome including hypertension, dysglycemia (e.g., IFG, IGT, T2DM, and GDM), hypertriglyceridemia, low HDL-C, dense LDL, increased concentrations of plasminogen-activator inhibitor-I (which is pro-thrombotic), hyperuricemia causing gout, acanthosis nigricans, nonalcoholic fatty liver, and nonalcoholic steatohepatitis. In women, hyperandrogenism, oligomenorrhea, amenorrhea, and infertility can be observed as a consequence of the polycystic ovarian syndrome. The many components of the metabolic syndrome are highly atherogenic, such as, diabetes, hypertension, and dyslipidemia. Because if its atherogenicity, cardiologists (as well as other physicians) may refer to the metabolic syndrome as the "cardiometabolic syndrome."

Galactose disorders

Galactosemia is not a single disorder (Fig. 34.10). Disordered galactose metabolism is observed in three inborn errors of metabolism that are inherited as autosomal recessive diseases: (1) galactokinase deficiency; (2) galactose-1-phosphate uridyl transferase deficiency; and (3) uridine diphosphate galactose-4-epimerase deficiency.

The reactions that occur as part of normal galactose metabolism are summarized below:

1. Galactose + ATP <--galactokinase--> Galactose-1-phosphate + ADP
2. Galactose-1-phosphate + UDP-glucose <--galactose-1-phosphate uridyl transferase--> UDP-galactose + Glucose-1-phosphate

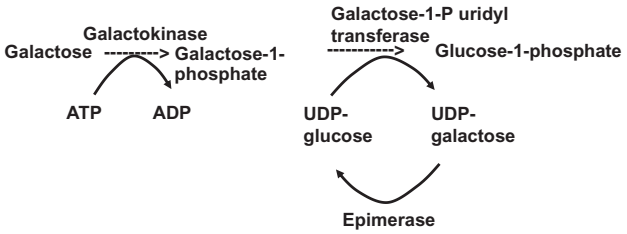

FIGURE 34.10 Galactosemia most commonly results from a deficiency of galactose-1-phosphate uridyl transferase. Galactokinase deficiency produces galactosuria and cataracts.

3. UDP-galactose <--uridine diphosphate galactose-4-epimerase--> UDP-glucose

Galactokinase deficiency, affecting 1 in ~40,000 infants, produces elevated serum galactose levels that lead to galactosuria. Aldose reductase converts galactose into galactitol. Excess galactitol draws water into the lens of the eye leading to cataract formation. Other than cataracts, galactokinase deficiency appears to be a benign condition. Galactokinase deficiency should be considered in any infant or child with cataracts.

Galactosemia, affecting 1 in ~48,000 infants, presents in the first weeks to months of life with hypoglycemia, failure to thrive, liver dysfunction (e.g., hyperbilirubinemia and hepatomegaly), and cataracts (from elevated galactose concentrations). Deficiencies of either galactose-1-phosphate uridyl transferase or uridine diphosphate galactose-4-epimerase are very serious. Transferase deficiency leads to elevated galactose with formation of cataracts. Galactose-1-phosphosate is also elevated. Galactose-1-phosphate is believed to be the toxic agent that damages the central nervous system (CNS), liver, and kidney in individuals with either the transferase or epimerase deficiency. Hypoglycemia may occur after lactose or galactose ingestion with glucose concentrations as low as 10 mg/dL. Elevated galactose-1-phosphate may interfere with glycogenolysis and gluconeogenesis. Sepsis has been reported in ~10% of cases of infants affected with galactosemia. Causes of sepsis include *Escherichia coli, Klebsiella, Enterobacter, Staphylococcus*, beta-streptococcus, and *Streptococcus faecalis*.

With untreated transferase deficiency, CNS injury can produce brain damage and serious development delay. Without a galactose-free diet, liver disease is progressive leading to fatty infiltration, pseudoacini formation, macronodular cirrhosis, and even ascites. Renal tubular dysfunction is manifested in a secondary distal (type 1) renal tubular acidosis, proteinuria, and amino aciduria. There are clinical variants of the transferase deficiency where dysfunctional alleles may have up to 50% of normal activity (such as the "Duarte" allele). Rarely, transferase activity is absent in the peripheral blood but clinical disease does not develop. This extraordinary condition may only occur in African Americans where hepatic and intestinal transferase activities are 10% of normal. Overall, transferase deficiency affects 1 in ~50,000 people in the United States.

Benign and malignant forms of epimerase deficiency have been reported. In the benign condition, epimerase is absent from the blood cells, but epimerase is present in other tissues. The serious form is similar to transferase galactosemia although cataracts have not been reported with epimerase deficiency or are far less common than in transferase deficiency. The treatment of all forms of galactosemia involves lactose and galactose restriction. Without treatment, transferase or epimerase deficiency can be fatal. For galactokinase and transferase deficiencies, such dietary restriction should be absolute and lifelong. With epimerase deficiency, a very limited amount of galactose is allowed in the diet.

Concerning neonatal screening, if the galactosemia screen is based on recognizing elevated galactose levels, several feedings must be provided before elevated galactose may be detectable. Screening for enzymatic defects is usually limited to detection of transferase deficiency. Such an assay is not dependent on feedings but will miss galactokinase and epimerase deficiencies. In summary, the diagnosis of galactosemia is based on a positive Benedict's test for reducing substances in the urine, a negative urine test for glucose by dipstick (e.g., the GO method), and an enzyme assay demonstrating reduced activity. Molecular analysis is available [88].

Self-assessment questions

1. A comatose patient who is on IV fluids who is taking nothing by mouth is in septic shock. A finger-stick capillary glucose is measured and is reported at <60 mg/dL (the lower limit of detection of the analyzer is 60 mg/dL and the reference interval for FPG is 70–99 mg/dL). What action should the clinical team take?
   a. Administer IV glucose (IV = intravenous injection).
   b. Administer IV insulin (IV = intravenous injection).
   c. Administer IV glucagon (IV = intravenous injection).
   d. Send a venipuncture sample to the lab for glucose measurement.
   e. Take no action at this time. No intervention is required.
2. A sample arrives in the core lab from an outside draw station 18 hours after being obtained. The patient is a 60-year-old healthy man who was being screened for diabetes mellitus as part of routine health care. The serum glucose in the red top tube is 40 mg/dL (reference interval for fasting serum glucose: 70–99 mg/dL). What is the most likely cause for this result?
   a. The tube was an serum separator tube and was spun prior to transport.
   b. The patient contracted his forearm repeatedly during the phlebotomy.
   c. Hyperinsulinism is likely present.
   d. The tube is likely a sodium fluoride tube and is not a red top tube.
   e. Delayed analysis is the cause of the low serum glucose result.
3. An adult woman with a history compatible with hypoglycemia undergoes an inpatient fast. Her glucose declines to 35 mg/dL at 8 hours into the fast and she feels very tired. Glucagon is administered, and 45 minutes later, her plasma glucose concentration rises to 100 mg/dL. After glucagon, the patient feels awake. What is the most likely diagnosis?
   a. Liver failure
   b. Hyperinsulinism
   c. Gluconeogenic defect
   d. Cortisol deficiency
   e. GH excess
4. In an adult woman, hypoglycemia is confirmed during a 72-hour fast. At the time of hypoglycemia, insulin and C-peptide are both elevated above the reference intervals for a normal FPG. What drug ingestion should be excluded before the workup for insulinoma begins in earnest?
   a. Ethanol
   b. Metformin
   c. Sulfonylureas
   d. Statins
   e. Cocaine
5. A 65-year-old lean man presents with polyuria and polydipsia. He has mild persistent hyperglycemia (FPG = 130 mg/dL; reference interval = 70–99 mg/dL) and an HbA1c of 6.9% (reference interval $\leq 6.5\%$). He is normotensive and has a normal lipid profile. What testing should next be ordered to determine the cause of his diabetes?
   a. Islet autoantibodies
   b. Insulin and C-peptide
   c. Cortisol and growth hormone
   d. Glucagon and epinephrine
   e. HLA typing
6. A 1-month-old infant develops dehydration and polyuria. The plasma glucose is found to be 300 mg/dL (reference interval for FPG: 70–99 mg/dL). What is the most likely etiology of the baby's problems?
   a. Glucagonoma
   b. Autoimmune beta cell destruction
   c. An inborn error in the beta cell

d. Pheochromocytoma
e. Insulin resistance

7. A woman of reproductive age reports to her family practitioner than she missed 1 menstrual period. In the office, her pregnancy test is positive. The patient's BMI is 33 kg/M^2, her blood pressure is elevated, and she has acanthosis nigricans. Her FPG is 145 mg/dL (reference interval = 70−99 mg/dL) and her HbA1c is 7.6% (reference interval $\leq$ 6.5%). What is the correct diagnosis?
a. T1DM mellitus
b. Type 2 diabetes mellitus
c. Impaired glucose tolerance
d. GDM
e. Normoglycemia

8. Comparing the diagnostic criteria for diabetes mellitus in nonpregnant adults and children, both do these criteria differ?
a. There are different definitions of fasting hyperglycemia.
b. There are different definitions for hyperglycemia at the 2-hour time point during an OGTT.
c. There are different definitions for hyperglycemia at the zero time point during an OGTT.
d. There are different definitions for an elevated HbA1c.
e. There are no differences in the definitions of hyperglycemia.

Chapter 35

Laboratory evaluation of kidney function

W. Greg Miller[1] and Lesley A. Inker[2]

[1]*Department of Pathology, Virginia Commonwealth University, Richmond, VA, United States,* [2]*Department of Medicine, Division of Nephrology, Tufts Medical Center, Boston, MA, United States*

Learning objectives

After reviewing this chapter, the reader should be able to:

- Discuss the physiology of kidney function.
- Explain the categories of chronic kidney disease.
- Measure and estimate glomerular filtration rate.
- Explain laboratory measurement of biomarkers of kidney function.
- Discuss limitations of biomarkers to assess kidney function.

Physiology of kidney function

The overall function of the kidney is to maintain a relatively constant extracellular environment necessary for normal cellular function and to eliminate metabolic waste products [1]. The kidney monitors the internal physiological environment and achieves a constant extracellular environment by secretion and excretion of products derived from dietary intake (e.g., water, hydrogen ion, and electrolytes) and of waste products derived from metabolism (e.g., urea, creatinine, and uric acid). The kidney also secretes hormones (e.g., renin, erythropoietin, and vitamin D) important for metabolic processes. Removal of metabolic waste products and toxins is called "clearance" and is achieved by filtration and secretion. Most of the kidney's functions can be achieved with only one kidney or low function in both kidneys, and indeed, because of adaptive processes, there may be minimal signs or symptoms of kidney damage until a severe reduction [usually defined as a glomerular filtration rate (GFR) of <30 mL/min/1.73 m^2] in kidney function occurs. The term uremia refers to the clinical signs and symptoms that occur with kidney failure due to accumulation of metabolic waste products. The specific products are not known, but they are generally thought to occur at GFR of <15 mL/min/1.73 m^2 or lower. Some consider the blood urea nitrogen (BUN) level as a marker of uremia, but even BUN concentrations of >100 mg/dL may not have apparent clinical effects in many clinical circumstances. In addition, BUN concentrations do not correlate with other retained nitrogenous waste products. Reduction in dietary protein intake does reduce the BUN without necessarily changing symptoms.

The structure of the kidney is designed to accomplish filtration, reabsorption, and secretion functions (Fig. 35.1). There are approximately 1 million individual anatomic units in each kidney called nephrons. Each nephron contains a glomerulus that is connected to a twisted tubule section that drains into a collecting duct and accompanying blood supply. The collecting ducts gradually develop into the urine collecting system at the renal pelvis. The renal pelvis of each kidney drains into a single ureter that carries the urine to the bladder.

The glomerulus receives blood from systemic circulation via the afferent arteriole. After filtration at the glomerulus, blood enters a capillary system called the vasa recta that perfuses the tubule segments and then returns to the body via the efferent arteriole. The glomerulus is composed of an interconnected series of capillary loops enclosed within Bowman's capsule. The role of the glomerulus is to filter water and small molecules, but retain larger molecules such as proteins and blood cells. The glomerular basement membrane is selective based on size and charge of a molecule. The pressure in the glomerulus is an important component of filtration. Surrounding mesangial cells assist to control glomerular surface area and filtration fraction.

The filtered fluids pass from Bowman's capsule into the tubules. Specific tubular segments perform excretion of water, electrolyte and hydrogen ion handling, and hormone production (renin, 1,25-dihydroxy vitamin D, and erythropoietin). The vasa recta bring the blood supply to the tubules and allow for continuous removal of waste products and toxins via tubular secretion into the filtration fluid, and reclaiming of needed molecules and ions via tubular reabsorption from the filtration fluid. The proximal tubule reabsorbs 70% of the filtered sodium and chloride and most of the glucose, amino acids, bicarbonate, potassium, phosphate, and sulfate. The homeostasis of water is

regulated by the varying permeability along the segments of the loop of Henle. The thin descending limb is permeable and the ascending limb is impermeable to water reabsorption, with passive diffusion of NaCl along the thin ascending limb and active reabsorption along the thick ascending limb. Thus a highly dilute urine enters the distal tubule. In the presence of antidiuretic hormone (ADH), aquaporins are inserted in the distal collecting duct principle cells, allowing movement of water from lumen to the interstitium and reabsorption of water. Thus the concentration of urine is based on the presence or absence of ADH. (Water and electrolyte balance is covered in Chapter 37) Renin is produced by the nephrons in response to blood volume and stimulates production of aldosterone by the pituitary. Aldosterone acts on the distal tubule to manage final water and sodium retention, and exchange of potassium and hydrogen ions (see Chapter 41, Adrenal function).

The kidney receives 20% of the cardiac output, and maintenance of systemic blood pressure is a major function of the kidney. The kidneys have the ability to maintain glomerular filtration despite wide fluctuations in systemic hemodynamics through a process called adaptation. Adaptation occurs via changes in hemodynamics, which are controlled by the renin−angiotensin−aldosterone system and other molecules such as prostaglandins. Prostaglandin-dependent vasodilation of the afferent arteriole preserves glomerular perfusion despite falls in kidney blood flow. Conversely, vasoconstriction at times of high systemic pressure protects the glomerular capillary from potential damage resulting from high blood pressure.

Chronic kidney disease

Definition

Chronic kidney disease (CKD) is defined by the Kidney Disease: Improving Global Outcomes (KDIGO) Clinical Practice Guideline for the Evaluation and Management of Chronic Kidney Disease as abnormalities of kidney structure or function, present for 3 or more months, with implications for health [2]. The primary biomarker for abnormal kidney function is GFR of <60 mL/min/1.73 m^2 and for kidney damage is urine albumin-to-creatinine ratio (ACR) of >30-mg albumin per gram of creatinine. In addition, urine sediment, electrolyte and tubular disorders, biopsy, and imaging may indicate kidney abnormality. Kidney damage is usually ascertained by biomarkers without a kidney biopsy.

CKD is recognized as a major public health problem, given the increasing prevalence of kidney failure with poor outcomes and high costs over the past decades. Kidney failure is the "end stage" of CKD and abbreviated end-stage renal disease (ESRD). Common risk factors for CKD include hypertension, diabetes, obesity, cardiovascular disease (CVD), and older age [2]. The prevalence of overall CKD is estimated at 12% of the U.S. population [3]. The number of persons with kidney failure who are treated with dialysis and transplantation in the United States is projected to increase from 470,000 in 2004 to over 2.2 million in 2030, and was 661,468 in 2013 [4].

The GFR is usually accepted as the best overall index of kidney function in health and disease. The normal GFR varies according to age, sex, and body size. Normal GFR in young adults is approximately 120−130 mL/min/1.73 m^2. A GFR of <60 mL/min/1.73 m^2 represents the loss of half or more of normal adult kidney function and is associated with an increased prevalence of systemic complications. GFR declines with age by approximately 1 mL/min/1.73 m^2/year after the third decade. More than 25% of individuals aged ≥ 70 years have GFR of <60 mL/min/1.73 m^2. The etiology of the reduced GFR in the elderly is not known. Some suggest that this may be due to normal aging, although there are many older adults who do not have decreased GFR, suggesting the decreased GFR may be secondary to subclinical forms of systemic diseases that cause kidney damage.

Categories of chronic kidney disease

The categories of CKD are shown in Tables 35.1 and 35.2 as described in the KDIGO guideline. The categories are defined using the two biomarkers GFR and ACR. The categories of CKD can be represented in a two-dimensional chart (Fig. 35.2), showing the combination of GFR and ACR values with different shades in the grid, representing the severity of the disease associated with different values for the biomarkers [2]. The adverse outcomes of CKD are not restricted to kidney failure but also include the

TABLE 35.1 Categories of chronic kidney disease by the level of glomerular filtration rate.

Category	GFR levels (ml/min/1.73 m^2)	Terms	Clinical action plan
G1[a]	>90	Normal or high	• Diagnose and treat the cause • Treat comorbid conditions • Evaluate for CKD risk factors • Start measures to slow CKD progression • Start measures to reduce CVD risk
G2[a]	60–89	Mildly decreased[b]	• Estimate progression
G3a	45–59	Mildly to moderately decreased	• Adjust medication dosages as indicated • Evaluate and treat complications
G3b	30–44	Moderately to severely decreased	
G4	15–29	Severely decreased	• Prepare for kidney replacement therapy (transplantation and/or dialysis)
G5	<15	Kidney failure (add D if treated by dialysis)	• Start kidney replacement therapy (if uremia present)

Notes: GFR in mL/min/1.73 m^2 may be converted to mL/s/1.73 m^2 by multiplying by 0.01667. *GFR*, Glomerular filtration rate; *CKD*, chronic kidney disease; *CVD*, cardiovascular diseases.

complications of decreased kidney function, such as hypertension, anemia, malnutrition, bone and mineral disorders, neuropathy, and increased risk of CVD. In addition, there is evidence for associations with cognitive impairment, infections, frailty, and decreased functional abilities. Risk for CVD, ESRD, and mortality start at levels of GFR of >60 mL/min/1.73 m^2 in most populations and increase linearly with decreasing GFR [5]. Similarly, for albuminuria, the risk for these outcomes appears to increase as a continuous function from concentrations even less than 30-mg albumin/g creatinine. For the other complications mentioned above, risk appears to correlate more with GFR than ACR, with increasing risk beginning at levels of GFR of <60 ml/min/1.73 m^2. Risk for CVD, ESRD, and mortality increases with lower GFR and higher albuminuria, and most recent data suggest a multiplicative relationship between the two [2,5].

Public health efforts

In 2002, the Kidney Disease Outcomes Quality Improvement (KDOQI) guidelines for identification and treatment of CKD [3] reported that millions of people with category 3 CKD were not being identified and consequently were not being treated. Treatment at this category was able to substantially slow progression of disease with reduction in complications, morbidity, and mortality. It was recognized that, although creatinine was commonly measured as part of many clinical encounters, physicians had difficulty relating small increases in concentration with the appropriate decrease in kidney function (see "Limitations of serum creatinine interpretation" section). The KDOQI guidelines recommended that estimated glomerular filtration rate (eGFR) calculated from serum (or plasma) creatinine be reported with the creatinine value to provide physicians with a parameter that was more easily understood and interpreted.

The National Kidney Disease Education Program (NKDEP) was formed by the National Institutes for Diabetes, Digestive and Kidney Diseases at the National Institutes of Health (United States) to educate high-risk patients, physicians, and clinical laboratories about CKD and how to identify patients for treatment. In 2006, the NKDEP recommended that clinical laboratories in the United States report eGFR when serum creatinine is reported [6]. Estimated GFR reporting practices have been reviewed and >90% of clinical laboratories in the United States now follow this practice [7]. Most laboratory and nephrology professional associations around the world have endorsed reporting eGFR. In most circumstances, eGFR is sufficient for clinical decision-making. However, as described below, for some patients, the error in eGFR can be substantial and a measured GFR is needed.

More recently, the National Kidney Foundation (United States) and the American Society for Clinical Pathology have recommended that laboratories offer a "Kidney Profile" that includes serum creatinine, calculated eGFR using the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation (see later section), and urine ACR [8]. The "Kidney Profile" follows evidence-based clinical practice guidelines to ensure physicians order the appropriate group of tests to more effectively

assess kidney function for patients, such as diabetics and hypertensives, who are at increased risk for CKD [9].

Measurement of glomerular filtration rate

Clearance methods

Clearance of a substance from the plasma as it passes through the glomerulus is used to measure the GFR. The ideal substance is a low-molecular-weight water-soluble molecule that freely crosses the glomerular membrane, is not bound to plasma proteins, is not reabsorbed nor secreted nor metabolized by kidney tubules, and is not eliminated by any nonkidney process.

Clearance is measured by elimination of an exogenous filtration marker from the blood. For such a substance, the amount that appears in the urine will equal the amount that crosses the glomerulus, and the rate of plasma flow through the glomerulus (the GFR) can be calculated as:

$$\begin{aligned}\text{GFR} = {} & (\text{concentration in urine}) \times (\text{volume of urine})/ \\ & (\text{concentration in plasma}) \\ & \times (\text{time of urine collection})(\text{units: mL/min})\end{aligned} \tag{35.1}$$

where the urine and plasma concentrations are in the same units (e.g., milligrams per deciliter or micromoles per liter), the volume of urine is in milliliter, and the time of urine collection is in minutes. Urine clearance measurements require a timed urine collection to average influence of diurnal variation in rates of excretion with hydration and physical activity. The timed urine collection is generally 24 h but can be shorter, especially when it can be performed under observation or in acute care settings. The primary disadvantage of urinary clearance measurements is the need for urinary collection, which is especially a concern in populations with incomplete bladder emptying, such as children and the elderly.

There is an increasing interest in measurement of clearance from plasma, because it avoids the need for a timed urine collection. GFR is calculated from plasma clearance of the marker after a bolus intravenous injection of an exogenous filtration marker. The GFR is calculated from the dose and the area underneath the disappearance curve. The decline in plasma concentration is secondary to the immediate disappearance of the marker from the plasma into its volume of distribution and a slower renal clearance. Plasma clearance is best estimated using a two-compartment model that requires blood sampling early (usually two or three time points until 60 min) to estimate the fast curve for volume of distribution and late (one to three time points from 120 to 300 min) to estimate the slow curve for renal clearance. For patients with very low levels of kidney function, a very late time point (e.g., at 24 h) is necessary to avoid overestimation of the GFR.

Kidney size is approximately proportional to body size. To enable standardized interpretation of GFR, the values obtained from plasma or urinary clearance methods are typically adjusted to a body surface area (BSA) of 1.73 m^2. BSA is calculated as [10]:

$$\begin{aligned}\text{BSA} = {} & \text{weight(kg)}^{0.425} \times \text{height(cm)}^{0.725} \\ & \times 7.1 \times 10^{-3}\left(\text{units:}m^2\right).\end{aligned} \tag{35.2}$$

The GFR corrected to 1.73-m^2 BSA is:

$$\text{GFR(adjusted)} = \text{GFR} \times 1.73/\text{BSA}\left(\text{units:mL/min/1.73}\,m^2\right). \tag{35.3}$$

Exogenous substances to measure glomerular filtration rate

Inulin has the properties of an ideal substance to measure GFR and has been the exogenous substance used as the gold standard. Classically, inulin is given via intravenous infusion using bladder catheterization to ensure complete bladder emptying. However this method is invasive, and inulin is difficult to maintain in solution and to measure accurately and as such is not often used in clinical practice. Other substances and methods have been used to measure GFR and are listed in Table 35.3. The most common markers used in the United States are iohexol and iothalamate. For all markers currently used, there have been concerns expressed regarding their ideal characteristics for renal handling, such that inulin remains the true gold standard. Nevertheless, with accurate assay calibration and quality control techniques, these alternative methods and markers can be used as reference standards in clinical practice and research studies [11].

Endogenous substances to measure glomerular filtration rate

Clearance of endogenous substances has been commonly used to measure GFR. An ideal endogenous filtration marker shares the same properties as an ideal exogenous marker; however, in addition, it is generated consistently by the body to maintain a constant plasma concentration. No endogenous substances have such ideal properties, and all endogenous filtration markers have non-GFR determinants of their plasma concentrations due to variation in generation of the biomarker within and between individuals, as well as excretion from the plasma space not due to glomerular filtration. The most common endogenous markers to estimate GFR are creatinine and cystatin C.

TABLE 35.3 Procedures used to measure glomerular filtration rate.

Marker	Method of administration	Comments
Inulin	Continuous IV	Gold standard; difficult to handle and measure accurately
Iothalamate	Bolus IV or subcutaneous	Can be administered as a radioactive compound with ^{125}I as the tracer or as a nonradioactive compound with assays using HPLC methods. In radioactive form, potential problem of thyroid uptake of ^{125}I. Iothalamate is secreted, leading to overestimation of GFR
99mTc-DTPA	Bolus IV	Dissociation of 99mTc leads to plasma protein binding and underestimation of GFR
51Cr-EDTA	Bolus IV	10% lower clearance than inulin
Iohexol	Bolus IV	Low incidence of adverse effects. Comparable with inulin. Assay by HPLC and IDMS.

GFR, Glomerular filtration rate; *HPLC,* high-performance liquid chromatography; *IDMS,* isotope dilution mass spectrometry.

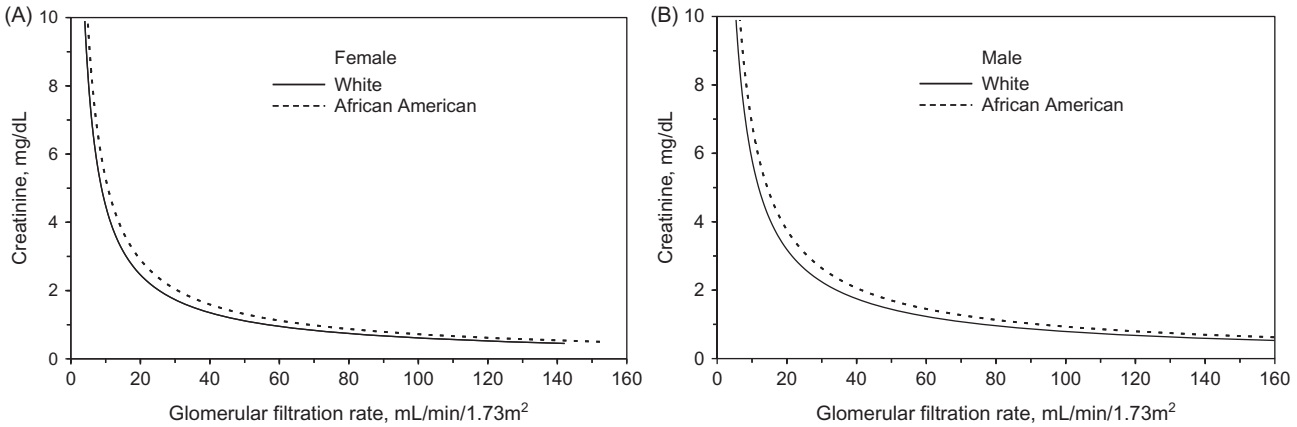

FIGURE 35.3 Inverse nonlinear relationship between serum/plasma creatinine and glomerular filtration rate. The relationship was estimated using the modification of diet in renal disease study equation for a male and a female 60-year-old individual.

Measured clearance of endogenous substances is more convenient than measured clearance of exogenous filtration markers and therefore provides a reasonably accurate method to estimate the GFR. However, because of the need for timed urine collections, these measurements are difficult to do correctly and lead to substantial errors in results. In addition, the presence of tubular reabsorption and secretion of the marker will lead to underestimate or overestimate of the GFR, respectively.

Creatinine

Physiology of creatinine

Creatinine is produced from breakdown of creatine in muscle metabolism and presents a relatively constant concentration in plasma that enters the glomerulus. Creatinine is freely filtered by the glomerulus and is excreted in the urine. Fig. 35.3 shows the inverse relationship between serum/plasma creatinine and GFR [12]. Note that the relatively small changes in creatinine concentration at earlier stages of kidney function decline (e.g., a GFR change from 120 to 60 mL/min/1.73 m^2) correspond to a serum creatinine increase from 0.8 to 1.4 mg/dL for a 30-year-old white male. However, there is substantial interindividual variation in the generation of creatinine that is primarily related to differences in muscle mass and diet. In addition, creatinine is moderately secreted (7%–10% in healthy individuals) by proximal tubules, and the rate of secretion typically increases as CKD progresses. Sickle cell disease can increase tubular secretion. Consequently, creatinine clearance is numerically larger than GFR, and the positive bias increases as kidney function deteriorates. Some conditions such as acute kidney necrosis can decrease tubular

secretion of creatinine, causing decreased creatinine excretion. Medications and specific diseases can affect secretion; most notably cimetidine and trimethoprim; dolutegravir and cobicistat used in antiretroviral regimens for HIV management; and poly(ADP-ribose) polymerase inhibitors, such as olaparib and rucaparib, and tyrosine kinase inhibitors, such as crizotinib, gefitinib, imatinib, pazopanib, sorafenib, and sunitinib used to treat cancer can block tubular secretion of creatinine. In addition, proximal tubulopathies that develop secondary to medications, such as tenofovir, cisplatin, or heavy metals, can lead to decreased creatinine secretion. Finally, there is some elimination of creatinine via the gut. Gut secretion is difficult to measure but likely increases with worsening kidney disease. A measured GFR should be used when conditions that alter creatinine elimination are present.

Measurement of creatinine

Creatinine can be measured by its reaction with alkaline picric ions (first described by Jaffe in 1886) to form an orange–red complex of unknown chemical structure. More recently, procedures using enzymes have been introduced. The Jaffe reaction is not specific for creatinine. Serum (or plasma) proteins, glucose, ketone bodies, ascorbate, bilirubin, hemoglobin F, other endogenous molecules, and several exogenous drugs also react to produce varying amounts of chromogenic product with picrate ion. These interfering substances have been called "noncreatinine chromogens." Implementations of the Jaffe reaction have been developed that varied the reaction conditions to minimize the influence of some of these potentially interfering substances. For example, some interfering substances react very quickly to form the picrate complex (e.g., acetoacetate) and others more slowly (e.g., albumin and immunoglobulins). Making a kinetic measurement of the reaction between approximately 20 and 60 s optimizes detection of the creatinine reaction period and minimizes the influence of several other substances. The reagent formulation and temperature have an important influence on reactivity of creatinine and other substances in the Jaffe reaction.

Another approach used by several manufacturers is to subtract a constant concentration from the measured value with a Jaffe reaction to correct (called compensate) for the average amount of noncreatinine chromogens in a sample. This approach works well as long as an individual sample has the same amount of noncreatinine chromogens as the average samples used to develop the correction factor. The compensation approach mainly corrects for proteins, not for other substances only found in some samples from diseased patients. Compensated methods have a limitation when used for pediatric or hospitalized patients who frequently have low albumin or immunoglobulin concentrations. In these cases, the correction is too large, causing an erroneously low creatinine concentration. The error can be a large percent change for younger children who may have creatinine concentrations in the range of 0.3–0.6 mg/dL.

Creatinine can also been measured using coupled enzyme reactions in an effort to develop more specific methods. Several reaction schemes have been developed. One of the more common approaches uses creatininase to convert creatinine to creatine, creatinase to convert the creatine to sarcosine and urea, and sarcosine oxidase to produce products including hydrogen peroxide, which is subsequently reduced to form a colored chromogen. Creatininase is specific for creatinine, and endogenous creatine and urea are removed in a prereaction incubation before creatininase is added. Some interfering substances may influence enzymatic methods, primarily by their reactions in the several coupled reaction steps. For example, bilirubin and ascorbate can react with hydrogen peroxide to decrease the amount of chromogen produced. In general, enzymatic methods are affected by fewer interfering substances than Jaffe-based methods; in particular, proteins do not interfere in enzymatic methods, making them well suited to pediatric and hospitalized patient groups.

Much of the older literature investigating interfering substances was not performed with the current implementations of Jaffe and enzymatic methods. A recent report examined the performance of four enzymatic and three Jaffe routine methods compared with an LC-isotope dilution mass spectrometry (IDMS) procedure when measuring individual patient samples selected to contain commonly encountered interfering substances [13]. Both Jaffe and enzymatic methods were influenced by interfering substances to different degrees. However, Jaffe methods were more susceptible to interfering substances particularly for patients with diabetes, CVD, protein abnormalities, and cephalosporin drugs. Enzymatic methods were minimally affected by those substances but were subject to interferences from hemolysis and elevated bilirubin that are easily identified by contemporary measuring systems. In addition, the influence of interfering substances was different for different implementations of a Jaffe or enzymatic procedure. Recent reports suggest that enzymatic methods for creatinine are preferred due to their improved selectivity, better precision, and smaller bias versus reference measurement procedures that are particularly important for pediatric populations [14–16].

Standardized calibration of creatinine measurements

Prior to approximately 2010, calibration of creatinine methods was poorly standardized among different methods and laboratories. Biases were reported to be 30%–40%

among different methods [6]. Consequently, different reference intervals were used by different methods, and uniform application of clinical practice guidelines was difficult. When the KDOQI recommended reporting eGFR with all creatinine results, the Laboratory Working Group of the NKDEP initiated a calibration standardization program for creatinine methods (including serum, plasma and whole blood samples). All creatinine methods from global manufacturers now have standardized calibration traceable to a Joint Committee for Traceability in Laboratory Medicine (JCTLM) listed IDMS reference measurement procedure that itself is calibrated with a primary reference material [SRM 914a crystalline creatinine from the National Institute of Standards and Technology (NIST)] [17]. A creatinine in frozen human serum reference material was developed by NIST (SRM 967) as a trueness control to assist in documenting traceability.

Limitations of serum creatinine interpretation

It has been difficult to establish useful adult reference intervals for creatinine, because a reference population without kidney disease is difficult to identify. Early CKD is not recognized by any clinical symptoms or laboratory biomarkers. Consequently, it is likely that some people in an apparently healthy reference population have some degree of CKD. As mentioned earlier, GFR declines approximately 1 mL/min/1.73 m^2/year after the third decade, which complicates selecting a reference population. A further complication is that, because of the interindividual variation in creatinine generation, reference intervals differ by gender, age, and race to reflect differences in muscle mass. Reference intervals have typically been stratified by age and sex for children and only by sex for adults. It is rare that laboratories stratify by age or race in adults despite changes in muscle mass in these groups. In addition, even stratified reference intervals cannot incorporate other causes for differences in creatinine generation, such as changes in diet or other extremes of muscle loss (e.g., amputation or muscle-wasting diseases). Consequently, reference intervals have not been satisfactory to discriminate normal from moderately diseased patients and physicians have had difficulty in identifying patients in early stages of kidney disease only on the basis of serum creatinine concentrations. Equations have been developed to transform serum creatinine into eGFR, which is more easily understood by physicians to identify patients with early kidney disease who can be helped by therapeutic intervention (see *Estimating Equations*).

Cystatin C

Physiology of cystatin C

Cystatin C is a lysosomal cysteine proteinase (13,000 Da) produced at a constant rate in nucleated cells. It is freely filtered at the glomerulus, not secreted by the tubules, and not eliminated other than by the kidney, and is completely reabsorbed and catabolized by the proximal tubules. Like creatinine, cystatin C concentration has an inverse nonlinear relationship to GFR. Cystatin C does not appear in the urine unless there is tubular damage. Consequently, urinary clearance of cystatin cannot be determined.

Cystatin C concentration in plasma has traditionally been thought to be generated at a constant rate by all nucleated cells. Lack of urinary clearance has made this hypothesis difficult to thoroughly evaluate, but data suggest that there are non-GFR determinants because of interindividual variation in generation of cystatin [18]. Factors that affect the concentration of cystatin C include age, sex, diabetes, inflammation, body habitus, urinary protein, thyroid status, and steroid use. Cystatin C is not dependent on muscle mass and diet and is useful in conditions when creatinine is not suitable.

Measurement of cystatin C

Cystatin C is measured by immunoassay. In-vitro diagnostic device (IVD) manufacturers have used different antibodies directed against different epitopes. An international federation of clinical chemistry and laboratory medicine (IFCC) working group for standardization of cystatin C has developed a certified reference material, ERM DA471/IFCC, that has been available since 2010 from the Joint Research Center of the European Union (JRC, EU). The certified reference material consists of recombinant cystatin C in a human serum pool and is intended for calibration of immunoassays. Some manufacturers have recalibrated their cystatin C methods to be traceable to the ERM DA471/IFCC reference material, and all are expected to achieve standardized calibration traceability. The availability of standardized cystatin C methods has enabled estimating equations for eGFR to be developed from large populations that can be used with any standardized cystatin C method. However, as of this writing, calibration of cystatin C assays is not completely standardized, and different methods give different numeric results [19,20].

Estimating equations

Estimated glomerular filtration rate

Estimating equations combine an endogenous filtration marker (e.g., creatinine or cystatin C) with easily measured surrogates for other non-GFR determinants that influence the serum concentration of the endogenous filtration marker. For both markers, the non-GFR determinants age, sex, race, or body size have been incorporated with creatinine or cystatin C in estimating equations. A summary of common eGFR equations can be found in

TABLE 35.4 Equations for estimation of glomerular filtration rate.

1) Cockcroft–Gault
CrCl (male) = ([140 age] × weight in kilogram)/(Scr × 72) if female, a multiplier of 0.85 is used where Scr is serum creatinine in mg/dL, and age is in years
2) MDRD (four-variable)
GFR (mL/min/1.73 m^2) = 175 × $(S_{cr})^{-1.154}$ × $(Age)^{-0.203}$ × (0.742 if female) × (1.212 if African American) where Scr is serum creatinine in mg/dL, and Age is in years
3) CKD-EPI creatinine
GFR = 141 × $\min(S_{cr}/\kappa, 1)^{\alpha}$ × $\max(S_{cr}/\kappa, 1)^{-1.209}$ × 0.993^{Age} × 1.018 [if female] × 1.159 [if black] where S_{cr} is serum creatinine in mg/dL, κ is 0.7 for females and 0.9 for males, α is −0.329 for females and −0.411 for males, min indicates the minimum of S_{cr}/κ or 1, and max indicates the maximum of S_{cr}/κ or 1, and Age is in years
4) CKD-EPI 2012 cystatin C
eGFR = 133 × $\min(S_{cys}/0.8, 1)^{-0.499}$ × $\max(S_{cys}/0.8, 1)^{-1.328}$ × 0.996^{Age} × 0.932 [if female] where Scys is cystatin C in mg/L, and Age is in years min indicates the minimum of $S_{cys}/0.8$ or 1 max indicates the maximum of $S_{cys}/0.8$ or 1
5) CKD EPI 2012 cystatin C–creatinine
eGFR = 135 × $\min(S_{cr}/\kappa, 1)^{\alpha}$ × $\max(S_{cr}/\kappa, 1)^{-0.601}$ × $\min(S_{cys}/0.8, 1)^{-0.375}$ × $\max(S_{cys}/0.8, 1)^{-0.711}$ × 0.995^{Age} × 0.969 [if female] × 1.08 [if black] κ = 0.7 (females) or 0.9 (males) α = −0.248 (females) or −0.207 (males) $\min(S_{Cr}/\kappa$ or 1) indicates the minimum of S_{cr}/κ or 1 $\max(S_{cr}/\kappa$ or 1) indicates the maximum of S_{cr}/κ or 1 $\min(S_{cys}/0.8, 1)$ indicates the minimum of $S_{cys}/0.8$ or 1 $\max(S_{cys}/0.8, 1)$ indicates the maximum of $S_{cys}/0.8$ or 1
6) Bedside Schwartz
eGFR = 0.413 × (height/S_{cr}) if height is expressed in centimeters OR 41.3 × (height/S_{cr}) if height is expressed in meters
7) CKiD
eGFR = 39.8 × $[ht/S_{cr}]^{0.456}$ × $[1.8/Scys]^{0.418}$ × $[30/BUN]^{0.079}$ × $[1.076^{male}]$ $[1.00^{female}]$ × $[ht/1.4]^{0.179}$ where BUN is blood urea nitrogen in mg/dL Scys is cystatin C in mg/dL ht (height) is in meters S_{cr} is standardized serum creatinine in mg/dL

Table 35.4. The equations and their properties are discussed below.

Creatinine-based estimating equations

Cockcroft–Gault equation

The Cockcroft–Gault (C–G) equation was published in 1976 and estimates creatinine clearance in milliliter per minute from serum or plasma creatinine, age, and body weight. There is an adjustment factor for women that is based on a theoretical assumption of 15% lower creatinine generation because of lower muscle mass. Comparison to normal values requires calculation of the patient's BSA and adjustment to 1.73 m^2.

The C–G equation has several key limitations. First, it estimates creatinine clearance rather than GFR; hence, it is expected to overestimate GFR. Second, inclusion of a term for weight in the numerator causes the formula to systematically overestimate creatinine clearance in patients who are edematous or obese and will produce changes in estimated creatinine clearance with weight loss. Third, it was derived using older assay methods for serum creatinine, which had different calibration than newer assay methods that causes

positive bias with creatinine results from methods with calibration traceable to IDMS. Fourth, its age term leads to a sharp and excessive decline in estimated creatinine clearance with age. As a result, it has been shown to be substantially less accurate than modification of diet in renal disease (MDRD) study or CKD-EPI equations (see below).

Modification of diet in renal disease study equation

The MDRD study equation uses serum creatinine, age, sex, and race (black versus white or other) to estimate GFR as measured by urinary clearance of ^{125}I-iothalamate. The original six-variable equation also included serum urea and albumin; however, the six-variable equation is not used in clinical practice, because it is not expressed for creatinine methods with calibration traceable to IDMS. The four-variable equation has been reexpressed for use with serum creatinine methods with calibration traceable to IDMS [21]. The four-variable equation has been validated in African Americans, people with diabetic kidney disease, and kidney transplant recipients, three groups not included in large numbers in the original MDRD study. The equation underestimates GFR in populations with GFR of >60 mL/min/1.73 m^2, such as patients with type 1 diabetes without albuminuria and people undergoing kidney transplant donor evaluation. Because of limitations in accuracy of the MDRD study equation at higher values, GFR estimates are reported as a numeric value only if eGFR is <60 mL/min/1.73 m^2 and as ">60 mL/min/1.73 m^2" for higher values. The MDRD study equation has not been validated in children, pregnant women, or the very old (age $>$ 85 years). The MDRD study equation has demonstrated less variability and greater overall accuracy than the C−G formula [12].

Chronic kidney disease epidemiology collaboration equation

The CKD-EPI 2009 creatinine equation, was developed from a large database of individuals from research studies and patients from clinical populations with diverse characteristics, including people with and without kidney disease, diabetes, and a history of organ transplantation [22]. The equation is based on the same four variables as the MDRD study equation, but uses a two-slope "spline" to model the relationship between GFR and serum creatinine that improves the underestimation of GFR at higher values observed with the MDRD equation. As a result, the CKD-EPI equation is as accurate as the MDRD equation at eGFR <60 mL/min/1.73 m^2 and more accurate at higher values. The CKD-EPI equation has somewhat better precision (less scatter in values), although either estimating equation has substantial scatter in the agreement of individual eGFRs vs. measured GFR due to limitations discussed in the next section. The CKD-EPI equation was validated for a wide range of characteristics, including age, sex, race, body mass index, and presence or absence of diabetes or history of organ transplantation. A review of 12 assessments of the CKD-EPI and MDRD equations indicated that the CKD-EPI equation gave more accurate results at eGFR >60 mL/min/1.73 m^2 and the MDRD gave better performance at lower eGFR. The authors concluded the CKD-EPI equation was preferred for a general practice and public health perspective [23]. Differences between the CKD-EPI vs. MDRD study equations lead to marked differences in the distribution of eGFR values in the U.S. National Health and Nutrition Examination Survey data, with a lower prevalence of eGFR <60 ml/min/1.73 m^2. Similar results have been observed in multiple studies around the world. The differences between equations also lead to differences in multivariable associations with prognosis for adverse events as shown in a meta-analysis of 25 general population cohorts of 940,366 people [24]. Reclassification among eGFR categories also gave more accurate risk prediction. That is, patients reclassified to lower categories (higher GFR) using the CKD-EPI equation had a lower adjusted risk for mortality, CVD mortality and kidney failure than those not reclassified. Conversely, subjects reclassified to a lower eGFR category had a higher risk for the aforementioned disease states. With the CKD-EPI equation, it is now possible to report eGFR for adults across the entire range of values with minimal bias and reasonable imprecision. The U.S. National Kidney Foundation and the KDIGO 2012 CKD guideline recommend using the CKD-EPI equation and most large reference laboratories in the United States have transitioned to use the CKD-EPI equation (in place of the MDRD study equation). Reporting eGFR values above 60 mL/min/1.73 m^2 allows clinicians to identify patients who are at high risk for CKD before they develop reduced GFR, and to follow the progression in those with known CKD (i.e., polycystic kidney disease or patients with albuminuria).

Limitations of creatinine-based estimates of glomerular filtration rate

The variables included in any equation account for the average difference in creatinine generation from muscle mass due to the influence of age, sex, race, or body size but cannot account for other sources of variation in creatinine concentration that may be caused by other factors in individual patients. The estimate assumes an individual has "average" characteristics regarding body size and muscle mass. There will be more uncertainty in the eGFR to the extent an individual differs from "average." Table 35.5 lists patients for whom GFR estimates are likely to have large errors and clinical circumstances in which decisions based on inaccurate estimates may have adverse consequences.

TABLE 35.5 Indications for measured glomerular filtration rate when glomerular filtration rate estimates based on serum creatinine are likely to have large errors or may have adverse consequences.

- Extremes of age and body size
- Severe malnutrition or obesity
- Disease of skeletal muscle
- Paraplegia or quadriplegia
- Evaluation for kidney donation
- Vegetarian diet
- Before administration of prolonged courses of toxic medications

For example, no creatinine-based equation is expected to be accurate for patients with extremes of creatinine generation such as amputees, muscle builders, patients with muscle-wasting conditions, chronically ill or hospitalized patients who frequently have reduced muscle mass, or people with high or low dietary meat intake. In addition, current estimates are not sufficiently accurate to determine normal kidney function in a person who is being evaluated for a kidney donation. Finally, although eGFR is sufficient for adjustment of many medications, measured GFR should be considered before initiation of prolonged and potentially toxic therapy, such as cancer chemotherapy. When these situations occur, measured GFR or measured creatinine clearance may be helpful in clinical decision-making [25].

Cystatin-C-based estimating equations

The CKD-EPI 2012 cystatin C equation and the CKD-EPI 2012 creatinine and cystatin C combined equation were developed from a diverse set of studies, similar to that used for development of the CKD-EPI creatinine equation [22]. The cystatin C equation had similar accuracy to the creatinine equation, whereas the equation that used both creatinine and cystatin C was more accurate than an equation that used either cystatin C or creatinine alone, with the improvement due to better precision rather than bias. There is similar higher accuracy of the combined creatinine and cystatin C equation in subgroups with a trend towards higher accuracy of eGFR from cystatin C vs. estimated GFR from creatinine for subgroups with lower BMI. Other studies have confirmed the findings that the combined equation is more precise than eGFR from creatinine or cystatin C. Based on a small number of studies, performance of the CKD-EPI 2012 cystatin C equations are better than the CKD-EPI 2009 creatinine equation in regions outside North America, Europe and Australia, requiring less or no modification by a local coefficient.

Despite the similarities of accuracy of estimating equations between creatinine and cystatin C, eGFR from cystatin C provides more precise risk associations than eGFR from creatinine, with the risk associations of eGFR from creatinine and cystatin C intermediate between the two. Reclassification among eGFR categories also showed large differences with the different equations. Overall, net reclassification index favored eGFR from creatinine and cystatin C over eGFR from creatinine for all cause and cardiovascular mortality, but no difference was observed for ESRD [26].

Estimating glomerular filtration rate in children

Children have lower concentrations of creatinine than adults. Consequently, the influence of bias, imprecision, and interfering substances on creatinine results has a larger proportional effect. Younger children frequently have lower total protein than adults, with potentially larger negative biases caused by over-correction (over-compensation) for "average" protein concentrations in some Jaffe methods. Very young children may have elevated bilirubin and hemoglobin F, which can interfere in many Jaffe and enzymatic procedures. The relative imprecision [coefficient of variation (CV) %] of all creatinine methods becomes larger at lower concentrations. Creatinine methods with lower imprecision and fewer interferences should be used for pediatric populations. Equations to estimate GFR in children have used serum creatinine and height, which is a good approximation of muscle mass and BSA in children. The bedside Schwartz equation is recommended to estimate GFR if only creatinine is available [27].

Cystatin C is a promising biomarker for use in children because it is not influenced by muscle mass. The CKiD study has developed an equation using cystatin C, BUN and creatinine [28]. However the cystatin C used in development of the equation had not been standardized and therefore the accuracy of the estimating equation is not known when used in different clinical laboratories. An IFCC working group has reported a cystatin C based GFR estimating equation that used a standardized cystatin C method and was validated with a cohort of 262 Dutch and 440 Swedish children [29]. The equation has not been validated for use with a broader demographic mix.

Kidney function assessment and drug dose adjustment

Before standardized calibration of creatinine methods, there was substantial variability in methods used to assay serum creatinine in different clinical laboratories and in pharmacokinetic (PK) studies to establish drug dose adjustment on the basis of kidney function. The results from the PK studies were incorporated into U.S. Food and

Drug Administration (FDA) drug labels. The recommended drug dosages based on PK studies (i.e., the FDA drug labels) have been inconsistently translated into clinical practice. Since the introduction of standardized creatinine methods approximately 10 years ago, there is now less variation in estimating kidney function and more consistent drug dosing.

Laboratories and clinical practitioners are now reporting eGFR determined by the MDRD or CKD-EPI equations using standardized creatinine methods that give the most accurate assessment of kidney function, whereas the older drug labeling recommendations for dosing based on C−Gderived estimated creatinine clearance (or creatinine concentration in some cases) generally using nonstandardized methods. A large simulation study compared drug-dosing recommendations based on eGFR using the MDRD equation and estimated creatinine clearance using the C−G equation, both calculated from standardized creatinine values, to dosing recommendations based on gold-standard measurements of GFR [30]. The results suggested that for most patients and for most drugs tested, there was little difference in the drug dose that would be administered using either equation to estimate kidney function.

On the basis of these and other considerations, a KDIGO controversies conference recommended to use the most accurate method available to assess kidney function when evaluating the GFR for drug dosing [31]. Because standardization of creatinine measurement procedures has caused creatinine values to decrease vs. older methods, the most accurate method will not be the C−G equation. Estimated GFR from CKD-EPI equations should be used (creatinine or creatinine-cystatin C). Because the CKD-EPI (or MDRD study) equations are expressed as adjusted for BSA, in very large or very small patients the reported eGFR should be multiplied by the estimated BSA to obtain eGFR in units of milliliters per minute for drug dose adjustment. The NKDEP also recommends to use a measured GFR or creatinine clearance for situations when estimates based on creatinine are likely to be incorrect (see Table 35.5) or for drugs with narrow therapeutic or toxic thresholds. Over the past 10 years, an increasing number of studies have used methods other than C−G for assessment of drug dosage.

Urine protein

Definitions

Plasma contains approximately 300 g of protein; yet, the final urine filtrate is virtually protein-free because of selectivity of glomerular filtration. This conservation of essential proteins is necessary for oncotic regulation, for immune protection, for normal coagulation, and other vital processes. Proteinuria refers to increased excretion of any urinary protein, including albumin and other serum proteins, and proteins synthesized by the tubule (e.g., Tamm−Horsfall glycoprotein) or in the lower urinary tract. Albuminuria refers to increased excretion of albumin. An increased protein excretion rate is usually due to kidney damage. The specific proteins excreted depend on the type of kidney disease. Increased excretion of albumin is a sensitive and specific marker for CKD due to diabetes, hypertension, and glomerular diseases. Therefore tests for albuminuria are preferred for detection of CKD because it is more sensitive and specific for the common causes of CKD.

Mild proteinuria does not generally cause clinical signs or symptoms, but when severe (>3 g/day), consequences such as hypoalbuminemia, hypercholesterolemia, hypercoagulability, and hemodynamic instability may occur. This constellation of signs and symptoms is referred to as nephrotic syndrome. Recognition of nephrotic-range proteinuria or nephrotic syndrome may help identify the etiology of the kidney disease. In addition, the degree of proteinuria is a risk factor for kidney disease progression. However, even the presence of mild elevations in albuminuria (e.g., $<$30mg/g creatinine) is an independent risk marker for CVD, particularly in patients with diabetes, hypertension, or advanced age.

The threshold for abnormally elevated concentrations depends on what is being measured (total protein or albumin) and the collection method. A 24-h collection has been regarded as the gold standard but is difficult to implement in routine practice and not generally used. Measurement of albumin or total protein concentration in a randomly collected sample avoids the need for collection of a timed urine specimen but is affected by the state of hydration. Taking the ratio of albumin- or total protein-to-urine creatinine concentrations minimizes hydration as a source of variation but is affected by urine creatinine excretion rate. Table 35.6 shows the thresholds for the definition of albuminuria and proteinuria according to collection method and sex where appropriate. Measurement of the ratio of albumin-to-creatinine or total protein-to-creatinine in a random (also called "spot") urine sample is recommended [32]. A first morning urine void has been shown to have comparable diagnostic utility to a 24-h collection when expressed as the ACR [33]. Both total protein and albumin excretion can be increased transiently because of several factors, including urinary tract infection, hemodynamic stress (exercise, fever, and congestive heart failure), and transient metabolic perturbations (ketosis and hyperglycemia), which emphasizes the importance of testing only in high-risk individuals who have a high pretest probability of disease and for repeated testing to confirm the diagnosis of CKD. Thus, to confirm persistence of proteinuria, two or three abnormal tests are required over a minimum of 3 months [2]. Repeat confirmation testing should be performed from a first morning

TABLE 35.6 Thresholds for the definition of albuminuria and proteinuria according to collection method and sex.

Measure	Categories		
	Normal to mildly increased	Moderately increased	Severely increased
AER (mg/24 h)	<30	30–300	>300
PER (mg/24 h)	<150	150–500	>500
ACR			
(mg/mmol)	<3	3–30	>30
(mg/g)	<30	30–300	>300
PCR			
(mg/mmol)	<15	15–50	>50
(mg/g)	<150	150–500	>500
Protein reagent strip	negative to trace	negative to +	+ or greater

ACR, Albumin-to-creatinine ratio; *AER*, albumin excretion rate; *PER*, protein excretion rate; *PCR*, protein-to-creatinine ratio.

collection to reduce the frequency of falsely elevated urine albumin [34].

Urine total protein measurement

Urine total protein is most frequently measured as turbidity after denaturation with trichloroacetic acid, sulfosalicylic acid, or benzethonium chloride; or a dye-binding reaction with pyrogallol red, molybdate or pyrocatechol-violet molybdate. Reactions with benzethonium chloride or the dye-binding reagents are the most common automated procedures. Each of these reactions gives a different response to different proteins, with albumin generally having the largest response. In addition, urine contains a large number of different proteins and other matrix solutes that contribute to variable responses among methods for total protein. There is no JCTLM-listed reference measurement procedure or reference material for urine protein. Because of these variables, there are large differences in measured results among methods for total protein that are not likely to be improved. Consequently, using generalized decision criteria to interpret urine protein will give different disease classifications based on the method used.

For patients with advanced kidney damage, large amounts of protein (>1 g/L albumin and others) are present in urine and will be detected by any method. Urine protein "dipsticks" typically detect approximately 300 mg/L of albumin and may not detect similar concentrations of other proteins such as Tamm–Horsfall glycoprotein associated with tubular damage. Urine protein is relatively insensitive to detect early kidney damage, and specific methods for urine albumin should be used for screening at-risk populations and for monitoring progression of kidney disease.

Urine albumin measurement

Urine albumin is the preferred analyte to detect early kidney damage and to monitor progression of CKD. Increased concentrations can be caused by excess glomerular leakage or by reduced tubular uptake. Albumin exists in plasma and urine as a heterogeneous molecule [32]. Plasma albumin is glycated, phosphorylated, nitrosylated, oxidized, binds many different ligands, and undergoes proteolytic modifications and truncation of C- and N-terminal amino acids. In addition, several genetic variants have been reported. Proteolysis also occurs in the tubules, bladder, and urine after collection. Urine concentrates many ligands, which alters the binding ratios, and urine itself has a widely varying matrix of solutes that can affect an antibody's binding reaction. Large (>5 kD) and small (500–5000 Da) fragments of albumin exist in plasma and in urine. Tubular uptake is receptor-mediated and may influence enrichment of modified plasma forms of albumin in urine. For example, glycated forms are a greater proportion in urine because of decreased uptake in the tubules.

Urine albumin is almost exclusively measured by turbidimetric or nephelometric immunoassay with typical limits of quantification being approximately 5 mg/L. Polyclonal and monoclonal antibodies are used, and different antibodies target different epitopes. The influence of molecular

forms of albumin on some immunoassays' responses has been investigated for a few partially cleaved and other conditions. Polyclonal antibodies were generally more efficient than monoclonal antibodies to recognize some modified albumin forms [32]. Urine albumin measured in 340 frozen individual urine samples using an LC-IDMS procedure found the same concentrations when quantitated from trypsin fragments near the amino- or carboxy-terminus or middle peptide regions of the molecule [35]. Measurement of urine albumin in 332 individual nonfrozen urine samples using 16 commercially available urine albumin immunoassay procedures found that bias was the dominating error component with differences in median values among methods of approximately 40% and CV from analytical error components of <5.8% for 14 of 16 methods [36]. In the same study, specimen-specific influences were 3.1%−6.6% for 12 of 16 methods, 13%−14% for three platforms from the same manufacturer, and could not be determined for one manufacturer due to analytical imprecision CV of 12.7%. These reports suggest that there was minimal influence of urine matrix or albumin molecular forms for most immunoassay methods. In addition, the results demonstrate that improvement in calibration standardization is needed for routine urine albumin methods to better utilize the clinical guidelines decision values for ACR.

Several reports used size-exclusion high-performance liquid chromatography (HPLC) to measure urine albumin and observed higher values than for immunoassays. These observations lead to a hypothesis that there were "nonimmunoreactive" forms of albumin in urine of diabetics. This hypothesis is no longer accepted on the basis of results such as the area under receiver-operator characteristic (ROC) curves for immunoassay being superior to HPLC for predicting cardiovascular events in diabetics [37] and demonstration that the increased values by HPLC were caused by coeluting proteins being erroneously quantified as albumin [32].

There is no JCTLM-listed reference measurement procedure or reference material for urine albumin. Most methods trace calibration to ERM-DA470, or its replacement ERM-DA470k/IFCC, Human Serum Proteins (JRC, EU) certified reference material. This reference material is intended for serum measurements and is diluted to achieve albumin concentrations measured in urine. Dilution protocols and diluent matrix are usually not specified, and it is not known if the diluted reference material is commutable with patient urine samples. Work is in progress to develop an IDMS-based reference measurement procedure and reference materials suitable for use for urine albumin measurements. NIST has released SRM 2925 pure human albumin intended for use to calibrate IDMS reference measurement procedures but not intended to calibrate immunoassays. NIST is preparing SRM 3666 albumin in frozen human urine that will have four concentrations of albumin and is intended for use to calibrate immunoassays. NIST, the Mayo Clinic, and the University of Minnesota are collaborating to develop LC-IDMS reference measurement procedures for urine albumin [38].

Urine creatinine measurement

Urine creatinine is measured using the same reagent systems as for serum or plasma, and the same reference measurement procedures have been used for urine samples. The urine matrix is lower in protein than serum and may have more concentrated solutes that may influence selectivity for creatinine. There is little information available on harmonization among results measured using different methods for urine creatinine, although the measurement is commonly made on urine samples as a correction for hydration and urine excretion rate influences on analyte concentrations. NIST has released SRM 3667 creatinine in frozen human urine for use to calibrate urine creatinine methods. SRM 3666 albumin in frozen human urine will have certified values for creatinine as well as for albumin.

Recommendations for measuring and reporting urine albumin and creatinine

An expert group of the NKDEP and IFCC recognized that standardization of urine albumin and creatinine measurement and reporting was needed, and that additional information was required to accomplish these goals [32]. The following recommendations were made regarding current practice for measuring and reporting urine albumin:

- A first morning urine sample has lower biologic variability than a random collection and is preferred. Twenty-four-hour urine collections are not needed and introduce collection errors.
- Albumin should be measured on fresh (nonfrozen) urine.
- Urine should be frozen at $\leq -70^{\circ}C$ (not $-20^{\circ}C$) when stored for investigational purposes.
- Urine ACR should always be reported. The reporting units should be albumin/creatinine as milligram per gram or milligram per millimole and be used uniformly in a country or region. The ACR should also be reported when a 24-h urine collection is used, because the interpretive guidelines are based on ACR, and complete 24-h collections are challenging.
- Albumin concentration (e.g., as milligram per liter) should not be reported by itself, because it is difficult to interpret without information on urine excretion rate.
- The term "urine albumin" should replace the term "microalbumin" as the name for the laboratory test, because the latter term is confusing to clinicians who are unsure of its meaning.

Experience showed that laboratories used inconsistent reporting practices for highly elevated values for urine albumin, ACR, total urine protein, and protein/creatinine ratio. Because physicians need quantitative values for highly elevated concentrations to appropriately monitor progression and response to therapy for advanced kidney disease, the NKDEP published updated recommendations for reporting these biomarkers [39]. The recommendations are to perform dilutions of urine containing elevated concentrations of albumin and/or total protein, and to report quantitative values. When the concentration of urine albumin or total protein exceeds the measuring capability after dilution, a greater than value for the concentration and for the ratio to creatinine should be reported based on the highest concentration that can be measured after dilution. It is not appropriate to simply report a value greater than the nominal analytical measuring range for undiluted urine samples.

Other biomarkers of kidney damage

Markers of tubular function

The tubules are active participants in homeostasis of minerals and other compounds. Therefore damage to the tubules can lead to abnormalities of potassium, bicarbonate, glucose, phosphate, amino acids, calcium, and water. It is more difficult to measure specific functions of the tubules than it is to measure GFR. Due to the adaptive nephron hypothesis, GFR decreases and so does the ability of the tubules to adapt to changes in the milieu. In addition, there are abnormalities that can be observed even at high levels of GFR with diseases that specifically affect the tubules. Abnormalities can be due to genetic abnormalities, changes in dietary intake of key nutrients, medications or toxins, infiltrative diseases in the kidney (e.g., cancer), or systemic diseases (e.g., rheumatic diseases). Thus abnormalities in any of these compounds might indicate tubular damage.

Urinalysis

Multiparameter dipstick urinalysis and microscopic examination are covered in Chapter 37, Water and electrolyte balance. Noting the presence of cellular components in urine is an indication of kidney damage. Cellular components present in urine in two or more examinations over at least 3 months can be diagnostic for CKD. Identification of the presence or absence of hematuria and proteinuria, as well as casts, may facilitate identification of an etiology for kidney disease. In particular, presence of hematuria, proteinuria, and cellular casts indicate glomerular disease, which often requires specific treatments.

Acute kidney injury and emerging biomarkers

Acute kidney injury (AKI) is defined by an increase in serum creatinine of 0.3 mg/dL or greater within 48 h, an increase in serum creatinine of 1.5-fold or greater above baseline that is known or presumed to have occurred within 7 days, or urine volume of <0.5 mL/kg/h for 6 h or more. Acute kidney disease is defined as kidney disease that is thought to have been present less than 90 days. AKI may occur in various settings. Most commonly, it occurs after exposure to hemodynamic insults (e.g., with massive volume depletion or after surgery) or after administration of nephrotoxic pharmaceutical agents (e.g., radiographic contrast, chemotherapy, or antimicrobials).

It is difficult to estimate an acute loss of kidney function from serum (or plasma) concentrations of the endogenous filtration markers creatinine or cystatin C, or from eGFR derived from equations, because the changes in serum concentrations lag behind the change in measured GFR. For example, after an abrupt decline in GFR, the serum concentration of creatinine will return to steady state after 2−3 days. In conditions in which the GFR is constantly changing (higher or lower), it will be even more difficult to estimate the GFR from serum concentrations of creatinine or cystatin C. The eGFR is important in managing patients with AKI because of the need for appropriate dosing of medications, and therefore estimation of GFR requires an analysis of the rate of change in eGFR and the absolute value at baseline.

To overcome the limitations of the serum filtration markers, there has been interest in novel biomarkers for early detection of kidney damage prior to the decrease in kidney function. AKI biomarkers provide evidence for tubule function, distinguish etiologies of AKI (particularly prerenal disease from acute tubular necrosis), or identify subclinical AKI that does not lead to decreased GFR but does portend a poor prognosis. Most AKI biomarkers are not ready for widespread clinical practice at this time. Only one AKI biomarker has been FDA cleared for clinical use. The NephroCheck test measures urine insulin-like growth factor-binding protein 7 (IGFBP7) and tissue inhibitor of metalloproteinases-2 (TIMP-2). Both of these molecules are inducers of G_1 cell cycle arrest, a key mechanism implicated in AKI. The test multiplies the two results to obtain a value that provides information on risk of development of AKI in the next 12 h. In the original validation trial, the combined biomarkers demonstrated an area under the curve in ROC analysis of 0.80 (0.76 and 0.79 alone). Furthermore, the combination of the two ([TIMP-2] · [IGFBP7] $(ng/ml)^2/1000$) significantly improved risk stratification when added to a nine-variable clinical model that included age, serum creatinine, apache III score, history of hypertension, nephrotoxic drugs, liver disease, sepsis, diabetes, and history of CKD [40].

Neutrophil gelatinase-associated lipocalin (NGAL) is approved for clinical use in several countries but not in the United States. NGAL is a protein (25 kD) found in human neutrophils and has a role in kidney embryology. Distal tubule injury upregulates the gene for synthesis, and the protein is secreted into blood and urine where it can be measured. NGAL is reported to increase in 2–6 h after AKI. NGAL can be elevated following injury to various tissues other than kidney, which has made diagnostic thresholds for AKI challenging to establish and limited its general use.

Kidney stones

Renal calculi, commonly called kidney stones, are solid aggregates that form in the renal pelvis, ureter, or bladder. Kidney stones occur when excess amounts of poorly soluble substances, such as calcium, oxalate, phosphate, urate, cysteine, and others, due to nonkidney pathophysiology are filtered through the glomerulus and form precipitates or aggregates, as the urine is concentrated by water reabsorption. Urine contains a large number of minerals and organic molecules being eliminated from the body many of which approach saturation concentrations and can be precipitated by moderately abnormal concentrations or pH in the urine. The frequently observed precipitates in refrigerated urine specimens demonstrate this phenomenon. The most common stones are calcium oxalate or a mixture of calcium oxalate and phosphate. However, a large range of minerals, organic molecules, and proteins can be found in kidney stones.

Although kidney stones are not useful as kidney function biomarkers, an analysis of the urine and the stone composition is useful to identify what substances are present in elevated concentrations. Stone composition analysis is usually performed by specialty laboratories using techniques such as infrared spectroscopy and X-ray diffraction analysis. Serum tests for PTH, vitamin D, and other molecules involved in mineral metabolism are also useful to understand the underlying pathophysiology. Once identified, treatment is based on controlling the concentrations of the components of the stone by pharmacological or diet strategies and staying well hydrated to prevent excessive concentration of urine that is conducive to formation of the insoluble stones.

Self-assessment questions

1. In which of the following scenarios should the CKD-EPI creatinine equation not be used?
   a. pregnant women
   b. people with amputations
   c. people with CKD
   d. people with muscular dystrophy
      i. all of the above
      ii. i, ii, and iv
      iii. i, ii, and iii
      iv. i and ii
2. What is the effect of eating a vegetarian diet on the concentration of serum creatinine and measured GFR, respectively?
   a. lower and higher
   b. higher and higher
   c. lower and lower
   d. no change in either
3. What is the definition for CKD?
   a. GFR $<$ 60 mL/min/1.73 m^2 or evidence of kidney damage that is present for $\geq$ 3 months
   b. eGFR $<$ 60 mL/min/1.73 m^2 and proteinuria that is present for $\geq$ 3 months
   c. eGFR $<$ 60 mL/min/1.73 m^2 and evidence of kidney damage that is present for $\geq$ 3 months
   d. eGFR $<$ 60 mL/min/1.73 m^2 or evidence of kidney damage
4. The CKD-EPI equation results in improved performance for estimation of measured GFR compared with the MDRD study equation in which of the following groups?
   a. people with CKD
   b. amputees
   c. people with rapidly changing kidney function
   d. people with higher GFRs
5. Which of the following statements is not correct?
   a. eGFR based on the CKD-EPI equation had stronger associations of risk for ESRD, mortality, and CVD compared with the MDRD study equation.
   b. eGFR based on the CKD-EPI equation lead to lower prevalence of CKD than with the MDRD study equation.
   c. Patients reclassified to lower CKD categories by the CKD-EPI equation had a lower adjusted risk for all risk mortality, CVD mortality, and kidney failure than those not reclassified.
   d. There is no difference between the eGFR from the CKD-EPI and MDRD study equations for assessment of CKD prevalence and risk for adverse outcomes.
6. Which is the preferred method for testing for urine albumin?
   a. first morning specimen to test for urine ACR
   b. first morning specimen to test for urine albumin
   c. random spot urine to test for urine ACR
   d. timed urine specimen to test for urine ACR
7. True or false? Adverse outcomes of CKD include CVD, kidney failure, anemia, abnormalities of mineral metabolism, infections, frailty, and cognitive impairment.
   a. true
   b. false
8. NKDEP recommends to report eGFR because
   a. It is easier to interpret a patient's kidney function from the eGFR than from serum creatinine.
   b. Physicians do not know how to perform the calculation.
   c. Patients with CKD are inadequately identified by serum creatinine.
   d. It gives a correct assessment of kidney function in all pathologic conditions.
      i. i and ii
      ii. i, ii, and iv
      iii. i, ii, and iii
      iv. i and iii
9. Measurement of serum cystatin C
   a. is clearly superior to serum creatinine as a marker of kidney function
   b. may be a useful biomarker in conditions when serum creatinine is a less reliable indicator of kidney function
   c. is standardized so any method can be used with any equation to calculate eGFR
   d. should become part of the basic metabolic profile

Chapter 36

Contemporary practice in clinical chemistry: blood gas and critical care testing

John Toffaletti
Duke University Medical Center, Durham, NC, United States

Learning objectives

After reviewing this chapter, the reader will be able to:

- Describe the physiological factors that regulate pH, pCO_2, pO_2, and the electrolytes.
- Interpret pH, pCO_2, and bicarbonate (total CO_2) results to evaluate ventilatory and metabolic acid–base disorders, and if appropriate compensation is present.
- Describe the binding of oxygen to hemoglobin and the factors that affect this binding.
- Evaluate pO_2 results to determine the adequacy of arterial oxygenation and calculate the alveolar–arterial pO_2 difference.
- Interpret cord blood data to identify possible hypoxia and/or acidosis in the neonate.
- Describe the clinical utility of blood lactate and glucose results in critical care.
- Describe the proper collection and handling of specimens for blood gas and critical care testing.

Introduction

The term "blood gases" refers to the parameters pH, pCO_2, and pO_2, which are commonly measured in blood. Note that the little "p" in pH stands for negative log, while the italicized *p* in pCO_2 and pO_2 stands for the partial pressure of each of these gases. Blood gases are commonly measured by electrochemical (potentiometric or amperometric) methods that use ion-selective or gas-selective electrodes. This chapter uses the unit mmHg for blood gases, because it is readily understood and because many journals use mmHg as the conventional and SI unit. To convert mmHg into kPa, multiply the value by 0.1333. Cooximetry refers to the measurement of various forms of hemoglobin (Hb), including oxyhemoglobin (O_2Hb) and carboxyhemoglobin (COHb), from which the term is derived. Modern cooximeters are specialized spectrophotometers that measure the absorbance of over 100 wavelengths over the range of 478–672 nm. The absorbance spectrum is then analyzed to calculate the concentrations of various Hb forms present in blood: O_2Hb, COHb, metHb, and total Hb.

Explanations of blood gas, acid–base, and cooximetry terms

pH

pH is an index of the acidity or alkalinity of the blood. If normal arterial pH is 7.35–7.45 (45–35 nmol/L), then a pH $<$7.35 indicates an acidic state and a pH $>$7.45 indicates an alkaline state. In critical care, a clinically acceptable range of 7.30–7.50 is sometimes used as a guideline (see Table 36.1). Acidemia refers to the condition of blood being too acidic, and acidosis refers to the metabolic process within the patient that causes the acidemia; the adjective for the process is acidotic. Similar terms are used for the alkaline state: alkalemia, alkalosis, and alkalotic. All enzymes and most physiological processes are affected by pH.

pCO_2

pCO_2 is a measure of the tension or pressure of carbon dioxide dissolved in the blood. The pCO_2 of blood represents the balance between cellular production of CO_2 and the ventilatory removal of CO_2. A normal, steady pCO_2 indicates that the lungs are removing CO_2 from the blood at about the same rate as tissues are releasing CO_2 into the blood. A change in pCO_2 indicates an alteration in

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00036-3

TABLE 36.1 Reference ranges and critical limits for venous and arterial blood.

Measurement	Reference range (mixed venous)	Reference range (arterial)	Critical limits (arterial)
pH	7.33–7.43	7.35–7.45	≤7.25 or ≥7.60
pCO_2	41–51 mmHg (5.5–6.8 kPa)	35–45 mmHg (4.7–6.0 kPa)	≤20 or ≥60 mmHg (2.6 or 8.0)
HCO_3	21–30 mmol/L (21–30 mEq/L)	21–28 mmol/L (21–28 mEq/L)	≤10 or ≥40 mmol/L
pO_2	35–50 mmHg (4.7–5.3 kPa)	83–100 mmHg (11.1–13.4 kPa)[a]	≤ 40 mmHg (>10.7 kPa[a])
sO_2	70–75	96–100	< 85%
$\%O_2Hb$	–	94–99	< 85%
Anion gap	3–12 mmol/L	3–12 mmol/L	–
Base excess	−3 to +3	−3 to +3	–

pO_2, Oxygen pressure.
[a]*pO_2 of arterial blood varies with age.*

this balance, usually due to a change in the ventilatory status. CO_2 is an acidic gas, with blood levels largely controlled by our rate and depth of breathing or ventilation, provided that the rate of metabolic production of CO_2 is constant. pCO_2 contributes to the respiratory or ventilatory component of acid–base balance and is also a key factor in calculating the alveolar pO_2 (see the section "Evaluation of oxygenation status and arterial oxygenation").

pO_2

pO_2 is a measure of the tension or pressure of oxygen dissolved in the plasma of blood. Note that although the O_2 dissolved in plasma and the O_2 bound to Hb are in equilibrium, it is only the O_2 dissolved in plasma that is detected as pO_2 by the oxygen electrode. The pO_2 of arterial blood is primarily related to the ability of the lungs to oxygenate blood with alveolar air. A decreased arterial pO_2 indicates one or more of the following circumstances:

- Decreased pulmonary ventilation (hypoventilation), for example, as caused by airway obstruction or trauma to the brain.
- Impaired gas exchange between the alveolar air and the pulmonary capillary blood, for example, as caused by bronchitis, emphysema, pulmonary edema, or asthma.
- Altered blood flow within the heart or lungs, as caused by congenital defects in the heart or shunting of venous blood into the arterial system without oxygenation in the lungs.
- Intrapulmonary shunting when blood passes through nonfunctional or nonventilated alveoli.
- Pulmonary embolism in which blood flow to a segment of the lung is blocked by a blood clot.

Bicarbonate

Bicarbonate ion (HCO_3^-) may be measured directly by some blood gas analyzers or calculated [HCO_3^-] from the measurements of the pH and pCO_2. Although the terms CO_2, total CO_2, and bicarbonate are sometimes used interchangeably, the term "total CO_2" refers to the sum of the [HCO_3^-] and the dissolved CO_2 in plasma. Bicarbonate is an indicator of the buffering capacity of blood, with a low bicarbonate concentration indicating that a larger pH change will occur for a given amount of acid or base produced. Bicarbonate is classified as the metabolic component of acid–base balance.

Base excess

Base excess (BE) is a calculated term that describes the amount of bicarbonate relative to pCO_2. Some believe it helps to determine quickly the amount of bicarbonate that a patient may need and arguably may provide more useful information about acid–base status than the bicarbonate and pCO_2 [1]. It is calculated as follows:

$$BE = 0.929(HCO_3 - 24.4 + 14.8(pH - 7.4)) \quad (36.i)$$

It is calculated for hypothetical anemic blood (Hb = 5 g/dL) on the principle that blood Hb effectively buffers both the plasma and the much larger extracellular fluid. It is as if the blood Hb were dispersed in the larger pool of extracellular fluid. Because BE and the simple difference between 24 mmol/L (a normal bicarbonate) and the measured bicarbonate typically agree within 2 mmol/L, either provides virtually the same clinical information.

Anion gap

The anion gap (AG) is a calculated term for the difference between the commonly measured cations (Na and

TABLE 36.2 Changes of anion gap in various acid–base disorders.

Disorder	Decreased	Gained	Effect on AG
Diarrhea	HCO_3^-	Cl	Little
Renal tubular acidosis	HCO_3^-	Cl	Little
Lactate acidosis	HCO_3^-	Lactate	Increased
Ketoacidosis	HCO_3^-	Ketoacids	Increased
Mixed disorder: ketoacidosis with metabolic alkalosis	HCO_3^-	Ketoacids and HCO_3^-	Increased (with little change in total CO_2)

AG, Anion gap.

sometimes K) and the commonly measured anions (Cl^- and HCO_3^-). Therefore, the AG represents the unmeasured anions such as lactate, acetoacetate, and albumin. The AG is usually calculated as:

$$\mathrm{AG} = \left[\mathrm{Na}^+\right] - \left[\mathrm{Cl}^-\right] - \left[\mathrm{HCO_3}^-\right] \quad \left(\text{Reference Range: } 3-12 \text{ mmol/L}\right) \tag{36.ii}$$

If K is included in the calculation, the formula is:

$$\mathrm{AG} = \left[\mathrm{Na}^+\right] + \left[\mathrm{K}^+\right] - \left[\mathrm{Cl}^-\right] - \left[\mathrm{HCO_3}^-\right] \quad \left(\text{Reference Range: } 7-16 \text{ mmol/L}\right) \tag{36.iii}$$

Note: While K is a commonly measured cation and would be relevant to the AG calculation, it is usually not included in the calculation.

The AG is useful in diagnosing a metabolic acidosis and differentiating among the causes, as shown in Table 36.2. For example, in metabolic acidosis due to hypoxia, the blood lactate increases, which increases the AG. While blood lactate has become a common measurement, it is considered an "unmeasured" anion in the AG calculation. In addition, in patients with a low albumin, the AG will be lower by about 2.5 mmol/L for each g/dL fall in albumin [2,3]. Although often very useful, AG calculated from three measurements is subject to variations of up to ± 3 mmol/L and is also affected by the normal variation in albumin concentrations [2,3]. Reference ranges for the above parameters are given in Table 36.1.

Strong ion difference

The strong ion difference (SID) is a concept developed by Peter A Stewart in 1981 to explain changes in pH and acid–base balance, using electroneutrality, conservation of mass, and the degree of dissociation (strongly or weakly) of electrolytes [1]. It is complex mathematically, but in simplest terms, it is calculated as:

$$\mathrm{SID} = \left(\mathrm{Na}^+ + \mathrm{K}^+ + \mathrm{Ca}^{++} + \mathrm{Mg}^{++}\right) - \left(\mathrm{Cl}^- + \text{lactate}\right) \tag{36.iv}$$

A normal SID is approximately 40–45 mEq/L, with a decreased SID indicating an acidosis and an increased SID indicating an alkalosis. Because measurement of numerous analytes is required to calculate the SID, it is subject to a large analytical variation and the theory suggests that ionized concentrations are more appropriate. While SID may have value in selected acid–base disorders, there is no consensus on whether it improves the understanding or interpretation or treatment of acid–base disorders [4].

Hb and its derivatives

Hb and its derivatives are measured by cooximetry. These include O_2Hb, deoxyhemoglobin (HHb), COHb, and methemoglobin (metHb). Briefly, O_2Hb has four oxygen molecules bound to each of the heme groups in the Hb molecule. COHb has carbon monoxide (CO) bound very tightly to an O_2-binding site on a heme group, which also causes the remaining O_2 molecules to bind very tightly to the other three heme groups. COHb cannot release O_2 until the carbon monoxide is released. MetHb is inactive Hb (unable to bind O_2), because its ferrous ion (Fe^{2+}) has been oxidized to a ferric ion (Fe^{3+}). Hb function is discussed later in this chapter.

Percent O_2 saturation and $\%O_2Hb$

The percent O_2 saturation (sO_2) is the percentage of *functional* Hb (O_2Hb + HHb) that is saturated with oxygen. sO_2 is calculated as the concentration of O_2Hb divided by the functional Hb. Although sO_2 is clearly related to oxygenation in the lungs, pO_2 is somewhat better for assessing that function, because it increases linearly with higher O_2 levels, while the sO_2 levels off as it approaches 100%.

$$sO_2 = \frac{O_2Hb}{O_2Hb + HHb} \quad (36.v)$$

The $\%O_2Hb$ (formerly called the fractional Hb saturation) is the percentage of total Hb that is saturated with oxygen. The $\%O_2Hb$ may be used for determining the oxygen content and, therefore, the oxygen delivery (DO_2) and oxygen consumption (VO_2) [5].

$$\%O_2Hb = \frac{O_2Hb}{O_2Hb + HHb + COHb + MetHb} \quad (36.vi)$$

COHb and Met-Hb

COHb and metHb together normally make up only 1%–2% of the total Hb in blood. Neither is able to perform O_2 carrying and releasing functions. Exposure to carbon monoxide will increase the %COHb from about 1% to 5%–10% in smokers and to 50% or more with exposure to toxic or lethal levels. MetHb is Hb that has its Fe^{2+} ion oxidized to an Fe^{3+}, which also inactivates the ability of met-Hb to bind O_2.

DO_2 and VO_2

Both DO_2 and VO_2 are parameters for assessing critically ill patients. There are now several ways of determining these parameters, with laboratory measurements sometimes used. DO_2 in mL/min requires measurement of the following values in arterial blood: Hb in g/L, $\%O_2Hb$ from 0 to 1.0, pO_2 in mmHg (of minor importance in this calculation), and cardiac output (C.O.) in L/min.

$$\begin{aligned} DO_2 &= CO \times (1.34 \times Hb \times \%O_2Hb + 0.03pO_2) \\ &= C.O.(O_2a) \end{aligned} \quad (36.vii)$$

where O_2a is the arterial oxygen content.

VO_2 is oxygen consumption by the organs and tissues of the body. Put simply, it is the difference in oxygen content between the arterial (O_2a) and venous (O_2v) blood times C.O.:

$$VO_2 = C.O. \times (O_2a - O_2v) \quad (36.viii)$$

Physiology of acids and bases

How are acids and bases produced?

Metabolic acid

The vast majority of our metabolic acid is from CO_2 produced in the mitochondria as one of the ultimate byproducts of glucose oxidation. However, CO_2 is considered the "respiratory" component of our acid base balance, because lung ventilation directly affects the blood pCO_2 and can rapidly change the blood pH.

Lactate acidosis

Common causes of increased lactate are from ischemia or from mitochondrial damage due to factors (O_2 radicals, cytokines, etc.) produced by inflammation, as with sepsis. Contrary to common belief, lactic acid is virtually *never* produced. The only reaction in humans that produces lactate is when pyruvate is converted into lactate, a reaction that actually *consumes* acid by the participation of NADH being converted into NAD + [6]. During an oxygen deficit, the acid comes many biochemical steps later, when adenosine triphosphate (ATP) depletion causes accumulation of ADP, phosphate, and hydrogen ions. Normally, oxidative phosphorylation reconverts these products back to ATP with little net change of H ions. However, without oxygen, the ADP and acid accumulate to cause an acidosis.

Ketoacidosis

Diabetic ketoacidosis develops when a person has too little insulin such that glucose cannot enter cells to produce sufficient ATP energy. The liver begins to break down fat for energy, which produces toxic ketoacids formed by the deamination of amino acids and the breakdown of fatty acids. The two common ketones produced in humans are acetoacetate and β-hydroxybutyrate. Ketoacidosis can also occur with people undergoing starvation as the body is forced to break down fat for sustenance due to their lack of outside nutrition. In ketoacidosis, unregulated ketone production causes a severe accumulation of keto acids in the blood.

Production of base

Generally, there is little metabolic production of bicarbonate or other alkaline substances in the body. Bicarbonate is generated from metabolic CO_2 after it combines with H_2O and releases H^+. The kidney retains or excretes HCO_3^- depending on the physiologic need. Bicarbonate can increase if Cl is lost by either vomiting or by renal loss from diuretics and can decrease if excess Cl accumulates. Generally, any loss of acid will increase the proportion of HCO_3^- from CO_2. Bicarbonate given in excess to treat an acidosis is an iatrogenic source of base.

Buffer systems

Bicarbonate–carbon dioxide

Bicarbonate is the buffer in highest concentration (~24 mmol/L) in blood plasma, which is also of central importance in acid buffering in the blood. CO_2 is a volatile acidic gas, is soluble in water, and is the major acid produced as a product of energy metabolism. CO_2 produced by cell metabolism diffuses into blood (with a lower pCO_2), combines with H_2O to produce carbonic

acid (H_2CO_3), then immediately dissociates to bicarbonate and hydrogen ions. pH, HCO_3^- (in mmol/L), and pCO_2 (in mmHg) are related by the equation:

$$\mathrm{pH} = \mathrm{pK} + \log\left[\frac{\mathrm{HCO_3}^-}{0.03 \times p\mathrm{CO_2}}\right] \qquad (36.ix)$$

Note that the pK is defined as the pH at which the HCO_3^- and H_2CO_3 (or $0.03 \times pCO_2$) are in equal concentrations. That is, their ratio is 1, and the log of 1 is equal to 0.

At the normal concentration ratio in blood of 20:1 ("ideal" would be 1:1) and with a pK of 6.1 ("ideal" would be 7.4), the HCO_3^--H_2CO_3 buffer system would seem to be ill-suited to buffering pH in blood. However, this excess of base (HCO_3^-) along with the volatility of CO_2 comprises an efficient system for preventing accumulation of excess acid. The lungs effectively make this an open system, with the loss of CO_2 providing a large buffering capacity. It is the ratio of HCO_3^- to H_2CO_3 that determines the pH. Thus, HCO_3^-:H_2CO_3 in a concentration ratio of 15:0.75 has the same pH as a ratio of 20:1.0.

Hb

In addition to its oxygen binding and releasing properties, Hb also acts as a buffer by transporting acid from the tissues to the lungs. A remarkable feature of Hb is that it increases its affinity for hydrogen ions (H^+) as it loses oxygen. That is, HHb has a greater affinity for H^+ than does O_2Hb. In tissue capillaries, O_2Hb enters an environment of low pO_2 and high acid. These conditions promote release of O_2, which also promotes binding of H^+. In the lungs, HHb encounters an environment of high pO_2 and low acid, which promote gain of O_2 and release of H^+. These relationships are shown in Fig. 36.1.

Phosphate

The HPO_4^{2-}-$H_2PO_4^-$ buffer pair is of minor importance as a buffer in plasma, with a concentration of ~1 mmol/L (3.1 mg/dL). It is of greater importance, and in higher concentration, as an intracellular buffer.

Albumin and other proteins

Largely due to the imidazole groups on the amino acid histidine, with a pK of ~7.4, albumin and other proteins are also pH buffers. Because albumin is normally the major "unmeasured" anion in blood, albumin also affects the AG. For every 1 g/dL decrease in albumin below a normal level of ~4.4 g/dL, the AG will decrease by about 2.5 to 3 mmol/L. Patients in intensive care commonly have hypoalbuminemia, which can lower the AG and possibly confuse the interpretation of this parameter [2,8].

Fody (Eds.), Clinical Chemistry: Principles, Procedures, Correlations, second ed., Lippincott, Philadelphia, PA [7].*

Acid-base regulation

Respiratory (ventilatory) system

CO_2 is continually produced by aerobic metabolism, diffuses into blood, and then is removed by ventilation. Given that arterial CO_2 is influenced greatly by the ventilatory rate, pCO_2 is considered the respiratory component of the bicarbonate−CO_2 buffer system. Slight changes in H^+ ion concentration affect ventilatory rate, which is a major factor for pH regulation. Provided there is a sufficient gradient of pCO_2 between the tissues and the blood, CO_2 will readily diffuse into the blood, forming HCO_3^- and H^+ ions, with Hb readily accepting the H^+ (see Fig. 36.1). As Hb enters a region of high pO_2 in the lungs, HHb picks up O_2 to become O_2Hb, which immediately promotes loss of H^+. H^+ quickly combines with HCO_3^- to produce dissolved CO_2, which diffuses into the alveolar air for ventilatory removal.

The arterial pCO_2 represents a balance between tissue production and diffusion of CO_2 into blood, and pulmonary removal of CO_2. An elevated pCO_2 usually indicates inadequate ventilation (hypoventilation) and a respiratory acidosis. Conversely, a decreased pCO_2 usually indicates excessive ventilation (hyperventilation) and a respiratory alkalosis. There are several causes of respiratory abnormalities [9]. Respiratory acidosis (ventilatory failure) can be caused by the following:

- Obstructive lung disease (e.g., chronic bronchitis or emphysema)
- Impaired pulmonary blood flow (pulmonary embolism)
- Impaired function of respiratory center (head trauma, sedation, or anesthesia)
- Hypoventilation by mechanical ventilator

Respiratory alkalosis (hyperventilation) can be caused by:

- Hypoxemia (which stimulates hyperventilation)
- Anxiety
- Hyperventilation by mechanical ventilator
- Metabolic acidosis
- Septicemia
- Trauma

Metabolic (renal) system

The renal regulation of acid−base balance is complex, but in simple terms, when the H^+ concentration deviates from normal, the kidneys respond by reabsorbing or secreting H^+ and exchanging Cl^- with HCO_3^-, and other ion exchanges to regulate the pH of blood. Because kidneys are the major regulator of HCO_3^-, HCO_3^- is considered the metabolic component of the HCO_3^--CO_2 buffer system. (Although H^+ is regulated by the kidney, the liver, through gluconeogenesis, is more important than the kidney in removal of H^+.) Metabolic acidosis may develop either if H^+ accumulates or if HCO_3^- ions are lost. Metabolic alkalosis may develop from either loss of H^+ or increase of HCO_3^-. Although a change in ventilatory rate can alter arterial pH in minutes, the kidneys require hours to days to affect significantly pH by altering the excretion of HCO_3^-. Thus metabolic compensation takes several hours to alter the pH significantly.

Compensation

Compensation is a homeostatic response to an acid−base disorder in which the body attempts to restore pH to normal by adjusting the ratio of HCO_3^- to H_2CO_3 ($0.03 \times pCO_2$) back to a normal ratio of 20:1. Compensation involves either a relatively rapid ventilatory response (change in pCO_2) to a metabolic abnormality, or a relatively slow metabolic response (change in HCO_3^-) to a ventilatory abnormality. Some facts to remember about compensation are:

- It is driven by changes in pH. As compensation returns pH to normal, the pH-driven compensation process slows, then stops.
- Significant respiratory compensation of metabolic acidosis by loss of CO_2 occurs in 12−24 hours, while full metabolic compensation of respiratory acidosis by renal loss of HCO_3^- takes 2−5 days.
- Respiratory compensation by hyperventilation in metabolic acidosis is fairly predictable.
- While the respiratory response to metabolic alkalosis is hypoventilation, other factors such as pain and hypoxemia can stimulate hyperventilation and overcome the hypoventilatory effect of metabolic alkalosis [8].

The expected compensation for each acid−base abnormality will be discussed in the sections "clinical abnormalities of acid−base balance" and "Mixed acid−base disorders."

Clinical abnormalities of acid−base balance

Metabolic (nonrespiratory) acidosis

Metabolic acidosis is any clinical process that leads to a decreased blood pH (acidemia) and a decreased HCO_3^- level. It may be caused by gain of an acid or loss of a base, usually bicarbonate (increased AG), or a gain of Cl (normal AG). Causes of metabolic acidosis include the following [8,10]:

Acidosis is usually associated with little change in AG:

- Loss of HCO_3^- and gain of Cl: diarrhea and renal tubular acidosis (RTA). In RTA, insufficient HCO_3^- is reabsorbed in exchange for Cl, such that HCO_3^- is lost in the urine and Cl increases in the blood.

Acidosis is usually associated with an increased AG (Table 36.2):

- Excess production of acid from ketoacidosis, hypoxia, or lactate acidosis. Because insulin deficiency inhibits glucose entry into cells, to maintain adequate production of ATP, fatty acids are oxidized that produce ketoacids. Hypoxia results in more pyruvate conversion into lactate.
- Ingestion of acids or acid-producing substances: salicylates, ethanol, ethylene glycol, methanol, ammonium chloride, etc.
- Renal insufficiency with inadequate renal excretion of acids from normal metabolism.

Use of the anion gap in metabolic acidosis

The AG, especially when elevated, may be useful in diagnosing the type of metabolic acidosis and in indicating the possibility of a mixed acid−base disorder, as shown in Table 36.2.

Expected compensation in metabolic acidosis

In the initial phase of metabolic acidosis, both pH and HCO_3^- are decreased and pCO_2 is still normal (Table 36.3 and Fig. 36.2). Acidemia stimulates medullary chemoreceptors causing hyperventilation, and this respiratory compensation by hyperventilation should start to lower blood pCO_2 within minutes and have a significant effect by 2 hours, with maximal effect in 12 to 24 hours. Respiratory compensation typically lowers pCO_2 in a predictable manner (Table 36.3). If the pCO_2 is more than

TABLE 36.3 Expected compensation for acid–base disorders.

Metabolic Acidosis—CO_2 excretion by the lungs
pCO_2 decreases 1–1.3 mmHg for every 1 mmol/L decrease in HCO_3^-; pCO_2 is within 2 of sum $(1.5 \times HCO_3) + 8$ pCO_2 within 2 of 2 digits after decimal in pH
Metabolic alkalosis—CO_2 retention by the lungs
pCO_2 increases by 0.6–0.7 mmHg for every 1 mmol.L increase in HCO_3^-; pCO_2 is within 3 of sum $(0.65 \times HCO_3^-) + 23$
Respiratory acidosis—HCO_3 retention by kidneys
Acute: HCO_3^- increases 1 mmol/L for every 10 mmHg increase in pCO_2; Chronic: HCO_3^- increases 3–5 mmol/L for every 10 mmHg increase in pCO_2
Respiratory alkalosis—HCO_3 excretion by kidneys
Acute: HCO_3^- decreases by 1–2 mmol/L for every 10 mmHg decrease in pCO_2; Chronic: HCO_3^- decreases 3–5 mmol/L for every 10 mmHg decrease in pCO_2(minimum 12–14 mmol/L)

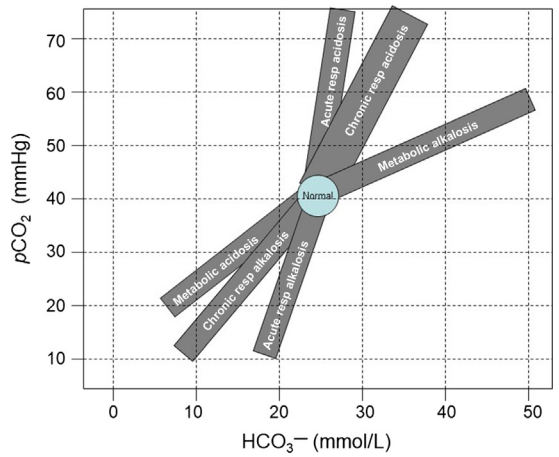

FIGURE 36.2 Expected relationships between HCO_3^- and pCO_2 during compensation for primary acid–base disorders. The areas shown are based on plots of equations shown in Table 36.3.

3 mmHg above the expected (calculated) value, the patient's lungs may not be fully capable of hyperventilating and may have an underlying respiratory acidosis. If the pCO_2 is less than 3 mmHg of this calculated value, an underlying respiratory alkalosis may be present.

Treatment of metabolic acidosis

The optimal treatment for metabolic acidosis is correcting the underlying cause, such as by administering insulin, improving DO_2, giving fluids as appropriate, correcting any electrolyte disorders, etc. If the condition must be corrected urgently, bicarbonate may be administered based on the blood bicarbonate level [8].

Metabolic (nonrespiratory) alkalosis

Metabolic alkalosis is an acid–base disorder characterized by an elevation in bicarbonate level above 26 mmol/L and an elevation in pH. Metabolic alkalosis is frequently associated with renal impairment, because a healthy kidney can excrete large amounts of HCO_3^- when it is in excess [1,10]. Causes of metabolic alkalosis include the following [1,8]:

- Loss of acid by vomiting or loss of acidic urine. The initial loss of gastric acid causes metabolic alkalosis, which may enhance renal tubular loss of K^+ to conserve H^+.
- Deficiency of Cl. Deficiency of Cl enhances HCO_3^- reabsorption in the renal tubule. Contraction of the intravascular volume can cause a Cl deficit and alkalosis ("contraction alkalosis").
- Hypokalemia. Hypokalemia stimulates distal tubular reabsorption of HCO_3^- ions.
- Administration of excess HCO_3^-. If excessive, HCO_3^- administration may lead to alkalosis, especially if renal function is compromised.
- Diuretics. Loop diuretics interfere with tubular reabsorption of Na and Cl, and thiazide diuretics enhance K loss, both of which can increase HCO_3^- levels.
- Corticosteroid excess, as in Cushing's syndrome or hyperaldosteronism, can lead to both metabolic alkalosis and hypokalemia.

Expected compensation in metabolic alkalosis

Although metabolic alkalosis consistently causes hypoventilation, the timing and degree of this ventilatory compensation response to metabolic alkalosis is not always predictable, because other factors such as pain and hypoxemia can stimulate hyperventilation and overcome the hypoventilatory stimulus of metabolic alkalosis [8]. The maximal respiratory compensation by hypoventilation can elevate arterial pCO_2 to >80 mmHg (Table 36.3 and Fig. 36.2) [8].

In the initial phase of metabolic alkalosis, both pH and HCO_3^- are increased and pCO_2 remains normal. Within 2 hours, compensation by hypoventilation is expected, but maximal compensation requires 12–24 hours, which increases the blood pCO_2 to match the elevated HCO_3^-

and restore the HCO_3^-/pCO_2 ratio to normal. In general, the increase in pCO_2 from compensation by hypoventilation increases according to the HCO_3^- level in a predictable manner, as described in Table 36.3. If the actual pCO_2 deviates from this expected pCO_2 by $>$ 3−4 mmHg, the patient may have a mixed disorder due to either an underlying respiratory acidosis (if >3 mmHg higher) or alkalosis (if >3 mmHg lower).

Treatment of metabolic alkalosis

The optimal treatment for metabolic alkalosis is correcting the underlying cause. In some cases, simple hydration will gradually correct metabolic alkalosis if renal function is normal. If Cl^- depletion is present, Cl^- replacement by administration of NaCl or KCl also allows the kidney to excrete HCO_3^-. Hypokalemia is corrected, if present. Rarely, intravenous dilute HCl administration is necessary [11].

Respiratory acidosis

Respiratory acidosis is ventilatory failure that leads to a decreased pH and increased pCO_2. Acute respiratory acidosis occurs by either: decreased breathing or ventilation, increased production of CO_2 by the body, or excess CO_2 in the inspired gas [1,8]. Normally, any increased production of CO_2 promptly stimulates hyperventilation, which maintains arterial pCO_2 at normal levels. If arterial pCO_2 is increased, it almost always involves a problem with ventilation. Causes of respiratory acidosis include the following:

- Impaired pulmonary gas exchange by alveoli, such as with chronic bronchitis, emphysema, or asthma.
- Acute airway obstruction caused by aspiration or blockage of airway tube.
- Insufficient delivery of blood to the lungs from circulatory failure or pulmonary embolism.
- Impaired function of respiratory center caused by head trauma, drugs (opiates, barbiturates, etc.), toxins, or anesthesia.
- Weakness of respiratory muscles.
- Mechanical ventilation that does not provide either adequate oxygen or adequate removal of CO_2 [12].

Expected compensation in respiratory acidosis

During the acute phase, plasma buffering of the elevated CO_2 increases the HCO_3^- slightly, by approximately 1 mmol/L for each 10 mmHg rise in pCO_2 (Table 36.3 and Fig. 36.2). Over the next few hours, the kidneys increase reabsorption of HCO_3^-, which elevates serum HCO_3^- by about 2 mmol/L. As this continues into the chronic phase (over 24 hours), the HCO_3^- slowly rises and plateaus after 2−5 days with normalization of the pH. The expected blood level of HCO_3^- may be calculated, as described in Table 36.3. As an example,

* In chronic respiratory acidosis, if the pCO_2 has increased from 40 mmHg to a steady state of 60 mmHg over 3 days, the HCO_3^- should have risen to about 8 mmol/L. That is, if the patient's normal HCO_3^- was 24 mmol/L, it would be about 32 mmol/L after 3 days of metabolic compensation, with a normal pH.

Treatment of respiratory acidosis

Treatment should be directed at correcting the underlying cause: (a) restore adequate lung ventilation by such means as endotrachial intubation or positive pressure ventilation; (b) restore pulmonary circulation; or (c) correct any drug overdose. Care must be taken to avoid correction of the elevated pCO_2 too rapidly. Administration of bicarbonate is rarely done, because HCO_3^- crosses the blood−brain barrier slowly, which can elevate the blood pH without affecting the CNS pH [8].

Respiratory alkalosis

Respiratory alkalosis is caused by any condition that leads to hyperventilation. If a normal ventilatory rate of 12−15/min increases to $\geq$ 20/min, CO_2 will be lost faster than it is produced, leading to an increased pH and decreased pCO_2. Causes of respiratory alkalosis include the following:

- Hypoxemia-induced hyperventilation, as caused by breathing oxygen-poor air or exposure to high altitude.
- Pulmonary embolism or pulmonary edema, in which oxygen transport across the alveolar membrane is impaired to a greater extent than is CO_2 transport.
- Hyperventilation induced by anxiety, pain, or pregnancy.
- Excess mechanical ventilation, usually from aggressive use of the ventilator to increase arterial oxygen tension.
- Drugs such as salicylate, nicotine, or progesterone, which can cause hyperventilation.
- Central nervous system disorders resulting from conditions such as sepsis or trauma.

Expected compensation in respiratory alkalosis

Because metabolic compensation by the kidney to increase excretion of HCO_3^- is relatively slow, it is time-dependent and occurs in two phases, as described in Table 36.3 (see also Fig. 36.2), for example:

- Acute respiratory alkalosis (<24 hours): If pCO_2 decreases from 40 to 30 mmHg, this 10-mmHg fall should be associated with a pH increase of 0.08

(pH ~ 7.48) and bicarbonate should decrease by about 2 to ~22 mmol/L.
- Chronic respiratory alkalosis (2–5 days): If the pCO_2 is 30 mmHg after 2 days of hyperventilation, the pH should be increased by 0.03 (pH ~7.43) and HCO_3^- should be decreased by about 4 to ~20 mmol/L.

Note that the lower limit for metabolic compensation in hyperventilation is a plasma HCO_3^- of ~12–14 mmol/L. If plasma HCO_3^- is <12 mmol/L, an underlying metabolic acidosis should be suspected.

Treatment of respiratory alkalosis

Treatment is aimed at correcting the underlying condition. Most urgently, hypoxemia must be corrected by giving oxygen. Salicylate or other drug overdoses should be treated appropriately. Any anxiety-induced respiratory alkalosis may simply be treated with reassurance or rebreathing expired air from a paper bag (higher CO_2 content) that can be helpful in otherwise healthy persons [8].

Detecting mixed acid–base disorders

Mixed acid–base disorders occur when multiple primary acid–base disorders occur at the same time. These are common in hospital populations, especially in the emergency department (ED) and in critical care. Although there are equations and diagrams that can aid in the diagnosis, these relationships will not hold in patients with complex acid–base disorders, especially if they occur and/or resolve at different times. There is no substitute for a careful review of a patient's clinical course and serial blood gas measurements.

The importance of identifying mixed acid–base disorders lies in their diagnostic and therapeutic implications. For example, the development of a primary metabolic alkalosis (increased [HCO_3^-]) in a patient with chronic obstructive airway disease who is being treated with diuretics should alert the clinician to possible potassium depletion. In another example, a patient presenting with a mixed respiratory alkalosis and metabolic acidosis should be evaluated for salicylate intoxication.

Does the expected compensation occur?

A simple concept to remember in a primary acid–base disorder is that if the expected compensation does not occur within an expected time frame, a mixed disorder should be suspected. For example, in a primary metabolic acidosis, the lungs are expected to compensate this excess metabolic acid by hyperventilating (a respiratory alkalotic process) to remove the respiratory acid CO_2 and return the pH toward normal. If this does not occur in the time or to the degree expected, the person is considered to have an underlying respiratory acidosis. Refer to the examples below and to Fig. 36.2 and Table 36.3 for the expected responses. *Note that these equations should only be used as guides and not as absolute diagnoses, especially when a patient has multiple acid–base disorders that have occurred over time.*

Metabolic acidosis

The body's natural response during the first 12–24 hours is hyperventilation (a respiratory alkalotic process), which decreases the blood pCO_2 in a somewhat predictable way and increases pH back toward normal.

Metabolic alkalosis

The response to metabolic alkalosis is respiratory hypoventilation (a respiratory acidotic process), which increases the pCO_2 and decreases pH back toward normal.

Respiratory acidosis or respiratory alkalosis

If a patient has a primary respiratory disorder, either acidosis or alkalosis, simple rules predict the expected pH changes versus the change in pCO_2 during the acute and chronic phases. During the acute phase of respiratory disorders, for each 10-mmHg rise or fall in pCO_2, the pH should decrease or increase (respectively), by 0.08. As this progresses into the chronic phase (1–2 days), for each 10-mmHg rise or fall in $pCO2$, the pH should have changed by only 0.03 [1,8,10]. Fig. 36.2 illustrates the relationships among pCO_2, pH, and HCO_3^- for acute and chronic respiratory changes. If the blood gas data clearly do not reflect these temporal relationships, it suggests an additional disorder is present and that the patient has a mixed disorder.

Delta ratio or delta gap: does the change in anion gap match the change in bicarbonate?

The delta ratio (DR) or the delta gap (DG) is the calculation that may be useful in a patient with metabolic acidosis to indicate if a mixed acid–base disorder may be present. Typically, in metabolic acidosis, an increase in AG from 12 mmol/L and a decrease in HCO_3 from 24 mmol/L should approximately equal each other. This is called the "DR" [8], calculated as:

$$\text{Delta ratio} = \frac{\text{AG} - 12}{24 - \text{HCO}_3} \tag{36.x}$$

Obviously, for these calculations to be useful, there must be a significant change in the AG from 12; otherwise, the DR will be zero. In a typical AG metabolic acidosis, this "DR" would be 1.0. If the DR is greater than 1,

TABLE 36.4 Examples of delta ratio and delta gap calculations for metabolic acidosis.

pH	Na	Cl	HCO_3^-	AG	DR	DG	Condition
7.40	140	104	24	12	0/0	0	Normal: no metabolic acidosis
7.25	140	104	12	24	12/12 = 1.0	0	High AG metabolic acidosis
7.15	140	110	14	16	4/10 = 0.4	− 6	High AG metabolic acidosis + normal AG metabolic acidosis
7.30	140	98	22	20	8/2 = 4.0	+ 6	High AG metabolic acidosis + metabolic alkalosis

AG, Anion gap; *DG*, delta gap; *DR*, delta ratio.

it suggests there is more HCO_3^- in the blood than expected from the increased AG, so that an additional metabolic alkalosis may be present. If the DR is less than 1, it suggests less HCO_3^- is present than expected from the increased AG, so that an additional non-AG metabolic acidosis, such as hyperchloremic metabolic acidosis, may be present.

This may also be calculated as a DG as follows:

$$DG = (AG - 12) - (24 - HCO_3)$$

$$DG = AG + HCO_3 - 36$$

Since the AG is Na−Cl−HCO_3, the DG calculation can be further simplified as follows:

$$DG = Na - Cl - 36$$

An elevated AG with a DG $\geq$ 6 suggests a mixed AG metabolic acidosis with a metabolic alkalosis, because the fall in HCO_3^- is less that the rise in AG. An elevated AG with a significant negative DG (≤ -6) suggests a mixed disorder: a high AG metabolic acidosis with a hyperchloremic (normal AG) metabolic acidosis is present, because the fall in HCO_3^- is greater than the rise in AG [13]. Table 36.4 gives some examples of DR and DG calculations for various metabolic acidosis.

Tips for diagnosing mixed acid−base disorders

The following are additional tips to diagnose mixed acid−base disorders:

- If the pH is well within normal and both the HCO_3^- and pCO_2 are abnormal, this strongly suggests a mixed disorder.
- Whenever HCO_3^- and pCO_2 are abnormal in the opposite direction, the compensatory response should always be in the same direction as the change caused by the primary disorder.
- Simple acid−base disorders do not overcompensate, that is, compensation will not cause an acidemia to become an alkalemia.

Evaluating blood gas results

Reference and critical ranges

The reference ranges for both arterial and venous blood are shown in Table 36.1 for the common blood gas and acid−base parameters [3,9], along with typical critical limits for each parameter. Notes:

- Venous pH and pCO_2 may be used to assess acid−base and ventilatory status, with venous pH approximately 0.02−0.04 units lower than arterial pH and venous pCO_2 approximately 3−7 mmHg higher than arterial values.
- Venous pO_2 has no clinical value and cannot be used to approximate arterial pO_2.
- The pO_2 of arterial blood varies with age, decreasing by about 1 mmHg with every year over 60 years of age.

Evaluating the acid−base status

Ideally, evaluating acid−base disorders, including mixed acid−base disorders, would include simultaneous information on the patient's clinical history, the electrolyte results, and the blood gas results. With modern blood gas analyzers, the blood gas results are often available with the electrolyte results.

The acid−base and blood gas results (pH, pCO_2, pO_2, and HCO_3^-) may be evaluated in several steps, as follows:

1. Evaluate the patient's clinical history and current status to anticipate conditions associated with acid−base disorders.
2. Evaluate the pH.
3. Evaluate the ventilatory (pCO_2) and metabolic (HCO_3^-) status to determine the primary disorder.
4. Evaluate laboratory and clinical data for a possible mixed disorder:
   a. For a primary metabolic (or respiratory) disturbance, is respiratory (or metabolic) compensation appropriate?

TABLE 36.5 Examples of the expected acid–base disorder associated with various clinical conditions.

Clinical condition	Expected acid–base disorder
Cardiac arrest	Metabolic acidosis
Pulmonary arrest	Respiratory acidosis
Hyperventilation (many causes)	Respiratory alkalosis
Blockage of endotrachial tube ⇒ (after removal of blockage from tube)	Respiratory acidosis ⇒ (respiratory alkalosis)
Congestive heart failure leading to hyperventilation	Respiratory alkalosis
Vomiting	Metabolic alkalosis
Diarrhea	Metabolic acidosis
Shock state (inadequate perfusion)	Metabolic acidosis
Pulmonary edema	Respiratory alkalosis (hypoxia leads to hyperventilation)
Severe pulmonary edema	Respiratory acidosis
Diuretic therapy	Metabolic alkalosis
Drug intoxication	Respiratory acidosis (respiratory arrest)
Bicarbonate therapy	Metabolic alkalosis
Poor perfusion	Metabolic acidosis

b. Do any other parameters, such as electrolytes, lactate, AG, or DR indicate that another acid–base disturbance is present?
c. Is the patient's history consistent with the blood gas results?

The evaluation of oxygen status is mostly independent of the acid–base interpretation, so it will be evaluated in a separate section.

Step 1: evaluate the patient's status and history to anticipate possible acid–base abnormalities

Many conditions are associated with acid–base disorders, as listed in Table 36.5. A perceptive clinical evaluation can be a most important part of evaluating a patient for acid–base disorders.

Step 2: evaluate the pH

An abnormal pH indicates that an acidosis or alkalosis has occurred and the extent of the acid–base disorder, and it may suggest that compensation has occurred. However, the pH by itself does not indicate whether a mixed disorder is present. Consider the following examples:

- pH 7.20 confirms that a severe acidosis is present and that compensation is either in its early stages or ineffective in controlling the acidosis. Further investigation is required to determine the metabolic or respiratory origin of the acidosis and whether more than one acidotic process is present.
- pH 7.48 indicates that a mild alkalosis is present. Further information is required to determine the cause of the alkalosis and whether the alkalosis is in its early stages (and may get worse), has been nearly compensated, or is part of a mixed disorder.
- A normal pH may indicate that the patient has no acid–base disorder, or a patient may have both acidotic and alkalotic events (primary or compensatory) that have offset each other. The patient's history and the HCO_3^- and pCO_2 should be considered.

Step 3: evaluate the ventilatory and metabolic statuses

The simplest approach to evaluating the pCO_2 and HCO_3^- is to consider each parameter separately as indicating acidosis, alkalosis, or normal status, then evaluate them along with pH to determine whether the primary disorder is respiratory or metabolic and whether a mixed disorder or compensation is present.

A decreased pCO_2 indicates a respiratory alkalotic process, which may be either primary or compensatory.

An increased pCO_2 indicates a respiratory acidotic process, either primary or compensatory. A decreased HCO_3^- indicates a metabolic acidosis, either primary or compensatory. An increased HCO_3^- indicates a metabolic alkalosis, either primary or compensatory.

Note: The terms "respiratory alkalosis," "metabolic acidosis," etc., refer to pathologic processes and not to compensation. However, to simplify interpretation, momentarily regard any decreased pCO_2, for example, as a respiratory alkalotic process. It will become clear whether it is a primary abnormality or appropriate compensation as other factors are considered.

A normal pCO_2 and HCO_3^- indicate normal ventilatory and metabolic status. However, if one of these parameters is normal when the other is abnormal, then a mixed disorder may be present. That is, a lack of an appropriate compensatory response suggests an additional disorder is present.

Examples

A pCO_2 result of 25 mmHg indicates that a respiratory alkalotic process is present. However, referring to Fig. 36.2, it could be an acute or chronic respiratory alkalosis, or even a compensated metabolic acidosis. It depends on the HCO_3^- and pH associated with this pCO_2 to determine whether it is a primary abnormality or appropriate compensation. If the HCO_3^- is 14 mmol/L (with a pH of ~7.32), then the pCO_2 of 25 mmHg probably indicates compensating hyperventilation (a respiratory alkalotic process) for a primary metabolic acidosis.

In another example for a pCO_2 of 25 mmHg, if the HCO_3^- is 23 mmol/L and the pH is ~7.53, this suggests acute hyperventilation, but this diagnosis would also depend on the duration of hyperventilation. If acute, the metabolic compensatory response to eliminate HCO_3^- is progressing about as expected. However, if the hyperventilation is chronic, then the higher than expected HCO_3^- suggests that, because the kidney is unable to compensate adequately by eliminating HCO_3^-, a metabolic alkalosis may also be present.

Steps 4a–4c: evaluate for a possible mixed disorder

4a. Is the compensation adequate for the primary disorder?

To evaluate whether or not the expected compensation is occurring for the primary acid–base disorder requires serial measurements of blood gas and electrolyte results; refer to Fig. 36.2 and Table 36.3 and the "Expected Compensation" descriptions in the sections "*Clinical Abnormalities of Acid-Base Balance*" and "*Mixed Acid-Base Disorders.*"

4b. Do other laboratory results suggest an additional acid–base disorder is present?

Several common laboratory tests may help determine whether additional acid–base disorders are present [8,10,12].

Potassium

Hypokalemia is frequently associated with a metabolic alkalosis.

pH

A normal pH combined with abnormal results for both HCO_3^- and pCO_2 warrants consideration of a mixed acid–base disorder.

Chloride

Hyperchloremia results from HCO_3^- loss, either from a primary metabolic acidosis as with renal loss of HCO_3^- with retention of Cl, or from the metabolic acidotic compensation for respiratory alkalosis. Hypochloremia may cause metabolic alkalosis by promoting renal reabsorption of HCO_3^- or may be caused by compensation for chronic respiratory acidosis (as HCO_3^- is retained and Cl^- is excreted).

Anion gap

An elevated AG $[(Na^+) - (Cl^- + HCO_3^-)]$ of >20 mmol/L indicates metabolic acidosis. AG is also useful in differentiating the causes of metabolic acidosis, as shown in Table 36.2 [2,13].

While often very useful, AG is calculated from three or four measurements and is subject to variation from these measurements. As an example, some patients with a clearly elevated blood lactate will not have an elevated AG [2,13].

Delta ratio

The "DR" should also be evaluated, as discussed earlier in the section "Detecting mixed acid–base disorders." Since this is based on the AG, it is also subject to analytical variations in the methods and also variation in a specific patient's "normal" AG.

Lactate

A rising blood lactate is a sensitive indicator of metabolic acidosis resulting from poor oxygenation of tissues or of mitochondrial dysfunction.

Creatinine

An elevated creatinine indicates renal insufficiency and possible uremic metabolic acidosis.

4c. Does the patient have other conditions associated with an acid–base disorder?

An evaluation of blood gas results must always include the patient's historical and physical findings. Many conditions are frequently associated with an acid–base disorder, with some common ones listed in Table 36.5, especially if the blood gas results cannot readily be explained by the patient's "primary" disorder. The presence of more than one such condition should alert the clinician to the possibility of a mixed acid–base disorder. Mixed acid–base conditions are quite common.

Evaluating oxygen status

Hemoglobin binding

Hb binding to O_2

Hb consists of four heme molecules attached to four globin molecules and has the essential abilities to (1) bind oxygen in the lungs then transport and release oxygen to the tissues, and (2) transport H^+ and carbon dioxide from the tissues to the lungs. Each of the four heme groups contains an Fe ion and can bind one molecule of oxygen. Structural changes occur with oxygen binding that results in color changes to the molecule [9].

Several factors affect Hb binding of oxygen. In addition to pO_2, these factors are H^+, temperature, pCO_2, and 2,3-diphosphoglycerate (2,3-DPG). The effects of these factors are easy to remember, because they are inversely related to oxygen binding. That is, an increase in H^+ concentration, temperature, carbon dioxide pressure, or 2,3-DPG concentration will decrease the affinity of Hb for oxygen. In the tissues, blood enters an area of relative warmth, acidity, elevated pCO_2, and low pO_2, conditions that promote loss of O_2 to tissues and binding of H^+ by Hb.

The role of 2,3 DPG on Hb binding and release of O_2 is more complex. 2,3 DPG is a molecule largely contained in RBCs that "cooperates" with O_2 to control when Hb binds or releases O_2. In the lungs with a high pO_2, oxygen binds to Hb, which promotes the release of 2,3-DPG. This release of 2,3-DPG further increases the affinity of Hb for O_2 so that Hb binds more O_2. The loss of 2,3-DPG favors a Hb conformation (R form) with a higher affinity for O_2 [14]. As blood enters the tissues, the increased H^+ ions and pCO_2 promote release of O_2, which then favors binding of 2,3-DPG to Hb. This causes a conformational change to the T form of Hb that has a lower affinity for O_2, therefore leading to further release of oxygen to the tissues. The sigmoidal relationship between pO_2 and sO_2 is well known as the Hb-oxygen dissociation curve, shown in Fig. 36.3.

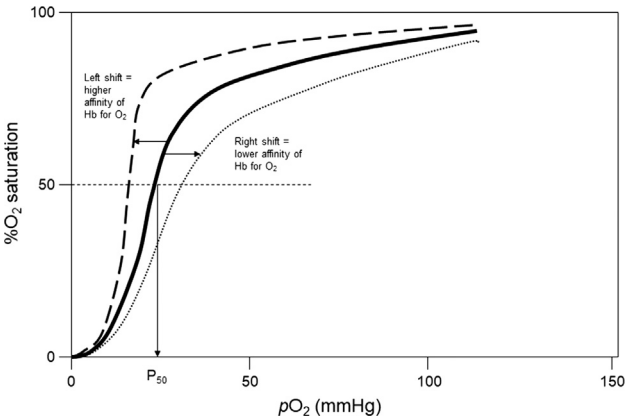

FIGURE 36.3 Oxyhemoglobin dissociation curve for whole blood. The solid middle curve represents the percent of hemoglobin that becomes saturated with oxygen as the oxygen pressure (pO_2) is increased. The dashed curve represents a *left shift* of the curve when the affinity of Hb for oxygen is increased by lower temperature, lower H ion concentration, lower oxygen pressure, etc. The dotted curve represents a *right shift* of the curve when the affinity of Hb for oxygen is decreased by higher temperature, higher H ion concentration, higher oxygen pressure, etc. The P_{50} is the oxygen pressure that gives Hb a 50% saturation and is an index of the overall affinity of Hb for oxygen. A *left shift* of the curve decreases the P_{50} and a *right shift* increases the P_{50}.

Fetal Hb, a form of Hb present in decreasing amounts during the first month of life, does not bind 2,3-DPG as well as adult Hb, so fetal Hb tends to stay in a conformation with a higher affinity for O_2 than does adult Hb. This is essential so that the fetal blood can take O_2 away from maternal blood. Fetal Hb also has a slightly altered absorbance spectrum, which can falsely elevate readings for COHb. Different wavelengths and various correction factors are used in the analyzers to minimize this interference.

Nitric oxide (NO) also plays a role in DO_2. NO regulates vascular tone, which can affect both blood perfusion and DO_2 to tissues. Being structurally very similar to molecular oxygen (O_2), NO also binds to the heme iron of Hb and can form both metHb and S-nitroso Hb. The binding and release of oxygen by Hb may selectively release NO to the cell membrane, where it affects blood pressure [15].

Disorders of oxygenation: hypoxemia and tissue hypoxia

Utilization of oxygen requires many processes to function smoothly:

- air intake by breathing or ventilation;
- air entry into the alveoli;
- pulmonary gas exchange with functional alveoli;
- oxygenation of blood and Hb;

- O_2 transport to tissues and cells, with adequate Hb and systemic blood flow;
- O_2 release and diffusion into cells; and
- O_2 utilization by the mitochondria to produce adequate ATP and so on.

Inadequate oxygenation of blood may be caused by:

- low *FI* O_2, such as from inadequate oxygen in inhaled anesthetics, fires, or high altitudes;
- hypoventilation leading to insufficient O_2 in alveolar air;
- mismatch of pulmonary ventilation to pulmonary perfusion: ventilation/perfusion (V/Q) mismatch;
- diffusion (gas exchange) impairment between alveolar air and blood: pulmonary embolism, emphysema, and pulmonary edema;
- intrapulmonary shunting: blood goes from the right heart to the left heart without contacting functional alveoli as with pneumonia; and
- anemia: insufficient O_2 carrying capacity in blood.

Poor tissue oxygenation or O_2 utilization may be caused by the following:

- inadequate blood flow to tissues due to diminished cardiac output or altered blood flow;
- inadequate uptake of O_2 by the tissues; and
- mitochondrial dysfunction

Both pO_2 and blood lactate may be used to evaluate these conditions.

O_2 delivery to tissues

Gas exchange in the lungs

The pO_2 of atmospheric air (21% O_2) is $\sim$150 mmHg, accounting for the contribution of water vapor (45 mmHg) to the atmospheric pressure: $(760-45) \times 0.21 = 150$ mmHg. An adult breathing air with a pO_2 of 150 mmHg should have an alveolar pO_2 $\sim$100 mmHg because of CO_2 in the alveolar air and an arterial pO_2 of 80–100 mmHg. The reference range for arterial pO_2 also depends on age [9].

Diminished gas exchange in the lungs may be caused by:

- pulmonary congestion caused by asthma, edema, or inflammation;
- fibrosis;
- alveolar dead space;
- intrapulmonary shunting;
- mucus hypersecretion (bronchitis);
- loss of alveolar compliance; or
- insufficient surfactant (neonatal respiratory distress syndrome).

Alveolar dead space refers to the gas volume in lungs that does not undergo gas exchange and is caused by unperfused alveoli. Dead space is evaluated by comparing the end-tidal pCO_2 with the arterial pCO_2, where a lower than expected end-tidal pCO_2 indicates a possible increased dead space. In intrapulmonary shunting, venous blood does not get oxygenated, because some blood passes through the pulmonary capillaries of nonfunctioning alveoli. When blood from these "shunts" mixes with oxygenated blood in the pulmonary vein, blood of a lower pO_2 and oxygen content is delivered to the systemic circulation [9]. Patients with excess pulmonary shunting require more oxygen than expected.

Blood flow to tissues

Although normal blood flow provides sufficient oxygen and nutrients to all organs and tissues, abnormalities in flow may develop that cause inadequate perfusion of general or localized areas of the body. Such conditions may lead to diminished oxygen content in arterial blood, shock states, tissue necrosis, and possibly death. Some common causes of poor perfusion are:

- inadequate cardiac output;
- decreased blood volume (hypovolemia);
- emboli;
- vasoconstriction;
- sepsis.

Evaluation of oxygenation status and arterial oxygenation

The blood gas parameters often used for assessing arterial oxygenation are as follows:

- the arterial oxygen tension (pO_2), especially in relation to the oxygen content of the air the patient is breathing (FIO_2);
- the sO_2 or the $\%O_2$-Hb in blood;
- the Hb concentration in blood.

The following parameters also may be calculated from the measured blood gas results:

- the oxygen content in blood;
- alveolar–arterial pO_2 difference or gradient;
- V/Q mismatch and intrapulmonary shunting of blood, in which blood flows into the lung but does not perfuse functional alveoli; and
- tissue oxygenation, assessed by blood lactate measurement.

Arterial O_2 tension and sO_2 of Hb

The pO_2 and sO_2 values often are used for assessing arterial oxygenation, with the pO_2 being a more linear reflection of the efficiency of blood oxygenation by the lungs,

and the sO_2 (along with Hb) being a better indicator of the O_2 content of blood. Hypoxemia is defined as an arterial pO_2 that is below the minimally acceptable limit for persons of a given age group breathing room air [9]. As pO_2 decreases <60 mmHg, the degree of hypoxemia intensifies, with severe hypoxemia occurring below 40 mmHg.

Ideally, the diagnosis of hypoxemia is made when the patient is breathing room air. However, if the patient is receiving oxygen therapy, changing the patient to breathing room air is likely not an option. So for a patient breathing oxygen-enriched air, the likelihood of hypoxemia may be predicted by comparing the arterial pO_2 with the FIO_2 (percent oxygen being breathed). If the arterial pO_2 (mmHg) is less than five times the FIO_2 (%), the patient's alveolar ventilation may be inadequate and the patient would probably be hypoxemic if breathing room air [9].

p_aO_2/FIO_2 ratio

The ratio of the p_aO_2 to FIO_2 is a simple, readily available clinical calculation used as one of the criteria to determine the presence and severity of the acute respiratory distress syndrome (ARDS). A higher ratio indicates better lung function or less severe disease [16]; p_aO_2/FIO_2 ratios follow:

- $\sim$350–500 = expected normal (lower values expected with aging);
- 201–300 = mild ARDS;
- 101–200 = moderate ARDS; and
- <100 = severe ARDS.

ARDS is a disorder characterized by diffuse damage to the alveolar–capillary membrane leading to noncardiogenic pulmonary edema and hypoxemia, caused by a number of insults, both pulmonary and nonpulmonary. The most common causes of ARDS include pneumonia, sepsis, aspiration, trauma, and pancreatitis, which lead to a systemic inflammatory response and injury to the alveolar–capillary interface. This causes exudation of protein-rich fluid into the alveoli and deficiency of surfactant, leading to alveolar collapse (atelectasis). ARDS is characterized by an acute onset of hypoxemic respiratory failure with a p_aO_2/FIO_2 ratio less than 300.

Hb concentration

Because a normal Hb concentration in blood (12–17 g/dL depending on gender) provides excess oxygen carrying capacity, a slightly decreased Hb of 10 g/dL is usually of no concern in critical care. Clinicians usually want to be sure the person is not severely anemic.

Blood O_2 content

Blood oxygen content is calculated from measurements of blood Hb and sO_2. Anemia will markedly lower the O_2 content, as will hypoxemia (low pO_2/sO2), hypercapnia (high pCO_2), acidemia (low pH), and hyperthermia, all of which cause Hb to be less saturated for a given pO_2.

Alveolar–arterial oxygen difference or gradient (A–a)

The alveolar–arterial pO_2 difference (A–a) is a measure of the pO_2 difference between the alveolar air and the arterial blood [10,17,18]. It may be useful for determining both the cause (i.e., ventilatory failure vs. oxygenation failure) and the severity of hypoxemia [19]. The alveolar pO_2 (p_AO_2) may be calculated as the difference between the atmospheric pO_2 of 150 mmHg [$(760-45)\times 0.21 = 150$ mmHg] (45 mmHg is atmospheric water vapor pressure) and the blood pCO_2 divided by a gas exchange factor (0.8) that represents the ratio between the arterial and alveolar pCO_2. Thus for typical conditions in a healthy person with measured arterial pCO_2 of 40 mmHg and arterial pO_2 of 95 mmHg (paO_2), the alveolar pCO_2 would be 50 (40/0.8) and the alveolar–arterial pO_2 difference would be:

$$p_AO_2 - paO_2 = \left(150 - 40/0.8\right) - 95 = 5 \text{ mmHg}.$$

- A low paO_2 with a significantly larger A–a difference, suggests oxygenation failure by poor alveolar gas exchange, caused by edema, inflammation, fibrosis, or increased pulmonary shunting.
- A hypoxemic patient with a normal A-a difference implies that the lungs are not ventilating enough air (hypoventilation).

V/Q mismatch and intrapulmonary shunting

The term V/Q refers to the amount of air entering the alveoli per minute (V) relative to the capillary perfusion (Q) of those alveoli.

- A V/Q ratio of 1.0 means that an amount of ventilation in an alveolar unit (such as 1 mL/min) is available to exchange gases with an equal amount of alveolar blood (1 mL/min).
- A V/Q ratio of 2.0 indicates twice as much alveolar ventilation for the amount of alveolar capillary perfusion.
- A ratio of 0.5 indicates half as much ventilation as perfusion [17].

A simple example of a condition leading to V/Q mismatch (V/Q > 1) would be a pulmonary embolism where a segment of the lung receives ventilation, but the blood flow to that ventilated area is blocked by a blood clot. Other conditions that can lead to V/Q mismatching include emphysema and pulmonary edema.

Intrapulmonary shunting is a condition of V/Q mismatching with a V/Q ratio of 0 for a given area of the lung leading to an overall V/Q < 1. A shunt indicates that blood flows through a portion of the lungs without coming in contact with functioning alveoli. This can occur in the setting of atelectasis, pneumonia, or complete bronchial obstruction where pulmonary blood perfuses nonfunctional or nonventilated alveoli.

The percent of shunted blood is the ratio of shunted cardiac output to total cardiac output, which may be estimated from O_2 content measurements of both arterial and venous blood. The following equation is an approximate calculation, assuming that blood in the pulmonary capillaries is 100% saturated:

$$\%\ \text{Shunt fraction} = \frac{100 - sO_{2\text{art}}}{100 - sO_{2\text{ven}}}$$

As an example, for a patient with an sO_{2art} of 92 and an sO_{2ven} of 70%, the % shunt fraction would be 27%.

Evaluating tissue oxygenation

Tissue oxygenation can be assessed from the calculations of DO_2 and VO_2, which require measurements of blood oxygen content and cardiac output. More simply, measurement of blood lactate is a laboratory test that provides a sensitive index of the overall state of DO_2 and oxygen utilization by mitochondria.

Collection and handling of samples for blood gas analysis

Use of arterial versus venous blood for blood gas and acid–base measurements

Perhaps more than any other analytes, pO_2, pCO_2, and to some extent pH change markedly from arterial to venous blood. Arterial blood is mostly preferred over venous blood for blood gas analysis of pH, pCO_2, and pO_2, because arterial pO_2 indicates the ability of the lungs to oxygenate the blood with alveolar air, and arterial blood provides an index of the oxygen and nutrients that will be provided to the tissues and cells.

Because typical venous blood collected from an arm vein represents oxygen metabolism only in the arm, venous blood representing oxygen metabolism of the entire body is sometimes needed. This requires that "mixed" venous blood be collected, which exists in the pulmonary artery and can be collected with a Swan–Ganz catheter [9]. Both mixed venous and arterial blood are needed when determining parameters such as P50 and VO_2.

Collection and handling of blood

Blood collected for blood gas analysis is highly susceptible to changes in pO_2. Anaerobic conditions during collection and handling are essential, because room air has a pCO_2 of nearly 0 and a pO_2 of ~150 mmHg. The factors that must be controlled are:

- removal of all air bubbles;
- use of the proper anticoagulant;
- appropriate use of plastic syringes (glass syringes rarely used);
- the temperature of storage before analysis;
  - agitation of the blood specimen; and
- the length of delay between collection and analysis of blood.

The complete removal of all air bubbles is especially important before sending blood in a syringe by pneumatic transport, which can markedly affect pO_2 by up to 25 mmHg, depending on the initial pO_2 [20,21]. pCO_2 is almost unaffected by air bubbles.

Although liquid heparin at <10% (vol./vol.) of the volume of blood should have a small effect on pH, pCO_2, or pO_2, the use of liquid heparin will dilute other constituents in blood, such as electrolytes and glucose that are typically analyzed simultaneously in current blood gas and electrolyte analyzers. Therefore only dry heparin should be used as an anticoagulant. While plastic syringes are used for nearly all blood gas measurements, they have a potential disadvantage due to their ability to absorb oxygen [22]. When stored in ice water, because of the increased oxygen affinity of Hb at cold temperatures, blood can absorb oxygen dissolved within the wall of the syringe and transmitted through the plastic. This effect is most pronounced in samples with a pO_2 of ~100 mmHg and above, that is, when Hb is already nearly fully saturated with oxygen and is unable to buffer any added O_2. A pO_2 of 100 mmHg may increase by 8 mmHg during 30 minutes of storage on ice.

When Hb is less saturated (for example, at a pO_2 of 60 mmHg), it is better able to buffer the additional oxygen, with little measurable change in pO_2. Because glass is not permeable to O_2, pO_2 is not affected in blood stored in glass syringes in ice.

Storage of blood specimen

In general, storage of blood in plastic syringes at room temperature is acceptable if analysis is within 15 minutes

[22]. When blood is stored at ambient temperatures (22°C–24°C; 72–75 °F) for >30 minutes, pO_2 has been reported to both increase and decrease, with the increase likely due to oxygen permeability of plastic syringes [22–24]. Storage for 30 minutes at ambient temperature changed pO_2 by about 2 mmHg at a pO_2 of 100 mmHg [22]. In most samples at ambient temperature, pCO_2 changes <1 mmHg, and pH changes <0.01 unit. However, samples from patients with extreme leukocytosis can dramatically change pH, pCO_2, and pO_2 (and glucose and lactate) when stored at room temperature [10]. These samples must be analyzed as soon as possible.

Cord blood gases

Blood gas values on blood collected from the umbilical cord at birth can provide valuable data for assessing the respiratory and metabolic status of the newborn. They are more objective than apgar scores at identifying hypoxia and acidosis in the neonate that may occur from asphyxia, respiratory distress, or other conditions. Note that umbilical venous blood reflects the combined effects of maternal acid–base status and placental function, while umbilical arterial blood represents the condition of the neonate. Therefore, in most cases, blood from the umbilical artery should be collected, because it contains blood returning from the fetus to the placenta and more accurately represents the neonatal acid–base status. Some studies have concluded that collection of both umbilical arterial and venous blood provides clinically useful information on the pathogenesis of acidosis [25,26].

When the fetus cannot eliminate sufficient CO_2 via the placenta, the pCO_2 increases leading to a "respiratory" acidosis. If O_2 exchange is inadequate (from multiple causes), a metabolic acidosis results. Some critical results for cord blood are:

- pH < 7.0 in arterial cord blood.
- pCO_2 difference between arterial cord blood and venous cord blood > 25 mmHg.

The relevance of pO_2 results on cord blood is not clearly established. Reference ranges for both arterial cord blood and venous cord blood have been published [25] and are summarized in Table 36.6.

Temperature correction of blood gas results

Whether to temperature-correct, or not correct, blood gas results appear to be a never-ending controversy, and the reader is referred to an excellent recent discussion on this issue [27]. While patients may have pathologic or environmental hyperthermia or hypothermia, the main issue is with patients who are deliberately cooled (therapeutic hypothermia) to increase survival in situations such as cardiac surgery, myocardial infarction, ischemic stroke, traumatic brain injury, or sepsis. With hypothermia, pCO_2 is decreased which increases the pH. The effects of temperature on pO_2 are more complex, but hypothermia by itself will lower the pO_2. The controversy is whether to temperature-corrected blood gas measurements back to the patient's body temperature (such as 30°C), which is called the "pH-stat" hypothesis, or interpret the results by the analyzers at 37°C, which is the "alpha-stat" hypothesis. This report cited other reports to conclude that for adult patients made hypothermic during cardiac surgery, uncorrected blood gas results are more appropriate for patient management, while for similar pediatric patients, corrected blood gas results appear more appropriate.

Usefulness of other tests on modern blood gas analyzer menus

Lactate

Blood lactate measurements have dramatically increased over the last 15 years, largely because they are frequently used in critically ill patients (notably in sepsis) to evaluate the initial condition of the patient and to monitor the effectiveness of therapy. In addition to the traditional view that elevated blood lactate is caused by an oxygen deficit to tissues, an elevated lactate can also be caused by mitochondrial dysfunction. This includes cyanide poisoning and sepsis, where several factors associated with sepsis inhibit mitochondrial function and elevate blood

TABLE 36.6 Reference ranges for both arterial and venous cord blood.

Analyte	Arterial cord blood reference range	Venous cord blood reference range
pH	7.14–7.42	7.22–7.44
pCO_2 (mmHg)	34–78	30–63
pO_2 (mmHg)	3–40	12–43

pO_2, Oxygen pressure.

lactate: inflammation, cytokines, platelet and endothelial activators, tissue necrosis factor, etc. Some common uses of blood lactate measurements include the following:

- In neonates during and after open-heart surgery for congenital heart disease.
- To evaluate patients who may require ECMO and for monitoring their progress.
- For triage in an ED setting to determine which patients need immediate care and for monitoring the effectiveness of therapy.
- In trauma patients, early identification of increased blood lactate followed by aggressive resuscitation improves survival. Survival was very high (98%–100%) in patients whose blood lactate normalized within 24 hours; was 75%–80% in patients whose blood lactate normalized in 24–48 hours; but was relatively poor in patients whose blood lactate could not be normalized by 48 hours [28].
- During open-heart surgery, patients are cooled to reduce VO_2. However, this can also cause perfusion abnormalities (vasoconstriction and shunting) that can lead to tissue hypoxia. Along with the anesthesia and drugs, these can all cause problems with oxygen metabolism and increase blood lactate. Thus, blood lactate measurements have become a means to monitor such patients.
- To identify high-risk ICU patients needing more aggressive therapy: For patients who responded to treatment by decreasing their lactate to less than 1.0 mmol/L, mortality was less than 7%.
- In goal-directed therapy for sepsis, blood lactate measurements have become an essential component of detecting high-risk patients (lactate >4.0 mmol/L), detecting hypodynamic state of low DO_2, and other lactate elevations due to inflammation, etc., but without evidence of tissue hypoxia [29]. As noted earlier, several factors associated with sepsis can elevate lactate, including inflammation, cytokines, platelet and endothelial activators, and tissue necrosis factor.

Glucose

The measurement of glucose in surgery and critical care is important as a means to maintain blood glucose levels within a range of about 140–180 mg/dL [30]. This more conventional range contrasts with the tight glycemic control with insulin infusion that has now been associated with higher rate of hypoglycemia and mortality [31]. A number of events unrelated to diabetes can also hinder the regulation of blood glucose levels in critically ill patients: infection and inflammation, fever, surgical trauma, general medical stress, glucocorticoid therapy, physical inactivity, etc. Hyperglycemia is also associated with undesirable effects, such as damage to certain brain and neuronal cells. While the optimal level of blood glucose to achieve is debatable, rapid measurements are necessary to avoid either hyperglycemia or hypoglycemia.

Met-Hb

Met-Hb may be used as a monitor or guide for appropriate use of inhaled NO which is used as a therapy of pulmonary hypertension in children after cardiac surgery. NO binds to Hb with great affinity and forms metHb by oxidation in the erythrocyte. Because the amount of functional Hb is thereby reduced, the patient may be more susceptible to anemia, acidosis, respiratory compromise, or cardiac problems. Typically, the proportion of NO in the inhaled gas is 5–40 ppm, which results in a maximum increase in metHb of 4% [32].

Self-assessment questions

1. Acid–base exercises: In the following table, use the pH, pCO_2, and HCO_3^- values along with the duration of observation to assess the acid−base status of each situation and choose from the answers a−f below. Determine the primary disorder, then evaluate if the expected compensation has occurred for the duration indicated. Use Fig. 36.2 for guidance as needed:

pH	pCO_2 (mmHg)	HCO_3 (mmol/L)	Duration of medical observation	Acid−base condition
7.40	40	24	–	Very normal acid−base results
7.34	32	18	12 h	_____
7.48	45	35	6 h	_____
7.44	27	18	2 d	_____
7.20	70	22	3 d	_____
7.28	55	25	2 h	_____
7.56	20	20	6 h	_____

   a. Acute respiratory acidosis
   b. Acute respiratory alkalosis
   c. Chronic compensated respiratory alkalosis
   d. Mixed respiratory acidosis and metabolic acidosis
   e. Partly compensated metabolic acidosis
   f. Partly compensated metabolic alkalosis
2. Which of the following statements regarding compensation is correct?
   a. Compensation seeks to return the ratio of bicarbonate to H_2CO_3 to normal.
   b. Compensation for respiratory acidosis involves renal excretion of bicarbonate.
   c. Compensation for metabolic alkalosis involves increased respiratory rate.
   d. Compensation typically causes pH to change to the opposite side of normal from that of the original acid−base disorder.
   e. Compensation typically involves altered renal excretion of sodium and potassium.
3. A patient has a COHb of 15%. Which parameter would an increase in COHb affect most?
   a. sO_2
   b. pO_2
   c. pH
   d. $\%O_2Hb$
   e. pCO_2
4. A patient has the following laboratory results (mmol/L): Na 141, K 5.4, Cl 106, and HCO_3 7. The differential for this acid−base abnormality includes all of the following, EXCEPT:
   a. lactate acidosis
   b. diabetic ketoacidosis
   c. severe vomiting
   d. ethylene glycol ingestion
   e. acute renal failure
5. A patient is noted to be hypovolemic, with pH 7.49 and the following electrolyte results (mmol/L): Na 135, K 4.8, Cl 90, and HCO_3 35. What is the most likely diagnosis and appropriate treatment?
   a. Contraction alkalosis; administer intravenous NaCl solution.
   b. Diarrhea; administer HCO_3 solution.
   c. Prolonged vomiting; administer dilute HCl solution.
   d. Respiratory alkalosis; induce hyperventilation.
   e. Respiratory alkalosis; rebreath exhaled air to increase pCO_2.
6. A patient has the following laboratory results: Na 139, K 4.4, Cl 85, HCO_3 42 (all mmol/L), pH 7.35, and pCO_2 79 mmHg. What is the most likely cause of these results?
   a. diabetic ketoacidosis
   b. metabolic alkalosis
   c. acute respiratory acidosis
   d. chronic respiratory acidosis
   e. respiratory alkalosis
7. A patient has an arterial pO_2 of 45 mmHg and a pCO_2 of 80 mmHg. What is the alveolar−arterial gradient (A−a)?
   a. 0 mmHg
   b. 35 mmHg
   c. 10 mmHg
   d. 50 mmHg
   e. 5 mmHg
8. Which condition would most likely increase the pO_2 in an arterial blood sample collected in a syringe from a person breathing room air?
   a. The sample is analyzed 45 minutes after collection and storage at room temperature.
   b. The sample is collected with a pea-sized air bubble in the syringe, then is sent to the lab by pneumatic transport.
   c. The sample is stored on ice for 20 minutes before analysis.
   d. Liquid heparin is used as an anticoagulant.
9. A 60-year-old man has the following lab results:

pH	7.58
pCO_2	35 mmHg
pO_2	95 mmHg
Na	133 mmol/L
K	4.5 mmol/L
Cl	80 mmol/L
HCO_3^-	42 mmol/L.

What is the most likely cause of these results?

a. Compensated metabolic acidosis
b. Five days of severe vomiting
c. Five days of severe diarrhea
d. Acute respiratory alkalosis
e. Chronic respiratory alkalosis

10. Which set of results would most likely be associated with a metabolic acidosis?

a. pH 7.30 pCO_2 55 mmHg HCO_3 27 mmol/L
b. pH 7.40 pCO_2 50 mmHg HCO_3 30 mmol/L
c. Na 136 mmol/L Cl 86 mmol/L HCO_3 36 mmol/L
d. Na 138 mmol/L Cl 87 mmol/L HCO_3 24 mmol/L
e. pH 7.35 pCO_2 30 mmHg HCO_3 17 mmol/L

11. Which cord blood results would NOT likely be a cause for concern?

a. Arterial cord blood pH of 6.96
b. Arterial cord blood pO_2 of 42 mmHg
c. Arterial cord blood pCO_2 of 75 mmHg with a venous cord blood pCO_2 of 40 mmHg
d. Arterial cord blood pH of 7.20 with a venous cord blood pH of 7.40

Chapter 37

Water and electrolyte balance

Anna E. Merrill[1] and Allison B. Chambliss[2]

[1]Department of Pathology, University of Iowa Hospitals and Clinics, Iowa City, IA, United States, [2]Department of Pathology, Keck School of Medicine of USC, Los Angeles, CA, United States

Learning objectives

After reviewing this chapter, the reader will be able to:

- Describe the distribution of water and major electrolytes among the intracellular and extracellular compartments of the body and the factors involved in their regulation.
- Discuss the clinical evaluation of patients with electrolyte and blood volume disorders and the utility of serum and urine tests in proper diagnosis.
- Explain preanalytical variables that can cause misleading electrolyte results.

Normal physiology of water and electrolytes

Distribution of water and electrolytes between body fluid compartments

In the average adult, water accounts for approximately 60% of the total body weight and exists within three body fluid compartments:

- intracellular fluid (ICF) compartment
- extracellular fluid (ECF) compartments, which consist of plasma and interstitial fluid

The ICF and ECF compartments are separated by cellular plasma membranes, while the capillary endothelium partitions the interstitial fluid from the plasma. The ICF and ECF compartments differ in their water, electrolyte, and protein content. The ICF and ECF compartment compositions are summarized in Table 37.1. Within the ICF, the major cations are potassium (K^+) and magnesium (Mg^{2+}), and the major anion is phosphate (in the forms HPO_4^{2-} and H_2PO_4). The predominant extracellular cations are sodium (Na^+) and calcium (Ca^{2+}), while the predominant extracellular anions are chloride (Cl^-) and bicarbonate (HCO_3^-). This chapter will focus on the analytical and clinical aspects of sodium, potassium, and chloride measurement and regulation. Other electrolytes are discussed elsewhere (see Chapter 36: Blood gas and critical care testing, for additional details on bicarbonate and see Chapter 45: Calcium biology and disorders, for a discussion on magnesium, calcium, and phosphate).

To maintain fluid balance, the average adult must take in ~1.5–2.5 L of water daily to account for renal (1200–1500 mL in urine), fecal (~100 mL in stool), and "insensible" losses (400–700 mL via evaporation from the skin and respiratory tract). Daily water and electrolyte requirements are significantly affected by activity level, environmental conditions, and disease states. Water intake is largely controlled by the sensation of thirst. Ingested fluid first enters the blood plasma by intestinal absorption and then moves between plasma and other compartments based on intercompartmental differences in osmotic, oncotic, and hydrostatic pressures.

Osmotic pressure is caused by a difference in the total molar concentration of compounds dissolved in solutions on either side of a membrane that does not allow for their free passage. Water moves from the compartment with lower total solute concentration to the one with higher total solute concentration to eliminate the imbalance. Osmotic balance is the most important factor regulating movement of water between the plasma and the intracellular spaces, as cell membranes do not permit free diffusion of electrolytes and proteins. The interplay between the hydrostatic and oncotic (colloid osmotic) pressures, along with capillary membrane permeability, determines water distribution between the plasma and interstitial compartments. Hydrostatic pressure exerted by flowing blood drives fluid and diffusible solutes from the vascular space, across the semipermeable capillary membrane, and into the interstitial compartment. Oncotic pressure due to proteins, predominantly albumin, pulls interstitial fluid into the intravascular compartment. Likewise, interstitial hydrostatic and oncotic pressures lead to fluid efflux to and influx from the vascular space, respectively. An imbalance in pressures can favor the accumulation of interstitial fluid (i.e., edema). In addition, certain

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00037-5

TABLE 37.1 Composition of body fluid compartments.

Fluid compartment	Total body water (%)	Major cations	Major anions	Relative protein concentration
Intracellular	50–65	K^+ and Mg^{2+}	$HPO_4^{2-}/H_2PO_4^-$	Very high
Plasma	10–12	Na^+ and Ca^{2+}	Cl^- and HCO_3^-	High
Interstitial	25–40	Na^+ and Ca^{2+}	Cl^- and HCO_3^-	Very low

pathologic conditions (e.g., septic shock) can drastically increase capillary membrane permeability to larger molecules, leading to decreased oncotic pressure, hypotension, and impaired perfusion to multiple organ systems.

The electrolyte compositions of the ECF compartments—plasma and interstitial—are similar, but differ significantly from the ICF compartment. For example, while sodium is the main extracellular cation ($\sim$140 mmol/L in ECF vs. $\sim$12 mmol/L in ICF), potassium is predominantly located intracellularly ($\sim$140 mmol/L in ICF vs. $\sim$4 mmol/L in ECF). Passive ion transport across capillary membranes is responsible for the consistency in electrolyte concentrations between the ECF compartments. The unequal ion distribution between the ICF and ECF compartments is accomplished by active ion transport against concentration gradients. The Na^+/K^+-ATPase enzyme pumps sodium from inside to outside the cell, simultaneously coupling potassium transport from outside to inside the cell.

Regulation of water

To avoid dehydration, daily water intake must replenish losses. Urine represents the main source of water loss, with the kidneys reabsorbing or excreting water based on variation in water intake. The complex regulatory system responsible for maintaining fluid balance relies on various mechanisms for matching water intake with losses and preventing changes in plasma osmolality or volume. In general, preservation of intracellular hydration status is prioritized over extracellular hydration status. Therefore water imbalances are initially reflected in the extracellular component.

Reduced ECF volume can be caused by many conditions, including dehydration, acute blood loss (e.g., trauma), vomiting, diarrhea, diuretics, and renal and adrenal diseases, leading to sodium wasting. Clinically, patients with decreased ECF content demonstrate thirst, anorexia, nausea, lightheadedness, orthostatic hypotension, tachycardia, syncope, oliguria, and decreased skin turgor, with severe cases leading to shock, coma, and death. Regulators of osmolality and volume respond to increases in osmolality and decreases in plasma volume, respectively, to restore ECF fluid balance. Increased ECF volume also has many possible etiologies, including heart failure, cirrhosis, and nephrotic syndrome. In addition, aggressive intravenous (IV) fluid administration can cause iatrogenic fluid overload. Patients with excess ECF typically present with weight gain, edema, dyspnea, tachycardia, jugular venous distention, and ascites due to portal hypertension.

Osmoregulators

The hypothalamus initiates a weak, yet sensitive response to minor increases in plasma osmolality ($\sim$1%) by activating two types of protective mechanisms:

- Thirst sensors stimulate water intake, which lowers osmolality, eventually returning it to normal. Water intake is the most important factor in maintaining normal water and electrolyte status. Thus patients who cannot respond to this signal, such as the elderly, newborns, and those with neurologic disorders or without access to water, are prone to dehydration.
- Antidiuretic hormone (ADH), also known as arginine vasopressin or vasopressin, is released from the posterior pituitary gland and acts on both the kidney and blood vessels. In the kidney, ADH increases the permeability of the collecting ducts to facilitate water reabsorption, thereby lowering plasma osmolality. In the blood vessels, ADH binds to receptors that cause vasoconstriction to maintain blood pressure until fluids are ingested or administered to restore blood volume (see Chapter 39: Disorders of the anterior and posterior pituitary, for further discussion on ADH).

Volume regulators

Normal daily regulation of water status is governed by osmolality, but the body can override the signal of the osmoreceptors, if necessary, to preserve normal plasma volume. Compared with the osmoregulators, the response of the following volume regulators is insensitive (requires a $\sim$5% decrease in plasma volume), yet potent:

- Thirst and ADH release are triggered by a decreased plasma volume, in addition to increases in osmolality.

- The renin–angiotensin–aldosterone system (RAAS) is a major protection against decreased plasma volume. Decreased renal blood flow or sodium concentrations reaching the distal convoluted tubule lead to a release in renin from the juxtaglomerular cells of the kidney. Renin catalyzes production of angiotensin I, which is then converted into angiotensin II. Angiotensin II is a potent vasoconstrictor, which increases renal blood flow, and stimulus for aldosterone secretion from the adrenal cortex. Aldosterone, in turn, acts on the collecting ducts to reabsorb Na^+ and water at the expense of K^+ and H^+ ions. Taken together, the RAAS increases blood pressure, plasma Na^+ retention, and urinary excretion of K^+ and H^+, and decreases urinary Na^+ excretion and plasma concentrations of K^+ and H^+.

Natriuretic peptides

If blood volume becomes abnormally elevated, an increase in cardiac stretch stimulates the production of natriuretic peptides [e.g., atrial natriuretic peptide and brain natriuretic peptide (BNP)] by the atria and ventricles of the heart, respectively. These peptides act on the blood vessels to induce vasodilation and on the kidney to increase urinary excretion of sodium (natriuresis) and water (diuresis). In addition, natriuretic peptides decrease production of renin, serving as an antagonist to the RAAS to decrease plasma volume. Note that plasma levels of BNP or N-terminal pro-BNP are widely used when assessing patients with suspected congestive heart failure, which is a common cause of increased ECF volume and edema (see Chapter 30: Biomarkers for coronary artery disease and heart failure, for further discussion of BNP).

Regulation of electrolytes

Renal regulation, along with thirst, is the body's main mechanism for maintaining water and electrolyte homeostasis. Renal insufficiency limits the ability of the kidneys to regulate the balance of water and electrolytes, which can make affected patients more susceptible to electrolyte abnormalities, particularly hyperkalemia. With normal renal function, the glomeruli freely filter water and electrolytes from the blood. The majority of filtered sodium and potassium are actively reabsorbed in the proximal convoluted tubules; consequently, water and chloride are passively reabsorbed to maintain electrical and osmotic balance. In the descending loop of Henle, an osmotic gradient leads to passive reabsorption of water. In the ascending loop of Henle, chloride and sodium are actively and passively reabsorbed, respectively. The transporters responsible for chloride reabsorption in the ascending loop of Henle include the Na–K–Cl cotransporter—the target of loop diuretics—and CLC chloride channels. Under the action of aldosterone, cells of the distal convoluted tubules and collecting ducts retain Na^+ and water and secrete K^+ and H^+. The collecting duct reabsorbs additional water when stimulated by ADH. In the absence of aldosterone, $\sim$3%–5% of extracellular sodium can be lost in the urine, leading to hyponatremia. In the cases of ADH deficiency, up to 10% of water may be excreted.

Sodium regulation in blood

Sodium is the major extracellular cation, playing a central role in maintaining the normal distribution of water and osmolality in the ECF compartment. Dietary sodium is nearly completely absorbed from the gastrointestinal (GI) tract, though daily intake drastically exceeds requirements in most cases. Excretion of excess sodium is accomplished by the kidneys and is primarily controlled by aldosterone. Plasma sodium concentration is regulated within an extremely narrow window. The average intraindividual variation in healthy people is $<$1.5%. Marked changes in sodium concentration can occur, however, with changes in plasma volume or inability to obtain water.

Potassium regulation in blood

Potassium is the major intracellular cation. Dietary potassium is absorbed in the GI tract, rapidly distributed, and taken up by cells. The kidney principally maintains total body potassium by matching excretion with intake. Rates of renal secretion occur slowly (on the order of hours) and are affected by mineralocorticoid (i.e., aldosterone) concentrations, intake of sodium and potassium, and acid–base balance. More immediate changes in plasma potassium concentrations are buffered by the movement of K^+ between the intracellular and extracellular compartments. Intracellular potassium movement is enhanced by alkalemia, insulin, and glucose. Catecholamines also affect rapid cellular uptake of potassium; catecholamine action on β-adrenergic receptors promotes cellular uptake, while action on α-adrenergic receptors impairs uptake.

Chloride regulation in blood

Chloride is the major extracellular anion; Cl^- ions are almost completely absorbed from the GI tract. Unlike sodium and potassium, concentrations of chloride are not homeostatically controlled; rather, chloride concentrations passively reflect the concentrations of other major ions and typically change in parallel with sodium concentrations. An exception is in acid–base disorders when chloride concentrations shift in response to bicarbonate changes, even if sodium concentrations are normal (e.g., depleted Cl^- due to $HCO3^-$ retention in respiratory acidosis and elevated Cl^- due to $HCO3^-$ excretion in

respiratory alkalosis; see Chapter 36: Blood gas and critical care testing, for further discussion on acid–base disorders).

Laboratory tests used to evaluate fluid and electrolyte abnormalities

When evaluating a patient with fluid and electrolyte abnormalities, the principal laboratory tests include electrolyte concentrations and osmolality, which can be measured in the blood and urine. Though hormones such as ADH, renin, and aldosterone play important roles in maintaining adequate water and electrolyte balance, they are not commonly measured in the context of fluid and electrolyte disorders.

Electrolytes

Electrolytes are typically measured in serum, plasma, whole blood, and/or urine. While expected concentrations of electrolytes are well established for blood-based specimens, urinary concentrations vary widely. However, measuring electrolytes in urine can indicate whether the renal response to changes in plasma concentrations is adequate or whether the kidneys are contributing to an electrolyte imbalance.

Historically, atomic absorption spectroscopy (AAS) and flame emission spectrophotometry (FES) were the most common methods for sodium and potassium analysis. The National Institute of Standards and Technology (NIST), Centers for Disease Control and Prevention (CDC), and American Association for Clinical Chemistry (AACC) recognize FES as the reference measurement procedure for serum sodium and potassium. The most precise method for chloride determination over a wide range of concentrations is coulometric titration, which is the reference measurement procedure for serum chloride designated by the NIST, CDC, and AACC.

In modern clinical laboratories, electrolytes are measured by ion-selective electrode (ISE) methods, which are discussed in detail elsewhere (see Chapter 9: Electrochemistry). These methods utilize potentiometry, the difference in circuit potential induced by the interaction of the selected ion with the ISE membrane, to determine electrolyte concentration. The electrode membranes contain ion-selective compounds, such as glass, valinomycin, or organic polymers. ISE methods are classified into two types: indirect and direct. With indirect ISE methods, the sample is first mixed with a large volume of diluent (typically 1:30–1:40) before introduction into the measurement chamber containing the electrodes. Alternatively, the sample is presented to the electrodes without dilution in direct ISE methods. Most high-throughput clinical chemistry analyzers incorporate indirect ISEs for electrolyte determination in serum, plasma, and urine matrices, while direct ISEs are used more commonly in blood gas and point-of-care devices where whole blood is the specimen of choice for analysis.

Measurements by indirect ISE are vulnerable to inaccuracies due to the electrolyte exclusion effect. Electrolytes that are not protein-bound are confined to the aqueous phase of plasma, which makes up approximately 93% of plasma volume in a normal sample, and are excluded from the solid phase of plasma. Indirect ISE measures the electrolyte concentration in the total plasma volume following a dilution step. To relate the measured concentration to the physiologic electrolyte concentration in plasma water volume, it is assumed that the solid fraction is consistent in volume (7%) (Fig. 37.1, top). In certain pathologic conditions, such as hyperlipidemia or hyperproteinemia, the volume of plasma occupied by solids significantly exceeds 7%. With indirect ISE, this leads to falsely low electrolyte measurements because the total plasma volume is disproportionately excluded by excess solids (e.g., pseudohyponatremia and pseudohypokalemia; see Fig. 37.1, bottom). Conversely, in the settings of decreased solids (e.g., severe hypoproteinemia in critically ill patients), indirect ISE electrolyte measurements will be falsely elevated (e.g., pseudohypernatremia and pseudohyperkalemia). Of note, direct ISE methodologies do not require sample dilution and measure ion concentrations in the aqueous portion of plasma; therefore, they are not affected by deviations in plasma composition. Though the electrolyte exclusion effect affects all electrolytes measured by indirect ISE, pseudohyponatremia and pseudohypernatremia are most noticeable because of the extremely tight regulation of plasma sodium content. For example, a 5% decrease in Na^+ may cause a normonatremic (~138 mmol/L) patient to appear hyponatremic (~131 mmol/L), whereas a 5% decrease in K^+ is clinically less significant (4.0 vs. 3.8 mmol/L).

Despite widespread use of ISE methods due to their robustness and cost-effectiveness, other methods for electrolyte measurement do exist. These methods couple electrolyte-specific enzyme activation with spectrophotometric detection. Enzymatic/spectrophotometric techniques are typically incorporated into smaller instruments with Clinical Laboratory Improvement Amendments (CLIA)-waived status for whole blood specimens, making them attractive for environments with limited testing resources. A few settings where these methods may be incorporated include physicians' offices and isolation laboratories for patients with highly infectious diseases (e.g., Ebola).

Sodium

A typical reference interval for serum or plasma sodium is 135–145 mmol/L (due to its univalency, 1 mmol/L

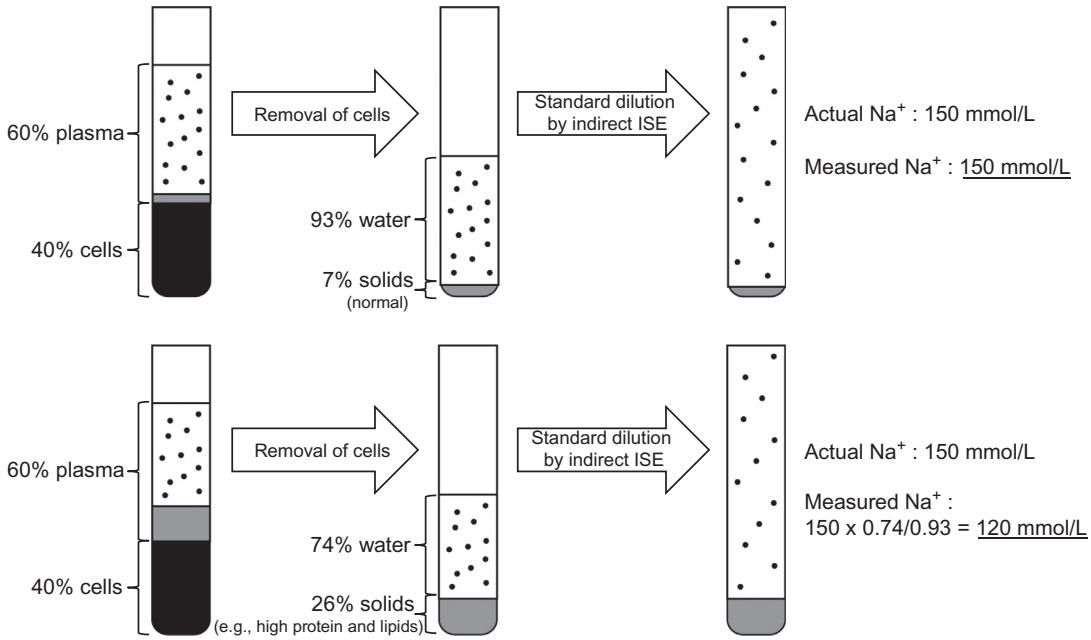

FIGURE 37.1 Example of dilution scheme for the indirect ion-selective electrode measurement of sodium in two samples with the same sodium concentration in plasma water but with different proportions of plasma solids: normal (7% solids, *top*) and elevated (26% solids, *bottom*). Although the two samples started with the same sodium concentration, the sodium result of the sample with elevated solids is significantly underestimated by the indirect ion-selective electrode method due to the electrolyte exclusion effect, demonstrating pseudohyponatremia.

$Na^+ = 1$ mEq/L Na^+). Urinary excretion of sodium varies with dietary intake, but a typical observed range is approximately 120−240 mmol/day. Determination of the fractional excretion of sodium may be more useful than urine sodium concentration alone in patients with acute kidney injury to differentiate prerenal disease and acute tubular necrosis as possible etiologies. This calculation provides an index of the urine sodium (U_{Na}) relative to the plasma sodium (P_{Na}) in proportion to the ratio of plasma (P_{Cr}) to urine creatinine (U_{Cr}). The formula for fractional excretion of sodium (FE_{Na}), expressed as a percent, is given in Eq. (37.1):

$$FE_{Na} = \frac{U_{Na} \times P_{Cr}}{P_{Na} \times U_{Cr}} \times 100 \qquad (37.1)$$

FE_{Na} of $<1\%$ typically indicates prerenal disease, while FE_{Na} of $>2\%$ indicates acute tubular necrosis; however, these classifications are of limited specificity, especially in patients taking diuretics or with other causes of sodium wasting.

Potassium

A typical reference interval for serum or plasma potassium is approximately 3.5−5.1 mmol/L (1 mmol/L $K^+ = 1$ mEq/L K^+). Urinary excretion of potassium varies with dietary intake, but a typical observed range is approximately 20−80 mmol/day. Serum and plasma potassium is particularly prone to collection-related pseudohyperkalemia, in large part, because intracellular K^+ concentrations in RBCs, white blood cells, and platelets exceed plasma K^+ concentrations by over 30-fold. Thus even minor cell lysis during the preanalytical phase can lead to falsely elevated potassium concentrations in the plasma. The most common cause of collection-related pseudohyperkalemia is hemolysis. Pseudohyperkalemia can also arise from the contamination of the specimen with potassium-containing IV fluids or an improper anticoagulant (e.g., K_2- or K_3-EDTA). Various sources of pseudohyperkalemia, along with mechanisms of interference and tips for prevention, are listed in Table 37.2.

Chloride

A typical reference interval for serum or plasma chloride is approximately 98−111 mmol/L (1 mmol/L $Cl^- = 1$ mEq/L Cl^-). Urinary excretion of chloride varies with dietary intake, but a typical observed range is approximately 110−250 mmol/day. Chloride ion concentrations are also determined in sweat specimens in the diagnosis of cystic fibrosis (CF), usually following a positive CF newborn screening result. Sweat production is stimulated by pilocarpine iontophoresis, and the collected specimens are submitted to the laboratory for quantitative chloride analysis. Sweat chloride concentrations of 60 mmol/L or higher are indicative of CF, while concentrations less than 30 mmol/L indicate that CF is unlikely. Given the expected chloride concentrations in sweat specimens from

TABLE 37.2 Causes of pseudohyperkalemia and tips for their prevention.

Cause	Mechanism	Tips for prevention
Traumatic phlebotomy	Release of intracellular K^+ from prolonged tourniquet application and/or fist clenching	Practice proper phlebotomy technique
Hemolysis	Release of K^+ from red cells due to mechanical lysis	Collect blood via venipuncture instead of indwelling lines Use larger bore/smaller gauge needles Hand-carry samples to laboratory
Improper order of draw or tube type	Contamination with K_2- or K_3-EDTA anticoagulant	Adhere to proper order of draw and tube type
Contamination with IV fluid	Contamination with K^+ replacement infusion	Collect blood via venipuncture Properly flush IV with multiple blood volumes prior to specimen collection
Delayed separation of serum/plasma from cellular material	Leakage of K^+ from blood cells due to time- and temperature-dependent inactivation of Na^+/K^+-ATPase	Promptly aliquot serum/plasma after collection Utilize serum or plasma separator tubes (SST or PST) and promptly centrifuge after collection
Thrombocytosis	Release of K^+ from platelets during clotting	Measure potassium in plasma specimen
Leukocytosis	Release of K^+ from white blood cells due to mechanical disruption and/or extremely fragile cells	Measure potassium in serum or whole blood specimen Hand-carry samples to laboratory

IV, Intravenous.

this patient population, it is recommended that instrumentation used for measuring Cl^- in sweat be capable of reliably measuring concentrations from 10 to 160 mmol/L. ISE methods are usually too imprecise at the low end of this concentration range. Therefore sweat chloride concentration is best determined by coulometric titration on specialized instruments.

Osmolality

Determination of serum/plasma and urine osmolality can be useful in the assessment of fluid and electrolyte disorders. Specifically, measured osmolalities in these two specimen sources can reveal the status of renal water regulation in settings of severe electrolyte disturbances [e.g., diabetes insipidus (DI) and syndrome of inappropriate antidiuretic hormone secretion (SIADH)]. In addition, the difference between the measured osmolality and the estimated osmolality, typically calculated using sodium, glucose, and blood urea nitrogen (BUN) concentrations (see Chapter 6: Laboratory calculations, for a discussion of this calculation), is known as the osmolality gap. An elevated osmolality gap suggests the presence of additional osmotically active substances, such as methanol, ethylene glycol, or ketoacids. A thorough clinical history and/or more specific testing are often needed to identify the source of the elevated osmolality gap. Osmolality can theoretically be measured by any of the four colligative properties of solutions: increased osmotic pressure, decreased vapor pressure, increased boiling point, and decreased freezing point. The magnitude of change in any of these parameters relative to water is directly proportional to the total number of solute particles dissolved in the solvent. In the clinical laboratory, osmolality is most commonly measured by freezing point depression. A typical reference interval for serum or plasma osmolality is approximately 275−300 mOsm/kg. In urine, expected osmolality is variable due to diet and hydration state but is often approximately 350−1050 mOsm/kg. Normally, the ratio of urine osmolality to plasma osmolality is typically 1.0−3.0.

Disorders of water and sodium

Abnormalities in plasma or serum sodium concentrations may be caused by disorders of sodium regulation or by disorders of body water regulation, producing a dilutional effect in sodium. Clinical signs indicating possible disorders of water or sodium include, for example, the presence of generalized or localized edema and/or low blood

pressure in hypovolemic patients. Nonspecific symptoms of hyponatremia may include weakness and fatigue, and, in severe cases, confusion or coma. However, slow changes in sodium concentrations may not be apparent; thus sodium is often monitored as part of a metabolic panel regardless of the presence of symptoms. Patients with hypernatremia may exhibit thirst and dry mucous membranes.

Obtaining a clinical history including recent diet, fluid intake, history of vomiting or diarrhea, kidney function status, and use of medications such as diuretics is critical to the workup of patients exhibiting electrolyte imbalance. Measurement of BUN and creatinine may aid in evaluating intravascular volume and determining renal function. An increased BUN/creatinine ratio may indicate decreased intravascular volume in cases of hyponatremia. Further, measurement of serum and urine osmolality may aid in determining the etiology of a sodium abnormality. Caution should be exhibited in the interpretation of sodium results from indirect ISE methods in patients with extreme plasma protein and/or lipid concentrations, as the plasma water displacement may cause pseudohypernatremia (with decreased solids) or pseudohyponatremia (with increased solids), as discussed above.

Disorders causing hyponatremia

Hyponatremia has been described as the most common electrolyte disorder encountered in clinical practice, occurring in an estimated 15%–30% of hospitalized patients. While many cases are mild and asymptomatic, occurrences that progress unrecognized and untreated may cause significant morbidity and mortality. Acute hyponatremia due to osmotically induced brain edema represents one of the most severe manifestations. Hyponatremia is typically defined as a serum or plasma sodium concentration less than 135 mmol/L. Causes of hyponatremia may be broadly categorized as disorders of decreased ECF sodium or disorders of increased ECF water. Various etiologies for both categories are described below and summarized in Table 37.3. Notably, healthy individuals possess compensatory mechanisms, such as thirst and ADH, to preserve normal sodium and body water.

Many cases of decreased plasma sodium are considered hypovolemic hyponatremia, by which the hyponatremia is simultaneously associated with a decrease in intravascular volume, and the sodium loss is in excess relative to the water loss. Hypovolemic hyponatremia may be the result of decreased sodium intake, extrarenal sodium losses, renal sodium losses, or increased ECF water. However, some cases of hyponatremia may present with no relative change in intravascular volume (euvolemic) or, rarely, with increases in intravascular volume (hypervolemic). Euvolemic or hypervolemic hyponatremia occurs when effective solutes other than sodium overpower plasma osmolality, causing osmotic movement of water out of cells and a dilutional decrease in plasma sodium. Hypervolemic hyponatremia is most commonly caused by severe hyperglycemia in diabetic patients, though similar effects have been observed after the administration of hypertonic mannitol or glycine.

Decreased sodium

Rarely, decreased intake of dietary sodium will result in hyponatremia. This cause may be considered in alcoholics or in those with anorexia nervosa. Extrarenal, or nonrenal,

TABLE 37.3 Summary of common causes of hyponatremia with typical laboratory features.

Etiology	BUN/Cr ratio	Plasma osmolality	Urine osmolality	Other notes
Osmotic dilution	↑	↑	Varies	Most commonly occurs with hyperglycemia; may rarely occur from mannitol or glycine
Nonrenal sodium loss	↑	↓	↑	GI (diarrhea) or skin (burns and sweat)
Renal sodium loss	↑	↓	↑	Common with thiazide diuretics; may rarely occur with loop diuretics or tubular damage/renal disease
Decreased aldosterone	↑	↓	↑	Adrenal insufficiency or drugs, which inhibit renin or aldosterone, and hyperkalemia and nonanion gap metabolic acidosis also present
Water overload	↑	↓	↓	Psychogenic polydipsia, over-replacement after strenuous exercise
SIADH	↓	↓	↑	Typically euvolemic by physical examination

ADH, Antidiuretic hormone; *SIADH*, syndrome of inappropriate antidiuretic hormone.

losses of sodium may occur through the GI tract (diarrhea) or through the skin (burns and sweat). These patients typically show relatively low excretion of sodium in the urine (spot urine Na^+ often <30 mmol/L) with otherwise high urine osmolality, often >500 mOsm/kg.

Significant sodium loss through the kidneys is most commonly due to the administration of diuretic therapies, such as those used in the treatment of hypertension. In particular, thiazide diuretics inhibit the Na^+/Cl^- cotransporter in the distal convoluted tubule and ultimately decrease sodium reabsorption. Risk factors such as old age, low body weight, and concurrent medications that impair water excretion may further contribute to thiazide-induced hyponatremia. In contrast, hyponatremia is rarely induced by loop diuretics, which impair Na^+/Cl^- transport in the ascending loop of Henle. At this location of the nephron, water retention is limited. A less common cause of renal sodium loss is intrinsic renal disease due to tubular damage or interstitial nephritis. Patients with renal sodium losses tend to show relatively elevated urinary sodium excretion (spot urine Na^+ often >30 mmol/L) with high urine osmolality.

Rarely, a deficiency of renin or aldosterone is the cause of renal sodium loss. In normal states, renin stimulates aldosterone secretion, and aldosterone subsequently increases sodium reabsorption via the expression of epithelial sodium channels in the distal tubule. Renin may be decreased in individuals with intrinsic renal damage caused by diabetes or interstitial nephritis, or in those taking certain medications such as nonsteroidal anti-inflammatory agents (NSAIDs) or calcineurin inhibitors. Aldosterone deficiency may occur with medications that inhibit its production, including angiotensin inhibitors and heparin. Hyponatremia from hypoaldosteronism may also be caused by primary adrenal insufficiency. Patients with significant deficiencies in renin and aldosterone exhibit high sodium excretion in urine, hyperkalemia, and nonanion gap metabolic acidosis.

Increased water

In addition to osmotic shifts caused by hyperglycemia (or rarely, mannitol or glycine), hyponatremia associated with increased water (dilutional hyponatremia) may be the result of excess water ingestion or excess secretion of ADH. Increased water retention often manifests clinically as edema. Excess water ingestion is a rare cause of hyponatremia but may occur if patients drink large amounts of water in a short amount of time. Excess water ingestion has been observed in psychiatric disorders (psychogenic polydipsia) or in patients attempting to replace fluid losses after strenuous exercise. These patients present with water-like urine with extremely low urine osmolality, electrolytes, and creatinine.

In a normal state, ADH production at the hypothalamus and secretion at the posterior pituitary gland are stimulated by increased plasma osmolality and by decreased blood volume. Once secreted, ADH acts at the collecting ducts of the kidneys to facilitate antidiuresis in order to restore plasma osmolality and blood volume. SIADH involves an uncompensated release of ADH despite decreased osmolality and normal to increased intravascular volume, features that should normally inhibit ADH production. The excess ADH stimulates continuous renal retention of water, and the patient will exhibit decreased plasma osmolality with urine that is inappropriately concentrated. Typical findings include urine osmolality >200 mOsm/kg without evidence of volume depletion. Measurement of plasma ADH itself is not often routinely available and is typically not necessary for diagnosis. Further, ADH concentrations are variably elevated in patients with SIADH, are often elevated in all types of hyponatremia, and are affected by many types of medications. Causes of excess ADH with accompanying hyponatremia are listed in Table 37.4 and include ectopic production, drugs such as carbamazepine, and adrenal insufficiency.

TABLE 37.4 Example conditions leading to excess or deficient ADH release and possible hypo- or hypernatremia.

Excess ADH → hyponatremia	ADH deficiency or resistance → hypernatremia

• Ectopic production in tumors (SIADH), for example, small cell lung cancer
• Drug-induced, for example, carbamazepine, diuretics
• Adrenal insufficiency (reduces blood pressure and cardiac output)
• Hypothyroidism (inhibits free water excretion)
• Alcohol withdrawal
	• Central DI
	  ◦ Pituitary tumors
	  ◦ Neurosurgery, stroke, or head trauma
	• Nephrogenic DI
	  ◦ Chronic lithium therapy
	  ◦ Persistent hypercalcemia
	• Granulomatous disease
	• Idiopathic, possibly autoimmune
	• Familial, autosomal dominant (rare)

ADH, Antidiuretic hormone; *DI*, diabetes insipidus; *SIADH*, syndrome of inappropriate antidiuretic hormone.

Importantly, in most cases of hyponatremia, sodium administration is not the mainstay of treatment. In patients with osmotic dilutions, such as in the case of hyperglycemia, plasma sodium will increase as the other solute resolves. In cases of excess water ingestion, fluid restriction restores the plasma sodium imbalance. Similarly, water restriction is the most common approach to SIADH, as administration of sodium will serve only to raise the urine sodium without correction of the plasma sodium in these patients. Hypertonic saline administration is generally considered only in severe, symptomatic cases of hyponatremia. The saline must be administered slowly and cautiously to avoid osmotic demyelination syndrome (ODS). Various sodium administration protocols are established depending on the patient's risk for ODS, which increases with severe hyponatremia (plasma sodium ≤ 105 mmol/L), hypokalemia, alcoholism, malnutrition, and advanced liver disease.

Disorders causing hypernatremia

Hypernatremia, typically defined as a serum or plasma sodium concentration greater than 145 mmol/L, occurs less frequently than hyponatremia. Because hypernatremia is avoided with adequate water intake, hypernatremia most often occurs in those without free access to water, such as infants or bedridden patients, or in those whose thirst mechanism does not function properly, such as the elderly and those with neurologic disorders. Patients with hypovolemic hypernatremia exhibit signs of dehydration with concentrated urine and increased BUN. A low urine sodium indicates extrarenal water losses and an appropriate response by the kidneys to conserve sodium and water in this setting. Treatment seeks to replace free water with administration of dilute oral or IV fluids. Once intravascular volume has been restored, BUN normalizes and sodium will fall.

Less commonly, hypernatremia may occur in the setting of normal ECF volume in patients with DI, a condition defined by inadequate production or action of ADH. DI is classified as either central or nephrogenic. Central DI is an ADH deficiency caused by CNS abnormalities that affect ADH production at the hypothalamus, such as tumors, stroke or head trauma, or granulomatous diseases. Causes of ADH deficiency with accompanying hypernatremia are summarized in Table 37.4. Nephrogenic DI describes a renal tubular resistance to ADH, which may be hereditary if present in children, such as from mutations in the vasopressin V2 receptor gene, *AVPR2*. In adults, nephrogenic DI may be caused by some drugs, such as in chronic lithium therapy, or persistent hypercalcemia. Despite the cause, DI manifests as polyuria with an extremely dilute urine (osmolality typically <100 mOsm/kg). In patients with an adequate thirst mechanism, fluid intake will offset much of the free water loss and hypernatremia will remain mild. Thus patients may only exhibit symptoms of polyuria and polydipsia. However, without access to water, patients will quickly become dehydrated, and overt hypernatremia may develop. Although not typically necessary for diagnosis, a water deprivation test may be performed, which will show no responsive increase in urine osmolality in patients with DI. Further, administration of ADH serves to differentiate central from nephrogenic DI; only patients with central DI will respond appropriately to the exogeneous ADH.

Rarely, hypervolemic hypernatremia may result from the administration of hypertonic fluids, such as hypertonic sodium or sodium bicarbonate, or in cases of accidental or surreptitious salt poisoning of infants or young children. In the worst cases, a rapid hypernatremia will develop with ODS. In these patients, free water replacement is imperative, or possibly dialysis in patients with acute kidney injury.

Case example

A 43-year-old male patient with focal epilepsy, who recently started a new therapy regimen due to increased frequency of seizures, visited his general practitioner for recurrent episodes of nausea and dizziness. A review of recent clinical and lab history suggested normal renal function with no thyroid or adrenal disorders. Labs at this visit indicated hyponatremia (plasma sodium of 128 mmol/L by indirect ISE) with no change when repeated with a direct ISE method. Upon further workup, urine sodium resulted as 45 mmol/L with a urine osmolality of 212 mOsm/kg. No abnormalities in kidney function or acid–base balance were observed. What is the likely etiology of the hyponatremia?

Case resolution

In light of recent medication changes, a review of medication history is warranted in the workup of new onset hyponatremia. This patient was recently prescribed carbamazepine for increased frequency of seizures. Carbamazepine, which is known to induce ADH release, likely caused excessive water retention and hyponatremia in this patient. Resolution of sodium concentrations upon cessation of carbamazepine would confirm the diagnosis.

Disorders of potassium

Unlike sodium, potassium abnormalities typically occur without changes in body water or volume. As potassium is the major intracellular cation, potassium abnormalities may result from disruptions in the balance of its intake, excretion, or shifts into and out of cells.

Disorders causing hypokalemia

Symptoms of hypokalemia often do not manifest until plasma potassium concentrations fall below 3.0 mmol/L and may include muscle weakness and irritability. Below 2.5 mmol/L, cardiac arrhythmias and electrocardiogram abnormalities are observed, such as prolonged QT interval. The evaluation of a patient with hypokalemia should consist of a review of history for diarrhea, vomiting, and use of diuretics and may necessitate assessment of urinary potassium excretion along with acid–base status. Hypokalemia is most often caused by renal potassium losses but may also result from significant shift of potassium out of the vasculature and into cells. These two causes are discussed in more detail below. Other causes of hypokalemia may include decreased dietary intake in malnutrition and GI losses from diarrhea and vomiting or nasogastric suction. Oral or IV potassium replacement is the mainstay of treatment for hypokalemia, in addition to treating the underlying cause. Various causes and mechanisms of hypokalemia are summarized in Table 37.5.

Renal potassium loss

Most commonly, loss of potassium through the kidneys is the cause of hypokalemia. Increased mineralocorticoid or glucocorticoid activity, such as in cases of hyperaldosteronism or Cushing's syndrome, will enhance aldosterone-mediated sodium reabsorption at the expense of potassium. These patients will show significant potassium in the urine in addition to their hypokalemia. Hypomagnesemia is often associated with hypokalemia and may itself cause hypokalemia; depletion of magnesium counteracts magnesium's inhibitory effect on luminal potassium channels. Another frequent cause of renal potassium loss is the use of loop and thiazide diuretics, which activate the RAAS and increase potassium excretion. If potassium intake is not sufficient to compensate, hypokalemia will occur. Bartter and Gitelman syndromes are inherited disorders that mimic the effects of loop and thiazide diuretics, respectively, and may cause hypokalemia. In addition, a common side effect of the antifungal medication amphotericin B is increased tubular membrane permeability to potassium, also causing hypokalemia.

TABLE 37.5 Example causes and mechanisms of hypokalemia.

Reduced potassium intake
• Malnutrition and poor diet (chronic)
Nonrenal potassium losses
• Diarrhea, vomiting, or nasogastric suction
Renal potassium losses
• Hyperaldosteronism or hypercortisolism
• Magnesium deficiency
• Loop and thiazide diuretics
• Bartter and Gitelman syndromes
• Amphotericin B
Increased cellular uptake
• Alkalemia
• Administration of insulin or glucose
• Excess of catecholamines or β adrenergic agonists

Shift of potassium into cells

Normal balance of potassium between cells and the ECF is maintained primarily by Na^+/K^+-ATPases within the cell membrane, which exchange intracellular Na^+ for extracellular K^+. Increased activation of this exchange causes increased potassium shift into cells that will decrease potassium in the plasma. Two major activators of such a shift toward intracellular potassium include alkalemia and the administration of insulin or glucose. In alkalemia, activity of the Na^+/K^+-ATPases is promoted and shifts plasma potassium into cells. Alkalemia-mediated hypokalemia is transient and will resolve when the underlying acid–base disorder is treated. Notably, the reverse mechanism may also occur; hypokalemia from other causes may lead to metabolic alkalosis. Insulin also activates the Na^+/K^+-ATPases. Patients presenting with diabetic ketoacidosis who are administered exogenous insulin often exhibit a significant, but transient, decline in serum/plasma potassium. In addition, elevated β-adrenergic activity via endogenous catecholamines is also known to shift potassium into cells.

Disorders causing hyperkalemia

Hyperkalemia may be physiological or artifactual, owing to preanalytical specimen issues. Like hypokalemia, clinical hyperkalemia often manifests with muscle weakness and paralysis. Prolonged concentrations above 7.0 mmol/L typically cause cardiac conduction abnormalities, such as peaked T waves on electrocardiogram. Hyperkalemia in this range, if true, is potentially fatal and requires emergent treatment. Etiologies of hyperkalemia include increased potassium intake, increased retention (decreased renal excretion), or redistribution of potassium out of cells. Increased intake alone, either by diet or supplements, does not typically cause hyperkalemia in the setting of normal renal function and potassium excretion. The evaluation of a patient with hyperkalemia should include a careful review of medication history and renal

TABLE 37.6 Example causes and mechanisms of hyperkalemia.

Increased potassium load (must have diminished renal function) • Intravenous (KCl or transfusions) • Oral intake (dietary supplements)
Decreased renal excretion • Acute and chronic kidney disease • Adrenal deficiency, Addison's disease • Drug-induced: ACE inhibitors, β-adrenergic blockers, and NSAIDs • Potassium-sparing diuretics (e.g., spironolactone)
Cellular loss • Acidemia: inhibits Na^+/K^+-ATPases • Digoxin toxicity: also inhibits Na^+/K^+-ATPases • Rapid cell destruction: rhabdomyolysis, hemolytic anemia, and tumor lysis syndrome • Insulin deficiency: blocks entry of K^+ into cells
Preanalytical, collection-related, and artefactual • Hemolysis, cell lysis, delayed centrifugation, and K_2- or K_3-EDTA contamination

ACE, Angiotensin-converting enzyme; *NSAID*, nonsteroidal antiinflammatory agents.

function. Various causes and mechanisms of hyperkalemia are summarized in Table 37.6.

Notably, preanalytical factors contributing to pseudohyperkalemia should be considered upon findings of unexpectedly elevated potassium results (Table 37.2). Failure to identify high potassium results as artifactual may result in unnecessary treatment that leads to dangerous hypokalemia; conversely, true hypokalemia that is viewed as within normal limits by preanalytic effects may prevent patients from receiving necessary potassium supplementation.

Decreased renal excretion

Decreased renal excretion is a common cause of hyperkalemia and may be exacerbated by drugs that have effects of reduced renal potassium clearance. Hyperkalemia is a frequent complication of acute and chronic kidney disease. Adrenal deficiency, such as in the setting of Addison's disease, will diminish aldosterone-mediated sodium reabsorption, and thus results in increased potassium retention at the tubules. Further, drugs that inhibit the RAAS, including angiotensin-converting enzyme (ACE) inhibitors, β-adrenergic blockers, and NSAIDs, also commonly cause hyperkalemia and should be discontinued if possible in the setting of severe hyperkalemia. Potassium-sparing diuretics (e.g., spironolactone) administered in excess may also cause hyperkalemia.

Shift of potassium out of cells

States of acidemia inhibit the Na^+/K^+-ATPase exchange, will shift potassium extracellularly, and may cause hyperkalemia in the absence of urinary or GI losses. As with alkalemia-mediated hypokalemia, acidemia-mediated hyperkalemia is transient and will resolve when the underlying acid–base disorder is treated. Cardiac glycosides such as digoxin function by inhibiting Na^+/K^+-ATPase activity; thus hyperkalemia is observed in cases of digoxin toxicity. Conditions that cause rapid cell destruction, such as rhabdomyolysis, hemolytic anemia, and tumor lysis syndrome, will also cause significant potassium release into the plasma, though hyperkalemia may not be observed unless renal function is insufficient. Finally, insulin deficiency prevents potassium from entering cells and contributes to increased plasma potassium concentrations. Patients with an acute hyperkalemic presentation may be administered insulin to facilitate rapid intracellular transfer of potassium.

Case example

A 76-year-old female was visited by a nurse as part of a home health care service for routine diabetes management. Otherwise, the patient appeared well, and blood was drawn for a basic metabolic panel. Later that evening, the patient's physician called the patient and instructed her to go to her closest emergency department (ED) due to an alarmingly high plasma potassium result of 6.3 mmol/L. The physician also noted moderately low glucose. Upon retesting in the ED, the patient's potassium resulted as 4.1 mmol/L, and she was discharged home. What was the cause of the discrepant potassium results?

Case resolution

After visiting the patient, the home health nurse visited several other patients over several hours prior to dropping off blood specimens in batch at the laboratory. The blood tube was not centrifuged in the meantime, allowing intracellular potassium to leak out into the plasma due to progressively reduced activity of Na^+/K^+-ATPases as glucose was depleted by ongoing glycolysis. The potassium result from the sample that was processed immediately after draw at the ED lab should be considered the preferred (true) result.

Disorders of chloride

Unlike sodium and potassium, abnormalities of plasma chloride concentrations alone are not associated with severe clinical consequences. However, assessment of chloride is useful in the differential diagnosis of acid–base disorders and in the determination of the anion gap. In the absence of acid–base disorders, chloride concentrations tend to follow the trends of sodium. In addition, CF is associated with mutations in the CF transmembrane regulator gene, which codes for chloride channels across epithelial membranes. Elevated chloride in sweat remains a mainstay diagnostic indicator for CF.

Disorders causing hypochloremia

Generally, disorders causing hyponatremia may cause concurrent hypochloremia. In particular, prolonged vomiting may deplete chloride to a higher degree than sodium due to the high proportion of chloride in gastric fluid. Hypochloremia may result from renal losses that also deplete sodium, such as osmotic dilution or use of diuretics. Hypochloremia with normal plasma sodium is observed in respiratory alkalosis, which may occur, for example, in the cases of pulmonary edema, chronic obstructive pulmonary disease, or asthma. Acute exacerbations of these conditions cause increased secretion of hydrogen ion at the proximal tubules, and sodium is retained preferentially as sodium bicarbonate rather than sodium chloride. Administration of chloride-containing solutions may be necessary in the cases of true chloride depletion.

Disorders causing hyperchloremia

Causes of hypernatremia may also cause hyperchloremia, such as dehydration or DI in the absence of water replacement. Overuse of normal saline solution, which has a chloride concentration of 154 mmol/L, may cause a hyperchloremia metabolic acidosis as bicarbonate is increasingly excreted. By the same mechanism, plasma chloride may rise in cases of compensated respiratory alkalosis.

Self-assessment questions

1. The renin–angiotensin–aldosterone system serves which of the following functions?
   - **a.** plasma K^+ retention, urinary excretion of Na^+, and increase blood pressure
   - **b.** plasma K^+ retention, urinary excretion of Na^+, and decrease blood pressure
   - **c.** plasma Na^+ retention, urinary excretion of K^+, and increase blood pressure
   - **d.** plasma Na^+ retention, urinary excretion of K^+, and decrease blood pressure
   - **e.** plasma retention and urinary excretion of both Na^+ and K^+, increase blood pressure
2. Which of the following techniques is a modern method for measurement of electrolytes that is preferred in cases of increased blood solids (e.g., hyperproteinemia and hyperlipidemia)?
   - **a.** direct ISE potentiometry
   - **b.** indirect ISE potentiometry
   - **c.** FES
   - **d.** AAS
   - **e.** coulometric titration
3. Which of the following techniques is preferred for the measurement of sweat chloride due to its precision at low chloride concentrations?
   - **a.** direct ISE
   - **b.** indirect ISE
   - **c.** FES
   - **d.** AAS
   - **e.** coulometric titration
4. Of the following causes of hyponatremia, which would most likely present with a high serum osmolality?
   - **a.** renal fluid and electrolyte losses
   - **b.** psychogenic polydipsia
   - **c.** syndrome of inappropriate antidiuresis (SIADH)
   - **d.** edematous states such as congestive heart failure
   - **e.** diabetes mellitus with extreme hyperglycemia
5. Which of the following conditions is likely to cause hypernatremia due to a deficiency of ADH (central diabetes insipidus)?
   - **a.** syndrome of inappropriate antidiuresis (SIADH)
   - **b.** use of diuretics
   - **c.** adrenal insufficiency
   - **d.** pituitary tumor
   - **e.** hypothyroidism
6. A patient with normal potassium 3 months ago is found to have a serum K^+ of 3.1 mmol/L. He had recently been started on several medications. From the following list, which medication is the most likely to have contributed to hypokalemia in this patient?
   - **a.** ibuprofen (NSAID)
   - **b.** enalapril (ACE)
   - **c.** furosemide (loop diuretic agent)
   - **d.** metoprolol (B-adrenergic blocking agent)
   - **e.** spironolactone (aldosterone antagonist)
7. Which of the following preanalytical factors contribute to falsely elevated potassium results?
   - **a.** delayed or incomplete separation of serum from cells
   - **b.** contamination with K_2- or K_3-EDTA anticoagulant
   - **c.** prolonged fist clenching during blood collection
   - **d.** a and b
   - **e.** all of the above
8. Blood chloride concentrations tend to follow trends of _____ but may deviate in certain acid–base disorders.
   - **a.** sodium
   - **b.** potassium
   - **c.** hydrogen
   - **d.** bicarbonate
   - **e.** magnesium

Chapter 38

Urinalysis

Shu-Ling Fan[1,2] **and Shi Bai**[1,2]

[1]*Department of Pathology, UMass Memorial Medical School, Worcester, MA, United States,* [2]*Department of Pathology, UMass Memorial Medical Center, Worcester, MA, United States*

Learning objectives

After reviewing this chapter, the reader will be able to:

- List the components of a complete urinalysis (physical, chemical, and microscopic examination).
- Discuss methods for evaluating urine appearance and concentration and recognize clinically significant abnormalities.
- Describe methods for identifying the chemical composition of urine.
- List the clinically significant abnormalities identified by microscopic analysis of urine.
- Discuss the limitations of physical, chemical, and microscopic examination techniques in urinalysis and learn the available alternative methods for analysis.

Introduction

Urinalysis is a valuable tool for the clinician. It is most commonly used in the assessment of the genitourinary system; in addition, it can aid in the diagnosis of certain systemic diseases, such as diabetes mellitus or hypertension of pregnancy. Complete urinalysis includes the physical, chemical, and microscopic examination of a urine specimen. Physical examination describes the urine's visual appearance and measured concentration. Chemical analysis is used to reveal and quantify key urine components and is mainly accomplished using dipstick technology. Microscopic evaluation is the third major component of urinalysis; it is the most time-consuming part, yet it remains essential in a number of diagnoses such as urinary tract infections and renal injuries.

Specimen collection and handling

Urine specimens should be collected in a clean, sterile container that has a tightly fitting lid to prevent contamination, evaporation, and spillage. A clean-catch, midstream collection prevents bacteria from the skin of the penis or vagina from contaminating the urine specimen. The sample should be free of vaginal secretions and other extraneous debris. Cleansing of the external genitalia is frequently recommended for women The first morning voided urine is usually the most desirable for urinalysis testing; it is the most concentrated of the day's urine and is also the most acidic (pH between 6.5 and 7.5), so that formed elements such as cells and casts are more stable than in dilute, less acidic urine. Random specimens may be collected at unspecified times and have the advantage of being convenient for patients. They are usually satisfactory for routine screening, although they may not accurately reflect the patient's status, because antecedent factors such as hydration can directly affect urine composition. Timed urine specimens are frequently used to quantitate various aspects of renal function. The urine collected must reflect excretion over a precisely measured duration of time. The specimen must not include urine that is present in the bladder before the timed test begins. The patient should be instructed to obtain a 24-hour urine specimen by discarding the first-voided morning urine on the first day and collecting all subsequent urine *up to and including* the first-voided morning urine on the second day.

Given that the physical, chemical, and microscopic characteristics of a urine specimen begin to change as soon as the urine is voided, urine specimens (except for long-term collections) should ideally be delivered to the laboratory for analysis immediately after collection, which is within 1 or 2 hours of the time of voiding. When this is not possible, steps should be taken to minimize the deterioration of the specimen until it can be transported to the laboratory. Refrigeration is the most commonly used means to preserve urine specimens for delayed analysis; however, it induces precipitation of amorphous or crystalline deposits, which can interfere with the urine microscopic examination. When performing dipstick analysis, the specimen must be allowed to come to room temperature before testing is performed, because low temperatures alter the time required for reactions to come to completion. If urine is allowed to sit unpreserved at room temperature, it will

TABLE 38.1 Changes in delay-analyzed, unpreserved, nonrefrigerated urine specimens.

Physical appearance
• Color may change because of oxidation or reduction of metabolites
• Turbidity may increase because of bacterial growth and possible precipitation of amorphous material
Chemical composition
• pH may increase because of the breakdown of urea to ammonia by urease-producing bacteria
• Glucose may decrease because of metabolic breakdown by patient cells and microorganisms
• Ketones may decrease because of volatilization
• Bilirubin may decrease because of photooxidation
• Nitrite may increase because of bacterial reduction of nitrate
• Bacteria may multiply
• Urobilinogen may decrease because of oxidation to urobilin
Microscopic appearance
• Body cells and casts may disintegrate, especially in dilute, alkaline urine

begin to decompose (Table 38.1). Preservatives work by stabilizing urine so that chemical changes associated with decomposition do not occur and by preventing growth and metabolism of microorganisms. Toluene, phenol, thymol, and acidic or basic preservatives are commonly used for urine chemistry determinations, as is excluding light (bilirubin). Ethanol (95%) or commercially available fixatives may be used to preserve cell structure.

Routine urinalysis

In the kidney, small-molecular-weight substances can freely pass through the glomerulus (see Chapter 35, Laboratory evaluation of kidney function). Most essential components are completely reabsorbed by the tubules; however, increased serum concentration of these substances may exceed the tubules' reabsorptive capacity and lead to their urinary excretion, as with glucose, bilirubin, urobilinogen, and ketones. Many hematological or congenital metabolic disorders can also be detected by increased urinary excretion of particular compounds. Small-molecular-weight or cationic proteins, such as Bence–Jones protein in multiple myeloma, myoglobin in rhabdomyolysis, and hemoglobin in paroxysmal nocturnal hemoglobinuria, may appear in urine through this mechanism. Some substances are normally excreted in urine because of their limited tubular reabsorption; waste products such as urea and creatinine make up most of the normal urinary solutes.

Normally, red blood cells (RBCs) and large-molecular-weight compounds (most serum proteins) are unable to pass through the glomerulus. Therefore the presence of such substances in urine is an indication of an abnormal interface between the bloodstream and the urinary filtrate. While most commonly this indicates the presence of glomerular disease, bleeding also causes blood and protein to be directly released to the urinary tract, which can also indicate nonglomerular diseases such as urinary tract infections, kidney stones, and tumors. As mentioned above, tubular reabsorption prevents the appearance of most small-molecular-weight substances in urine, yet with tubular disease, compounds such as glucose can be found in the urine even with normal blood glucose concentrations, for example, in diabetic nephropathy (see Chapter 35, Laboratory evaluation of kidney function, for more details). Casts and crystals may form directly in the tubular lumen as local concentration of substances is increased by water reabsorption. Such findings can thus point to the presence of intrinsic renal disease. A standard urinalysis historically includes physical examination of the urine, a few simple chemical tests, and microscopic examination of urine sediment.

Physical examination

Appearance

Color

The color of urine is determined to a large degree by its concentration; normal urine varies widely from colorless to deep yellow. Interpretation of color is subjective and varies with each laboratory analyst. It is useful to use

TABLE 38.2 Colors of urine.

	Common causes		
Colors	**Food/drugs**	**Metabolites**	**Clinical conditions**
Yellow to colorless			Polyuria
Yellow	Food color	Urochrome	Healthy patients
Yellow-orange	Warfarin, carotene, and rhubarb	Urobilin and bilirubin	Dehydration
Yellow-green		Bilirubin–biliverdin	Jaundice
Yellow-red-brown	Beets, laxatives (senna), and rhubarb	Hemoglobin, myoglobin, and porphyrin	Hematuria, hemoglobinuria, myoglobinuria, and menstrual contamination
Brown-black	Chloroquine	Porphyrin, melanin, methemoglobin, homogentisic acid, and L-dopa	Alkaptonuria, ochronosis, and rhabdomyolysis
Blue-green	Amitriptyline	Indicant	*Pseudomonas* infection

standardized colored objects in the laboratory as reference points and to use defined colors to describe the urine, avoiding ambiguous terms such as "straw" or "bloody." The clinical significances of common colors of urine are summarized in Table 38.2. Numerous drugs are associated with color changes in urine and should also be considered when interpreting urine color (Table 38.2).

Turbidity

Although cloudy urine is not necessarily pathologic, turbidity in an uncentrifuged urine should be microscopically investigated. Turbidity can be due to the presence of epithelial cells, microorganisms, blood cells, amorphous or crystalline solids, or spermatozoa. Urinary infections and contamination by genital secretions are among the most common causes. Turbidity may also be caused by blood clots, menstrual discharge, pieces of tissue, small calculi, clumps of pus, and fecal material (sometimes from a fistula between the colon or rectum and bladder).

Odor

While the odor of urine is usually given little importance in clinical diagnosis, it can be used to provide clues to certain abnormalities. Normal fresh urine has a faint odor. An offensive, fetid, or ammoniac odor can indicate infection or that a specimen is too old for accurate analysis; a foul odor in a specimen collected more than 2 hours earlier and not preserved or refrigerated indicates an unacceptable specimen. Foul smelling urine in older children and adults is usually due to the presence of infectious agents or accumulation of sulfur-containing compounds in patients with advanced liver disease. In properly collected samples, an ammonia-like odor is suggestive of urea-splitting bacteria, such as *Proteus*, *Pseudomonas*, *Klebsiella*, *Staphylococcus*, and *Mycoplasma*. A few additional characteristic odors can give clues to a medical or congenital disease. Fruity odors indicate the presence of acetone (ketone). A sweet odor is suggestive of the presence of glucose or another sugar, as in diabetes mellitus and maple syrup urine disease. Phenylketonuria is associated with a "mousy" odor and tyrosinuria with a "rotten" odor. Rarely, chemicals derived from food, such as asparagusic acid from asparagus, may be detected.

Concentration

The kidneys control body fluid and electrolyte homeostasis by regulating the volume of excreted water and solutes. Therefore the total urine solute concentration reflects the kidneys' ability to concentrate and dilute urine. This, in turn, is useful in evaluating hydration status. Osmolality and specific gravity both measure the proportion of dissolved solid components in a specimen.

Specific gravity

Specific gravity is a measure of density. More specifically, it is the ratio of the mass of a solution compared with the mass of an equal volume of water. In normal urine, the largest contributors to specific gravity are urea, sodium chloride, sulfate, and phosphate. A number of techniques are available for the measurement of specific gravity. The strip method is an indirect, colorimetric technique using a reagent strip, which contains an electrolyte–dye mixture that elicits a pH change based on the ionic concentration (pKa) of the urine. The reagent-strip

test is fast and simple, and requires no additional equipment. The manufacturer states that there is no interference by glucose, protein, or radiographic dye, all of which interfere with refractometers and urinometers. Disadvantages of reagent strips include their poorer sensitivity than refractometers (units of 0.005), and urine with a pH of 6.5 or greater requiring a correction factor. The refractometer is another indirect method for testing specific gravity. It measures refractive index, which is the ability to bend light, and there is usually a close relationship between the refractive index and the specific gravity. Some large compounds have disparate effects on these two properties and will therefore introduce error. The urinometer is a direct measure of specific gravity and tests buoyancy; however, it is not the method of choice due to the need for larger sample volume and temperature precision. The falling drop method is also a direct measure of specific gravity and is performed by timing a drop of urine and a separate drop of water as they pass through oil. It is more accurate than the refractometer and more precise than the urinometer.

Osmolality

Osmolality measures the total number of dissolved particles per unit of solution (in mmol/L or mOsm/kg water) and reflects the concentrating ability of the kidney better than specific gravity. The normal kidney is capable of producing a urine osmolality ranging from about 40−80 mOsm/kg during diuresis to 800−1400 mOsm/kg during dehydration. In normal urine, over 80% of osmotic activity is due to urea and creatinine, with lesser proportions due to charged solutes such as electrolytes. In normal patients, protein and glucose do not contribute appreciably to urine osmolality. Osmolality is most commonly tested using freezing point depression. For example, 1000 mOsm/kg water depresses the freezing point by 1.86°C.

Chemical examination

A number of chemical constituents are routinely analyzed in urinalysis. The most commonly used techniques include semiquantitative and qualitative reagent strips (dipsticks), tablet tests, and fully quantitative methods for protein, electrolytes, and porphyrins. Some of the factors interfering with urine chemical tests are listed in Table 38.3. The normal ranges of urine components are reviewed in Table 38.4.

Reagent-strip testing

A reagent test strip (or dipstick) is a narrowband of plastic 4−6 mm wide and 11−12 cm long with a linear series of small absorbent pads attached to it. Each pad contains reagents for a separate reaction, so several tests can be carried out simultaneously. Reagent-strip tests have enabled urinalysis laboratories to generate valuable

TABLE 38.3 Interfering factors in urine chemical tests.

Test	Interferences
Specific gravity	Dipstick tests measure ionic strength, which correlates poorly with actual concentration in hospitalized patients; proteinuria and alkaline pH also lead to incorrect results
pH	None
Protein	Alkaline pH may cause false-positives; Bence−Jones protein is not detected
Glucose	Hydrogen peroxide and bleach causes false-positives; ascorbic acid, salicylate, ketones, and L-dopa may cause falsely decreased results
Ketones	Phenylketones, L-dopa, methyldopa, acetylcysteine, captopril, and phthaleins may cause false-positives; ascorbic acid rarely causes false-negatives
Blood	Bleach and microbial peroxides may cause false-positives; ascorbic acid falsely lowers results; high specific gravity or strongly acidic urine can prevent RBC lysis causing a false-negative
Bilirubin	Rifampin and chlorpromazine cause false-positives; exposure to light, ascorbic acid, and nitrite cause false-negatives
Urobilinogen	Many drugs produce false-positives with the Ehrlich method (e.g., sulfonamides)
Nitrite	Contamination may cause false-positives; ascorbic acid may cause false-negatives; Gram-positive bacteria and *Pseudomonas* infections are not detected
Leukocyte esterase	Ascorbic acid, proteinuria, and formalin produce false-negatives

RBCs, Red blood cells.

TABLE 38.4 Composition of urine from healthy subjects.

Constituents	Value (men)	Value (women)
Specific gravity	1.003–1.035 random (1.016–1.022 over 24 h)	
Osmolality	500–850 mOsm/L	
pH	4.6–8.0	
Total protein	< 100 mg/24 h	
Albumin	< 30 mg/24 h or <30 mg/g of creatinine	
Creatinine	20 mg/kg/24 h	15 mg/kg/24 h
Glucose	Usually not detected (<100 mg/dL)	
Ketones	Not detected (<50 mg/dL)	
Total bilirubin	Not detected or ≤ 0.02 mg/dL	
Urobilinogen	< 1 mg	
Urea nitrogen	6–17 g/24 h	
Sodium	Varies with quantity ingested	
Chloride	Similar to sodium excretion	
Potassium	Varies with quantity ingested	
Oxalate	< 45 mg/24 h	
Calcium	<300 mg/24 h	<250 mg/24 h
Uric acid	300–800 mg/24 h	250–750 mg/24 h

semiquantitative chemical results in a rapid, accurate, and efficient manner. In general, properly performed urine test strips are sensitive, specific, and cost-effective. Automated dipstick readers (reflectance photometers) are widely available. To ensure the best results, the urinalysis laboratory should perform the tests according to the following guidelines:

- Test urine promptly at room temperature; use properly timed test readings only.
- Beware of interfering substances.
- Understand the advantages and limitations of the test.
- Employ controls.

Confirmatory testing: tablet and chemical tests

Tablets and chemical tests are sometimes necessary to confirm results obtained by dipstick methods when there are differences in sensitivity (e.g., bilirubin) or specificity (e.g., sulfosalicylic acid for proteins), or to avoid interferences when pigments in the specimens mask the colors obtained on the reagent pads. A confirmatory test should have either the same or better specificity, be based on a different principle, and have a sensitivity equal to or better than that of the original test.

Tests results *often* indicating urinary tract disease

Protein

Healthy individuals will have a daily protein excretion of about 100 mg/day, a very small fraction of the plasma protein content. The normal glomerulus is permeable only to proteins with a molecular weight less than 68,000 Da. Once filtered, proteins are almost completely reabsorbed in the proximal tubule. Proteinuria, therefore, can be the result of either increased or abnormal filtration or decreased reabsorption. Proteinuria, defined as increased protein in the urine, can be classified as transient or persistent. Transient causes include strenuous physical exercise, pregnancy, exposure to extreme cold, relative concentration due to increased water reabsorption, psychological stress, fever, or other acute illnesses. Persistent proteinuria can be subcategorized as glomerular, tubular, or overflow. Glomerular proteinuria is nonselective, and albumin is the predominant urine protein. Tubular proteinuria occurs with tubular injury, resulting in an inability to reabsorb the glomerular filtrate; low-molecular-weight proteins predominate over albumin in this type of proteinuria. Overflow proteinuria occurs when the amount

of low-molecular-weight protein in plasma overwhelms the tubular reabsorptive capacity, as seen with hemoglobinuria, multiple myeloma, and myoglobinuria.

Protein remains the single most useful test on a dipstick for the detection of intrinsic disease of the kidney and urinary tract. Proteinuria is often associated with urine sediment abnormalities, which further aid the diagnosis. Reagent-strip tests are a rapid, inexpensive screening procedure for proteinuria; however, a few important limitations exist. Sensitivity ranges from 6 to 30 mg/dL protein; thus modest increases in urine protein may be missed, including microalbuminuria. In addition, the specificity of these dye-based strip tests is weighted to the detection of albumin, making them unsatisfactory for detection of Bence–Jones proteins, tubular proteinuria, or overload proteinuria. It is recommended that the laboratory communicates these limitations to clinicians and simultaneously performs an alternate method for the detection of all types of protein.

The reagent-strip tests are pH-sensitive. The presence of protein on the strip changes the pH environment of the dye embedded in the pad, resulting in a color change. Highly buffered, alkaline urine can result in a false-positive test.

$$\text{Tetrabromophenol blue} \xrightarrow{\text{pH3}} \text{positive result (green-blue)}$$

$$\text{Tetrabromophenol blue} \xrightarrow{\text{pH3}} \text{negative result (yellow)}$$

A positive or faintly positive result should be confirmed with a more specific test such as the trichloroacetic acid or the sulfosalicylic acid tests. A mildly positive test strip result and a grossly positive turbidity test result may indicate the presence of drugs or Bence–Jones proteins, which can be confirmed on a urine protein electrophoresis.

Blood

The presence of blood in the urine (hematuria) is an important indicator of diseases involving the urinary system. RBCs come from a variety of sources, including the kidneys, ureters, bladder, urethra, prostate gland, uterus, and vagina. Among the more common diseases resulting in hematuria are bladder and kidney infections, tumors, trauma to the kidneys, glomerulonephritis, pyelonephritis, renal calculi, and bleeding disorders related to anticoagulant use. RBCs may be found intact or lysed, which releases hemoglobin and results in hemoglobinuria. Hemoglobinuria, however, is less common than hematuria, and may be associated with trauma, transfusion reactions, severe burns, and poisonings.

From a clinical perspective, hematuria is usually defined by microscopic means, with greater than three RBCs per high-powered field, warranting further workup. The dipstick method provides a low-cost adjunct to microscopy, but its exact role in detecting hematuria is not clearly defined. A positive result deserves further investigation, but a negative result cannot reliably rule out hematuria. The dipstick method detects heme by the peroxidase-like activity of the proteins:

$$H_2O_2 + \text{chromogen} \xrightarrow{\text{Myoglobin or hemoglobin}} \text{oxidized chromogen(blue)} + H_2O$$

Importantly, a positive dipstick test can also indicate hemoglobinuria or myoglobinuria. Myoglobin is a ferrous porphyrin similar to hemoglobin that is commonly seen in urine after crush injuries and muscle trauma and is occasionally seen after intense physical exercise. When myoglobin is released in the circulatory system, it is rapidly excreted by the kidney. The distinction between myoglobinuria and hemoglobinuria must be made using additional tests. Myoglobin may be quantified via immunoassay; however, the presence of markedly elevated serum creatinine kinase is a useful surrogate.

Oxidizing agents such as iodides, bromides, and microbial peroxidases in the urine may cause false-positive results. In menstruating women, a positive result is the rule rather than the exception. False-negative results can occur with high concentrations of ascorbic acid or any compound that can interact with H_2O_2 due to slow down in peroxidase activity. False-negative results may also occur in very concentrated specimens, because the lysing agent may not lower concentration enough to hemolyze the cells and release hemoglobin. False-negative results may also occur in strongly acidic urine specimens, again due to incomplete cell lysis. It may occasionally be important to separate myoglobin from hemoglobin as a cause of a positive result. To confirm hemoglobinuria, the serum from the same patient would be red (hemoglobinemia). In myoglobinuria, the serum would be clear.

Leukocyte esterase

The leukocyte esterase dipstick test is a rapid, inexpensive surrogate for identifying elevated numbers of white blood cells (WBCs) in the urine, that is, pyuria. Common causes of pyuria include pyelonephritis, cystitis, interstitial nephritis, glomerulonephritis, calculi, and corticosteroid and cyclophosphamide (Cytoxan) use. Bacterial infection is the single most common cause of pyuria, and because of this relationship, clinicians may initiate empiric antibiotic treatment in symptomatic pyuric patients. Pyuria is also frequently used to distinguish between true bacteriuria and contamination.

A positive leukocyte esterase test corresponds to approximately 10,000 neutrophils/mL when measured by hemocytometer (see microscopic examination below). An exact definition of pyuria is not universally accepted;

however, a positive leukocyte esterase test is generally considered significant in the proper clinical setting. Leukocyte esterase activity is due to proteins found in primary (azurophilic) granules, which are present in neutrophils, monocytes, eosinophils, and basophils. The reagent strips will detect both lysed and intact leukocytes. The enzymes catalyze the hydrolysis of esters, releasing alcohols and acids that are then used in a color reaction. The intensity of the color is proportional to the number of leukocytes in the specimen.

Most studies have shown good correlation between the presence of neutrophils in the urine sediment examination and a positive leukocyte esterase; however, occasional discrepant results occur, particularly with fewer than 10 WBCs/high-power field (hpf). Leukocyte cell lysis is another cause of discrepant results. Ascorbic acid in very high concentrations may inhibit color development, as will mark proteinuria and aminoglycoside antibiotics. A positive leukocyte esterase (and/or nitrite, see below) occurs in approximately 90%–95% of patients with symptomatic urinary tract infections, and thus warrants a reflex to a urine culture. However, it is much less sensitive in patients with asymptomatic infections, as commonly occurs in the elderly or during pregnancy. Oxidizing agents and formalin preservative may give false-negative results.

Nitrite

This test provides an effective and rapid screening method for detecting the presence of a bacterial infection. The test is based on the principle that most bacteria found in urine have the ability to reduce nitrate, a plentiful constituent of urine, to nitrite. These organisms include *Escherichia coli*, *Klebsiella*, *Proteus*, *Staphylococcus*, and *Pseudomonas*, to mention a few. The determination of clinical bacteriuria is of major significance when culture shows the presence of more than 10^5 colonies/mL. Bacterial infections of the urinary tract are usually accompanied by the presence of large numbers of WBCs in the urine, most often neutrophils. Therefore the nitrite test serves as a valuable screening tool, along with the leukocyte esterase test, in defining whether a urinary tract infection is present. Concomitant negative dipstick results from both tests provide a predictive value of greater than 95% that urine culture will be negative.

The chemical basis of the nitrite reaction is that in an acidic environment, nitrite reacts with an aromatic amine (sulfanilamide or *p*-arsanilic acid) to form a colored diazonium salt that in turn reacts with hydroxybenzoquinoline to provide a pink color (Griess reaction). A positive reaction occurs when the bacterial content is greater than 10^5/mL. It is imperative that fresh urine samples are used when this test is interpreted to eliminate the possibility that the nitrite has been produced by bacterial contamination. First morning voided urine is preferable, because bacteria require up to four hours converting nitrate into nitrite. If bacterial infection is present in the urinary tract, a single dipstick test will be positive in 80%–90% of patients when the first morning specimen is promptly examined. The dipstick nitrite test is qualitative, and any shade of pink produced is considered a positive result, indicative of bacterial infection of the urinary tract.

Negative test results for nitrite are found when the particular species of bacteria does not reduce nitrate. Yeasts and a significant number of nonnitrite-producing, Gram-positive cocci, such as *enterococci*, *streptococci*, or *staphylococci*, may cause infection of the urinary tract and produce a negative nitrite dipstick test. Therefore a negative result should always be verified by urine culture and/or microscopy of the sediment when the patient is suspected of having an infection. False-negative results can also be caused by the presence of high levels of ascorbic acid and urobilinogen, or low pH. Adequacy of diet, especially vegetables, which allow sufficient nitrates to be formed, is essential to the proper interpretation of this test. Antibiotic agents may inhibit the growth of bacteria, even if bacteria are present, and a false-negative result is reported. False-positive results are obtained when various dyes, such as pyridium, discolor the strip test pad pink or red.

Test results *occasionally* indicating urinary tract disease

pH

The kidneys and lungs are the primary regulators of acid–base homeostasis. In healthy individuals, urine pH varies from 4.5 to 8 and most commonly falls between 6 and 6.5. The major pH regulatory mechanisms of the kidney include elimination of hydrogen ions as ammonium, and the reabsorption and production of bicarbonate. Given the kidneys' integral role in acid–base balance, urine pH reflects both renal function and serum pH status. Urine pH is therefore used to recognize certain disease processes, such as renal disease, respiratory disease, and metabolic disorders. It may also be helpful in suggesting the nature of calculi or urine crystals (Table 38.5).

Acidic urine is promoted by dietary consumption of meat protein and some fruits, such as cranberries. Acidic urine is also seen in the cases of metabolic or respiratory acidosis; however, depletion of certain electrolytes, including chloride and potassium, may result in paradoxically acidic urine during systemic alkalosis. Under normal circumstances, the collecting duct reabsorbs chloride in order to eliminate excess bicarbonate, but this function is impaired if the chloride content in the urinary tract is too low, resulting in hypochloremic alkalosis. In hypokalemia, the collecting duct conserves potassium by releasing hydrogen ions in

TABLE 38.5 Crystals in urine.

Objects	Characteristics	pH	Significance
Bilirubin	Brownish red, granular, or needle shape	Acid	Obstructive jaundice
Calcium oxalate	Colorless and octahedral (envelope shape)	Base, neutral	Commonly seen; abnormal in large numbers as with small bowel diseases
Cholesterol	Large, flat, colorless, rectangular, "staircase" pattern, and birefringent	Acid, neutral	Nephrotic syndrome, tumors, and filariasis
Cystine	Flat, hexagonal, and colorless	Acid	Abnormal; seen in inherited reabsorption disorder, renal tubular diseases, and Wilson's disease
Drugs	Dependent on the drug (e.g., sulfadiazine and ampicillin)		Usually high dosage
Leucine	Spherical, brownish yellow, oily-appearing, and refractile	Acid, base	Abnormal; seen in severe liver diseases and maple sugar urine disease
Amorphous phosphate	Fine, granular, birefringent, and white to colorless	Base, neutral	Commonly seen in alkaline urine
Triple phosphate	Birefringent, "coffin-lid" shape, and colorless	Base, neutral	Usually none; often seen in infected urine
Tyrosine	Elongated-needle shaped, colorless to pale yellow, or even black	Acid	Usually abnormal; seen in severe liver disease and inherited metabolic disorders
Uric acid	Various shapes, granular, birefringent, and colorless to pale yellow or reddish brown	Acid	Commonly seen; high numbers seen in tumor lysis and Lesch–Nyhan syndrome, with uric acid calculi

the H^+/K^{+-} ATPase channel, resulting in acidic urine despite systemic alkalosis. Acidic urine may also be induced with medications such as ammonium chloride, methenamine mandelate, and methionine. These are typically used to prevent the formation of certain calculi, namely calcium carbonate, which preferentially forms in alkaline urine.

Alkaline urine may be seen in patients consuming a vegetarian diet or large amounts of citrus fruits. In the cases of metabolic or respiratory alkalosis, alkaline urine is expected. It can also be seen following a large meal, due to gastric acid secretion, a phenomenon commonly known as "postprandial alkaline tide.". Drugs like acetazolamide, potassium citrate, and potassium bicarbonate are used to promote alkaline urine and prevent the formation of certain calculi, namely calcium oxalate, cystine, or uric acid, which preferentially form in acidic urine. Sodium bicarbonate may increase calcium excretion, and therefore is less preferably used in treating calcium stone. Maintaining alkaline urine can also provide a more effective environment for some antibiotic agents.

In patients with renal tubular acidosis (RTA), urine pH may help distinguish the various forms of this condition when combined with other laboratory data. Type 1 RTA is due to impaired hydrogen ion secretion in the collecting tubules, leading to inappropriately elevated urine pH >5.3, despite systemic acidosis. Type 2 RTA is due to impaired bicarbonate reabsorption in the proximal nephron, leading to urinary bicarbonate wasting and elevating the urine pH > 5.3, despite systemic acidosis. (Type 3 is rarely used as a classification, because it is now thought to be a combination of type 1 and type 2.) Type 4 RTA is due to aldosterone deficiency or resistance. This results in a loss of sodium and compensatory reabsorption of potassium. The ensuing hyperkalemia is managed by the H^+/K^{+-} ATPase exchanger, leading to systemic acidosis with appropriately acidic urine, usually pH <5.3.

Measurement of urine pH is made easy by dipstick methodology. The pH pad is impregnated with two indicators, methyl red and bromothymol blue, which change color according to the pH of their environment. The range of blue, green, and orange corresponds to pH between 5 and 9, in half unit increments. To minimize postcollection alteration of pH, the urine should be analyzed promptly and maintained in a tightly sealed container with minimal headspace. Open containers allow gas exchange and the release of carbon dioxide, which increases pH. Urine pH may also increase due to the growth of bacteria and breakdown of urea.

Sugars

Glucose is one of a variety of reducing substances that may be present in the urine, and from a clinical

standpoint, it is of particular interest due to its various disease associations. Small amounts of glucose may be present transiently in the urine of healthy patients, especially after ingesting foods or beverages that have a high concentration. Glucose is freely filtered by the glomerulus and almost entirely reabsorbed by the renal tubules, so that under normal circumstances, little is found in the urine. Glycosuria is defined as the presence of detectable glucose in the urine. This generally occurs when blood levels of glucose exceed 180 mg/dL. At these levels, with similar concentrations occurring in the glomerular filtrate, the renal threshold for reabsorption is exceeded, and any excess glucose is excreted in the urine.

In diabetes mellitus, serum concentrations of glucose may reach very high levels, and glucose may be seen in the urine. Glucose may also be found in the urine in other pathological conditions such as those affecting the central nervous system (stroke and neoplasms), kidneys (uremia), endocrine system (overproduction of adrenocorticotropic hormone), and liver (glycogen storage disease) or may be related to general metabolic problems, such as feeding after starvation. Some pharmaceutical agents, such as diuretics and birth control pills, may also cause glycosuria.

Reducing sugars other than glucose are occasionally seen in urine in patients with inherited metabolic disorders. Galactosemia is one such disorder. Deficiency of galactose-1-phosphate uridyltransferase (GALT) or galactokinase is associated with developmental delay and other sequelae that may be limited with early dietary restriction of galactose. Congenital lactase deficiency results in lactosuria, malabsorption, and diarrhea starting at birth; management with lactose-free formula is life-saving. Sucrase deficiency is less common than lactase deficiency but has similar symptoms; it results in sucrosuria. Other sugars that may be present in the urine are fructose and pentose, both infrequent causes of nonglucose mellituria.

Glucose can be measured in various ways. Reagent strips employ the specific enzyme activity of glucose oxidase. The enzyme catalyzes the conversion of glucose into gluconic acid and hydrogen peroxide. A second enzyme, peroxidase, promotes the reaction of hydrogen peroxide with a chromogen (e.g., iodine complex) to form a brown oxidized compound. The chromogen varies with the manufacturer, as does the sensitivity.

$$\text{Glucose} + O_2 \xrightarrow{\text{Glucose oxidase}} \text{gluconic acid} + H_2O_2$$

$$H_2O_2 + \text{chromogen} \xrightarrow{\text{Peroxidase}} \text{oxidized colored chromogen} + H_2O$$

Results of the glucose dipstick are semiquantitative and reported in a 1 + to 4 + format, which are equated to concentrations ranging from approximately 100−2000 mg/dL. Other sugars do not give a positive dipstick test. False-positive results occur when oxidizing agents act directly on the chromogen; these include bleach and microbial peroxides. False-negative results may occur when reducing agents like ascorbic acid prevent the oxidation of the chromogen. False-negative results may also occur when glucose has been metabolized by bacteria in samples that have been allowed to stand after voiding.

The copper reduction tablet or Benedict's test (Clinitest, Bayer Diagnostics) provides an additional method for testing urine sugar. In addition to glucose, Benedict's test will detect the presence of all reducing sugars, including galactose, lactose, fructose, maltose, and pentoses. It is, therefore, an important method for use in pediatric patients to screen for disorders of carbohydrate metabolism. The goal of this screen is primarily to detect galactosemia, as other disorders of carbohydrate metabolism are rare and generally more clinically benign. Sucrose is not a reducing sugar and will not be detected. To verify the presence of a nonglucose-reducing sugar, comparisons should be made with a dipstick result from the same patient.

The copper reduction method is performed in a test tube by adding urine and water to a tablet composed of copper sulfate, sodium citrate, sodium carbonate, and sodium hydroxide. The sodium carbonate and citric acid act as effervescents, rapidly dissolving the tablet. Sodium hydroxide creates an alkaline environment and reacts with citric acid and water to produce heat. In this environment, the cupric ion reacts with reducing substances in the urine to produce cuprous ions. Shortly after the components are combined, if reducing sugars are present, red color will develop in the solution. The bottom of the test tube will be hot and should not be touched. The amount of sugar present is then quantitated by comparing the color of the products with a color chart.

$$\text{Cupric ions} + \text{glucose (or reducing substances)} \xrightarrow{\text{Heat and alkali}} \text{cuprous oxide (red)}$$

The Clinitest tablet will detect reducing substances at a concentration of 250 mg/dL or greater. Clinitest is both less specific and less sensitive than the reagent strip; it cannot be used as a confirmatory test for a positive reagent-strip glucose test. False-positive results occur in the presence of ascorbic acid and certain drugs, such as nalidixic acid, probenecid, and cephalosporins and in patients with kidney injury and/or liver disease. Normal newborns may excrete sugars such as glucose, galactose, fructose, and lactose during the first 10−14 days of life. Normal pregnant and postpartum women may excrete lactose. For these reasons, screening for carbohydrate metabolism disorders by the Bayer Clinitest reagent tablets, which have been discontinued by the manufacturer, or any other similar method, is no longer recommended. Urine tests for carbohydrates can be used in lieu of this test as well.

Rather than detecting reducing substances in urine, the current recommended method uses a blood specimen and

detects the activity of the deficient enzyme in galactosemia (GALT). This method has improved sensitivity and specificity compared with the previously used urine test. Thin-layer chromatography can also be utilized in the specific identification of nonglucose-reducing sugars when inherited inborn metabolic diseases of sugar metabolism are considered.

Test results *rarely* indicating urinary tract disease

Ketones

Ketone production is a result of metabolic alterations that occur in the setting of inadequate carbohydrate supply. Normally, the body completely breaks down fatty acids into carbon dioxide and water. However, when the supply of carbohydrate is poor, there is an increase in lipolysis. Some of this fat is metabolized into ketones using the Krebs cycle intermediate, acetyl-coenzyme A. Through sequential reactions, acetyl-coenzyme A is converted into acetoacetic acid, acetone, and beta-hydroxybutyric acid, which are collectively referred to as "ketone bodies." These three products appear in the blood (ketosis) and urine (ketonuria), with acetone accounting for only 2%, acetoacetic acid for 20%, and beta-hydroxybutyrate making up the remainder. Acetoacetic acid and beta-hydroxybutyrate are acids and can contribute to the development of ketoacidosis.

Diabetes mellitus is the most common cause of ketoacidosis, and screening for urinary ketones is an important part of disease monitoring. Patents with type 1 diabetes are at higher risk of developing ketosis and ketoacidosis than are type 2 diabetics. Nondiabetic causes of ketonuria include low carbohydrate dieting, cachexia, anorexia nervosa, extreme calorie deprivation, and acute illnesses accompanied by vomiting and diarrhea. An inherited metabolic disorder should be considered in infants with severe, prolonged ketonuria. In pediatric patients, ketonuria can be caused by an acute febrile illness.

Dipstick testing for ketone bodies is based on the principle that both acetone and acetoacetic acid react with sodium nitroprusside in an alkaline buffer solution to produce a purple complex (Legal's test, Chemstrip). Some reagent strips (Multistix) do not contain alkali, and thus do not react with acetone. Beta-hydroxybutyric acid does not react with either strip formulation. The lower limit of detection for reagent-strip testing is approximately 5 mg/dL acetoacetic acid and 70 mg/dL of acetone.

$$\text{Acetoacetic acid} + \text{sodium nitroprusside} + \text{glycine} \xrightarrow{\text{AlkalinepH}} \text{purple color}$$

Reagent strips correlate only moderately well with serum ketones. False-positive results can be due to dyes, large amounts of phenylketones, acetylcysteine, methyldopa, captopril, L-dopa metabolites, or the preservative 8-hydroxyquinolone. Reagents are labile, and false-negative results can occur due to the deterioration of reagents.

Nitroprusside tablet tests (Acetest, Bayer Diagnostics, discontinued) also exist for the detection of urinary ketones and can be used on serum samples as well. The color reaction is slightly different and may be helpful when the urine has an interfering color. The lower limit of detection is 5 mg/dL acetoacetic acid and 20 mg/dL acetone. Beta-hydroxybutyrate is not detected. Sources for false-positives and negatives are otherwise identical to those seen in the dipstick method. Since neither the dipstick nor the tablet method detects beta-hydroxybutyrate, a serum test was developed for a quantitative result.

Bilirubin

Bilirubin is a breakdown product of hemoglobin and is formed in the reticuloendothelial cells of the liver, spleen, and bone marrow. It is water-insoluble and travels through the bloodstream bound to albumin (termed indirect or unconjugated bilirubin). Unconjugated bilirubin cannot be excreted by the kidneys, because albumin is not normally filtered through the glomerulus. Even in the cases of renal failure, the quantity of albuminuria and bilirubinemia is typically not sufficient to reach a detectable range of bilirubin in the urine.

Within the liver, bilirubin is chemically conjugated to glucuronic acid, which creates a water-soluble form (termed direct or conjugated bilirubin). Conjugated bilirubin is freely filtered across the glomerulus. In normal circumstances, however, most conjugated bilirubin never reaches the kidney, because it is secreted into bile. Normal urine contains small quantities of conjugated bilirubin ($\sim$0.02 mg/dL), but concentrations this low are not detectable using ordinary dipstick methodology. Therefore the presence of conjugated bilirubin in the urine usually reflects a pathologic increase in serum bilirubin. This can occur in two general circumstances, either biliary obstruction or hepatocyte dysfunction resulting in an inability to excrete conjugated bilirubin into bile. Causes of biliary obstruction include gallstones in the common bile duct, pancreatic carcinoma, drug-induced cholestasis, and periportal inflammation and fibrosis. Causes of hepatocyte dysfunction include acute hepatitis due to viruses, drugs, alcohol, and other toxins, as well as congenital Dubin–Johnson and Rotor syndromes. Bilirubinuria may occasionally be diagnosed before clinical jaundice appears. One crude but rapid method for the determination of bilirubinuria is vigorous shaking of a urine-filled test tube. Shaking produces yellow foam in the presence of increased quantities of bilirubin, whereas urine with a normal amount of bilirubin will produce white foam.

Dipstick methodology for the semiquantitative determination of bilirubinuria utilizes a reaction between the bilirubin and a diazotized aniline dye, resulting in a colored azobilirubin compound. The exact aniline dye used in the dipstick and the resulting color varies with the manufacturer. Results are interpreted as negative (<0.5 mg/dL) to 1+ (small amounts of bilirubin) to 3+ (large amounts of bilirubin). Ictotest reagent tablets (Bayer Diagnostics, discontinued) can serve as a confirmatory test. The tablets utilize similar diazotized dyes but are more sensitive (as low as 0.05 mg/dL) than the dipstick pads and less affected by interfering substances.

$$\text{Bilirubin glucuronide} + \text{diazonium salt} \xrightarrow{\text{acid}} \text{azobilirubin (colored)}$$

It is important that the urine be tested for bilirubin immediately after voiding, because bilirubin is unstable when exposed to light and breaks down rapidly. The conjugated form is quickly hydrolyzed into free bilirubin, which is less reactive. Prolonged exposure to light will cause the dipstick pad to become negative, owing to the oxidation of bilirubin to biliverdin, a substance that is nonreactive to diazo dyes. False-negative results are also obtained with the dipstick method when the tested urine contains large quantities of ascorbic acid or nitrites (released because of bacterial growth). False-positives may be due to colored drugs and their metabolites, including rifampin, chlorpromazine, and phenazopyridine. The tablet method is less affected by the hydrolysis of the glucuronide form and is not affected by ascorbic acid or nitrites.

Urobilinogen

Urobilinogen is also a product of hemoglobin metabolism and is formed by bacterial degradation of bilirubin in the colon. Approximately one half of urobilinogen is reabsorbed into circulation from the intestine. This reabsorbed urobilinogen is mostly removed from portal venous circulation and reexcreted into the bile. Only a small amount of urobilinogen typically reaches systemic circulation, amounting to a urinary excretion of no more than 4 mg per day. A random urine sample may be expected to contain 0.1−1 mg/dL urobilinogen.

The level of urobilinogen in the serum and urine is useful in narrowing the clinical differentials for jaundice. In the absence of obstruction, urobilinogen levels generally rise with increased bilirubin production. If bilirubin does not reach the lower gastrointestinal (GI) tract, however, as occurs with obstruction of the upper GI tract or common bile duct, urobilinogen is not produced and will not be detected in the urine. Elevated urobilinogen levels may also be seen when the liver simply cannot remove urobilinogen from the portal venous blood, as occurs in severe liver disease, such as cirrhosis.

Two dipstick methods for detecting urobilinogen are available and are sensitive to concentrations greater than 0.2−0.4 mg/dL. In the Ehrlich aldehyde reaction (Multistix), urobilinogen is mixed with dimethylaminobenzaldehyde in an acid buffer, resulting in a tan to orange-colored compound. The Ehrlich method is not specific for urobilinogen and will react with porphobilinogen, sulfonamides, procaine, indole, methyldopa, 5-hydroxyindoleacetic acid, and aminosalycylic acid metabolites. The Ehrlich reaction may be inhibited by high concentrations of nitrites, produced in bacterial metabolism, resulting in a false-negative result. The newer Chemstrip method is specific for urobilinogen. In this test, urobilinogen reacts with a diazonium compound in an acid medium, producing a red azo dye. Both methods are affected by drugs and metabolites that mask the color of the test strip and lead to erroneous interpretations; these include phenazopyridine and drugs containing azo dyes. False-negative results using either methodology can be obtained when testing is delayed, since urobilinogen can be converted into urobilin, which is nonreactive. False-negative results can also occur for both methods if formaldehyde is used as a urine preservative, since it will inhibit the reaction.

Microscopic examination

The microscopic evaluation of urine sediment is utilized for the early recognition of infectious, inflammatory, and neoplastic conditions of the urinary system. The ideal specimen for microscopic examination is a first morning voided urine; however, a randomly collected sample is likely satisfactory for most screening purposes. If a sample cannot be examined within 2 hours, it should be preserved, but one must be familiar with the limitations of the preservation technique. Refrigeration minimizes bacterial growth and associated metabolic changes to the sample, but it may result in the formation of crystals or other amorphous elements. Formalin preserves cellular details but can interfere with dipstick and other chemical tests.

Following proper sample collection, the urine may be concentrated using centrifugation, followed by slide preparation. Each laboratory uses different methods, which means that each must establish its own reference values for microscopic examination. Standardization of microscopic urinalysis is essential to reduce ambiguity and minimize subjectivity. Aspects of the microscopic examination that should be standardized are:

1. volume of urine analyzed,
2. duration and force of centrifugation,
3. resuspension volume and concentration of sediment,
4. volume and amount of sediment examined, and

5. terminology and reporting format.

A number of techniques are available for sediment examination. Standardized bright-field microscopy is still the most common technique employed. Supravital staining can be combined with bright-field microscopy to enhance cellular details. Typically, a small quantity of the supravital stain (e.g., crystal violet and safranin) is added to the concentrated sediment. Polarizing filters are also used to supplement bright-field microscopy and can distinguish certain morphologically similar elements. Phase-contrast microscopy is probably the best method for rapid urine sediment evaluations without the use of stains and is particularly useful in visualizing translucent objects.

Quantification of formed elements is commonly accomplished using a hemocytometer chamber. The chamber contains a known volume of sample and a grid. The formed elements within a portion of the grid are counted and converted into an overall sample concentration. Commercially available standardized slide methods are a practical alternative to the hemocytometer and are far superior to the conventional glass slide and coverslip method. Systems to automate partially the microscopic urinalysis are utilized by some laboratories and are becoming increasingly sophisticated. One method uses a laminar flow chamber to detect various elements within a given volume and present them as images that can be sorted and identified by the user. Flow cytometry is mainly utilized for counting cells and casts.

Crystals

Crystalline forms are not normally seen in the freshly voided urine sediment; however, precipitation of crystals will occur during refrigeration or when the urine has been allowed to stand. There are only a few types of clinically significant crystals, and their proper identification is often reliant upon both microscopic examination and pH at the time of crystal formation. The pH of normal urine varies from acid to alkaline, and each crystal type is associated with a specific pH range. The formation of crystals is also related to the concentration of various salts, which, in turn, depends on the patient's metabolic state, diet, and hydration status. Crystals seen in normal alkaline urine include amorphous phosphates, triple phosphates, and calcium carbonate. Normal acidic urine may also include small quantities of crystals, including uric acid and calcium oxalate. Most such normally occurring crystals have little if any pathologic significance. Crystals and associated disease states are summarized in Table 38.5.

Blood cells

Red blood cells

Hematuria accompanies a number of clinical conditions (see chemical analysis of hematuria above) and is typically defined as three or more RBCs per hpf. Microscopic analysis of the sediment is essential to the clinical categorization of hematuria. Three major categories exist and serve to locate the origin of the RBCs, allowing the clinician to narrow the differential diagnosis. Glomerular hematuria indicates a glomerular source for the RBCs and is distinguished by the presence of significant proteinuria, dysmorphic RBCs, and erythrocyte casts. The most common cause of glomerular hematuria is IgA nephropathy. Nonglomerular hematuria presents with significant proteinuria but no dysmorphic RBCs or erythrocyte casts. This pattern is due to tubulointerstitial, renovascular, or metabolic diseases. Urologic hematuria is hematuria without proteinuria, dysmorphic RBCs, or erythrocyte casts. Associated diseases include tumors, infection, and calculi.

RBCs that enter the urine proximal to the tubules are more likely to become deformed by passage through the highly concentrated loop of Henle, leading to dysmorphic RBCs and enabling the observer of such cells to deduce a glomerular origin. These dysmorphic RBCs include any deviation from the normal RBC morphology but most commonly include acanthocytes. Erythrocyte casts are indicators of glomerular bleeding. They can rarely be seen in tubulointerstitial disease and have also been identified in healthy individuals participating in contact sports.

White blood cells

In the centrifuged urinary sediment, WBCs are normally present in relatively small numbers, usually fewer than five per hpf. Increased numbers of leukocytes in the urine represent inflammation of the urinary tract and can be due to infectious or noninfectious causes. Localized infections are termed cystitis, pyelonephritis, urethritis, prostatitis, or balanitis. Staphylococcal and enteric bacteria are the most common infectious agents. Noninfectious causes of pyuria include interstitial nephritis, glomerulonephritis, systemic lupus erythematosus, tumors, calculi, fever, certain drugs, and even strenuous exercise.

While neutrophils are by far the predominant leukocyte present in urine, other WBC types may also be seen. An increased proportion of lymphocytes and mononuclear cells is suggestive of a chronic infection, while eosinophils are an important indicator of acute interstitial nephritis. WBC casts are another important diagnostic element. Their presence indicates renal involvement, most commonly due to bacterial pyelonephritis.

Epithelial cells

Renal tubular epithelial cells

RTE cells originate in the proximal and distal convoluted tubules and are best identified using the Papanicolaou stain. They are large, oblong cells with granular cytoplasm,

which can make it difficult to distinguish them from granular casts. The nucleus is small, dense, and often eccentric. Multinucleation can be seen. RTE cells are normally found in the urine in small numbers because of physiologic sloughing and regeneration. Slightly larger numbers of these cells can be seen in normal newborns but are otherwise considered pathologic. The specific etiologies for increased numbers of RTE cells in the urine are numerous and include acute tubular necrosis, acute ischemic injury, heavy metal poisoning, mushroom poisoning, and drug toxicity, particularly aminoglycosides, nonsteroidal antiinflammatory drugs, and immunosuppressants. Cytoplasmic inclusions may also be present and include lipid, hemosiderin, bilirubin, and melanin. Lipid inclusions are called oval fat bodies and support a diagnosis of nephrotic syndrome when accompanied by proteinuria.

Collecting duct epithelial cells

Collecting duct cells are cuboidal, columnar, or polygonal but never round. They have a large, slightly eccentric nucleus. Increased numbers are seen in renal transplant rejection, acute tubular necrosis, ischemic insults, malignant nephrosclerosis or acute glomerulonephritis with tubular damage, as well as drug or chemical injuries. Salicylate intoxication is included among these. A cluster of three or more collecting duct cells is called a renal epithelial fragment and is indicative of ischemic necrosis. The presence of renal epithelial fragments is frequently accompanied by pathologic casts and reflects a more severe injury with basement membrane disruption.

Urothelial cells

These are frequently present in the urine sediment (0−1 per hpf) owing to their high turnover rate. The cells are smaller than squamous cells and have a round, centrally located nucleus, small nucleoli with abundant homogeneously granular, or finely vacuolated cytoplasm. The cytoplasm is usually round or pear-shaped, and occasionally has a tail-like projection. Increased numbers of urothelial cells can be seen in certain inflammatory conditions affecting the urinary tract. Large numbers of polymorphonuclear neutrophils, plasma cells, and lymphocytes are also indicative of inflammation. Urothelial cells are rarely of pathological significance except when they are seen in large groups or sheets in the absence of instrumentation. Clusters of atypical urothelial cells can be seen in urothelial carcinoma. In such cases, an additional sediment sample should be obtained for cytologic examination.

Squamous cells

Squamous cells are easy to recognize, because they are large, flat, contain a small central nucleus, and frequently encountered. In a well-collected, midstream, "clean-catch" specimen, there should be fewer than 1−2 per hpf. While some squamous cells can be exfoliated and picked up from foci of squamous metaplasia in the trigone of the bladder (especially in women), larger numbers of squamous cells in the urine could also represent cervicovaginal/genitourinary contamination. One special type of squamous cell is the "clue" cell, an epithelial cell with a distinctive stippled or cloud-like appearance owing to the numerous bacteria coating the cell surface. Clue cells are a sign of bacterial vaginosis, which is caused by *Gardnerella vaginalis*, a Gram-negative coccobacillus. These bacteria displace the normally seen lactobacilli, which are Gram-positive rods, and cause inflammation, increased pH, and foul smelling vaginal discharge.

Casts

Casts are formed when a particular component in urine solidifies during passage through the tubule. For example, Tamm−Horsfall protein is a high-molecular-weight protein that is secreted by tubular epithelial cells. As water is reabsorbed, the concentration of this protein increases; under extreme circumstances, this leads to the formation of a gel that partially solidifies and takes the shape of the tubule in which it formed, termed a cast. The Tamm−Horsfall-derived cast matrix is either hyaline or waxy; waxy casts are a denser, highly refractile matrix. Factors that enhance cast production include increased protein concentration, increased ionic concentration, lower pH, and stasis or obstruction of the nephron by cells or cellular debris. Even a normal amount of urine protein excretion may precipitate when urine becomes highly concentrated; hence, casts are a common feature in extreme dehydration, after exercise, and during fever. Additional proteins contributing to cast formation include Bence−Jones as well as albumin; the latter may be seen in glomerular injury or extreme exercise.

The size and shape of casts indicate the condition of the tubules where the precipitation occurred; thus wide casts occur in dilated tubules (as seen in patients with renal failure), convoluted casts develop in the convoluted tubules, etc. When a cast forms, it traps any cells that are also present in the urine; thus casts serve as a "biopsy" of the environment within the kidney. The classification of renal casts is simple and based on morphologic appearance. In the normal state, only two varieties of casts appear in the urinary sediment: hyaline casts and finely granular casts. Any additional cast forms must be considered abnormal and are most often associated with generalized metabolic or intrinsic renal disease. Casts, in contrast to cells, are quantitated in the sediment as the number per low-power microscopic field. Common urinary casts are summarized in Table 38.6.

TABLE 38.6 Common renal (urinary) casts.

Types	Characteristics	Significance	Associated disease(s)
Physiologic or pathologic			
Hyaline	Transparent	Exercise, dehydration, and fever	Nonspecific
Granular	Semitransparent containing refractile granules representing protein, salts, or other cellular material	Exercise, dehydration, fever, and glomerular and tubular disease	Nonspecific
Pathologic			
Cellular			
Erythrocytic	Semitransparent or granular cylinder containing distinct erythrocytes	Renal parachymal bleeding, glomerular leakage	Acute glomerulonephritis, IgA nephropathy, lupus nephritis, and renal infarction
Blood	Yellow to red granular cylinder but intact erythrocyte stroma not seen	The same as above	The same as above
Leukocytic	Transparent granular or waxy cylinder containing segmented neutrophils	Interstitial inflammation	Tubulointerstitial disease (pyelonephritis), glomerular disease, interstitial nephritis, and lupus nephritis
Renal tubular epithelial	Semitransparent granular or waxy cylinder containing intact or necrotic renal tubular epithelial cells	Tubular damage	Acute tubular necrosis, acute allograft rejection, tubulointerstitial disease, viral disease, and drugs
Noncellular			
Waxy	Sharply defined, broad, with broken off borders and indentations, homogeneous, and highly refractile	Cellular degeneration, tubular inflammation, and extreme urinary stasis	Nonspecific; seen in many disease processes
Fatty	Semitransparent or granular cylinder containing large, highly refractile vacuoles or droplets	Lipiduria	Nephrotic syndrome
Bilirubin	Deep yellow to brown, transparent, granular waxy cylinder	Elevated conjugated bilirubin	Obstructive jaundice and liver dysfunction
Crystal	Crystalline inclusion in a semitransparent or granular cylinder	Deposition of crystals in the tubule or collecting duct	Nonspecific
Other			
Broad	Width of cylinder two to six times that of other casts; most commonly waxy or granular types	Tubular dilation and stasis	Advanced renal disease

Microorganisms

In a properly collected and processed urine specimen, the presence of microorganisms is clinically significant. The identification of bacteria on an uncentrifuged specimen using Gram staining is suggestive of greater than 10^6 organisms/mL, which is considered significant. Bacteria is best quantified and identified through the microbiology laboratory, where the presence of 10^5 colony forming units per mL or greater is usually associated with a urinary tract infection.

Fungi may also be identified in the urine sediment. *Candida* species are the most common among these and are typically observed in the yeast form. As with bacteria, the presence of fungi may represent contamination from the female genital tract or the environment. Parasites such as *Trichomonas vaginalis* or parasitic ova may also be seen. Since these organisms are more commonly observed due to genital or fecal contamination, a repeat clean-catch urine specimen is recommended. Finally, viral cytopathic effects may be observed in the epithelial cells of the urine sediment and are more commonly seen in immunosuppressed patients.

Some of the more common causative viral agents include herpesviruses, cytomegalovirus, and polyomavirus. Cytologic techniques should be used for accurate identification.

Automated urinalysis platforms

Automated urinalysis platforms have been introduced in the last decade. Some have a urine chemistry analyzer integrated with an automated microscopy analyzer on a common sample track (i.e., Beckman Iris system), and some are desktop point-of-care urinalysis strip readers (i.e., Siemens CLINITEK Status system). The point-of-care urinalysis strip readers can now perform protein-to-creatinine ratio or albumin-to-creatinine ratio for diabetes or chronic kidney disease and human chorionic gonadotropin pregnancy test, which would be extremely valuable in the Emergency Department. With the expansion of test menu and automated technology, urinalysis can be more accurate, reliable, and efficient.

Self-assessment questions

1. What are the components of a complete urinalysis?
   - **a.** Concentration, chemical examination, and microscopic examination
   - **b.** Physical examination, dipstick analysis, and microscopic examination
   - **c.** Concentration, dipstick analysis, cell, cast, and crystal analysis
   - **d.** Physical examination, chemical examination, and microscopic examination
2. Which of the following can occur due to delayed analysis of an unpreserved, unrefrigerated urine specimen?
   - **a.** Decreased bilirubin, urobilinogen, ketones, glucose, and nitrites
   - **b.** Increased bacterial count, turbidity, pH, ketones, and nitrites
   - **c.** Decreased bilirubin, urobilinogen, ketones, glucose, pH, and casts
   - **d.** Increased bacterial count, turbidity, pH, ketones, and darkened color
3. Which of the following associations is incorrect?
   - **a.** Red urine due to beets and rhubarb ingestion
   - **b.** Brown-black urine due to methemoglobin and porphyrin
   - **c.** Orange urine due to bilirubin and urobilinogen
   - **d.** Green urine due to pseudomonas infection
4. Which of the following associations is incorrect?
   - **a.** Mousy odor due to phenylketonuria
   - **b.** Sweet smell due to maple syrup urine disease
   - **c.** Fruity odor due to tyrosinuria
   - **d.** Fetid odor due to urinary tract infection
5. A clinically hydrated patient is found to have a urine specific gravity of 1.050. Which of the following potentially explains this scenario?
   - **a.** The patient recently received radiocontrast media.
   - **b.** This is a normal result for a hydrated patient.
   - **c.** The patient has diabetes insipidus.
   - **d.** The patient has acidic urine.
6. Which method of protein detection is not able to detect immunoglobulin light chains (i.e., Bence–Jones proteins) in urine at a level >10 mg/dL?
   - **a.** Immunoelectrophoresis
   - **b.** Reagent-strip protein test
   - **c.** Sulfosalicylic acid precipitation test
   - **d.** Coomassie blue dye-binding colorimetric method
7. Reagent-strip testing for hematuria is expected to be positive in which of the following circumstances?
   - **a.** Strongly acidic urine
   - **b.** Crush injury with myoglobinuria
   - **c.** High concentrations of ascorbic acid
   - **d.** High urine specific gravity
8. Leukocyte esterase is _____.
   - **a.** a protein found in primary granules of many leukocytes
   - **b.** a dipstick test that delivers false-positive results with the use of formalin-preserved specimens
   - **c.** a bacterial enzyme that catalyzes the hydrolysis of esters, releasing alcohols and acids

d. a dipstick test that is only activated by lysed leukocytes

9. Which of the following dipstick tests rely upon formation of a colored diazonium salt and, therefore, react with significant amounts of nitrite?
a. Glucose
b. Ketones
c. Blood
d. Bilirubin

10. Two methods are used to assess the presence of glucose in a urine specimen. The reagent test strip impregnated with glucose oxidase–peroxidase reagent yields a negative result, but Benedict's test yields a positive result. What is the best explanation?
a. Benedict's test is more sensitive than the strip method.
b. A nonglucose, reducing substance is present in the urine sample.
c. The urine sample has been contaminated by hypochlorite.
d. The urine sample has been contaminated by peroxide.

11. A routine urinalysis is performed on a young child suffering from diarrhea. The reagent test strip is negative for glucose but positive for ketones. These results may be explained by which of the following statements?
a. The child has Type I diabetes mellitus.
b. The child is suffering from lactic acidosis, and the lactic acid has falsely reacted with the impregnated reagent area for ketones.
c. The child is suffering from increased catabolism of fat because of decreased intestinal absorption.
d. The reagent area for ketones was read after the maximum reading time allowed.

12. Ascorbic acid can cause false-negative results for which reagent-strip tests?
a. Blood
b. Ketones and glucose
c. Leukocyte esterase
d. Nitrite
e. All of the above

13. A urine specimen tests positive for bilirubin but negative for urobilinogen. Both tests use a diazonium-based method. What is the most likely clinical scenario?
a. Obstruction of the common bile duct
b. Cirrhosis
c. Acute viral hepatitis
d. Administration of rifampin

14. The identification of unstained cellular components and casts in urine sediments provides a practical method for the detection and differentiation of formed elements in urinary sediment. Which microscopic technique is used for this procedure?
a. Fluorescent microscopy
b. Phase-contrast microscopy
c. Polarized microscopy Bright-field microscopy

15. Oval fat bodies, fatty, waxy renal tubular casts, and cholesterol crystals are seen in which of the following diseases?
a. Nephrotic syndrome
b. Chronic glomerulonephritis
c. Acute renal allograft rejection
d. Chronic pyelonephritis

Chapter 39

Disorders of the anterior and posterior pituitary

Nichole Korpi-Steiner[1] and Robert D. Nerenz[2]

[1]*Department of Pathology and Laboratory Medicine, University of North Carolina, Chapel Hill, NC, United States,* [2]*Department of Pathology and Laboratory Medicine, Dartmouth-Hitchcock Health System, Lebanon, NH, United States*

Learning objectives

After reviewing this chapter, the reader will be able to:

- List the anterior and posterior pituitary hormones, their sites of action and expected physiological effects.
- Define the regulatory mechanisms governing the synthesis and release of the anterior and posterior pituitary hormones.
- Describe clinical signs and symptoms consistent with dysregulated pituitary hormone function.
- Recommend appropriate laboratory tests for the initial evaluation of suspected pituitary dysfunction and recognize patterns of test results associated with each condition.
- Suggest provocative testing to identify the mechanism responsible for apparent pituitary dysfunction.

Introduction

The pituitary gland (hypophysis) is composed of two anatomically and physiologically distinct portions: the anterior pituitary (adenohypophysis) and the posterior pituitary (neurohypophysis). The anterior pituitary is frequently referred to as the endocrine "master gland" due to its central role in coordinating many essential endocrine systems. Anterior pituitary hormones are responsible for maintaining reproductive health [luteinizing hormone (LH) and follicle-stimulating hormone (FSH)], regulating metabolic rate and promoting cognitive function in childhood [thyroid-stimulating hormone (TSH)], responding to stress [adrenocorticotropic hormone (ACTH)], promoting linear growth in childhood [growth hormone (GH)], and stimulating lactation (prolactin). Posterior pituitary hormones regulate water balance [antidiuretic hormone (ADH)] and stimulate uterine contraction during childbirth and milk letdown following delivery (oxytocin). It is important to note that some of these hormones exert their effects on a single end-organ target (LH, FSH, TSH, and ACTH), while others act on multiple sites throughout the body (GH, prolactin, ADH, and oxytocin).

Anatomy

The pituitary is located at the base of the brain, immediately inferior to the hypothalamus, and is encased by the bony sella turcica. Although it plays a crucially important role, the pituitary is small with an approximate weight of 0.5−0.6 g. It is typically larger in women than men and reaches its largest size at the conclusion of pregnancy. During this period of enlargement, the pituitary is particularly susceptible to infarction if a woman experiences substantial blood loss during childbirth, leading to hypovolemic shock. This results in postpartum panhypopituitarism (pituitary hormone insufficiency) known as Sheehan's syndrome.

While the anterior and posterior pituitaries are located within close proximity of one another, the mechanisms responsible for hormone synthesis and release in the two lobes are fundamentally different. The posterior pituitary is an extension of the infundibulum, the narrow stalk-like structure that protrudes from the base of the hypothalamus toward the pituitary (Fig. 39.1). Because of this relationship, the posterior pituitary can be considered as an extension of the hypothalamus. Neurosecretory cells in the hypothalamus synthesize ADH and oxytocin, which are transported through the axons of these neurosecretory cells through the infundibulum to the posterior pituitary. Following appropriate hypothalamic stimuli, the posterior pituitary releases ADH and/or oxytocin into the surrounding capillary network for distribution throughout the body. Because the role of the posterior pituitary is limited to hormone release rather than synthesis, it is viewed as a reservoir for hormones synthesized upstream in the hypothalamus rather than a discrete endocrine organ.

By contrast, the anterior pituitary is not an extension of the hypothalamus but is a physically distinct entity (Fig. 39.1). The hypothalamus regulates anterior pituitary

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00039-9

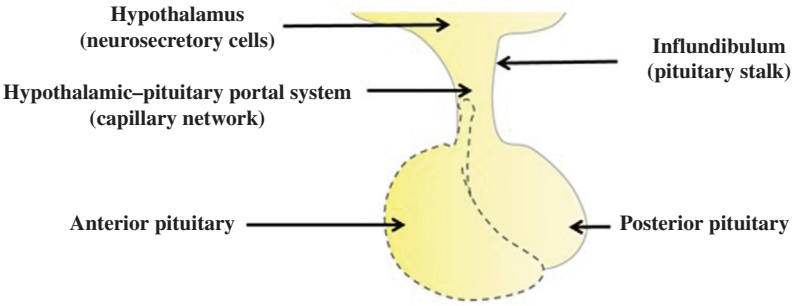

FIGURE 39.1 Hypothalamus and pituitary gland anatomy.

function by releasing regulatory hormones into the hypothalamus−pituitary portal system, a capillary network that connects the anterior pituitary and hypothalamus. These hypothalamic regulatory hormones either stimulate or repress hormone synthesis by specialized cells in the anterior pituitary. Approximately 50% of the anterior pituitary hormone-secreting cells are somatotrophs (GH-secreting cells), 10%−25% are lactotrophs (prolactin-secreting cells), 10% are gonadotrophs (FSH- and LH-secreting cells), 10%−20% are corticotrophs (ACTH-secreting cells), and 10% are thyrotrophs (TSH-secreting cells) [1]. In contrast to the posterior pituitary, the cells of the anterior pituitary are capable of hormone synthesis in addition to storage and release. The hypothalamus−pituitary portal system also permits retrograde flow, allowing anterior pituitary hormones to travel upstream to the hypothalamus and inhibit further release of hypothalamic regulatory hormones.

Physiology and regulation

The synthesis and release of most anterior pituitary hormones are stimulated by hypothalamic regulatory hormones that bind to specific receptors on the surface of hormone-producing anterior pituitary cells. With the exception of ACTH, anterior pituitary hormones are larger than their corresponding hypothalamic regulatory hormones (Table 39.1). Gonadotropin-releasing hormone (GnRH) binds to the GnRH receptors on gonadotrophs, stimulating the synthesis and release of LH and FSH. Similarly, thyrotropin-releasing hormone (TRH) stimulates thyrotrophs to produce TSH, corticotropin-releasing hormone (CRH) stimulates corticotrophs to produce ACTH, and growth hormone-releasing hormone (GHRH) stimulates somatotrophs to produce GH. Secreted anterior pituitary tropic hormone(s) travel through the vasculature to target endocrine tissue(s) and stimulate the production and release of endocrine secretory hormone(s). In order to prevent uncontrolled pituitary hormone synthesis, LH, FSH, TSH, ACTH, and GH are subject to negative feedback inhibition. The products synthesized by endocrine glands in response to these pituitary hormones bind to receptors in the hypothalamus and pituitary, preventing further release of the appropriate pituitary hormone. Feedback inhibition of LH, FSH, ACTH, and GH occurs primarily at the level of the hypothalamus, while inhibition of TSH occurs primarily at the level of the anterior pituitary (Fig. 39.2).

There are some notable exceptions and additions to the regulatory mechanism illustrated in Fig. 39.2. Prolactin is the only anterior pituitary hormone whose release is under a constant state of suppression. The hypothalamus produces dopamine that prevents prolactin release, leading to its alternate name of prolactin release inhibiting hormone (PRIH). By contrast, high concentrations of TRH observed in secondary hypothyroidism may stimulate prolactin release. GH regulation by the hypothalamus is also unique in that the hypothalamus primarily stimulates GH release through GHRH, and can also inhibit GH release through somatostatin [somatotropin release inhibiting hormone (SRIH)]. Lastly, while ACTH production is predominantly stimulated by hypothalamic CRH, it can also be stimulated by certain inflammatory cytokines or very high concentrations of ADH.

The mechanisms controlling the release of the posterior pituitary hormones ADH and oxytocin are very different from the mechanism shown in Fig. 39.2, and will be described later in this chapter.

Anterior pituitary hormone pathophysiology and lab findings

Disorders caused by atypical pituitary function can be divided into two categories: those marked by excessive pituitary hormone production (hyperfunction) and those marked by deficient pituitary hormone production (hypofunction). A summary of anterior pituitary disorders is provided in Table 39.2.

Hyperfunction

With the exception of hyperprolactinemia, which has many nonneoplastic causes, anterior pituitary adenomas are the most common cause of anterior pituitary hyperfunction.

TABLE 39.1 Anterior pituitary hormones and their source, composition, and associated hypothalamic regulatory hormone.

Hormone	Abbreviation (alternative name)	Source	Subunits	Molecular weight (amino acids)	Hypothalamic regulatory hormone (amino acids)
Adrenocorticotropic hormone	ACTH (corticotropin)	Corticotroph	1	4.5 kDa (39)	CRH (41)
Thyroid-stimulating hormone	TSH (thyrotropin)	Thyrotroph	2	28 kDa (alpha: 92; beta: 118)	TRH (3)
Growth hormone	GH (somatotropin)	Somatotroph	1	22 kDa (191) 20 kDa (176)	GHRH (44) SRIH (14)
Luteinizing hormone	LH (gonadotropin)	Gonadotroph	2	32 kDa (alpha: 92; beta: 121)	GnRH (10)
Follicle-stimulating hormone	FSH (gonadotropin)	Gonadotroph	2	30 kDa (alpha: 92; beta: 111)	GnRH (10)
Prolactin	PRL (lactotropin)	Lactotroph (mammotroph)	1	22 kDa (198)	PRIH

Adenomas are discovered either during the evaluation of symptoms caused by excessive anterior pituitary hormone production or following complaints of vision changes, persistent headache, impaired sense of smell, or other complications related to the compression of neighboring tissues by the growing tumor, a phenomenon known as "mass effect." Adenomas less than 1 cm are known as microadenomas, and these tumors often secrete anterior pituitary hormones. Microadenomas are discovered relatively early, because the excessive pituitary hormone production results in altered endocrine function, prompting patients to seek medical care. By contrast, adenomas 1 cm or greater are known as macroadenomas. These tumors often do not secrete anterior pituitary hormones, and as a result, patients with a macroadenoma may not experience clearly identifiable symptoms consistent with altered endocrine function. This may cause delay in diagnosis until the tumor reaches a sufficient size to interfere with the function of neighboring tissue. Prolactinomas are the most common anterior pituitary adenoma, followed in frequency by nonsecretory gonadotropinomas (nonsecretory is a bit of a misnomer as these tumors may produce free alpha subunit but not the biologically active intact alpha/beta heterodimer), corticotropinomas (ACTH), somatotropinomas (GH), and thyrotropinomas (TSH, exceedingly rare) [2]. Occasionally, hormone-secreting adenomas may produce and secrete multiple anterior pituitary hormones (e.g., GH and prolactin cosecretion), but production of a single anterior pituitary hormone is more common, as these tumors arise from a single specialized cell that maintains many of its original characteristics.

Hypofunction

Disorders of anterior pituitary hypofunction can be caused by hypothalamic disease, pituitary disease, or disruption of the hypothalamus–pituitary portal system (not true for prolactin, which is increased in cases of hypothalamus–pituitary portal system disruption). In contrast to the short list of conditions responsible for anterior pituitary hyperfunction, there are many possible causes of pituitary hypofunction, including infection, inflammation, trauma, surgical or radiological treatment of a previously diagnosed tumor, congenital malformations, or infarction (Sheehan's syndrome and pituitary apoplexy). As these mechanisms are not specific to one unique anterior pituitary cell type, they typically result in deficiencies in many (and often all) anterior pituitary hormones, a phenomenon known as panhypopituitarism. Single hormone deficiency may result from genetic defects in anterior pituitary hormones themselves, hormone receptors, or other hormone-specific signal transduction pathways that disrupt the function of only one anterior pituitary hormone while leaving the remaining anterior pituitary hormone regulatory pathways intact.

Adrenocorticotropic hormone

ACTH, also referred to as adrenocorticotropin and corticotropin, plays a key role in stimulating adrenal glucocorticoid (e.g., cortisol) production, which is centrally regulated by the hypothalamus–pituitary–adrenocortical axis (Fig. 39.3). The hypothalamus produces corticotropin-releasing hormone (CRH; 41 amino acid polypeptide) that travels to the anterior pituitary via the hypothalamus–pituitary portal system. In the anterior pituitary, CRH binds to receptors on corticotropic cells (i.e., corticotrophs or corticotropes) and stimulates ACTH production. ACTH is a peptide hormone product of the precursor protein proopiomelanocortin (POMC). POMC is cleaved to produce ACTH as well as additional fragments, including melanocyte-stimulating hormones (MSHs), lipotropins, and β-endorphin (Fig. 39.4). Following release into circulation, ACTH binds to receptors on cells in the adrenal cortex to stimulate cortisol production.

An important biological variable for many endocrine hormones, including ACTH and cortisol, is the cyclic production pattern over a 24-hour period, which is referred to as circadian rhythm or diurnal variation. Cortisol exhibits diurnal release where peak concentration is typically found in the early morning and nadir concentration in the evening. Similarly, plasma ACTH concentration is typically highest in the early morning. This cyclic pattern of release is regulated by neurotransmitters in the

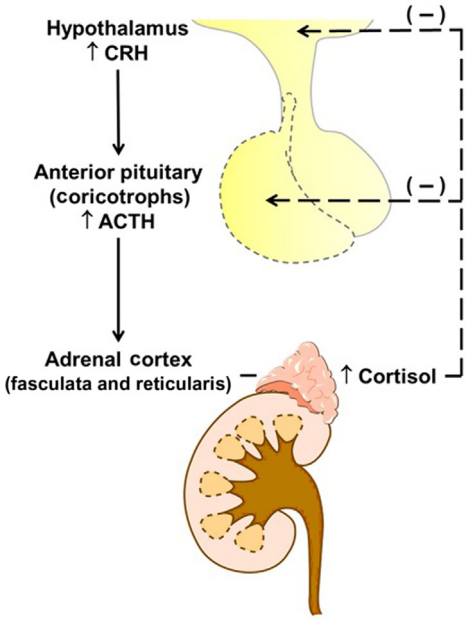

FIGURE 39.3 Hypothalamus–pituitary–adrenal axis. Adrenal production of cortisol in the zona fasciculata is stimulated by pituitary adrenocorticotropic hormone, which, in turn, is regulated by hypothalamic corticotropin-releasing hormone. Corticotropin-releasing hormone is predominantly responsible for stimulating adrenocorticotropic hormone production, while cortisol provides negative feedback primarily at the level of the hypothalamus and to a lesser extent at the pituitary.

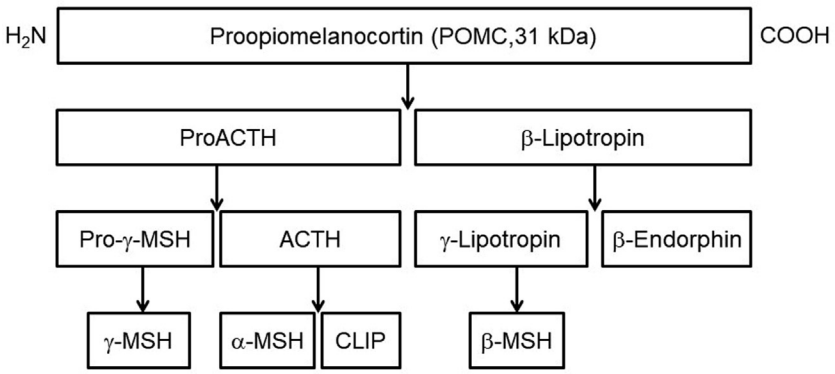

FIGURE 39.4 Proopiomelanocortin and its precursor relationship to derivative hormones (adrenocorticotropic hormone, lipotropins, melanocyte-stimulating hormone, and endorphins) produced by proteolytic degradation.

hypothalamus and influenced by each individual's biological clock. For example, a night-shift worker's sleep and eating patterns can alter the typical timing pattern of peak and nadir cortisol concentrations. It is important to consider preanalytical biological variation in the interpretation of patient ACTH and cortisol results.

Pituitary disease resulting in overproduction of ACTH can cause dysregulation in the downstream production of cortisol from the adrenal cortex. Cortisol is a glucocorticoid that plays a critical role in glucose metabolism and in the body's response to stress. Signs, symptoms, and sequelae associated with hypercortisolism (i.e., cortisol excess) may include central obesity, hyperglycemia, hypertension, hirsutism, muscle weakness, and others, which is commonly referred to as Cushing's syndrome. There are numerous potential etiologies for hypercortisolism, which are categorized as ACTH-dependent or ACTH-independent. In primary adrenal disease, hypercortisolism is ACTH-independent and may result from overproduction of cortisol by the adrenal gland(s) (e.g., cortisol-secreting adrenocortical adenoma or carcinoma, and adrenal hyperplasia) or from exogenous glucocorticoid (e.g., prednisone) administration used as treatment in a variety of medical conditions. The hypothalamus−pituitary−adrenal axis negative feedback regulatory loop is maintained in primary adrenal disease; accordingly, the excess cortisol causes suppression of CRH and ACTH production. In Cushing's disease, hypercortisolism is due to a functioning secretory pituitary tumor (e.g., adenoma) and accounts for 75%−80% of ACTH-dependent hypercortisolism [3]. Overproduction of ACTH by a functioning adrenal adenoma causes ACTH excess and continuous stimulation of the adrenal glands, leading to hyperplasia and overproduction of cortisol. ACTH-dependent hypercortisolism can also occur from a nonpituitary ectopic source, such as bronchial carcinoid or small cell lung cancer. Ectopic ACTH production accounts for 15%−20% of ACTH-dependent hypercortisolism and is associated with suppression of CRH production and pituitary-derived ACTH [3]. Additional information on hypercortisolism can be found in Chapter 41, Disorders of the adrenal cortex and medulla, of this book.

Pituitary disease resulting in ACTH deficiency can also cause endocrine dysregulation with inadequate production of cortisol from the adrenal cortex. Signs, symptoms, and sequelae associated with hypocortisolism (i.e., glucocorticoid deficiency) may include weakness, malaise, weight loss, hypoglycemia, and others. There are numerous potential etiologies for glucocorticoid deficiency, which are stratified based on a mechanism of dysfunction that may occur in the adrenal cortex, anterior pituitary, or hypothalamic gland. Addison's disease, also referred to as primary glucocorticoid deficiency or primary adrenal insufficiency (with concomitant mineralocorticoid deficiency), is a disorder of the adrenal glands, resulting in the insufficient production of cortisol that can be life-threatening. Patients with Addison's disease may appear hyperpigmented (e.g., skin appears bronze color) on presentation due to increased production of MSH in concert with ACTH (Fig. 39.4). Secondary glucocorticoid deficiency refers to a form of hypopituitarism that causes insufficient production of ACTH; consequently, there is diminished stimulation of the adrenal cortex, leading to low circulating cortisol concentrations. Tertiary glucocorticoid deficiency occurs when cortisol deficiency is due to a hypothalamic disorder that causes inadequate CRH production and downstream hypopituitarism with insufficient ACTH production.

Laboratory testing is the key to diagnosis of hypercortisolism or hypocortisolism and identifying the etiology of hormone dysregulation. Nonspecific signs and symptoms of cortisol abnormalities as well as various etiologies of potential dysfunction in the hypothalamus−pituitary−adrenocortical axis collectively contribute to challenging differential diagnoses. It is important to determine the etiology of hypercortisolism or hypocortisolism for appropriate patient treatment and management.

The first step in the evaluation of suspected Cushing's syndrome is to confirm hypercortisolemia. Tests for hypercortisolemia include 24-hour urinary free cortisol, overnight low-dose dexamethasone suppression testing, and midnight salivary cortisol testing. These tests are

TABLE 39.3 Summary of expected results in the evaluation of hypercortisolism or hypocortisolism.

Pathophysiology	24-h urinary free cortisol	Plasma ACTH
Primary adrenal disease (primary hypercortisolism)	↑	↓
Cushing's disease	↑	↑
Ectopic ACTH	↑	↑
Addison's disease (primary glucocorticoid deficiency)	↓	↑
Secondary glucocorticoid deficiency	↓	↓
Tertiary glucocorticoid deficiency	↓	↓

ACTH, Adrenocorticotropic hormone.

described in detail in Chapter 41, Disorders of the adrenal cortex and medulla, of this book. The 24-hour urinary free cortisol test is generally preferred to assess potential hypercortisolism, whereas a random serum cortisol test is of little clinical value, considering the diurnal variation in cortisol production. An elevated 24-hour urinary free cortisol result supports the presence of hypercortisolemia, and subsequent testing aims to localize the source of cortisol excess. Measurement of plasma ACTH is the key, as plasma ACTH concentrations will be suppressed if the source of hypercortisolemia is the adrenal gland itself. Conversely, plasma ACTH will be within or elevated above reference interval if there is an ACTH-producing lesion in either the pituitary gland or an ectopic location (Table 39.3). In such cases, dexamethasone suppression testing can help identify the location of excess ACTH production.

Dexamethasone suppression test

Dexamethasone suppression testing protocols can vary, and, in general, this test involves repeated administration of low- and/or high-dose dexamethasone (e.g., 0.5 or 2 mg every 6 hours for 2 days) with serial collection of serum and plasma samples for cortisol and ACTH measurements, respectively. Patients with hypercortisolemia due to constitutive production of ACTH from an ectopic source show minimal suppression of ACTH production following high-dose dexamethasone suppression testing (HDDST; Fig. 39.5A). Conversely, patients with Cushing's disease still retain some degree of negative feedback in the hypothalamus–pituitary–adrenocortical axis and show suppression of ACTH following HDDST (Fig. 39.5B). Radiologic imaging studies of the pituitary can be helpful; however, ACTH-secreting pituitary tumors are often too small to visualize. Bilateral inferior pituitary sinus sampling (BIPSS) can also help determine the source of excess ACTH production. The inferior petrosal sinuses receive drainage from the pituitary gland without admixture with blood from other sources. Catheters are advanced bilaterally to the inferior petrosal sinuses in order to obtain samples localized at the pituitary, along with simultaneous peripheral venous blood collection. The collected pituitary and venous samples are tested for ACTH, and the pituitary-to-peripheral ACTH ratios are calculated. An elevated pituitary-to-peripheral ACTH ratio (e.g., ratio >3) is indicative of Cushing's disease, whereas a low ratio (e.g., ratio <2) supports an adrenal or ectopic source of ACTH. BIPSS may not be available at all centers, because this is an invasive procedure that should be performed by expert vascular radiologists at experienced centers. Expected hormone profiles in healthy individuals or patients with primary adrenal disease are shown for comparison (Fig. 39.5C and D); however, dexamethasone suppression testing is typically unnecessary in these cases.

Laboratory testing for suspected glucocorticoid deficiency begins with confirmation of hypocortisolism followed by dynamic testing to identify the etiology of dysfunction in the hypothalamus–pituitary–adrenocortical axis. Dynamic testing under controlled conditions can help determine the etiology of hormone dysregulation and may include one or more of the following: (1) ACTH (e.g., cosyntropin and synacthen) stimulation test; (2) insulin tolerance test (ITT); (3) metyrapone test; and (4) CRH stimulation test.

Adrenocorticotropic hormone stimulation test

Cosyntropin is an ACTH derivative that includes the first 24 amino acids of ACTH and maintains ACTH activity. The ACTH stimulation test generally involves intravenous (IV) or intramuscular administration of cosyntropin (e.g., 250 μg), with collection of serum and measurement of cortisol at baseline as well as 30–120-minute poststimulation. Under normal physiological conditions, the adrenal gland responds to cosyntropin administration with increased production of cortisol to a peak concentration of $\geq 18–20$ μg/dL (Fig. 39.6) [4]. In primary adrenal insufficiency (e.g., Addison's disease), there is diminished cortisol production in response to cosyntropin, because the adrenal cortex is dysfunctional, damaged, or destroyed. Finding an elevated basal ACTH concentration

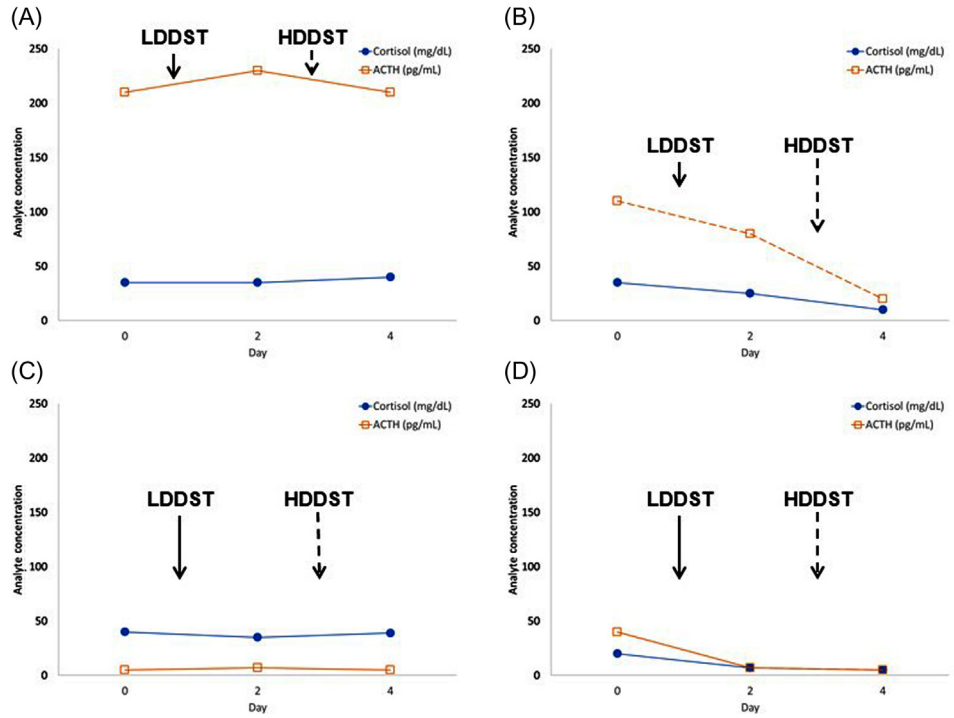

FIGURE 39.5 Expected hormone responses to low-dose and high-dose dexamethasone suppression tests. (A) Expected adrenocorticotropic hormone and cortisol results for ectopic adrenocorticotropic hormone syndrome. High plasma concentrations of adrenocorticotropic hormone and cortisol are unresponsive to low-dose dexamethasone suppression testing and high-dose dexamethasone suppression testing. (B) Expected adrenocorticotropic hormone and cortisol results for Cushing's disease. Suppression of the elevated adrenocorticotropic hormone and cortisol are incomplete with low-dose dexamethasone suppression testing, but >50% suppression with high-dose dexamethasone suppression testing. (C) Expected adrenocorticotropic hormone and cortisol results for a cortisol-secreting adrenal tumor. Autonomous cortisol production by the adrenal tumor causes adrenocorticotropic hormone suppression, even before administration of dexamethasone. (D) Expected adrenocorticotropic hormone and cortisol results with normal hypothalamus–pituitary–adrenal function (no cortisol excess). Plasma adrenocorticotropic hormone and cortisol results are within reference intervals at baseline and become markedly suppressed by low-dose dexamethasone suppression testing.

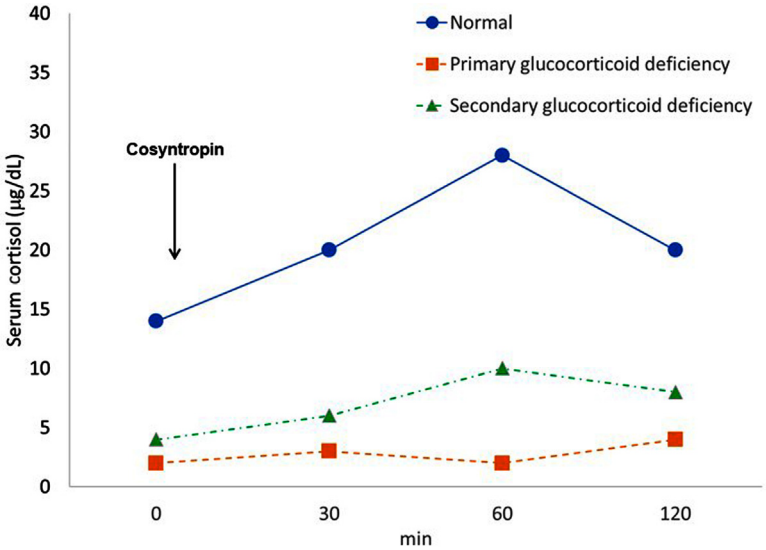

FIGURE 39.6 Expected cortisol responses to the cosyntropin (adrenocorticotropic hormone) stimulation test. The squares represent expected cortisol response in primary adrenal insufficiency showing a low baseline cortisol concentration that is unresponsive to the adrenocorticotropic hormone stimulation test. The expected cortisol response with secondary adrenal insufficiency (triangles) often shows a mild increase in serum cortisol with adrenocorticotropic hormone stimulation; however, the cortisol response is blunted due to adrenal atrophy that can occur with adrenocorticotropic hormone insufficiency. The circles represent expected cortisol response under normal physiological conditions. Serum cortisol is within reference interval at baseline and rises >18 μg/dL after adrenocorticotropic hormone stimulation.

is also consistent with primary dysfunction in cortisol production. In secondary or tertiary glucocorticoid deficiency, an increase in cortisol production following cosyntropin stimulation is expected; however, if ACTH deficiency is severe and prolonged, it may have induced adrenal atrophy, resulting in a blunted or diminished cortisol response to cosyntropin (Fig. 39.6) [5].

Insulin tolerance test

The ITT can be used to assess glucocorticoid deficiency, because hypoglycemia is a strong stressor that stimulates rapid activation of the hypothalamus–pituitary–adrenocortical axis. The ITT test generally involves IV administration of insulin (e.g., 0.1 U/kg) following an overnight fast, with collection of samples at baseline, 30, 60, 90, and 120 minutes (times may vary) for cortisol, glucose, and ACTH testing. Hypoglycemia is achieved when the nadir glucose concentration is reduced >50% from baseline or <45 mg/dL [5]. Under normal physiological conditions, ITT should induce a cortisol response of ≥20 μg/dL. In primary glucocorticoid deficiency, the cortisol response is deficient, and an elevated ACTH value is observed. Conversely, in secondary or tertiary glucocorticoid deficiency, both cortisol and ACTH responses are deficient. The ITT must be performed with caution under experienced medical supervision because of the risks of hypoglycemia (e.g., obtundation, seizures, and death).

Metyrapone test

Metyrapone is an inhibitor of the 11β-hydroxylase enzyme that normally catalyzes the conversion of 11-deoxycortisol to cortisol during steroid synthesis, thereby decreasing the negative feedback of cortisol in the hypothalamus–pituitary–adrenocortical axis. The overnight metyrapone test involves oral administration of metyrapone (e.g., 30 mg/kg) at midnight with collection of plasma or serum samples the following morning for measurement of cortisol and 11-deoxycortisol. Criteria for defining a normal metyrapone test vary. In general, a normal physiological response to metyrapone inhibition results in accumulation of the precursor 11-deoxycortisol, reduced cortisol, and increased ACTH production. Abnormal findings further support adrenal insufficiency. The metyrapone test is rarely performed and not recommended in suspected primary glucocorticoid deficiency because of serious risk of precipitating an adrenal crisis (Addisonian crisis).

Corticotropin-releasing hormone stimulation test

The CRH stimulation test can be used to help differentiate between secondary (pituitary) and tertiary (hypothalamic) glucocorticoid deficiencies. The CRH test involves administration of an IV bolus of ovine CRH (e.g., 1 μg/kg) followed by serial collection of samples (e.g., baseline, +5, +10, +15, +30, +45, +60, +90, and +120 minutes) for ACTH testing. Under normal physiological conditions, there may be doubling of ACTH concentration at 10–15 poststimulation compared with baseline value, or stimulation of ACTH values of 20–100 pg/mL. However, individual responses to exogenous CRH are highly variable, and thresholds for normal responses are not well-defined, which limit the clinical usefulness of this test [5]. A normal ACTH response to CRH stimulation indicates tertiary glucocorticoid deficiency (i.e., CRH deficiency) and some form of hypothalamic disturbance or dysfunction in the hypothalamus–pituitary portal system. In secondary glucocorticoid deficiency (i.e., ACTH deficiency), there is a deficient ACTH response to CRH stimulation, supporting a pituitary disorder.

Thyroid-stimulating hormone

TSH, produced by thyrotrophs of the anterior pituitary, stimulates thyroid follicular cells to produce the thyroid hormones T4 (thyroxine) and T3 (triiodothyronine) by binding to transmembrane receptors expressed on the follicular cell surface. T4 and T3 play important roles in fetal and early childhood neurological development, promote linear growth in children, and regulate the metabolic rate throughout life. TSH is a member of the glycoprotein hormone family that also includes LH, FSH, and human chorionic gonadotropin (hCG). All four of these hormones are heterodimers, consisting of an identical alpha subunit and a unique beta subunit that confers biological specificity (Fig. 39.7). However, the beta subunits show substantial sequence homology, and cross-reactivity with other glycoprotein hormone receptors has been observed at high concentrations. For example, high concentrations of hCG consistent with early pregnancy can activate the TSH receptor, stimulating T4 and T3 production.

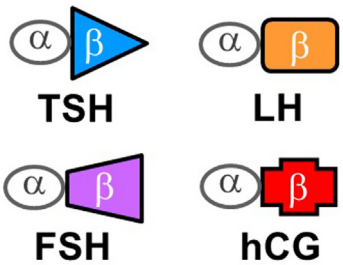

FIGURE 39.7 Glycoprotein hormone family members include thyroid-stimulating hormone, follicle-stimulating hormone, luteinizing hormone, and human chorionic gonadotropin. The alpha subunit is identical for all four hormones, and the beta subunit confers biological specificity. The beta subunits are highly conserved, and cross-reactivity with other glycoprotein hormone receptors may occur at high hormone concentrations.

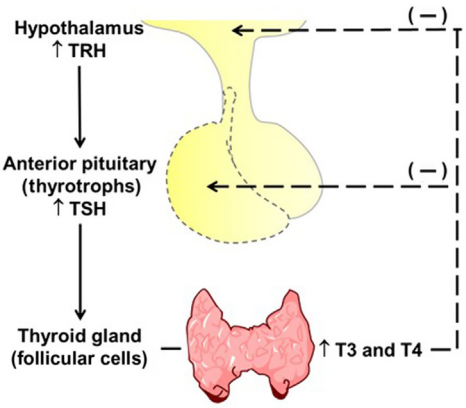

FIGURE 39.8 Hypothalamus−pituitary−thyroid axis. Thyroid-stimulating hormone production by the anterior pituitary is stimulated by hypothalamic thyrotropin-releasing hormone and suppressed by free thyroxine (fT4), which feeds back primarily at the level of the pituitary and to a lesser extent at the hypothalamus.

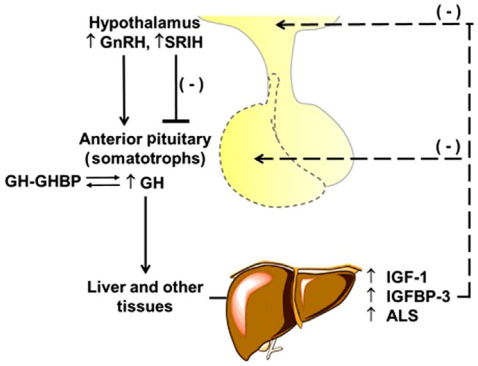

FIGURE 39.9 Growth hormone regulatory axis. Hypothalamic growth hormone-releasing hormone promotes growth hormone release by the pituitary, while hypothalamic somatotropin release inhibiting hormone suppresses growth hormone release. Growth hormone acts throughout the body and also stimulates hepatic insulin-like growth factor 1, insulin-like growth factor binding protein 3, and acid-labile subunit production, which provide negative feedback primarily on the hypothalamus and to a lesser extent on the pituitary.

TSH secretion is controlled by both positive stimulus in the form of TRH produced by the hypothalamus and negative feedback inhibition by the biologically active, nonprotein bound fraction of T4 (free T4 or fT4) (Fig. 39.8). The TSH regulatory axis is unique in that free T4 feeds back primarily at the level of the pituitary, while endocrine products that inhibit the production of other anterior pituitary hormones act primarily at the level of the hypothalamus. The anterior pituitary is exquisitely sensitive to plasma free T4 concentrations, and thyrotrophs rapidly increase or decrease TSH production to maintain free T4 within a narrow physiologically appropriate range. Provocative testing of the hypothalamus−pituitary−thyroid axis is not required, because even mild thyroid dysfunction causes TSH concentrations to fall outside of the expected reference interval. The development of third generation TSH immunoassays with a lower limit of detection of 0.01 μIU/mL has made it possible to identify states of hyperthyroidism, hypothyroidism, and euthyroidism with a single screening test, although many providers choose to measure TSH and free T4 simultaneously. It is important to note that TSH, like the other anterior pituitary hormones, is secreted in a pulsatile pattern and has a short half-life of 1−2 hours. Despite this, TSH and free T4 can be measured any time of day, as they do not show substantial diurnal variation. Intraindividual variation in TSH is approximately 20% over time intervals of 1 week to 1 year.

Thyroid hormone synthesis, transport, biological activity, and analytical measurement methods are discussed in detail in Chapter 40, Laboratory evaluation of thyroid function.

Growth hormone

In contrast to the other anterior pituitary hormones, GH is not limited to a single target endocrine gland but rather acts on many different sites throughout the body that express GH receptors. Most important among these are the liver and sites of bone growth during childhood. In the liver, GH stimulates the production of insulin-like growth factor 1 (IGF-1), insulin-like growth factor binding protein-3 (IGFBP-3), and the acid-labile subunit. These three proteins form a complex that provides a reserve of circulating IGF-1 that maintains stable concentrations of serum free IGF-1 (not bound to GH-binding protein). It was initially thought that the liver was the sole source of IGF-1 production, but it is currently accepted that, while most plasma IGF-1 is hepatic in origin, many cell types produce IGF-1 that has autocrine or paracrine functions. GH production and release by the anterior pituitary are largely stimulated by hypothalamic GHRH, but hypothalamic SRIH does provide a modest inhibitory signal. IGF-1 also prevents GH secretion through feedback inhibition, primarily at the level of the hypothalamus (Fig. 39.9).

GH directly elicits some of its biological effects, while others are mediated by IGF-1. GH directly raises plasma glucose by inducing insulin resistance and also increases free fatty acid plasma concentrations. In contrast, IGF-1 is primarily responsible for promoting linear growth in children, but it is important to note that locally produced IGF-1 has a greater effect on growth than circulating hepatic IGF-1. Adding further complexity is the fact that two distinct forms of GH are secreted by the anterior pituitary: a 191 amino acid (22 kDa) complete form and a 176 amino acid (20 kDa) form produced by alternative splicing in which a portion of exon 3 that encodes amino acids 32−46 is removed. However, the two forms demonstrate equivalent growth-promoting and lipolytic properties, and the only substantial physiological difference between the two is the diminished lactogenic activity

exhibited by the 20-kDa form. The larger 22-kDa form constitutes 80%−85% of GH found in circulation.

GH deficiency is generally not a concern in the adult population but should be considered in children with short stature and slow growth velocity once other causes including Turner's syndrome, hypothyroidism, malnutrition, and chronic illness have been excluded [6]. Because GH is secreted in short pulses that typically occur at night, measurement of GH in a randomly collected plasma or serum specimen is unlikely to be informative. For this reason, initial screening for GH deficiency is typically performed by measuring IGF-1 as a surrogate marker for GH activity that demonstrates more constant plasma concentrations throughout the day. Plasma IGFBP-3 also reflects GH activity but rarely provides additional information beyond measuring IGF-1 alone. If IGF-1 is within the age/gender-appropriate reference interval, GH deficiency can be ruled out. However, a low IGF-1 result does not confirm GH deficiency, as GH is not the sole determinant of IGF-1 concentration. Low IGF-1 can also be observed in patients with hypothyroidism, malnutrition, malabsorption, renal failure, chronic inflammation, and other disease states. While most providers choose to screen for GH deficiency by measuring IGF-1, screening can also be accomplished by performing provocative testing that assesses the patient's ability to secrete GH in response to stimulus. Using this approach, GH is measured in a single specimen collected after 20 minutes of vigorous exercise or 60−90 minutes after administration of a compound known to stimulate GH release, including L-dopa (non-United States), clonidine, arginine, or glucagon. Depending on the assay used, the appropriate physiological response is a stimulated GH concentration between 7 and 10 ng/mL [7].

Following an abnormal screening test, the appropriate next step is a formal stimulation test. These are conceptually similar to the screening tests but require the collection of multiple specimens at regular intervals following pharmacologic stimulus. In addition to L-dopa, clonidine, arginine, and glucagon, insulin may also be used for definitive testing. However, as described previously, other pharmacologic options are frequently preferred over insulin. Recommended doses and times of collection for the formal stimulation tests are listed in Table 39.4. In practice, it is common to perform two sequential stimulation tests using different pharmacologic compounds (e.g., clonidine followed by arginine). Like the screening tests, a single GH concentration between 7 and 10 ng/mL at any time point following administration of either stimulatory compound is considered an appropriate response. Stimulated GH values of <7 ng/mL in children and <3−5 ng/mL in adults are consistent with GH deficiency. In order to reduce the occurrence of falsely low GH stimulation test results in peripubertal children without GH deficiency, pretreatment with sex steroids may be performed (Table 39.5). However, this practice is controversial, and several studies have documented no statistically significant difference in the diagnostic yield

TABLE 39.5 Sex steroid priming prior to growth hormone testing in peripubertal children.

Agent	Dose
Ethinyl estradiol	50−100 μg/day × 3 days
Premarin	5 mg/day × 3 days
Diethylstilbestrol	5 mg/day × 3 days
Testosterone	100 mg/day × 3 days

of GH stimulation tests between patients who undergo sex steroid priming and those who do not [8].

In very rare cases, individuals with clinical signs and symptoms of GH deficiency may have elevated GH values and low IGF-1 values in a random plasma specimen. Once more common causes of GH insufficiency, such as malnutrition, renal failure, and hepatic disease have been excluded, GH resistance should be considered. Mutations in the GH receptor or downstream signaling proteins have been identified in patients with GH resistance.

GH excess that develops in adulthood is known as acromegaly and is characterized by physical changes that include enlargement of the hands, feet, heart and/or liver, coarsened facial features, metabolic changes that include insulin resistance/diabetes mellitus, increased sweating, myopathy, and premature cardiovascular disease [9]. Ninety-five percent of acromegaly cases are caused by anterior pituitary GH-secreting adenomas. Occasionally, these GH-secreting adenomas also secrete prolactin, resulting in galactorrhea and menstrual irregularities in women and decreased libido and breast enlargement in men, in addition to the acromegaly symptoms listed above. Five percent of acromegaly cases are caused by a hypothalamic GHRH-secreting tumor, and the remainder are due to GH- or GHRH-secreting tumors located outside of the hypothalamus and pituitary. GH excess that develops in childhood is known as gigantism and is marked by extreme tall stature due to excessive GH activity prior to fusion of the growth plates. In addition to tall stature, individuals with gigantism also exhibit the constellation of features observed in acromegaly.

Some cases of acromegaly may be recognized on the basis of physical features alone, but laboratory testing is frequently required to make a formal diagnosis, particularly in relatively mild cases with subtle physical changes. Most individuals with active acromegaly will have random GH concentrations above the upper limit of the reference interval, but a random GH measurement within the reference interval does not exclude disease. As in the workup of GH deficiency, plasma IGF-1 is a useful screening test, as random IGF-1 values often reflect disease severity more accurately than random GH measurements. If GH excess is suspected on the basis of physical observation or elevated plasma GH and/or IGF-1 measurements, provocative testing in the form of the glucose suppression test may be performed. Briefly, individuals undergoing the glucose suppression test fast overnight, remain at bed rest, and submit baseline plasma specimens for GH and glucose measurement prior to consuming 75-g glucose. Subsequent plasma specimens are collected 30, 60, 90, and 120 minutes later. As glucose suppresses GH release, plasma GH concentrations are expected to fall below the assay's lower limit of quantitation (typically 1 or 2 μg/L) in individuals without acromegaly. In patients with acromegaly, plasma GH is not suppressed and occasionally shows a paradoxical increase.

Most commercially available GH measurement methods are two site "sandwich" immunometric assays, but it is important to note that these immunoassays are poorly standardized due to the use of different antibodies and reference calibrator materials. Some assays selectively recognize the 22-kDa form, while others demonstrate significant cross-reactivity with both the 22- and 20-kDa forms, and yet others detect only the 20-kDa form. As a result, differences of 15%−20% may be observed when testing a single patient sample on multiple analytical platforms, which has important implications for GH stimulation tests that are interpreted in the context of a single pan-manufacturer cutoff. Given the variability between analytical platforms, the use of a pan-manufacturer cutoff is inappropriate and may lead to misinterpretation of stimulation test results. Unfortunately, manufacturer-specific cutoffs are not available, but significant efforts are aimed at harmonizing GH assays to eliminate this problem.

Recently, LC-MS/MS methods that provide independent measurements of both the 22- and 20-kDa GH forms have been developed for the detection of GH doping to improve athletic performance. These LC-MS/MS methods consist of an initial antibody-based enrichment of all GH forms, followed by proteolytic digestion and quantification of specific peptides associated with each proteoform. Natural GH production typically results in a ratio of ~12:1 (22−20 kDa), but exogenous supplementation with the 22-kDa form suppresses pituitary secretion, resulting in an elevated ratio.

Like GH assays, commercially available immunoassays for IGF-1 and IGFBP-3, as well as LC-MS/MS IGF-1 methods, are also poorly standardized. However, manufacturer-specific reference intervals are available for both pediatric and adult patients, which facilitates result interpretation.

Follicle-stimulating hormone and luteinizing hormone

FSH and LH are glycoprotein hormones produced by gonadotrophs of the anterior pituitary that are composed of an identical alpha subunit (also shared by TSH and hCG) and a unique beta subunit that confers biological specificity (Fig. 39.7). FSH is responsible for stimulating the growth and maturation of ovarian follicles, promoting ovarian estrogen synthesis and stimulating testicular spermatogenesis. LH is responsible for triggering ovulation and forming the corpus luteum at the midpoint of the menstrual cycle and stimulating the development and function of testicular Leydig cells that produce testosterone. Collectively, FSH and LH control gonadal function in both females and males. In states of reproductive health, plasma FSH and LH concentrations rise and fall in a tightly regulated pattern in response to positive and negative stimuli from

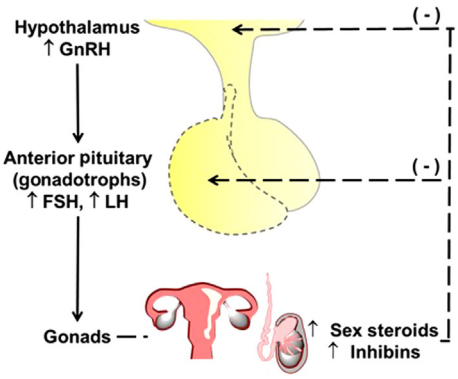

FIGURE 39.10 Hypothalamus–pituitary–gonadal axis. Follicle-stimulating hormone and luteinizing hormone production by the anterior pituitary is stimulated by hypothalamic gonadotropin-releasing hormone and suppressed by sex steroids and inhibins.

hypothalamic and gonadal hormone products. Alterations in this signaling pathway result in reproductive dysfunction, and hormone measurement in the clinical laboratory is often essential to identify the underlying pathology and select an appropriate course of treatment.

Similar to the other anterior pituitary hormones (with the exception of prolactin), FSH and LH release is positively stimulated by the hypothalamus (Fig. 39.10). However, this regulatory mechanism is unique in that a single hypothalamic releasing hormone (GnRH) promotes the synthesis and release of two different pituitary hormones (FSH and LH) from a single cell type. Furthermore, although FSH and LH are produced by the same cell type, they are not always cosecreted, indicating that gonadotrophs must respond to unique signals that promote release of the appropriate hormone at the appropriate time. One determinant of gonadotroph response is the magnitude and pulsatility of GnRH signaling [10]. Under normal conditions, GnRH is released episodically, which elicits an appropriate response from the pituitary. If the interval between GnRH pulses is shortened, a phenomenon observed in many women with polycystic ovary syndrome (PCOS), the rate of LH release increases relative to that of FSH. If GnRH pulsatility is lost altogether and the pituitary is continuously exposed to high GnRH concentrations, the expression of gonadotrophic GnRH receptors is suppressed, the pituitary becomes less responsive to GnRH signaling, and FSH and LH release is inhibited. This observation has led to the development of GnRH agonists and analogs to treat conditions like precocious puberty and prostate cancer in which downregulation of gonadotrophic activity is desirable.

Adding to the complexity of the hypothalamus–pituitary–gonadal axis is the existence of different feedback inhibitory mechanisms in men and women. In men, testosterone and inhibin produced by the testes feedback on the pituitary and hypothalamus, inhibiting further FSH and LH release. In women, estradiol, progesterone, and inhibin produced by the ovaries provide negative feedback inhibition on the hypothalamus and pituitary, but this effect varies depending on the stage of the menstrual cycle. Estradiol inhibits FSH and LH release in the early follicular and luteal phases but actually provides positive feedback on the pituitary in the late follicular phase, promoting the LH surge required to trigger ovulation of the dominant ovarian follicle [11].

Following permanent cessation of ovarian activity at menopause, which typically occurs after approximately 45 years of age, plasma estradiol, progesterone, and inhibin fall to concentrations well below those observed in women of reproductive age. This is not a sudden change but rather occurs over a period of 4–5 years. This has important consequences for pituitary function, as the ovarian hormones that previously provided feedback inhibition have now been removed from the hypothalamus–pituitary–gonadal regulatory axis. This derepression of the pituitary leads to increased FSH production and substantially higher plasma FSH concentrations in postmenopausal women relative to premenopausal women at any stage of the menstrual cycle. Postmenopausal plasma LH concentrations are also increased relative to the follicular and luteal phases of the menstrual cycle but are generally lower than those observed in the ovulation phase of the menstrual cycle following the LH surge. Derepression of the pituitary following menopause may also result in the secretion of very small amounts of hCG. This modest hCG secretion from the pituitary often results in plasma concentrations above the upper reference limit for nonpregnant women of reproductive age and urine concentrations that are sufficiently high to generate positive qualitative test results. The prevalence of pituitary hCG secretion in postmenopausal women is unknown, but positive hCG test results obtained during a presurgical workup intended to exclude pregnancy before initiating the procedure may cause confusion among clinicians and their patients. In women who may be perimenopausal or postmenopausal, a pituitary source of hCG is most likely if the plasma concentration is <20 IU/L and plasma FSH is >45 IU/L. Suppression of plasma hCG following 2 weeks of estradiol supplementation further supports a pituitary source. If hCG remains elevated, hCG-producing malignancies, such as gestational trophoblastic disease, must be considered [12].

Measurement of FSH and LH in the evaluation of pituitary dysfunction is helpful in individuals with clinical signs and symptoms of hypogonadism. In children, hypogonadism presents as delayed puberty, while in adults, signs and symptoms include decreased libido, sexual dysfunction, menstrual abnormalities, and infertility. As discussed in greater detail in Chapter 43, Laboratory testing in reproductive disorders, of this book, low plasma concentrations of gonadal sex steroids can support a diagnosis of

hypogonadism. While men do not experience an abrupt cessation of testosterone production similar to that experienced by women at menopause, plasma testosterone concentrations decrease gradually with age. A plasma total testosterone concentration below the lower limit of the age-appropriate reference interval or a low free testosterone in the context of a normal total testosterone is consistent with male hypogonadism. In women, low plasma estradiol and progesterone concentrations are consistent with female hypogonadism, although these values must be interpreted in the context of the stage of the menstrual cycle when the specimen is collected. Relatively low estradiol and progesterone concentrations are expected in the early follicular phase, while, similarly, low concentrations in the mid-luteal phase suggest an underlying pathology.

Hypogonadism can be further subdivided into two groups with distinct mechanistic causes. Hypergonadotropic hypogonadism is characterized by gonadal failure (inability of the gonads to produce sex steroids in response to FSH and LH), while hypogonadotropic hypogonadism is defined by a central defect (inability of the hypothalamus to produce GnRH or of the pituitary to produce FSH and LH). Measurement of plasma or serum FSH and LH in the unstimulated state is often sufficient to distinguish between the two conditions, particularly if the concentrations of the two hormones are above the reference interval. Elevated FSH and LH in an unstimulated specimen establish the diagnosis of hypergonadotrophic hypogonadism and allow the clinician to eliminate other possible causes. On the other hand, because FSH and LH are secreted in a pulsatile fashion, a single unstimulated specimen with FSH and LH concentrations below the reference interval does not rule in hypogonadotropic hypogonadism. To avoid misinterpretation of a single low value, it is recommended to collect three serum or plasma samples with a 20−30-minute interval between each sample collection. FSH and LH can be measured either in each independent sample (three FSH and LH measurements) or in a mixed specimen created by pooling equal volumes of each of the three samples (one FSH and LH measurement). Low LH and FSH values observed under these conditions indicate insufficient pituitary production and strongly suggest a diagnosis of hypogonadotropic hypogonadism.

Stimulatory testing designed to provoke an FSH and LH response is generally unnecessary in adults but may help differentiate between hypogonadotropic hypogonadism and delayed puberty in children with low basal FSH and LH values. The GnRH stimulation test is conceptually similar to other provocative tests of pituitary function in that IV access is first obtained, followed by collection of a baseline sample for FSH and LH measurement. GnRH is then infused at an appropriate weight-based dose (2.5 μg/kg up to a maximum of 100 μg), and sequential specimens are collected up to 90 minutes after GnRH infusion at 15−20-minute intervals. Simpler variations of this procedure include subcutaneous injection of 100-μg GnRH followed by LH and FSH measurement at 40-minute postinjection or subcutaneous injection of the GnRH agonist leuprolide at 20 μg/kg up to 500 μg followed by LH and FSH measurement at 180-minute postinjection. Elevated LH and FSH after GnRH infusion support a diagnosis of delayed puberty, while low LH and FSH indicate hypogonadotropic hypogonadism. In contrast to the GH stimulation tests that define a "normal" response on the basis of a maximal GH concentration, GnRH stimulation tests are interpreted on the basis of a rise in FSH and LH relative to the patient's baseline values. It is also important to note that the GnRH stimulation test has limited diagnostic specificity, as there is substantial overlap in stimulated FSH and LH values between adolescents with hypogonadotropic hypogonadism and those with delayed puberty [13].

Hypergonadism is generally not caused by pituitary hyperfunction but is rather due to other pathophysiological conditions marked by excessive sex steroid production in peripheral tissues. These include androgen- or estrogen-secreting tumors derived from adrenal or gonadal tissue, PCOS, adult-onset congenital adrenal hyperplasia, or Cushing's syndrome. While these are serious health issues, they are beyond the scope of this chapter. Refer to Chapters 42, Laboratory testing in pregnancy, and Chapter 43, Laboratory testing in reproductive disorders, of this book for further discussion of FSH and LH in normal reproductive function and reproductive disorders.

Prolactin

Prolactin is the principal endocrine hormone that controls the initiation and maintenance of lactation. Prolactin is comprised of 199 amino acids and is produced and secreted by the anterior pituitary lactotroph (also referred to as mammotroph) cells. Other names for prolactin include lactogen, lactotropin, luteotropin, mammotropin, and lactogenic or luteogenic hormone. Dopamine is a neuroendocrine hormone produced in the hypothalamus and is the major regulator of prolactin (Fig. 39.11). Notably, dopamine suppresses prolactin production and release, which is dissimilar to other anterior pituitary hormones that exhibit stimulated release by hypothalamic regulatory hormones. Because of this inhibitory effect on prolactin release, dopamine may also be referred to as PRIH.

Approximately 85% of circulating prolactin is monomeric (23 kDa, also known as "little" prolactin) and is biologically active. Heterogenous forms of prolactin have also been detected in plasma, including dimeric prolactin (referred to as "big" prolactin) and polymeric forms (e.g., tetrameric, referred to as "big−big" prolactin). Select patients may also develop autoantibodies (e.g., IgG) that

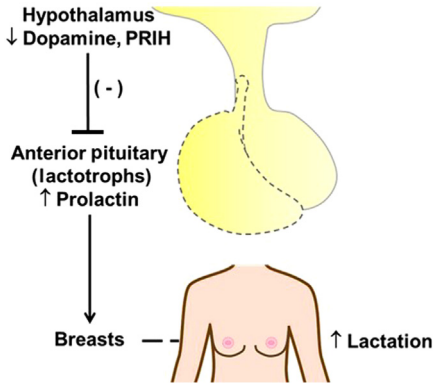

FIGURE 39.11 Prolactin regulatory axis. Prolactin production is under a constant state of repression by hypothalamic dopamine (prolactin release inhibiting hormone). Following removal of dopamine repression, prolactin is released into circulation where it stimulates differentiation of mammary alveoli and lactation.

bind to prolactin. These larger forms of prolactin are referred to as "macroprolactin." Macroprolactin has been suggested to have limited bioavailability, and can accumulate in circulation due to prolonged clearance [14,15]. The presence of macroprolactin does not reflect a pathologic process and is not associated with any specific disease state. However, it is important for laboratorians to recognize macroprolactin as a benign cause of elevated serum/plasma prolactin to spare the patient unnecessary evaluation and treatment. Biologically active monomeric prolactin binds to cell-surface receptors on target tissues (e.g., breast, ovaries, testes, prostate, kidney, and liver) and induces signal transduction for the modulation of gene transcription. With proper hormonal priming of breast tissue (e.g., estrogen), prolactin stimulates the differentiation of the mammary alveoli and subsequent synthesis of milk proteins, including casein and lactalbumin. Prolactin also plays an essential role in steroidogenesis and has been suggested to modulate immune system and metabolic functions.

Hyperprolactinemia (i.e., prolactin excess) is one of the most common hypothalamus–pituitary disorders encountered in clinical endocrinology practice. Signs, symptoms, and sequelae associated with hyperprolactinemia vary and may include amenorrhea or oligomenorrhea, galactorrhea, infertility, oligospermia, impotence, hypogonadism, and bone loss, or individuals may remain asymptomatic. Hyperprolactinemia can develop from several different physiological, pathophysiological, and pharmacological causes (Table 39.6). Physiologic stimuli known to stimulate prolactin release include coitus, pregnancy, lactation, sleep, stress, and exercise. During pregnancy, serum prolactin concentrations may increase 10-fold and reach concentrations of 150–300 ng/mL (150–300 μg/L) by term. Measurement of serum prolactin is not recommended in pregnant patients with prolactinomas (i.e., benign tumor) in order to minimize risk of potential misinterpretation and unnecessary testing triggered by prolactin concentrations greater than reference interval. Pathophysiologic prolactinomas, which are benign tumors (i.e., adenoma) that develop from lactotroph cells, cause nonpuerperal hyperprolactinemia and account for approximately 40% of all pituitary tumors [14]. Hypothalamic disease or interruption of the hypothalamus–pituitary portal system can occur due to several different etiologies and cause diminished dopamine suppression of prolactin secretion, resulting in hyperprolactinemia. In addition, prolactin can be released from the anterior pituitary in response to high concentration of TRH found with hypothyroidism. Several therapeutic drugs can stimulate

prolactin release and create a biochemical picture of prolactinoma in an otherwise healthy individual. A careful patient history is needed to rule out the possibility that medications are not the cause for elevated prolactin.

The diagnosis of hyperprolactinemia is established based on laboratory testing for serum prolactin that show results greater than the reference interval [14]. Serum prolactin reference intervals are method-specific, though values are higher in females than in males and are generally <25 ng/mL (<25 μg/L). Determining the etiology of hyperprolactinemia is more challenging, however, and necessitates a comprehensive patient history, review of the patient's medications list, potential imaging studies (e.g., MRI of brain), and interpretation of the absolute concentration of measured prolactin in the clinical context. In patients with prolactinomas, serum prolactin concentrations generally parallel tumor size with prolactin elevations of >250 ng/mL. However, select drugs including risperidone and metoclopramide may cause prolactin elevations of >200 ng/mL in patients without clinical evidence of adenoma. Serum prolactin >500 ng/mL is diagnostic of a macroprolactinoma, which are macroadenomas >10 mm in diameter that secrete prolactin that may or may not include macroprolactin. Dynamic tests for prolactin secretion using TRH, L-dopa, nomifensine, and domperidone are not recommended.

Evaluation for potential high-dose hook interference

In patients with prolactinomas, serum prolactin concentrations generally parallel tumor size with prolactin elevations of >250 ng/mL. Prolactin-secreting macroadenomas can sometimes produce exceedingly high serum prolactin concentrations that can paradoxically cause measurement of falsely low prolactin concentrations by immunometric assays. In these situations, very high concentrations of prolactin saturate both the capture and detection antibodies in the assay, which subsequently blocks the formation of the capture antibody−prolactin−detection antibody "sandwich," resulting in falsely low prolactin results (i.e., high-dose hook interference). If clinical findings show the presence of a pituitary tumor and symptoms of prolactinoma but lower than expected serum prolactin concentration, an evaluation for potential falsely low serum prolactin measurement due to high-dose hook interference should be considered. Investigation of suspected high-dose hook interference involves serial dilutions (e.g., 10-, 100-, and 400-fold dilutions) of the serum sample in order to minimize the analytic artifact, with testing of these diluted samples using the same prolactin immunometric assay. If results show linear dilution and expected recoveries (e.g., ±20%) compared with the prolactin concentration in the neat sample (i.e., undiluted), then high-dose hook interference is ruled out. If significantly increasing concentrations of prolactin are found after dilution of the serum, then high-dose hook interference is observed and should be communicated with the clinical care team for appropriate patient management.

Evaluation for potential macroprolactinemia

In patients with asymptomatic hyperprolactinemia, assessment for potential presence of macroprolactin should be considered [16]. Immunoassay cross-reactivity with macroprolactin moieties is variable and method-dependent. Investigation of potential presence of macroprolactin can be performed by pretreating the serum sample with polyethylene glycol (PEG) followed by centrifugation that precipitates high molecular mass moieties. The supernatant containing monomeric prolactin is subsequently tested using the same prolactin immunoassay, and the result is compared with the prolactin concentration obtained in the neat sample (i.e., untreated, total prolactin). Of note, the dilution effect that occurs during sample pretreatment with PEG and the coprecipitation of monomeric prolactin must be taken into consideration. The precipitated prolactin concentration is calculated by subtracting the unprecipitated prolactin value (i.e., PEG-pretreated sample) from the total prolactin value. The percentage of precipitated prolactin to total prolactin is an indicator of the presence or absence of macroprolactin. When the fraction (i.e., percentage) of PEG-precipitated prolactin is ≤60% of total prolactin, the sample is considered negative for macroprolactin, and other causes for hyperprolactinemia should be evaluated. When the fraction of PEG-precipitated prolactin is >60% of total prolactin, the sample is considered positive for the presence of macroprolactin. While a 60% threshold for PEG-precipitated prolactin is described above for example purposes, this threshold is method-dependent and should be established using PEG-precipitated reference sera [17]. Careful interpretation of prolactin results in conjunction with clinical findings is needed, because the finding of macroprolactin does not exclude the possibility of concomitant presence of a prolactin-secreting pituitary adenoma and true hyperprolactinemia.

Posterior pituitary hormone pathophysiology and lab findings

Antidiuretic hormone

The major physiological functions of ADH [also referred to as arginine vasopressin or vasopressin] are to conserve free water and stimulate vasoconstriction, thus, ADH also plays key roles in maintaining blood pressure and osmolality of the extracellular space. ADH is a 9-amino acid peptide that

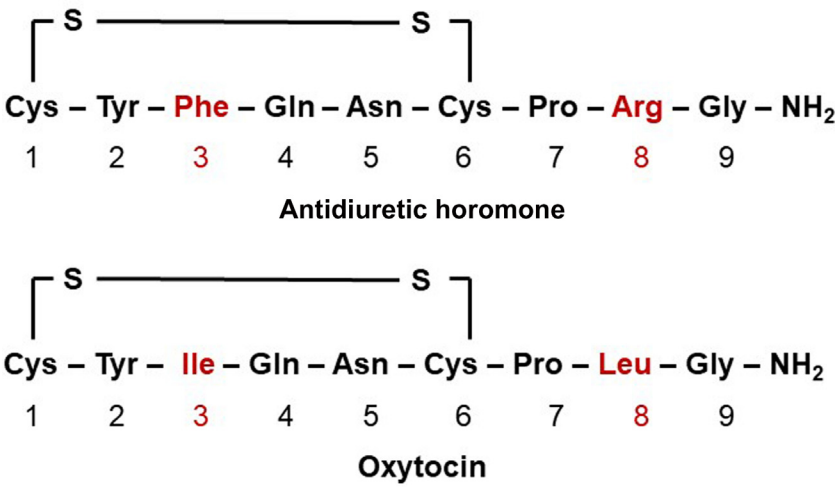

FIGURE 39.12 Amino acid sequences of antidiuretic hormone and oxytocin.

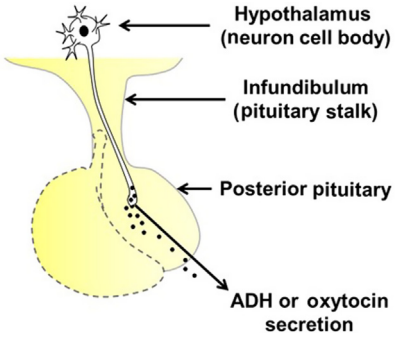

FIGURE 39.13 Posterior pituitary hormone secretion. Note that posterior pituitary hormones are synthesized in the hypothalamus and released by the posterior pituitary. *Adapted from W. Winter, N.S. Hardt, N.S. Harris, Disorders of the anterior and posterior pituitary.* Contemporary Practices in Clinical Chemistry*, third edn., 2016.*

is synthesized by neurosecretory cells in the hypothalamus (Fig. 39.12). Axons from neuron cell bodies originating in the hypothalamus transport ADH through the infundibulum to the posterior pituitary gland for storage (Fig. 39.13). A key regulator of ADH secretion into circulation by the posterior pituitary gland is the osmolality of the blood. Osmoreceptors located on hypothalamic neuron cell bodies respond to changes in plasma osmolality where an increase in plasma osmolality of $<1\%$ can stimulate ADH secretion. The secretion of ADH is also regulated by baroreceptors through a pressure−volume mechanism. High-pressure arterial baroreceptors of the aortic arch and carotid sinus, as well as low-pressure volume receptors in the pulmonary venous system and atria, respond to alterations in blood volume. Baroreceptors detection of decreased circulating blood volume or decreased blood pressure results in the stimulation of ADH secretion. Baroreceptor regulation of ADH secretion is relatively insensitive compared with osmoreceptors and requires a decrease of approximately 5% plasma volume, though upon activation elicits a potent response. While baroreceptors play a key role in maintaining plasma volume and pressure, this mechanism works in concert with the renin−angiotensin−aldosterone system, which is the major endocrine system regulating blood volume and pressure. Other stimuli for ADH secretion include pain, stressful conditions, and chemical agents (e.g., anesthetics, barbiturates, catecholamines, opiates, and prostaglandins). Altogether, daily water homeostasis is predominantly regulated by osmolality via osmoreceptor-mediated ADH secretion and its downstream effects, though this regulatory mechanism may be overridden by blood volume and pressure regulatory mechanisms in order to maintain normal plasma volume.

ADH binds to vasopressin receptors in order to mediate free water reabsorption and vasoconstriction. Vasopressin type 1 receptors are expressed on vascular smooth muscle cells and other tissues. The binding of ADH to type 1 vasopressin receptors on vascular smooth muscle cells promotes vasoconstriction. ADH also binds to vasopressin type 2 receptors expressed on collecting duct epithelial cells, which stimulates the kidney to reabsorb water in order to help maintain water homeostasis. The binding of ADH to vasopressin type 2 receptors signals the relocation of aquaporin-2 from an intracellular pool to the apical plasma membrane of collecting duct cells (Fig. 39.14). Aquaporin-2 is a water channel that, when localized in the luminal plasma membrane, increases the collecting ducts' permeability to water supporting free water reabsorption. Following water entry into collecting duct cells via aquaporin-2, water exits these cells into circulation via other water channels, including aquaporin-3 and aquaporin-4. Collectively, this physiological process promotes free water movement down an osmotic gradient. An incidental consequence of this renal reabsorption of water is concentrated urine and reduced urine volume. ADH can also bind to vasopressin type 3 receptors that are expressed on the anterior

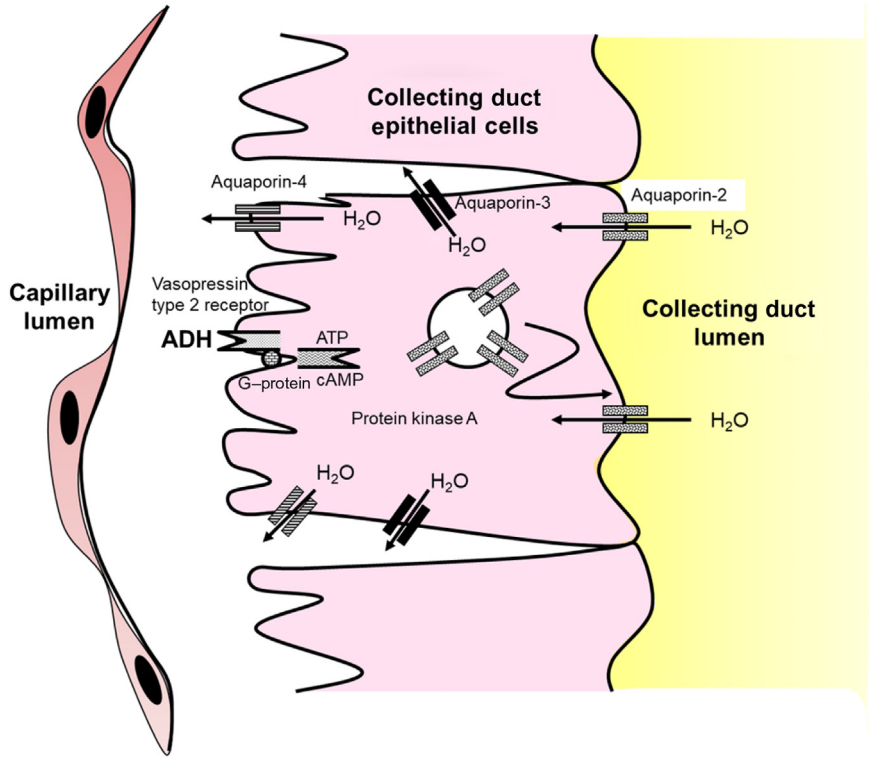

FIGURE 39.14 Mechanism of free water reabsorption stimulated by antidiuretic hormone. Antidiuretic hormone stimulates the relocation of aquaporin-2 into the apical plasma membrane of epithelial cells in the renal collecting duct, facilitating reabsorption of free water from the renal filtrate into circulating plasma. *Adapted from W. Winter, N.S. Hardt, N.S. Harris, Disorders of the anterior and posterior pituitary.* Contemporary Practices in Clinical Chemistry, *third edn., 2016.*

pituitary corticotrophs, resulting in the stimulation of ACTH secretion in response to high ADH concentration.

Syndrome of inappropriate antidiuretic hormone (SIADH) refers to autonomous production and secretion of ADH in the absence of known physiological stimuli. In this syndrome, plasma ADH concentration is "inappropriately" elevated relative to low plasma osmolality and to an increased or normal plasma volume. There are numerous potential etiologies for SIADH, including acute or chronic disorders of the central nervous system (CNS), ectopic ADH production by malignancy (e.g., small cell lung carcinoma), pulmonary disease, or a side effect of select drug therapies (ACE inhibitors, first generation sulfonylureas, second generation antipsychotics, and antidepressants). SIADH in patients with unrestricted fluid intake causes inappropriate antidiuresis, because the high ADH concentrations stimulate excessive reabsorption of free water by the kidneys, leading to water retention with reduced urine output. This increase in intravascular volume can cause hemodilution accompanied by dilutional hyponatremia and a low plasma osmolality, features that should normally inhibit ADH secretion. Volume expansion also suppresses the renin–angiotensin–aldosterone system, resulting in urinary sodium loss with elevated urine osmolality and urinary sodium concentration. Despite modest volume expansion in patients with SIADH, edema is not commonly observed. Clinical manifestations of hyponatremia may arise and vary from mild to severe (e.g., weakness, apathy, lethargy, coma, and seizure); however, there are no clinical signs or symptoms that are specific for SIADH.

Diabetes insipidus (DI) refers to a pathological condition due to inadequate production or action of ADH. Signs, symptoms, and sequelae associated with DI include polyuria with excretion of large volumes (>10 L/day) of dilute urine due to excess urinary free water loss that consequently causes potential hypernatremia and associated elevated plasma osmolality. In patients with intact thirst sensors (refer to Chapter 37: Water and electrolyte balance, of this book for more information on this topic), the elevated plasma osmolality stimulates thirst, and patients may report polydipsia in addition to polyuria. In such cases, excess intake of free water can help compensate for the excessive urinary loss of water, and patients may exhibit only mild hypernatremia. If free water is unavailable or the patient has dysfunction of a normal thirst mechanism, dehydration can occur due to excessive urinary loss of water, leading to a decline in blood pressure and tachycardia.

DI is categorized as central DI or nephrogenic DI, depending on the mechanism of dysfunction. Central DI can arise from any destructive hypothalamic lesion, infundibular lesion, or posterior pituitary lesion that impedes the production or secretion of ADH, resulting in ADH deficiency (Fig. 39.15). There are numerous potential etiologies of central DI, including CNS abnormalities such as

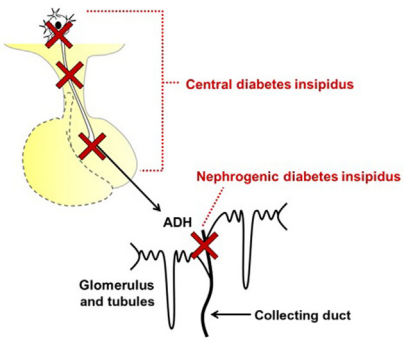

FIGURE 39.15 Pathophysiological mechanisms of central and nephrogenic diabetes insipidus. Central diabetes insipidus is caused by a defect in antidiuretic hormone production and/or secretion, whereas nephrogenic diabetes insipidus is caused by partial or complete resistance to antidiuretic hormone by the kidneys. *Adapted from W. Winter, N.S. Hardt, N.S. Harris, Disorders of the anterior and posterior pituitary.* Contemporary Practices in Clinical Chemistry*, third edn., 2016.*

hypothalamic or pituitary tumors, stroke, head trauma, infiltrative disease (e.g., sarcoidosis), and others. Contrastingly, DI arising from partial or complete resistance to ADH action due to renal tubular dysfunction or disease is referred to as "nephrogenic DI." Nephrogenic DI is a rare kidney disorder that can be inherited or acquired. One form of hereditary nephrogenic DI is an X-linked recessive disorder that causes an inactivating mutation of the vasopressin type 2 receptor (AVPR2 gene), leading to ADH resistance. Other congenital forms of nephrogenic DI include autosomal recessive or autosomal dominance loss-of-function mutations of aquaporin-2 (AQP2 gene), leading to dysfunctional water channels and reduced water reabsorption despite ADH stimulation. Acquired forms of nephrogenic DI are more commonly observed than hereditary nephrogenic DI. A common cause of acquired nephrogenic DI is patient exposure to drugs, notably chronic use of lithium, as well as various antimicrobial drugs (e.g., amphotericin B, rifampin, and methicillin) and antineoplastic drugs (e.g., cisplatin and ifosfamide). Moreover, nephrogenic DI can manifest due to any form of renal tubular injury accompanied by impaired water reabsorption (e.g., polycystic kidney disease, medullary cystic kidney disease, chronic pyelonephritis, obstructive uropathy, sickle cell nephropathy, and renal amyloidosis).

Routine laboratory testing together with a comprehensive patient history and physical examination are needed to diagnose SIADH and DI. Testing for ADH itself is not usually needed for diagnostic purposes, because ADH excess or deficiency is evident by clinical assessment of fluid balance (e.g., blood pressure and heart rate) and changes in serum and urine osmolalities, serum and urine sodium concentrations, and urine volume. Measurement of urine specific gravity is a simple screening test that helps assess the kidney's ability to concentrate urine and can provide insight into a patient's urine osmolality. Urine specific gravity is the ratio of the mass of a urine sample compared with the mass of an equal volume of water. Urine specific gravity is typically between 1.002 and 1.030 under normal physiological conditions. In general, patients with SIADH have a high urine specific gravity, whereas patients with DI typically have a low urine specific gravity value. The urine specific gravity test should not be performed in patients exhibiting proteinuria, hematuria, glycosuria, or excretion of other osmotically active compounds, such as contrast dyes. In these cases, a urine osmolality test is a better measure of a patient's ability to concentrate urine.

If a patient has a history of polyuria and polydipsia with an abnormal urine specific gravity result, additional testing should be performed, including serum and urine osmolalities, as well as a basic metabolic panel. Osmolality can be measured directly using freezing point depression. Additionally, serum osmolality (Osm_s) can be estimated using measured concentrations of the predominant osmotic substances in plasma including sodium (Na^+), blood urea nitrogen, and glucose. The following formulas are commonly used for estimating Osm_s:

$$\begin{aligned}\text{Serum Osm}_s = &\left(1.86 \times \left[\text{Na}^+\right](\text{mmol/L})\right) \\ &+ \left([\text{BUN}](\text{mg/dL}) \div 2.8\right) \\ &+ \left([\text{glucose}](\text{mg/dL}) \div 18\right) + 9\end{aligned} \tag{39.1}$$

or

$$\begin{aligned}\text{Serum Osm}_s = &\left(2 \times \left[\text{Na}^+\right](\text{mmol/L})\right) \\ &+ \left([\text{BUN}](\text{mg/dL}) \div 2.8\right) \\ &+ \left([\text{glucose}](\text{mg/dL}) \div 18\right)\end{aligned} \tag{39.2}$$

In Eq. (39.1), the constant 1.86 is the osmotic coefficient of sodium (0.93) multiplied by 2 to account for the dissociated anion paired with sodium. The osmotic coefficient is <1.0 due to incomplete electrolyte dissociation at typical plasma concentrations. The constant 9 accounts for the other osmotically active plasma components, including potassium, calcium, and other electrolytes, and proteins found at lower molar concentrations. Eq. (39.2) simplifies the calculation but often results in a higher calculated osmolality relative to Eq. (39.1). Under typical physiological conditions, the difference between measured and calculated Osm_s (osmolal gap) is expected to be <10 mOsm/kg, and a larger gap suggests the presence of unmeasured osmotically active substances.

The calculation of urine osmolality is conceptually similar but includes potassium and associated anions:

$$\begin{aligned}\text{Urine Osm} = &\left(2 \times \left[\text{Na}^+ + K^+\right](\text{mmol/L})\right) \\ &+ \left([\text{urea nitrogen}](\text{mg/dL}) \div 2.8\right) \\ &+ \left([\text{glucose}](\text{mg/dL}) \div 18\right)\end{aligned} \tag{39.3}$$

The urine osmolal gap typically falls between 10 and 100 mOsm/kg and can be used as a surrogate marker of urine ammonium (NH_4) excretion, but this is rarely done in routine clinical practice.

Serum and urine osmolality results vary depending on the patient hydration status, though, under normal physiological conditions, the reference intervals are typically between 275−295 and 300−900 mOsm/kg, respectively. The ratio of urine osmolality to Osm_s is typically 1−3 under normal physiological conditions, reflecting a wide range of urine osmolalities.

In SIADH with inappropriate antidiuresis and excessive free water retention, there are aberrations in several routine clinical laboratory values. Patients with SIADH exhibit reduced Osm_s (e.g., <275 mOsm/kg) and hyponatremia (e.g., <135 mEq/L). In the setting of hyponatremia and low Osm_s, the normal physiological response is to maximally dilute urine, leading to a urine osmolality of 50−80 mOsm/kg. However, in patients with SIADH, the kidneys inappropriately concentrate urine (e.g., urine osmolality >100 mOsm/kg) and have reduced urine output. The urine osmolality may not exceed the Osm_s in SIADH but will show inappropriate urine concentration relative to Osm_s. This pattern of lab values together with clinical evidence of volume expansion supports the diagnosis of SIADH. The water loading test is a dynamic test, which is sometimes used to help differentiate potential causes of hyponatremia; however, this test is contraindicated in patients with SIADH, because excess fluid intake can exacerbate hyponatremia with potential serious adverse outcomes.

The diagnosis of DI involves routine clinical laboratory testing to evaluate potential excessive urinary free water loss. A low urine osmolality of <300 mOsm/kg and elevated Osm_s of >300 mOsm/kg (or hypernatremia is present) support the diagnosis of DI. A water deprivation test with desmopressin challenge may also be performed to differentiate whether the etiology of DI is central or nephrogenic, or be used when the diagnosis of DI is uncertain.

Water deprivation test

A water deprivation test typically begins in the morning at which point the patient is given water to drink (e.g., 20 mL/kg) over a 15−30-minute period, and food and water are withheld throughout the duration of the test. Serial collections of blood and urine samples (e.g., baseline, hourly, or bi-hourly) are performed with measurement of serum and urine osmolalities, respectively. A rising trend in Osm_s while urine osmolality remains low during the water deprivation test is an indicator of DI (Fig. 39.16). The water deprivation testing continues for 8−10 hours unless the lab values establish the diagnosis of DI prior to completion, or test termination is prompted by mental status changes or hypotension. In order to further determine if DI is from a central or nephrogenic etiology, a desmopressin challenge test can be performed during the clinical water deprivation procedure.

Desmopressin challenge test

Desmopressin (i.e., desamino-D-arginine, DDAVP) is a biologically active analog of endogenous ADH (vasopressin) that can be administered during the water deprivation test followed by measurement of serum and urine osmolalities. In patients with central DI, the kidneys respond to desmopressin stimulation by increasing water reabsorption and subsequently have more concentrated urine with an increase (e.g., >doubling) in urine osmolality (e.g., Fig. 39.16A). Conversely, patients with nephrogenic DI exhibit minimal renal response to exogenous desmopressin, and urine osmolality remains low (Fig. 39.16B).

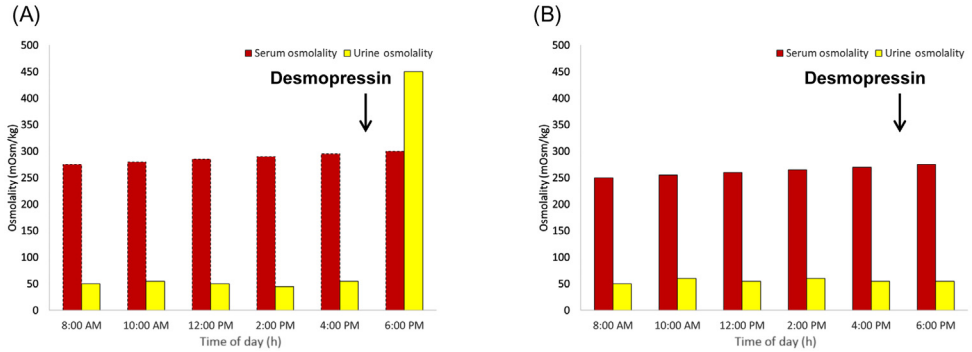

FIGURE 39.16 Expected serum and urine osmolality responses to water deprivation testing with desmopressin challenge in the setting of diabetes insipidus. Inappropriately, low urine osmolality and elevated plasma osmolality following water restriction are consistent with diabetes insipidus. The desmopressin challenge is an additional provocative test to help differentiate central versus nephrogenic diabetes insipidus. (A) Marked renal response with an increase in urine osmolality following desmopressin administration is consistent with central diabetes insipidus. (B) Minimal change in urine osmolality following desmopressin administration is consistent with nephrogenic diabetes insipidus.

Oxytocin

Oxytocin plays major roles in parturition and lactation. Similar to ADH, oxytocin is a nonapeptide (9-amino acids) that is synthesized in the hypothalamus and packaged into secretory granules that migrate down nerve exons into the posterior pituitary lobe for storage (Figs. 39.12 and 39.13). The release of oxytocin is controlled primarily by neuroendocrine reflex, leading to hypothalamus−posterior pituitary stimulation. The neuroendocrine reflex is activated by neural stimuli originating in the uterus and genital tract (distension of the vagina and cervix), as well as the nipples (i.e., suckling). Upon neural stimulation, oxytocin is released from the posterior pituitary via calcium-dependent exocytosis and circulates in plasma in an unbound form. Oxytocin binds to G-protein coupled cell-surface receptors on smooth muscle cells, leading to an increase in intracellular Ca^{2+} concentration, which promotes contraction of the smooth muscle cells of the uterine myometrium during parturition, as well as the contractile elements of the mammary alveoli associated with milk letdown during nursing. Oxytocin stimulation of smooth muscle contraction is dependent on estrogen priming of the uterus and mammary alveoli. Exogenous oxytocin (also referred to as Pitocin) can be administered for patient care in select settings. More specifically, exogenous oxytocin is FDA-approved for therapeutic use for the induction of labor in patients who have medical indications for induction (e.g., preeclampsia and premature rupture of membranes), stimulation, or reinforcement of uterine contraction, and as an adjunctive therapy in the management of incomplete or inevitable abortion. Laboratory testing for the measurement of plasma oxytocin concentration is not routinely performed, in part, because of limited evidence of physiological relevance to human reproductive disorders and limited clinical usefulness in clinical decision-making for patient care.

Chapter 40

Laboratory evaluation of thyroid function

David C. Lin[1] and Joely A. Straseski[2]

[1]Department of Pathology, Ann & Robert H. Lurie Children's Hospital of Chicago, Northwestern University Feinberg School of Medicine, Chicago, IL, United States, [2]Department of Pathology, University of Utah School of Medicine, ARUP Laboratories Salt Lake City, UT, United States

Learning objectives

After reviewing this chapter, the reader will be able to:

- Outline the steps involved in thyroid hormone synthesis, including the roles of the following: thyroid-stimulating hormone (TSH), thyroglobulin, pendrin, Na^+/I^- symporter, and thyroperoxidase.
- Explain the roles of thyrotropin-releasing hormone, TSH, thyroxine, and triiodothyronine in the regulation of the hypothalamus–pituitary–thyroid axis.
- Compare and contrast the relative concentrations and binding characteristics of the predominant binding proteins of thyroid hormones.
- List the differences between Graves' disease and Hashimoto's thyroiditis in terms of: (1) clinical features; (2) biochemical changes; and (3) presence of specific autoantibodies.
- Define the difference between direct and indirect measurements of free thyroid hormones, as well as list the clinical scenarios in which direct testing may be preferred.

Thyroid: anatomy, physiology, and biochemistry

The thyroid gland, or simply the thyroid, is located in the lower anterior of the neck, just below the larynx and in front of the trachea. It is an "H"-shape organ that consist of two lobules, bridged by a band of thyroid tissue called the isthmus. The thyroid is one of the largest endocrine glands in the body, and is responsible for the production and secretion of thyroid hormones, which are vital for normal growth, development, and metabolism. Thyroid hormones act on virtually all organ systems and can trigger an array of biological effects (summarized in Table 40.1).

Thyroid hormone regulation

Hypothalamus–pituitary–thyroid axis

Secretion of thyroid hormones is regulated by the hypothalamus–pituitary–thyroid axis (HPTA) (Fig. 40.1). This axis involves several key regulatory hormones, including thyrotropin-releasing hormone (TRH) and thyroid-stimulating hormone (TSH), also referred to as thyrotropin. TRH is a 3-amino acid-long peptide chain (glutamic acid-histidine-proline), whereas TSH is a glycoprotein that consists of two subunits: an alpha subunit of 89 amino acids and a beta subunit of 112 amino acids. The alpha subunit of TSH is identical to that found in luteinizing hormone (LH), follicle-stimulating hormone (FSH), and human chorionic gonadotropin (hCG).

In the HPTA, the hypothalamus produces TRH, which enters the circulation and reaches the anterior pituitary via a network of blood vessel connections known as the hypophyseal portal system. TRH binds to a class of G-protein-coupled receptors (thyrotropin-releasing hormone receptor) found on endocrine cells, called thyrotrophs, in the anterior pituitary. This triggers the thyrotrophs to secrete TSH. TSH then binds to another G-protein-coupled receptor found on the membrane of the thyroid cells, activates a signal cascade involving adenylate cyclase, and causes an increase in intracellular cyclic adenosine monophosphate (cAMP) concentration.

Post TSH-binding, the increase of cAMP concentration in the thyroid cells results in: (1) thyroid cell proliferation and hypertrophy; and (2) synthesis and secretion of the thyroid hormones 3, 5, 3', 5' -tetraiodothyronine [thyroxine (T_4)] and 3, 5, 3'-triiodothyronine [triiodothyronine (T_3)] by the follicular cells. T_4 and T_3 secreted by the thyroid, as well as T_3 formed from T_4 in the periphery (see the next section), all provide negative feedback to the hypothalamus and pituitary to inhibit further secretion of TRH and TSH, respectively (discussed further at the end of this section).

Thyroid hormone synthesis

The thyroid gland is comprised of two types of cells—follicular and parafollicular ("C") cells. The follicular and C

TABLE 40.1 Systemic effects of thyroid hormones.

Systems affected	Effects
Nervous system	• Maturation and development of the CNS • ↑ sensitivity to catecholamines (via induced expression of catecholamine receptors)
Musculoskeletal system	• ↑ linear growth (via promotion of hypertrophic differentiation of the growth plate chondrocytes)

Metabolism	• ↑ basal metabolic rate[a]
	  ◦ ↑ oxygen consumption[b]
	  ◦ ↑ body heat production/thermogenesis[c]
	• ↑ carbohydrate metabolism
	  ◦ ↑ gluconeogenesis
	  ◦ ↑ glycogenolysis
	  ◦ ↑ glucose absorption
	• ↑ lipid metabolism
	  ◦ ↑ lipolysis
	• ↑ protein metabolism (overall more catabolic state)

Cardiovascular system	• ↑ cardiac output • ↑ blood flow • ↑ heart rate • ↑ sensitivity to catecholamines (leading to ↑ heart rate)

↑, Increased; *CNS*, central nervous system.

[a] *Metabolic rate at rest.*
[b] *In most tissues, via increased synthesis and activity of Na^+/K^+ adenosine triphosphatase.*
[c] *In part due to increased fuel oxidation and production of adenosine triphosphate.*

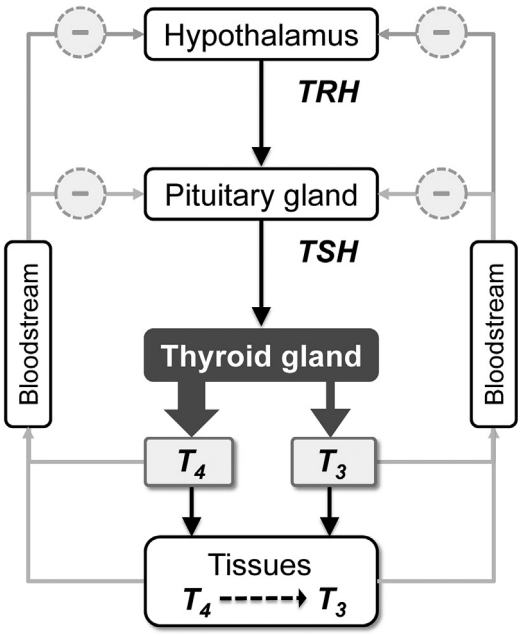

FIGURE 40.1 Hypothalamus–pituitary–thyroid axis. Thyrotropin-releasing hormone from the hypothalamus stimulates thyroid-stimulating hormone release from the pituitary gland. Thyroid-stimulating hormone then initiates thyroid hormone release from the thyroid gland, with more thyroxine produced than triiodothyronine. Triiodothyronine is predominantly produced via conversion of thyroxine within peripheral tissues. Triiodothyronine and thyroxine both provide negative feedback to the pituitary (predominantly) and hypothalamus (lesser) to halt further production. T_3, Triiodothyronine; T_4, thyroxine; *TRH*, thyrotropin-releasing hormone; *TSH*, thyroid-stimulating hormone; −, negative feedback.

cells are capable of producing thyroid hormones and calcitonin, respectively. The secretory units of the thyroid gland are called follicles (Fig. 40.2A). Each follicle consists of follicular cells surrounding the colloid, a gelatinous, amorphous material comprising newly made thyroid hormone bound to thyroglobulin (Tg). The follicles are separated by the interstitium, which is interspersed with capillaries, venules, and C cells.

Generation of thyroid hormones requires two main "ingredients": tyrosine (from Tg) and iodine (from the diet). Tg acts as the "platform" upon which these two ingredients combine to form the final thyroid hormone products. Given the central role of Tg, its production is compulsory to the remaining steps in thyroid hormone synthesis. Additionally, iodine must be transported to the appropriate thyroid region and converted into the correct chemical state before thyroid hormone "manufacturing" can take place. Thyroid hormones are synthesized through a complicated and unique series of steps occurring within the thyroid follicles, which are regulated by TSH. These steps are outlined below, with the numbers of each step corresponding to Fig. 40.2B.

1) Thyroglobulin synthesis

Tg, previously known as colloid antigen, is a 660-kDa glycoprotein that is only found within the thyroid. It is produced by the follicular cells and stored within the colloid. Tg is synthesized from tyrosine molecules by the

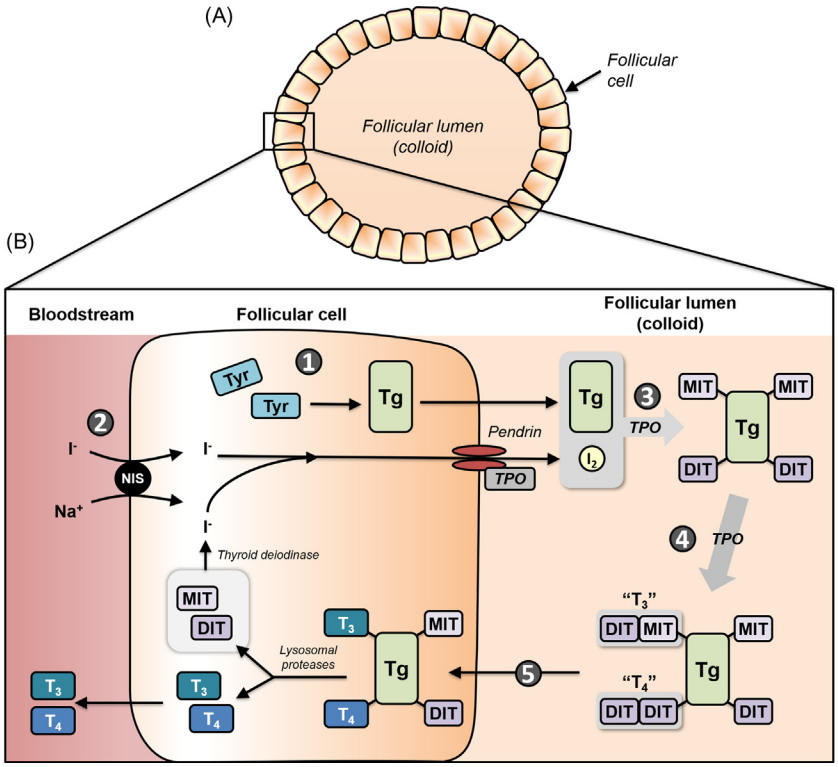

FIGURE 40.2 Anatomy and biochemistry involved in thyroid hormone synthesis. (A) General structure of the thyroid follicle, with follicular cells encompassing a lumen filled with colloid. (B) Major steps involved in thyroid hormone synthesis. Numbers correspond to steps detailed within the text (see "Thyroid hormone synthesis" section). *DIT*, Diiodotyrosine; I^-, iodide; I_2, iodine; *MIT*, monoiodotyrosine; *NIS*, Na^+/I^- symporter; T_3, triiodothyronine; T_4, thyroxine; *Tg*, thyroglobulin; *TPO*, thyroid peroxidase; *Tyr*, tyrosine.

follicular cells, packaged in secretary vesicles, and released into the follicular lumen via exocytosis. It is responsible for the majority of total protein and total protein synthesis within the thyroid gland. Although Tg is tyrosine-rich, only a small portion of the tyrosine residues can be iodinated (approximately 20%) and are involved in thyroid hormonogenesis.

2) Iodine transportation and processing

Iodine (I_2) is an essential component in thyroid hormone synthesis. Dietary sources, such as seafood and iodized table salt, contain the anionic form of the iodine atom, iodide (I^-), which needs to be absorbed and converted into I_2 before it can be utilized to generate thyroid hormones. I^- is absorbed through the gastrointestinal tract and distributed in the extracellular fluid (ECF). From the ECF, I^- can be excreted in the urine, or transported into the thyroid follicular epithelial cells via the sodium–iodide cotransporter (Na^+/I^- symporter). These cotransporters are found at the basal membrane of follicular cells and facilitate transport of I^- along with a charge-balancing Na^+ ion. I^- is then transported into the follicular lumen via an anion transporter protein called pendrin, which is present at the apical membrane of the follicular cells. An enzyme called thyroid peroxidase (TPO), or thyroperoxidase, then further oxidizes I^- to I_2.

3) Monoiodo tyrosine and diiodotyrosine formation

Inside the follicular lumen, I_2 binds to tyrosine residues of Tg to form monoiodo tyrosine (MIT) or diiodotyrosine (DIT) (see Fig. 40.3A). MIT has one iodine coupled to it, whereas DIT has two. The coupling reaction between Tg and I_2, sometimes referred to as "organification," is catalyzed by TPO. In the presence of excess I^-, organification is inhibited in order to protect against excess thyroid hormone synthesis. This is known as the Wolff–Chaikoff effect, and has historically been used as the basis for hyperthyroidism treatments.

4) Triiodothyronine and thyroxine formation

T_3 and T_4 are formed from MITs and DITs within the colloid. T_3 is formed when one MIT is coupled to one DIT, whereas T_4 is formed when two DITs are coupled (see Fig. 40.3B). Reverse triiodothyronine (rT_3) is formed similarly to T_3 but in opposite spatial configuration. The aforementioned coupling reactions are also mediated by TPO. The iodinated Tg (i.e., Tg with T_3, T_4, MIT, and/or DIT attached) serves as the I_2 storage compartment in the thyroid and accounts for approximately 90% of total body I_2 concentration (6000–12,000 μg) [1]. This is an important physiological feature, because thyroid hormones can affect numerous biological functions (Table 40.1).

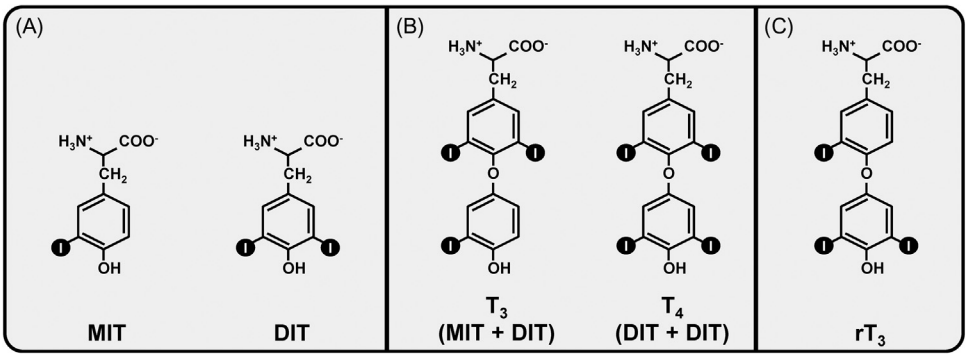

FIGURE 40.3 Chemical structure of thyroid hormones and their precursors. The phenol ring positioned nearest the amino acid terminal is referred to as the alpha ring, and the ring located on the hydroxyl terminal is the beta ring. *DIT*, Diiodotyrosine; *MIT*, monoiodotyrosine; *rT3*, reverse triiodothyronine; *T3*, triiodothyronine; *T4*, thyroxine; I, iodine atoms.

As such, having a pool of iodinated Tg allows the body to readily secrete thyroid hormone when needed. It also explains the transient hyperthyroidism that may be observed in the initial stages of hypothyroid disease; acute autoimmune destruction of the thyroid gland results in rapid release of these stored hormones (referred to as "Hashitoxicosis").

5) Thyroid hormone release and monoiodo tyrosine/diiodotyrosine recycling

Release of thyroid hormone is tightly controlled by TSH and the HPTA. Furthermore, the thyroid gland is capable of recycling the individual components of thyroid hormone synthesis, such as MIT and DIT. These features, along with the readily available iodinated Tg pool, allow for an effective thyroid hormone "factory," where: (1) production is tightly regulated; (2) unconsumed components are recycled to reduce waste; and (3) stored supply is available on demand.

When the thyroid is stimulated via TSH, Tg is taken up from the colloid into follicular cells via pinocytosis. Follicular lysosomes fuse with the endosome and lysosomal proteases digest Tg to release T_3, T_4, MIT, and/or DIT. T_3 and T_4 are transported out of the follicular cells and into the circulation. Due to their lipophilic nature, T_3 and T_4 must be transported in the circulation via binding proteins. MIT and DIT are deiodinated by thyroid deiodinase and release their I^-, which is then recycled for future production of thyroid hormones.

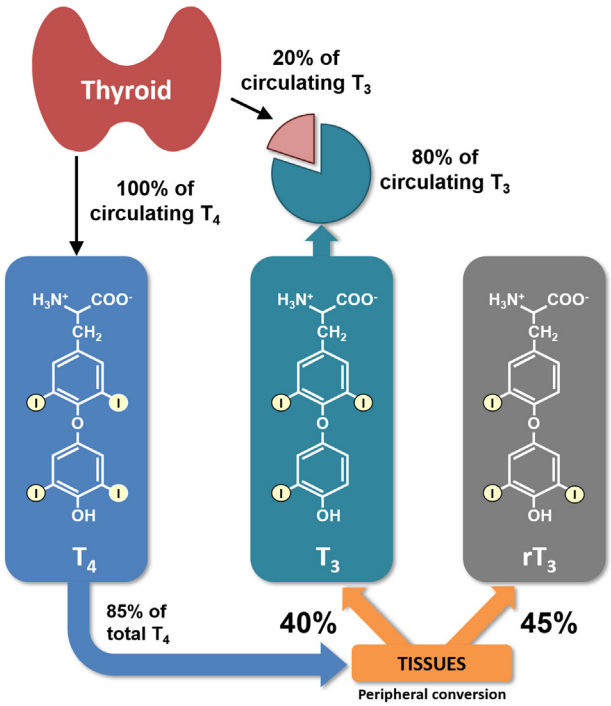

FIGURE 40.4 Relative secretion of thyroxine and triiodothyronine by the thyroid gland and further conversion of thyroxine into triiodothyronine or reverse triiodothyronine. The thyroid gland is the only source of circulating thyroxine, whereas the majority of triiodothyronine is produced via conversion of thyroxine at the peripheral tissues. Approximately equal amounts of triiodothyronine and reverse triiodothyronine are produced during thyroxine conversion. Regulation of these percentages can effectively regulate systemic thyroid functionality, as triiodothyronine is the biologically active hormone form and reverse triiodothyronine has no biological activity. *T3*, Triiodothyronine; *T4*, thyroxine; *rT3*, reverse triiodothyronine.

Thyroxine versus triiodothyronine

In general, the thyroid gland secretes more T_4 than T_3. The majority of T_3 is instead generated within the peripheral tissue by deiodination of T_4 (Fig. 40.4). Despite being produced at lower quantity than T_4 by the thyroid, T_3 is considered the more biologically active hormone, whereas T_4 is considered a prohormone. In the circulation, T_4 is relatively more protein-bound than T_3 (99.97% of T_4 versus 99.7% of T_3 is protein-bound). This, in turn, contributes to T_4's longer half-life and, therefore, higher concentration (Table 40.2). While the total T_4 concentration is approximately 50 times that of total T_3, the

TABLE 40.2 Concentrations of total and free thyroid hormones in the circulation.

Thyroid hormone	Total concentration	Free hormone percent	Free hormone concentration	Typical half-life
Thyroxine	4–12 μg/dL	~0.03%	0.8–2.7 ng/dL	6–7 days
Triiodothyronine	70–170 ng/dL	~0.3%	0.2–0.48 ng/dL	1–1.5 days

concentration of circulating free, unbound T_4 is only four-to-five times that of free triiodothyronine (FT_3) [2].

Although the majority of the circulating thyroid hormones are protein-bound, only the free forms are readily taken up by cells in the peripheral tissues. Binding proteins act as a buffer to maintain the free fractions within very narrow limits. Bound T_3 and T_4 then serve as a "reservoir" of functional hormone. Changes in concentration of thyroid hormone-binding proteins, which will be discussed later in this chapter, may alter the total but not free hormone concentrations. Increased concentrations of thyroid hormone-binding proteins in the blood cause more T_3 and T_4 to be bound. This, in turn, reduces the amount of "free" thyroid hormone in the circulation. Since FT_3 and free thyroxine (FT_4) concentrations are tightly regulated via the HPTA, this triggers TSH secretion by the pituitary, which stimulates the release of thyroid hormones from the thyroid. This leads to a redistribution of the thyroid hormone between the bound versus unbound states. The end result is a new steady state where the total (i.e., bound plus unbound) thyroid hormone concentration is increased, but concentration of the free form remains the same. This has significant implications on the testing and interpretation of thyroid hormone measurements, and will be discussed more later.

Thyroid hormone transport, conversion, and mechanism of action

Given that T_3 is considered the more biologically active hormone, the main downstream effects of thyroid hormones require the following steps: (1) transportation of T_4 and T_3 from the thyroid to the tissue; and (2) conversion of T_4 to T_3.

Thyroxine and triiodothyronine transport to tissues

In circulation, over 99% of T_3 and T_4 are bound to plasma proteins, namely thyroxine-binding globulin (TBG), transthyretin (TTR, also known as prealbumin), and albumin. The binding characteristics of these proteins are summarized in Table 40.3. In general, T_4 is more tightly bound than T_3 to these plasma binding proteins. Of note, TBG is found in the lowest concentration but has the highest affinity for and binds the greatest percentage of thyroid hormones. Conversely, albumin has the lowest affinity but is present at a significantly higher concentration in the circulation compared with the other thyroid hormone-binding proteins. Several factors can affect the concentration of the thyroid hormone-binding proteins (Table 40.4). As described earlier, changes in thyroid hormone-binding protein concentration can cause a redistribution of free versus bound thyroid hormone. This can lead to a new steady state, where the total thyroid hormone concentration is increased, but concentration of the free/unbound thyroid hormone remains the same.

Conversion of thyroxine into triiodothyronine

Thyroid hormone conversion is a finely tuned process. This is important because different thyroid hormones have varying degrees of biological activity, e.g., T_3 being most biologically active. Regulation of the conversion process can therefore directly influence the overall impact thyroid hormones have on the body. At the peripheral tissue, T_3 and T_4 enter from the circulation via specific thyroid hormone transporters. T_4 can be converted to T_3, the more biologically active hormone, or rT_3, a biologically inactive form of the hormone (Fig. 40.4). Both conversions are catalyzed by iodothyronine deiodinase, which removes an iodine atom from T_4 to generate T_3 or rT_3.

Deiodination can occur at different tissues and to varying degrees, but the liver and kidneys are considered primary sites. Peripheral deiodination of T_4 to T_3 is responsible for producing approximately 80% of the circulating T_3. The remaining circulating T_3 is derived directly from the thyroid gland. The deiodination process controls the balance between biologically active versus inactive thyroid hormone. Under normal physiological condition, peripheral deiodination generates roughly equal amounts of T_3 and rT_3. Approximately 40% and 45% of T_4 are deiodinated into T_3 and rT_3, respectively [3].

Reverse triiodothyronine

T_3 and rT_3 differ only by the position upon which iodine is attached to the tyrosine ring (Fig. 40.3C). Physiologically, T_3 can increase the metabolic rate of most tissues, whereas rT_3 is metabolically inactive.

TABLE 40.3 Characteristics of thyroid hormone-binding proteins.

Plasma binding protein	Thyroxine-binding globulin	Transthyretin	Albumin
Percent of hormone bound	~75% of total T_4	~20% of total T_4	~5% of total T_4
	~75% of total T_3	<5% of total T_3	~20% of total T_3
Concentration in blood	~0.37 μM *(lowest)*	~4.6 μM *(intermediate)*	~590 μM *(highest)*
Binding affinity, *that is, how tightly it binds to thyroid hormones*	$K_a = 10^{10}$ *(highest; higher affinity for T_4 than T_3)*	$K_a = 10^7$ *(intermediate)*	$K_a = 10^5$ *(lowest)*

Ka, Association constant; *T_4*, thyroxine; *T_3*, triiodothyronine.

TABLE 40.4 Examples of factors affecting thyroid hormone-binding protein concentrations.

	Effect on concentration	Explanation
Condition / disease		
• Cirrhosis	↓	Decreased hepatic production of binding proteins
• Nephrotic syndrome	↓	Increased renal clearance of binding proteins
• Malnutrition	↓	Decreased production of binding proteins
• Pregnancy	↑	Estrogen stimulation of TBG production by the liver
• Acute hepatitis	↑	Increased TBG synthesis during acute-phase response
• Acute intermittent porphyria	↑	Mechanisms not clearly established
Drugs		
• Estrogen	↑	Stimulation of TBG production by the liver
• Androgens	↓	Mechanisms not clearly established
• Glucocorticoids	↓	Suppression of TBG synthesis
Others		
• Genetics	↑ or ↓	Genetic variations can lead to ↑ or ↓ production of binding proteins

↑, Increased; ↓, decreased; *TBG*, thyroxine-binding globulin.

Although T_3 and rT_3 are produced at approximately the same rate within peripheral tissues, medications, chronic illness (e.g., chronic liver or kidney disease), medical/surgical stress, or starvation can alter this balance. In the latter state, a lower metabolic rate is physiologically desirable to decrease energy expenditure. As such, increased conversion of T_4 to rT_3 has often been described as a compensatory mechanism by the body to aid survival. In clinical scenarios, such as the ones listed above (also see "Nonthyroidal illness" section), increased conversion of T_4 into rT_3 may ultimately cause a decrease in the T_3/rT_3 ratio [4]. The T_3/rT_3 ratio may provide more clinical information than rT_3 measurements alone. Overall, measurement of rT_3 is considered controversial due to large practice variation in test ordering patterns and little evidence to support frequent ordering of this test [5].

Mechanism of action

Thyroid hormones act on virtually every cell type in the body, with T_3 being the most biologically active form. Until 1970, it was assumed that the lipophilic nature of thyroid hormones allowed them to enter target cells via simple (passive) diffusion. It is now understood that T_4 and T_3 enter the target cells of most organs from the circulation via carrier-mediated transporters, and they require binding to specific intracellular

receptors in order to exert their actions within the cell [6]. Inside the target cells, T_3 exerts most of its actions through regulation of gene transcription. Briefly, T_3 can: (1) bind to thyroid hormone nuclear receptors inside the nucleus; (2) form a complex that can bind to specific DNA sequences; and (3) upregulate or downregulate the transcription of specific target genes. This subsequently affects the amount of the target mRNAs transcribed and proteins synthesized.

The above process allows the thyroid hormones to have a myriad of effects on different cell types, target tissues, and organ systems (Table 40.1). Tissue responsiveness to thyroid hormone can be dependent upon the type and distribution of nuclear receptors within the tissue. The mechanism of thyroid hormone bioactivity may be regulated via processes, such as T_3 conversion rates, the distribution of transport carriers on various cell types, and the type of nuclear receptors located within the cell. These continue to be areas of active research.

Another critical component of thyroid hormone function is reliant upon the relationship between serum concentrations of TSH and FT_4. TSH production by the pituitary is tightly regulated to maintain optimal thyroid hormone concentrations in the blood, predominantly via the negative feedback loop of the HPTA. To accomplish this, there is an inverse log−linear relationship between changes in circulating thyroid hormone and production of TSH, that is, a two-fold change in FT_4 concentration in the blood results in a 100-fold (inverse) change in TSH (Fig. 40.5). As such, measurement of serum TSH concentration is highly sensitive to changes in serum thyroid hormone concentration, and thus diagnostically useful as the first indication of disease. This is particularly important in scenarios where TSH may be abnormal despite normal serum FT_4 (referred to as subclinical disease, see the next section).

Clinical assessment of thyroid function

Overview

In general, thyroid hormones stimulate physiological functions, e.g., cardiac output and heat production. Therefore too much thyroid hormone production (hyperthyroidism) can lead to signs and symptoms of a hypermetabolic state, while thyroid hormone deficiency (hypothyroidism) can result in the opposite presentation. The asymptomatic state with normal thyroid gland function is referred to as euthyroid. An overview of common causes and symptoms of hyperthyroidism and hypothyroidism is summarized in Table 40.5.

Thyroid disease may result from endogenous [e.g., autoantibodies (autoAbs)] or exogenous (e.g., drugs) causes, and present with either overt or subclinical ("mild") conditions. In overt thyroid conditions, signs and symptoms are often present, along with abnormal thyroid laboratory results (Fig. 40.6). In subclinical cases, patients may present with no or minimal clinical symptoms, along with normal to slightly abnormal laboratory results.

Thyroid diseases may also be classified as primary, secondary, or tertiary, depending on what organ the dysfunction originated in. In primary thyroid conditions, the pathology is localized to the thyroid. Oversecretion or undersecretion of hormone by the thyroid will consequently affect the negative feedback loop and overall TSH and TRH production. In secondary and tertiary (also jointly referred to as "central") conditions, the problem originates *outside* the thyroid, typically within the pituitary and hypothalamus, respectively. In these cases, production of TSH (and, less frequently, TRH) is directly affected by pituitary or hypothalamic dysfunction, and downstream production of thyroid hormone will be affected. Primary thyroid disease is much more common

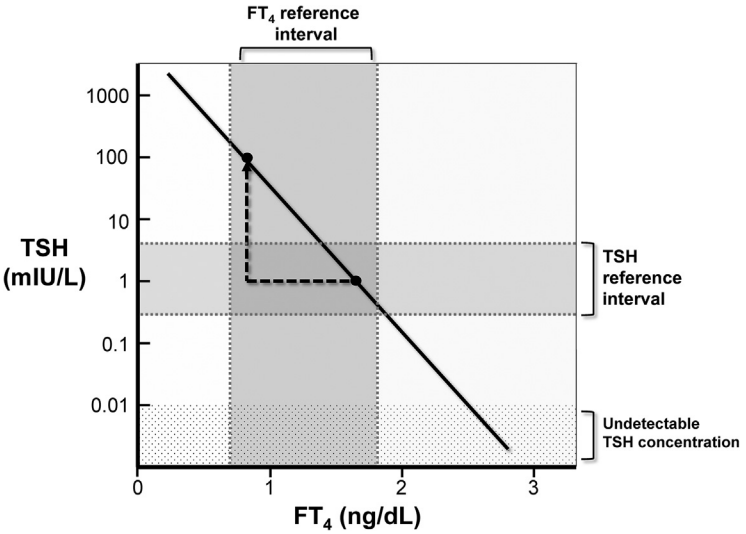

FIGURE 40.5 Graphical representation of the inverse log−linear relationship between serum thyroid-stimulating hormone and free thyroxine concentrations. The logarithmic relationship dictates that small fluctuations in free thyroxine concentrations will be reflected in large differences in thyroid-stimulating hormone values. This relationship explains the utility of thyroid-stimulating hormone as the preferred initial screen for thyroid dysfunction. Dashed arrow: two-fold change of free thyroxine (from 1.6 to 0.8 ng/dL) corresponding to a 100-fold change in thyroid-stimulating hormone (from 1 to 100 mIU/L).

TABLE 40.5 Examples of causes and symptoms associated with hyperthyroid and hypothyroid disease states.

	Hyperthyroidism	Hypothyroidism
Causes	Endogenous	Endogenous

	• Autoimmune thyroid disease
	  ◦ Graves' disease
	• Toxic nodules / toxic multinodular goiter
	• Solitary toxic adenoma
	• Gestational thyrotoxicosis
	• Pituitary tumor
	• Thyroid neoplasm
		• Autoimmune thyroid disease
		  ◦ Hashimoto's thyroiditis
		• Congenital, for example, inborn errors of thyroid hormone biosynthesis
		• Idiopathic atrophic hypothyroidism
		• Pituitary tumor

	Exogenous	Exogenous
	• Excess T_4 or T_3 intake • Exogenous iodine or iodine-containing drugs	• Iodine deficiency • Iatrogenic therapy-related, such as radioiodine (I^{131}), postsurgery, and antithyroid drugs
Signs and symptoms	• Increased metabolism • Weight loss • Increased cardiac output • Heat intolerance • Hyperventilation • Goiter • Tremor • Warm and moist skin • Eyelid retraction	• Decreased metabolism • Weight gain • Decreased cardiac output • Cold intolerance • Hypoventilation • Goiter • Slow muscle relaxation • Lethargy

T_3, Triiodothyronine; *T_4*, thyroxine.

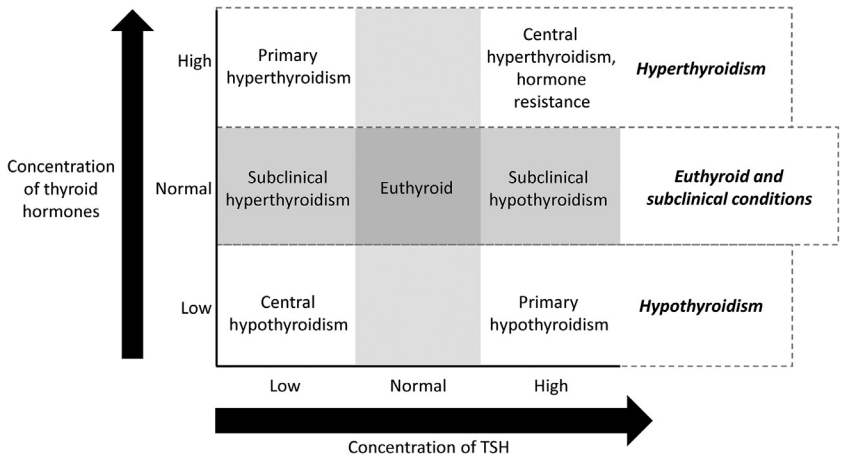

FIGURE 40.6 Relative concentrations of thyroid hormones (triiodothyronine and thyroxine) and thyroid-stimulating hormone in different hyperthyroid and hypothyroid states. Primary and central diseases of the thyroid can be differentiated by thyroid hormone and thyroid-stimulating hormone measurements. The subclinical state is often asymptomatic in presentation, with thyroid-stimulating hormone values outside of the reference interval while free thyroxine remains normal.

than central conditions; this chapter will focus on primary and secondary hyperthyroidism and hypothyroidism.

From the laboratory's perspective, investigation of hyperthyroidism or hypothyroidism generally involves an analysis of hormones associated with the HPTA, namely TSH, T_4, FT_4, T_3, and/or FT_3. Table 40.6 compares the expected changes in TSH, T_4, and T_3 concentrations in primary and secondary disorders. A general overview of a typical testing algorithm for thyroid function evaluation is also shown in Fig. 40.7.

Autoantibodies

Autoimmune thyroid diseases (AITDs) are the most common autoimmune diseases and include both hyperthyroid and hypothyroid conditions (Graves' disease and Hashimoto's thyroiditis, respectively). While the presence of autoAbs—or antibodies (Abs) that bind to self--antigens—in thyroid disease will be discussed further within their respective sections, their central role in AITD warrants a more detailed introduction. Thyroid autoAbs

TABLE 40.6 Comparison of laboratory results between primary and secondary hyperthyroid and hypothyroid disease states.

	Primary hyperthyroidism	Secondary hyperthyroidism	Primary hypothyroidism	Secondary hypothyroidism
Disease	Graves' disease	Pituitary adenoma[a]	Hashimoto's thyroiditis	Pituitary adenoma[a]
Thyroid hormone	↑①	↑②	↓①	↓②
TSH	↓②	↑①	↑②	↓①

↑, Increased concentration; ↓, decreased concentration; ①, initial change; ②, secondary response; *TSH*, thyroid-stimulating hormone.
[a]*Both secondary hyperthyroidism and hypothyroidism may be caused by pituitary adenoma. However, pituitary adenoma is more commonly associated with secondary hypothyroidism, as thyroid-stimulating hormone-producing pituitary adenomas are rare.*

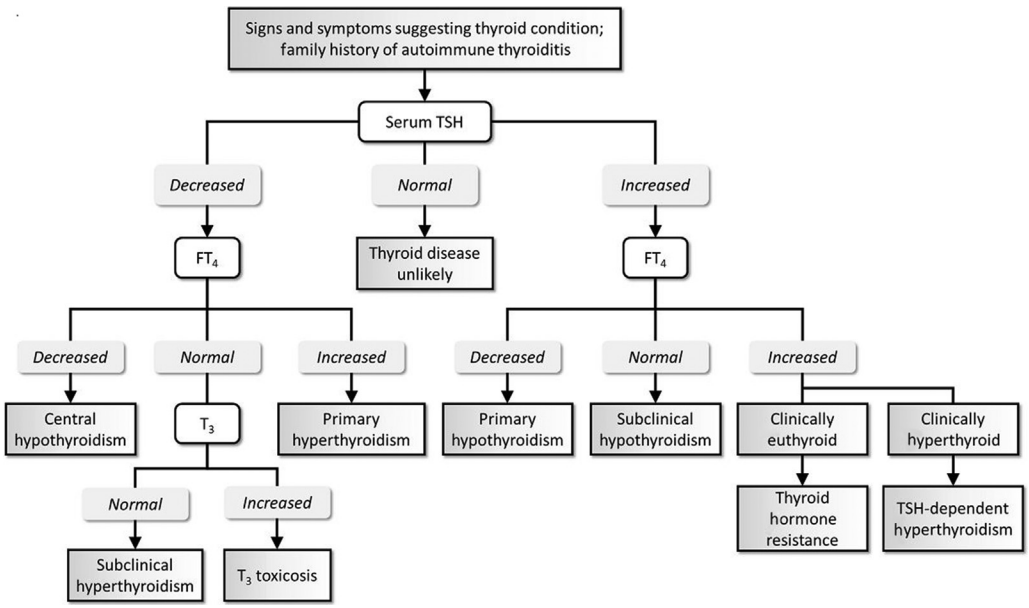

FIGURE 40.7 Example of a typical thyroid disorder diagnostic algorithm. Thyroid-stimulating hormone is central to common testing algorithms, as the best test to screen for initial disease. Thyroid autoantibody testing may be considered in some conditions.

are not usually necessary for diagnosis, but may prove useful in correlation with other thyroid hormone measurements and the clinical presentation of the patient. AutoAbs can target different protein components of the thyroid (see Table 40.7). These include proteins that are critical for the thyroid to receive regulatory signals from the pituitary gland [e.g., the thyroid-stimulating hormone receptor (TSHR)], as well as those involved in the synthesis (e.g., TPO) and transport (e.g., Tg) of thyroid hormones.

Thyroid-stimulating hormone receptor antibodies (TSHRAbs, or simply TRAbs) is a term that encompasses two types of autoAbs: (1) those that stimulate; and (2) those that block the function of the TSHR (neutral autoAbs have also been described, but their function is not well defined). Thyroid-*stimulating* immunoglobulins (TSIs) bind the TSHR and induce the same cAMP signaling pathways that TSH is capable of inducing, resulting in: (1) proliferation of thyroid cells; and (2) synthesis and secretion of thyroid hormones by the follicular cells. This increased production of thyroid hormone leads to the hypermetabolic symptoms associated with Graves' disease, a hyperthyroid condition. Conversely, TSHR-*blocking* Abs, also known as thyrotropin-binding inhibitory immunoglobulins (TBIIs), prevent TSH binding and the subsequent signal cascade required to produce thyroid hormone, leading to the hypothyroid state. Somewhat confusingly, TSI and TBII can actually have overlapping epitope specificities on the TSHR, and both may be found within the same patient. TRAbs are not routinely detected in the general population. The specifics of TRAb and TSI assays will be detailed in "Laboratory measurements of thyroid function."

AutoAbs may also be formed against TPO [thyroid peroxidase antibody (TPO Ab)] and Tg [thyroglobulin antibody (TgAb)], and, when present, they are commonly

TABLE 40.7 Common thyroid-related autoantibodies found in autoimmune thyroid disease states.

Target of AutoAb	AutoAb	Typical findings in different disease states		
		Healthy population	Graves' disease	Hashimoto's thyroiditis
TSHR	TSI	--	++	--
	TRAb	--	-- / +	-- / +
TPO	TPO Ab	~10%	+	++
Tg	TgAb	~10%	+	+

--, Absent; +, less commonly present; ++, commonly present.
Tg, Thyroglobulin; *TgAb*, thyroglobulin antibody; *TPO Ab*, thyroid peroxidase antibody; *TPO*, thyroid peroxidase; *TRAb*, thyroid-stimulating hormone receptor antibody; *TSHR*, thyroid-stimulating hormone receptor; *TSI*, thyroid-stimulating immunoglobulin.

found within the same individual. These Abs tend to be more common in women than in men, and their prevalence increases with age. TPO Ab and TgAb have been identified in approximately 10% of healthy individuals [7,8]. However, due to differences in assay sensitivity and specificity, and therefore reference intervals, reports vary as to whether TPO Ab and TgAb are truly present in the healthy, euthyroid population. With respect to clinical utility, whether TPO Ab presence may act as a predictor of future hypothyroidism has not been confirmed and is likely dependent upon the sensitivity of the assay used. TgAb may be present in individuals with thyroid cancer, but have not been definitely associated with disease progression. TgAb presence is known to interfere with the measurement of Tg; therefore concurrent TgAb measurements are recommended to ensure the validity of Tg results (see "Laboratory measurements of thyroid function" section). Serial measurement of these autoAbs is not necessary or recommended for routinely monitoring disease progression or response to treatment [9].

Hyperthyroidism (thyrotoxicosis)

Hyperthyroidism is defined as the excess production of thyroid hormones. The most common clinical features include weight loss, heat intolerance, warm and moist skin, and tremor and goiter (swelling at the front of the neck due to enlargement of the thyroid gland) (Table 40.5). Of note, the presence of goiter can result from both hyperthyroid and hypothyroid conditions. Another hallmark symptom that may be present is bilateral eyelid retraction (lag), which is the result of exophthalmos, an abnormal protrusion of the eyeball(s). The term thyrotoxicosis refers to the clinical effects of excess thyroid hormone, that is, increased serum FT_4 and/or FT_3, regardless of the cause.

Graves' disease, toxic nodules (or toxic multinodular goiter), and solitary toxic adenoma together account for more than 90% of hyperthyroid cases in the United States. Hyperthyroidism can also, somewhat paradoxically, be observed in the early stages of autoimmune hypothyroidism (Hashimoto's thyroiditis). In this case, immune-mediated destruction of the thyroid at disease onset can release stored thyroid hormone into circulation, appearing as hyperthyroidism (referred to as Hashitoxicosis). Gain-of-function mutations in the TSHR have also been described. Central hyperthyroidism is rare, but may be caused by pituitary adenoma and mutations, resulting in thyroid hormone resistance. Exogenous causes of hyperthyroidism often involve excess thyroid hormone intake or iodine-containing drugs.

Laboratory findings

TSH may aid in differentiating primary versus secondary hyperthyroidism. In general, serum TSH concentration will be low in primary hyperthyroidism and high in secondary hyperthyroidism (see Table 40.6). Other laboratory results consistent with hyperthyroidism include increased serum FT_4, total T_4, and total T_3. In 10%–15% of hyperthyroid patients, T_3 concentration may be increased, while T_4 remains normal. This is known as T_3 toxicosis, and is often observed during the progression of Graves' disease from the subclinical to the overt state.

Graves' disease

Graves' disease is the most common cause of hyperthyroidism. It accounts for 60%–80% of hyperthyroidism cases, and is more common in women than men (5:1 ratio). It also most commonly presents in individuals between 40 and 60 years of age. Graves' disease is an AITD that results in overproduction of thyroid hormone and frequently involves TRAb or, more specifically, TSI. These autoAbs chronically stimulate the TSHR to produce thyroid hormone. Perhaps counterintuitively, TBII and neutral Abs may also be present in these patients, reflecting the heterogeneous nature of the Abs produced in AITD. Although multiple Ab types may be present in Graves' disease, the clinical effects of hyperthyroidism result when TSI activity dominates the activity of any blocking autoAbs that may be present.

Excess thyroid hormone elicits the myriad of symptoms observed, including weight loss, warm and moist skin, and heat intolerance. The classic triad of clinical signs in Graves' disease includes goiter, exophthalmos, and pretibial myxedema (characteristic waxy skin lesions). Orbitopathy is observed in approximately 30% of patients diagnosed with Graves' disease. It has been proposed that TSI binding to TSHR expressed in retro-orbital tissue may be the mechanism responsible for exophthalmos observed in this disease.

Laboratory findings

The typical laboratory results observed in cases of Graves' disease can be found in Table 40.8. Along with the clinical signs described above, Graves' disease is diagnosed by classic hyperthyroid laboratory findings: low TSH, elevated FT_4, and/or T_3. While TSIs are present in 90% of diagnosed individuals and their presence is considered a classic finding in Graves' disease, TSI measurements are often not necessary for definitive diagnosis of the hyperthyroid patient with orbitopathy [10]. TSI and/or TRAb may be helpful in cases with nonclassical presentation, mild symptoms, or no identifiable goiter. They may also be useful in discriminating between AITD and nonimmune causes of thyrotoxicosis, such as toxic nodular goiter. Other autoAbs such as TPO Ab and TgAb may also be present in approximately 80% or 40%–70%, respectively, of patients diagnosed with Graves' disease (Table 40.7). However, these autoAbs are not exclusive to Graves' disease and are more commonly found in Hashimoto's thyroiditis. Radioactive iodine uptake (RAIU, a measure of iodine usage by the thyroid) is commonly elevated in patients with Graves' disease, indicating hyperactivity of the thyroid.

Nodule/multinodular goiter

Thyroid nodules are an abnormal growth of thyroid cells within the thyroid gland. The term thyroid nodule includes both nodular and multinodular goiters. These nodules, sometimes referred to as "toxic" nodules or "toxic" multinodular goiters, are a relatively common cause of hyperthyroidism, with a prevalence of 5% in women and 1% in men in iodine-replete countries [11]. The likelihood of developing thyroid nodules increases with age. Thyroid nodules are typically benign and originate in the colloid. The nodules can develop as colloid benign nodules, cysts, follicular adenomas (i.e., toxic adenoma; "tumor") or less frequently as carcinoma (7%–15%) [11,12]. Nodules may also result from gain-of-function mutations of the TSHR, which cause hyperactivity of the thyroid tissue.

Laboratory findings

Laboratory results will be similar to those seen in Graves' disease, including decreased TSH and increased thyroid hormones (FT_4, total T_4, and T_3). However, unlike Graves' disease, antithyroid Abs are typically absent and can be used to distinguish between the two disease states. Furthermore, despite the growth of one or more nodules, the thyroid gland is generally not diffusely enlarged, as observed in Graves' disease.

In cases where thyroid ultrasound reveals a high-risk nodule, a fine needle aspirate (FNA) may be ordered for further cytological assessment of malignancy. If there is a family history of thyroid malignancy, genetic testing may also be useful (see "Thyroid cancer" section).

RAIU may be increased in patients with toxic nodules or toxic multinodular goiter. However, thyroid scan results will reveal a heterogeneous or "patchy" pattern, rather than the homogeneous pattern observed in Graves' disease.

TABLE 40.8 Comparison of laboratory findings with different thyroid conditions.

Thyroid condition	TSH	Total T4	FT_4	Total T_3 or FT_3	rT_3
Overt primary hyperthyroidism					
Graves' disease	↓	↑	↑	↑	n/u
Central hyperthyroidism	N or ↑	↑	↑	↑	n/u
Subclinical hyperthyroidism	↓	N	N	N	n/u
Nonthyroidal illness	N or ↓	N or ↓	N or ↓	↓	↑
Subclinical hypothyroidism	↑	N	N	n/u	n/u
Central hypothyroidism	N or ↓	↓	↓	↓	n/u
Overt primary hypothyroidism					
Hashimoto's thyroiditis	↑	↓ or N	↓ or N	↓ or N	n/u

↑, Increased; ↓, decreased; *FT_3*, free triiodothyronine; *FT_4*, free thyroxine; *N*, normal; *n/u*, not useful (results are typically normal); *rT_3*, reverse triiodothyronine; *T_3*, triiodothyronine; *T_4*, thyroxine; *TSH*, thyroid-stimulating hormone.

Hypothyroidism

Although statistics vary in the literature, hypothyroidism is more commonly found in the population than hyperthyroidism; approximately 4% of the population may be considered hypothyroid, while approximately 1% is considered hyperthyroid [7]. Hypothyroidism is defined as deficient production of, or impaired response to, thyroid hormones. Symptoms associated with hypothyroidism include weight gain, cold intolerance, lethargy, and goiter (Table 40.5).

Hashimoto's thyroiditis is the most common endogenous cause of primary hypothyroidism in developed countries. Less common causes include idiopathic atrophic hypothyroidism and congenital diseases. Pituitary tumors and adenomas are fairly rare, and their development may lead to either secondary hyperthyroidism or hypothyroidism; the latter is more common. Central hypothyroidism may also result from hemorrhage or trauma, as well as rare genetic mutations.

Exogenous causes of hypothyroidism are often iatrogenic and associated with hyperthyroidism therapy (e.g., radiation-induced hypothyroidism, antithyroid drugs) or surgical procedures (e.g., removal of thyroid gland). Drug-induced hypothyroidism may also occur, most notably from agents such as amiodarone and glucocorticoids. Iodine deficiency is the most common cause of hypothyroidism worldwide, although it is exceedingly rare in developed countries with adequate iodine fortification.

Laboratory findings

Similar to the case of hyperthyroidism, TSH is also a useful marker to differentiate primary versus secondary hypothyroidism. In general, TSH concentrations will be elevated in primary hypothyroidism and decreased in secondary hypothyroidism (Table 40.6). Other laboratory results consistent with hypothyroidism include decreased serum FT_4 and total T_4. Analysis of T_3 is not generally considered a useful test in suspected hypothyroidism as T_3 may remain within normal limits for much of the disease course.

Thyroid replacement therapy (usually with T_4, more rarely with T_3) is used to treat hypothyroidism. T_4 suppresses the pituitary secretion of TSH, which can be measured to monitor response to therapy. Ideally, hormone replacement will return TSH to within the reference interval. If the plasma TSH concentration is not within the reference interval—high TSH suggests inadequate treatment, whereas low TSH may suggest excessive replacement—then FT_4 and FT_3 (in cases where T_3 supplementation is used) should also be measured. This is in part, because the change in plasma TSH concentration can be delayed behind the increases in FT_4 and/or FT_3 from the replacement therapy.

Thyroid autoAbs are often present in hypothyroidism, and their detection can help in the differential diagnosis of difficult or nonclassical hypothyroid cases. Almost 90% of hypothyroid individuals will have thyroid autoAbs in their circulation, predominantly TPO Ab and TgAb. In contrast to hyperthyroidism, RAIU is not as frequently performed in hypothyroidism, and is often not necessary for the diagnosis of specific hypothyroid conditions, such as Hashimoto's thyroiditis.

Hashimoto's thyroiditis

Hashimoto's thyroiditis, or chronic autoimmune thyroiditis, is the most common cause of hypothyroidism in iodine-sufficient countries. It is also currently considered the most common autoimmune disease and most common endocrine disorder [13]. It is a condition characterized by autoimmune destruction of the thyroid gland. Like Graves' disease, autoAbs are also commonly found in patients with Hashimoto's thyroiditis, primarily TPO Ab. Although this condition may occur at any age in either of the sexes, it is significantly more common in females (7:1), particularly in women between 40 and 50 years of age. Gradual loss of thyroid function proceeds to permanent hypothyroidism in a small percentage of cases.

Laboratory findings

The typical laboratory results observed in Hashimoto's thyroiditis are shown in Table 40.8. Depending on the stage of the disease, the FT_4, total T_4, total T_3, and FT_3 may be decreased or remain normal. However, as is common in thyroid disease, TSH tends to be the first analyte to become significantly increased. During the initial subclinical stage, TSH is elevated, while T_4 and T_3 remain normal. As the disease progresses, FT_4 concentrations will begin to decrease, followed by T_3. In prolonged disease, both FT_4 and T_3 can be abnormally low.

In Hashimoto's thyroiditis, TPO Ab and TgAb are present in approximately $>90\%$ and $60\%-80\%$ of diagnosed individuals, respectively [13]. Thyroid autoAbs do not need to be serially measured in patients with overt hypothyroidism; however, these Abs may indicate progression to overt disease in individuals with subclinical, or mild, hypothyroidism [9]. The presence of TgAb provides very little additional diagnostic information over Abs, such as TPO Ab, which are present at higher frequency in Hashimoto's thyroiditis.

Other causes

Hypothyroidism can result from various other causes, including: (1) iodine deficiency; (2) iodine excess; and (3) congenital hypothyroidism.

Iodine deficiency is a rare cause of hypothyroidism in North America due to the availability of iodine in the diet; however, it is the leading cause globally, affecting approximately 2-billion people worldwide. Interestingly, iodine *excess* can also cause hypothyroidism through the Wolff–Chaikoff effect. The Wolff–Chaikoff effect involves suppression of I_2 organification in the presence of excess I^-. This, in turn, suppresses thyroid hormone synthesis in a paradoxical effort to avoid excess hormone production when surplus iodine is present [14].

Congenital hypothyroidism is one of the most common preventable causes of intellectual disability [15]. It is defined as the presence of thyroid hormone deficiency at birth and occurs in approximately 1:4000 of newborns. Roughly 85% of cases are sporadic and due to abnormal development of the thyroid, with the remainder due to hereditary causes. Congenital hypothyroidism may also be transient. The most common cause of transient congenital hypothyroidism worldwide remains iodine deficiency. In cases where the mother has AITD, maternal thyroid autoAbs may cross the placenta and lead to congenital hypothyroidism in the newborn. This cause is uncommon, and the effects are usually transient.

Laboratory findings

In iodine deficiency, TSH may be normal to elevated, while the T_4 may be normal to decreased, and T_3 is normal or mildly elevated. The mild elevation of T_3 is thought to be in part due to preferential secretion by the thyroid and/or increased conversion of T_4 into T_3 in peripheral tissues. This is an important feature, as T_3 is significantly more potent than T_4 but requires only 75% of the amount of the iodine for hormone synthesis. In contrast, in severe iodine deficiency, an increased serum TSH level is more likely to be accompanied by a pronounced decrease in both T_4 and T_3. Iodine excess, traditionally due to pharmaceutical sources such as radiocontrast dyes and amiodarone, has a different presentation depending upon the dosage and/or duration. In acute iodine excess, TSH may be increased, but T_4 and T_3 are only mildly increased. In chronic iodine excess, the patient may be clinically euthyroid, and serum TSH, T_4, and T_3 may all appear to be normal due to presumed "escape" from the Wolff–Chaikoff effect and continued organification of iodide. Chronic iodine excess may be associated with increased incidence of goiter and either hyperthyroidism or hypothyroidism, depending on the clinical scenario.

In congenital hypothyroidism, serum TSH concentration may be elevated, while the thyroid hormone concentrations (e.g., total or FT_4) are low or low-normal. Depending on the laboratory findings, congenital hypothyroidism can also be further classified as subclinical (high TSH and normal FT_4), primary (high TSH and low FT_4), or central (low or normal TSH and low FT_4). Most screening programs for congenital hypothyroidism involve TSH determination, supported by T_4 measurements.

Nonthyroidal illness

It is possible to have abnormal thyroid test results in the absence of thyroid disease. This typically occurs in severely ill, hospitalized, or nutritionally deprived patients, and has also been referred to as "sick euthyroid syndrome," "euthyroid sick syndrome," or "low T_3 syndrome." Hospitalized patients often have altered protein production, circulating factors that inhibit protein binding, and may have received medications that affect thyroid function. Due to this, it is widely accepted that thyroid function should not be assessed in severely ill patients, unless there is a strong indication for thyroid dysfunction. Additional causes of nonthyroidal illness (NTI) include trauma, malignancy, and inflammatory disease.

While the pathogenesis of this condition has yet to be fully elucidated, it is presumed that a lower metabolic rate is physiologically desirable during states such as chronic illness and starvation, as it decreases the overall energy expenditure. Peripheral conversion of T_4 to T_3 therefore declines markedly during starvation and illness. Increased deiodination of T_4 to rT_3, along with concurrent decreases in T_3 production and rT_3 degradation, results in an apparent increase in rT_3 concentrations relative to T_3. Conversion of T_4 to the biologically inert rT_3 has been described as a survival mechanism; however, whether this physiological change is truly an adaptive response remains controversial.

Laboratory findings

Common laboratory findings observed in this population can be found in Table 40.8. Importantly, TSH measurements should not be used alone to assess thyroid function in patients with NTI. Low serum concentrations of T_3, followed by FT_4 and T_4, are commonly found, and TSH may also be low or low-normal. The decrease in serum FT_3 and total T_3 is in part due to decreased conversion of T_4 into T_3 and decreased elimination of rT_3.

Serum T_3 may be particularly useful to measure in hospitalized patients with low serum TSH to help distinguish between hyperthyroidism (elevated T_3) and NTI (low T_3). Although concentrations of rT_3 may be

significantly increased in NTI patients, measurement of rT_3 is not particularly useful. Rarely, it may aid in distinguishing between central hypothyroidism (low rT_3) and NTI (elevated rT_3).

Overall protein concentrations (including thyroid hormone-binding proteins TBG, TTR, and albumin) may be low in severely ill patients, which can affect interpretation of thyroid hormone measurements. For example, T_4 measurements may be low due to TBG deficiency rather than truly impaired synthesis; therefore care must be taken when considering total hormone concentrations in this population.

For the reasons listed above, serum FT_4 concentrations are considered a more reliable marker of thyroid status than total T_4, particularly in patients with NTI. The method used to detect FT_4 is also important, because results may be affected by changes in thyroid hormone-binding capacity (see "Laboratory measurements of thyroid function" section).

Thyroid function and pregnancy

While certainly not a pathological condition, the physiological changes and clinical ramifications of thyroid function during pregnancy warrant their own discussion.

The increased metabolic requirements of the growing fetus cause considerable changes in the thyroid physiology of the mother. During pregnancy, there are increases in iodine requirements for the developing fetal brain, therefore an observed increase in thyroid gland size and thyroid hormone production by the mother. Expected changes in physiology during pregnancy lead to elevations in T_3 and T_4 (due to hCG stimulation of the TSHR), decreased TSH (due to negative feedback following hCG-mediated stimulation of the TSHR), and increases in TBG concentrations (due to estrogen-mediated stimulation of overall protein production).

Graves' disease is the most common cause of autoimmune hyperthyroidism in pregnant women, affecting up to 1% of all pregnancies [16]. More commonly, "gestational thyrotoxicosis" results from hCG's ability to stimulate the TSHR (recall hCG and TSH share the same alpha subunit). The markedly elevated hCG concentrations present within the first and early second trimesters may cause transient hyperthyroidism in 1%–3% of pregnancies [17]. Gestational thyrotoxicosis may also be associated with hyperemesis gravidarum. Rarely, molecular variant forms of hCG or TSHR mutations can also result in gestational thyrotoxicosis.

Overt hypothyroidism affects up to 0.5% of all pregnancies, with 2%–3% of pregnancies affected by subclinical hypothyroidism [18], primarily due to Hashimoto's thyroiditis. T_4 plays a critical role in neurologic development of the fetal brain, and deficiencies have been associated with diminished neuropsychological development and cognitive function in early childhood [19]. The increased demand for thyroid hormone can naturally result in hypothyroidism later in pregnancy, particularly in women that had borderline or limited thyroidal reserve prior to conception.

Some studies have shown the presence of thyroid autoAbs (particularly TPO Ab) during pregnancy to be associated with increased risk of postpartum thyroid disease. However, most current guidelines for thyroid management during pregnancy do not recommend universal TPO Ab screening in this population due to insufficient evidence of this relationship [18,20]. Recently, the American Thyroid Association (ATA) revised their recommendation to include testing for TPO Ab in pregnant women with TSH values of above 2.5 mU/L [21]. It should also be noted that screening of asymptomatic pregnant women for thyroid function is controversial. Universal screening prior to or during pregnancy is not formally recommended by current practice guidelines in light of conflicting evidence of its overall benefit to mother and child [18,20,21]. However, these guidelines do support thyroid function testing for women at increased risk for thyroid dysfunction, particularly hypothyroidism.

Laboratory findings

As mentioned, the healthy pregnant woman will have elevated laboratory values for TBG, T_4, and T_3, and decreased TSH values compared with nonpregnant individuals. T_4 and T_3 values may be increased up to 1.5-fold over nonpregnant women. Because of these considerable differences in thyroid physiology as the gestational period progresses, trimester- and method-specific reference intervals are suggested, most notably for TSH and FT_4 [21]. Additionally, direct measurements [isotope dilution–mass spectrometry following dialysis or ultrafiltration (UF), see "Laboratory measurements of thyroid function" section] for FT_4 and FT_3 have been recommended in this population due to the abnormalities in binding protein concentrations observed during pregnancy [21,22]. In the absence of this specialized testing, clinical practice guidelines suggest free thyroxine index (FTI; see "Laboratory measurements of thyroid function" section), or total T_4 measurements may be more reliable than immunoassay methods for FT_4 during pregnancy [18,21]. However, this recommendation has been controversial, particularly within the laboratory community [23].

As in nonpregnant individuals, thyroid function during pregnancy is often first evaluated by measuring TSH, with abnormal values further investigated by measuring FT_4 (or comparable measurement). Gestational thyrotoxicosis will result in increased production of T_4 (and rarely,

T_3) and, therefore, low or undetectable TSH. TRAb testing may help distinguish between autoimmune and gestational causes of hyperthyroidism. Hypothyroidism is diagnosed with increased TSH and decreased FT_4 concentrations; however, in all cases, care should be taken to use trimester- and method-specific reference intervals.

Thyroid cancer

Thyroid cancer is the most common cancer of the endocrine system. While the incidence of thyroid cancer has risen by an average of 3.1% annually over the past 10 years, the 5-year survival rate has increased to over 98% [24]. This is likely attributed to an increase in imaging use, which has prompted earlier diagnoses and improved prognoses.

As mentioned earlier, thyroid nodules are an abnormal growth of radiologically distinct cells within the thyroid tissue that are found frequently in the general population and are commonly benign. However, 7%−15% of thyroid nodules are malignant, which dictates the clinical importance of their identification [11,12]. Papillary thyroid carcinoma (PTC) and follicular thyroid carcinoma (FTC) are the two most common types of thyroid cancer. These are differentiated thyroid cancers (DTCs) that derive from malignant follicular cells and together make up 70%−80% and 10%−15% of all thyroid cancers, respectively. Notably, PTC is the most common and least aggressive thyroid malignancy and makes up the majority of new thyroid cancer diagnoses. Medullary thyroid carcinoma (MTC) is responsible for approximately 2% of thyroid cancers and originates from malignancy of the C cells. These are less differentiated and generally more aggressive cancers. Anaplastic thyroid carcinoma is considered the most aggressive undifferentiated thyroid cancer of follicular cells and contributes to less than 1% of all thyroid cancers. The next section will focus on laboratory testing associated with PTC, FTC, and MTC.

Laboratory findings

Suspected thyroid nodules are initially investigated by ultrasound and for functionality (ability to produce thyroid hormone) by measuring TSH concentrations. Low TSH values indicate excess thyroid hormone and are followed up with RAIU testing. "Hot" nodules take up radioactive iodine and indicate hyperfunctioning nodules, which are rarely malignant. Patients with "cold," or nonfunctioning, nodules or elevated TSH values are further investigated by FNA and/or ultrasound.

PTC and FTC are of follicular origin; therefore serum Tg measurement may be useful in the context of thyroid cancer. Of note, current ATA guidelines do not recommend routine measurement (or screening) of serum Tg for the initial evaluation of thyroid nodules [11]. This is based on the finding that serum Tg may be elevated in several other thyroid conditions and lacks both sensitivity and specificity for diagnosis of thyroid cancer. Similarly, routine preoperative measurements of serum Tg or TgAb are not recommended in thyroid cancer patients. However, postoperative serum Tg, for example, measured several weeks after thyroidectomy and prior to radioiodine remnant ablation, can help guide risk stratification and clinical management decisions. Elevated postoperative serum Tg concentrations have been associated with increased risk of DTC recurrence and decreased survival. The risk of persistent disease increases with elevated or progressively higher postoperative Tg concentrations. Serum TgAb measurements should accompany all Tg measurements, due to possible interference (see "Laboratory measurements of thyroid function" section). Rising trends in serial TgAb values have also been suggested as an indicator of disease recurrence and possible surrogate marker for DTC [11,25].

As described earlier, in MTC, the malignancy originates in the C cells, which are largely responsible for secretion of calcitonin. Calcitonin is therefore used as a tumor marker of MTC; however, it may also be elevated in conditions not related to thyroid neoplasms. Current guidelines therefore do not specifically recommend routine measurement of serum calcitonin in patients with thyroid nodules [11]. However, in specific cases where thyroid nodule evaluations via FNA biopsies are inconclusive or suggestive of MTC, calcitonin measurements may be useful to guide diagnosis or treatment approach [26]. Postoperatively, serum calcitonin evaluation may be used to help detect residual disease or recurrence of MTC. Elevated calcitonin after surgery for MTC has been associated with a worse prognosis. Although not a specific marker of the disease, carcinoembryonic antigen (CEA) measurements have also been described for monitoring disease progression in MTC patients postthyroidectomy. However, it is not recommended for use in diagnosis [26]. Calcitonin and CEA measurements should be monitored for doubling times postthyroidectomy, as these rates have been associated with MTC progression [26].

It is worth noting that beyond the circulating thyroid-related biomarkers described (e.g., Tg, TgAb, calcitonin, and CEA), several molecular targets have been identified in different thyroid cancer types. For instance, BRAF gene mutations and RET/PTC (PTC1 or PTC3) gene rearrangements have both been observed in PTC patients. On the other hand, RAS point mutations and PAX8-PPARγ rearrangements have been implicated in FTC, and point mutations of RET have been associated with MTC. Testing panels encompassing these cancer-associated mutations may be performed on FNA samples or excised tissue. Specific molecular profiles, or combinations of

oncogenic mutations, have been associated with worse PTC outcomes [11]. In general, molecular markers are most useful when FNA cytological results are indeterminate. While genetic counseling and testing for MTC should be considered in very specific clinical scenarios, for example, patients with first-degree relatives diagnosed with hereditary MTC, it currently remains unclear whether the use of single or multiple molecular markers is beneficial for managing patients with thyroid nodules in routine clinical practice [11,26]. Several methods are available for detecting the aforementioned alterations in these molecular targets, including IHC, FISH, RT-PCR, and sequencing. The methods available will depend on the mutation of interest, and are described in more detail elsewhere in this text.

Laboratory measurements of thyroid function

Overview

The signs and symptoms of thyroid conditions are generally nonspecific. As such, in addition to medical history and physical examination, laboratory tests for thyroid functions are an important component in diagnosis of the underlying condition. Laboratory assessment of thyroid function typically involves measuring analytes, such as TSH, FT_4, and/or T_3, in the serum or plasma. Accurate measurement is essential and requires adequate sensitivity to detect low concentrations of thyroid hormones. Sufficient analytical specificity is also required to differentiate between structurally similar hormones.

Although published several years ago, many recommendations regarding thyroid testing originated with the Laboratory Medicine Practice Guidelines published by the National Academy of Clinical Biochemistry (NACB, now known as the AACC Academy) [27], which is referenced by many current clinical practice guidelines [9,18,21], including those by the ATA and the American Association of Clinical Endocrinologists (AACE). A commonly followed approach for testing thyroid abnormalities is to start with TSH measurement (Fig. 40.7). The ATA/AACE describe serum TSH as "the single best screening test for primary thyroid dysfunction for the vast majority of outpatient clinical situations" [9]. Recall the inverse log-linear relationship between TSH and FT_4 (see Fig. 40.5). This describes the increased sensitivity of TSH to thyroid hormone changes and its ability to detect abnormalities before FT_4 measurements will. If an individual's TSH measurement is within the defined reference intervals and they are asymptomatic, the patient is considered euthyroid. Due to the diagnostic value of TSH and improved assay measuring ranges accommodating most hyperthyroid and hypothyroid disease states, testing beyond a euthyroid TSH value is most often not required. Values outside of the traditional reference intervals warrant additional testing, usually of FT_4, to investigate hypothyroidism or hyperthyroidism and determine primary versus secondary causes. Testing beyond these points in the algorithm is indicated only in rare situations and is often unnecessary. Proper laboratory test utilization efforts have encouraged the use of testing algorithms, such as this, in an effort to minimize unneeded testing.

Despite reported traceability to reference methods, preparations, or standards, many immunoassays for total and free thyroid hormones and TSH still do not provide comparable results. TSH standardization, in particular, is complicated by its heterogeneity; circulating TSH is a mixture of different glycoforms and therefore not easily standardized against a singular preparation. The International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) formed the Working Group for Standardization of Thyroid Function Tests (WG-STFTs) to address this concern. They have proposed efforts to harmonize TSH and standardize FT_4 assays that are currently underway [28].

It should be noted that screening for thyroid disease in the general population remains controversial, as studies providing direct evidence of the benefits and harms of screening are lacking [9]. While not currently recommended in asymptomatic adults, ATA practice guidelines suggest screening in patients over the age of 60 and in the presence of other abnormal thyroid findings; however, supportive data are limited [9].

Thyroid-stimulating hormone (thyrotropin)

Overview and indications

The inverse log−linear relationship dictates that serum TSH concentrations are highly sensitive to changes in serum thyroid hormone concentrations (recalling a two-fold change in FT_4 leads to a 100-fold change in TSH) and thus often provide the first indication of disease. Modern TSH assays also have improved sensitivity that allows for detection of values expected in both hyperthyroid and hypothyroid states. These two factors have contributed to the current clinical practice guidelines for both hyperthyroidism and hypothyroidism, concluding that serum TSH measurement is the single best screening tool for primary thyroid dysfunction in the majority of outpatient scenarios [9,10]. Measurement of thyroid function in the critically ill and hospitalized populations should still be limited to highly suspect cases.

Methods

Clinical laboratories utilize immunoassays for measuring serum TSH. As noted earlier in this chapter, TSH consists of two subunits: an alpha subunit, which is identical to those found in LH, FSH, and hCG, and an unique beta subunit. Immunoassays for TSH must therefore avoid potential cross-reactivity with LH, FSH, and hCG. TSH concentration is expressed in milli-international units of activity per liter of serum (mIU/L) largely due to historical origins. TSH was originally measured using in vivo and in vitro bioassays, involving animal thyroid tissue and cultured follicular cells. The minimum amount of TSH required to trigger a biological response was defined as the international unit and subsequently adopted as the unit of measure for TSH.

Current methods for measuring TSH concentrations generally employ a two-site "sandwich" heterogeneous immunometric technique. Briefly, these immunoassays involve two Abs—a "capture" Ab and a "signal" Ab. The combination of two Abs confers the specificity required to differentiate between TSH and analytes that share a similar alpha subunit. A variety of detection systems are available, including (electro)chemiluminescent, photometric, fluorescent, or enzymatic methods.

Considerations

Different "generations" of TSH immunoassays have evolved over many years. In short, TSH assays have customarily been classified into different generations based on the limit of quantitation (LOQ) (functional sensitivity; 20% between-run coefficient of variation) achieved. Each generation has exhibited a 10-fold improvement in sensitivity (e.g., 1.0 mIU/L for the first generation, 0.1 mIU/L for the second generation, and 0.01 mIU/L for the third generation assays). Some manufacturers have also claimed 0.001-mIU/L sensitivity for the newer, "fourth" generation assays. Current third generation assays surpass the minimum LOQ of 0.02 mIU/L proposed as the standard of care in the hospitalized setting [27]. It is thought that this level of sensitivity allows for the accurate diagnosis of primary hyperthyroidism (profound TSH suppression), as well as for the differentiation of hyperthyroid from subclinical patients and those with other NTI. Beyond sensitivity, TSH assays also require a sufficiently wide measurement range to accommodate the varied concentrations—up to five orders of magnitude difference—expected between hyperthyroid and hypothyroid conditions.

As with all immunoassays that will be described, potential assay interferences exist and should be considered when interpreting thyroid function tests (reviewed in [29], also see Chapter 12, Immunoassays). These include, but are not limited to, cross-reactivity with similar compounds, the presence of Abs to TSH, heterophile Ab interference with reagents, TSH molecular variants, and drug interferences.

Defining the upper reference limit for TSH is widely debated, with no true consensus. With improvements in TSH assay sensitivity and specificity and better defined reference populations, upper reference limits have declined steadily over time. Given the prevalence and asymptomatic nature of subclinical hypothyroidism, it is reasonable that a small percentage of hypothyroid individuals have been included in historic reference interval determinations. This would result in higher mean values for the upper limits than what would be expected in an entirely healthy population. Previous data suggest that 95% of healthy individuals, without subclinical thyroid disease or the presence of thyroid autoAbs, have TSH values of up to 2.5 mIU/L [27], while current ATA practice guidelines suggest an upper limit of 4.12 mIU/L based on data from the US NHANES III population [7,9]. The value used to define the upper TSH limit of a reference population will affect the number of people investigated for hypothyroidism; thus this remains an important point to be clarified. Currently proposed upper limits vary from 2.5 to 4.5 mIU/L, depending on the professional organization and the population studied [9].

Due to lack of harmonization between assays and differences in epitope recognition, it is recommended that assay- and laboratory-specific reference intervals are determined. Individuals with thyroid autoAbs or other indications of thyroid dysfunction should be omitted from reference populations.

Although most studies have revealed that mean TSH values increase in euthyroid individuals with each decade, with wider variability within age groups, age-specific reference intervals are not recommended within the adult population [7,27,30].

Total thyroxine

Overview and indications

The thyroid gland primarily secretes T_4, which is more protein bound and has a longer half-life than T_3 (Table 40.2). Subsequently, circulating T_4 concentrations are approximately 50−100 times those of total T_3. These higher concentrations, along with the tight regulation of T_4 production by TSH and the HPTA, have resulted in T_4's use as another marker of thyroid function. Total T_4 concentrations are not commonly measured, but may be indicated in the absence of protein-binding abnormalities or to investigate discordant FT_4 results.

Methods

The most common method used to measure total T_4 in the clinical laboratories is immunoassay. Given the structural similarities between T_4, T_3, and rT_3, the anti-T_4 Ab used in these assays must be highly specific for T_4. In addition, because the majority of T_4 in circulation is protein-bound, immunoassays for total T_4 often involve a dissociation step to remove T_4 from tightly binding proteins, such as TBG and TTR. This is commonly achieved using blocking agents, for example, 8-anilino-1-napthalene-sulfonic acid (ANS), and barbital can displace T_4 bound to TBG and TTR, respectively. After this displacement step, both unbound and FT_4 are available, thus allowing for the measurement of "total" T_4. Accurate and precise measurement of total T_4 is therefore dependent upon complete displacement of these T_4−protein complexes.

Unlike TSH assays, where the analyte of interest is a sufficiently large protein molecule compatible with the "sandwich" immunoassay format, T_4 is a considerably smaller molecule. As such, competitive immunoassays are commonly used to measure circulating T_4 concentrations, including chemiluminescent assays, enzyme multiplied immunoassay technique, and cloned enzyme donor immunoassay. The availability and use of pure T_4 standards for assay calibration has allowed for better interassay standardization than with other hormones, but challenges still exist.

Reference methods for total T_4 using isotope dilution−liquid chromatography−mass spectrometry have been described [31] along with other chromatographic methods, but these are not in routine use. As with immunoassay, these methods require liberation of T_4 from binding proteins, often with an acidification step.

Considerations

In clinical practice, total T_4 measurements have largely been replaced by FT_4 assays. Free hormone assays can provide more accurate measurements in cases of protein-binding abnormality, such as pregnancy, severe illness, or in the presence of drugs. In these situations, the total T_4 concentration may change, while the biologically relevant FT_4 remains the same. Historically, total T_4 concentrations have also been used in conjunction with TBG to approximate free hormone concentrations (see "Indirect measurement of free thyroxine: index methods" section).

Free thyroxine

Overview and indications

As described earlier, free or unbound hormone is considered the biologically active form and most directly correlates with the clinical status of the thyroid. As such, the human body puts great effort into maintaining a constant concentration of the free thyroid hormone fraction. This is evident by the fact that alterations in circulating hormone-binding protein concentrations can lead to changes in total T_4 without significant changes in thyroid function. This fact, along with the increasing availability and adoption of FT_4 assays in clinical laboratories, has resulted in FT_4, becoming the preferred test for thyroid diagnostics downstream of initial TSH testing.

Free hormone measurements may utilize one of two approaches: (1) "direct" measurements that physically separate free from protein-bound hormone; or (2) estimated ("indirect") measurements. Estimated measurements of free hormones include mathematical calculations ("index" methods) and immunoassays that approximate the free fraction from the total measurement.

"Direct" measurements have evolved as reference methods for free hormone measurements. Clinically, they are considered most useful in cases where FT_4 and TSH results are discordant with the clinical picture. They are also considered the best measure of free hormone in pregnant patients [21]. "Index" approaches have primarily become obsolete in light of the availability of alternative methods. However, it is still worthwhile to understand how the concentration of FT_4 can be estimated, and why current methods offer a more direct assessment of free thyroid hormone concentration.

Methods

Direct measurement of FT_4

In order to measure FT_4, two challenges need to be overcome: (1) measuring the concentration of FT_4 without disturbing the equilibrium between FT_4 and bound T_4 (most of the T_4 being in the latter state); and (2) obtaining adequate analytical sensitivity to accurately quantify the exceedingly low concentrations of circulating FT_4.

To overcome the first challenge, several approaches have been used, including equilibrium dialysis (ED) and UF. ED involves the separation of bound and FT_4 using a semipermeable membrane. In brief, unbound T_4 are able to freely cross the semipermeable membrane. After reestablishing equilibrium, the dialysate side of the membrane now contains the protein-free, unbound T_4, that is, FT_4. Similarly, in UF, bound ("large") and unbound ("small") hormones are separated by size through a semipermeable membrane during high-speed centrifugation. Following these separation procedures, FT_4 may be directly quantified in the dialysate or ultrafiltrate.

To overcome the second challenge—being able to accurately quantify low concentrations of circulating FT_4—methods including immunoassay and mass

spectrometry (MS) are often employed. Techniques involving further purification of dialysate have also been used. The dialysate is subjected to further extraction methods, such as solid-phase or liquid-phase extractions, to isolate the FT_4 prior to downstream analysis by liquid chromatography–tandem mass spectrometry (LC–MS/MS) [32]. This preprocessing step can further enhance the sensitivity of the analysis, allowing more accurate determination of FT_4 concentration.

Considerations

When direct LC–MS/MS methods for FT_4 have been compared with TSH concentrations, the expected inverse log–linear relationship is evident, with no correlation to TBG or albumin concentrations [33]. In contrast, studies using indirect FT_4 immunoassay measurements show strong correlations with TBG and albumin, and the inverse TSH relationship is absent, suggesting inadequacy of the measurement. While direct measurement of free hormones is considered a superior assessment in the clinical scenarios described, these methods do have limitations. While UF may be a faster procedure compared with ED, it is prone to the effects of temperature changes and absorption of analyte onto the membrane. Both of these can affect the reproducibility of free thyroid hormone recovery. In contrast, ED is susceptible to factors, such as dilution by the dialysis buffer, changes in the dialysis buffer composition, and binding inhibitors included in the dialysis. Nevertheless, both of these methods used in combination with downstream LC–MS/MS analysis have reported comparable results, and ED with isotope dilution–liquid chromatography–tandem mass spectrometry (ID–LC–MS/MS) is the reference procedure proposed by the IFCC WG-STFT for FT_4 [34]. ED with ID–LC–MS/MS is also the recommended measurement for FT_4 in pregnant women [21]. Currently, direct measurements of FT_4 (as well as FT_3) via ED or UF filtration are performed only in specialty laboratories and not routinely available.

Indirect measurement of free thyroxine: index methods

The phrase "index method" refers to a group of calculations that mathematically estimate free hormone concentrations from total hormone and binding protein measurements. Overall, these calculations "normalize" the total hormone concentration with respect to the amount of thyroid hormone-binding protein, primarily TBG. There are several tests that belong to this group (some with multiple names), including T_3 (or T_4)-uptake [T_3U, also referred to as T_3-resin uptake, thyroxine-binding capacity, or simply T-uptake], thyroid hormone-binding ratio, thyroid hormone/TBG ratio, FTI, and T7. Due to their limited use, this chapter will simply highlight two of these tests: T-uptake and FTI.

The T-uptake test approximates the T_4-binding capacity of TBG by determining the number of available T_4-binding sites. Excess labeled T_4 (or, historically, isotopically labeled T_3) is added to saturate any unoccupied binding sites on TBG. It is presumed that the more unoccupied binding sites that are available to bind this labeled hormone, the less T4 hormone that was present in the initial sample. Results are often reported as a percent of the values obtained from a euthyroid population. The T-uptake result alone does not provide much clinical utility; rather, it is more often used as a component of the FTI calculation. FTI is a mathematical approximation of the FT_4 concentration, which is considered a more reliable indicator of thyroid function than total T_4 when alterations in protein-binding concentrations are present. FTI is calculated by multiplying the total T_4 concentration by T-uptake.

By taking the concentration of thyroid hormone-binding proteins into account, this helps compensate for abnormal binding protein concentrations that might be present in patients due to various factors (see Table 40.4). Despite the utility of FTI, alternative methods have been developed to allow direct measurement of FT_4. Currently, direct FT_4 or immunoassay measurements are considered preferable test alternatives to FTI in most clinical situations.

Indirect measurement of free thyroxine: immunoassay

Indirect measurement of FT_4 does not require physical isolation of the unbound hormone fraction prior to analysis. As such, it is the method of choice for automated immunoassay analyzers. Two general approaches have been described: simultaneous one-step and sequential two-step methods. Both methods utilize similar principles; however, the latter is more widely used by automated analyzers.

The "one-step" method is essentially a competitive heterogeneous immunoassay. Briefly, labeled or signal-generating hormone analogs of T_4 (e.g., chemically modified T_4) and anti-T_4 Abs are added to the patient specimen. The FT_4 analog design prohibits binding to serum proteins, but it competes with FT_4 in the patient's specimen for binding sites on the anti-T_4 Abs. These Abs are generally immobilized on a solid support or conjugated to paramagnetic particles to allow capture and separation of the Ab–ligand complex.

By allowing a new equilibrium to be established after the addition of the hormone analog, signal generated by the labeled FT_4 analogs will be inversely proportional to the endogenous FT_4 concentration. In other words, the less endogenous FT_4 that is present in the patient specimen, the more labeled T_4 analog that is able to bind to

the anti-T_4 Abs; upon removal of the Ab−ligand complexes, less signal will be detected.

In the two-step method, the FT_4 in the patient's specimen is first allowed to equilibrate between the endogenous thyroid hormone-binding proteins and the anti-T_4 Abs, which are typically immobilized. After removing the unbound serum, labeled or signal generating T_4 is added, which will bind to the remaining unoccupied sites on the immobilized anti-T_4 Abs. This is followed by a wash step to remove the unbound labeled T_4 before the signal (from the labeled Ab bound to immobilized Ab) is quantified; that is, the more endogenous FT_4 that is present, the less unoccupied binding sites on the immobilized Ab for the labeled T_4 to bind. Ultimately, the signal detected will be inversely proportional to the FT_4 concentration in the patient specimen.

Considerations

Practically, the use of immunoassay for FT_4 measurements can grow out of necessity and the lack of readily available MS-based methods. Indirect FT_4 methods are frequently employed, in part due to the ease of automation. Compared with indirect FT_4 estimates, direct FT_4 values have been shown to correlate better with log-TSH values in patients with abnormal or normal thyroid hormone−protein-binding levels. It has also been demonstrated that LC−MS/MS-based FT_4 measurements, considered the current gold standard, are less affected by albumin or TBG concentrations compared with immunoassay-based methods [33].

In the case of one- and two-step methods, the presence of anti-T_4 Abs could potentially disrupt the equilibrium between bound and unbound thyroid hormones. This, in turn, can affect the determination of the FT_4 concentration. It is therefore essential that only small amounts of total hormone are sequestered by these newly formed complexes (often less than 3% of the total hormone concentration). This amount exceeds the actual free hormone concentration, therefore causing an insignificant disruption of the equilibrium. This allows both methods to provide a fairly accurate approximation of the FT_4 concentration. Nonetheless, measurements using ED and UF followed by LC−MS/MS are still the preferred methods in situations where the patient may have significant changes in thyroid hormone-binding protein concentrations, for example, elevated TBG in pregnant women.

Total triiodothyronine and free triiodothyronine

Overview and indications

T_3 is more biologically active than T_4, but is secreted at lower concentration by the thyroid. Most of the circulating T_3 is generated at the peripheral tissue through conversion of T_4 into T_3. Relative to T_4, T_3 is less protein-bound in the circulation and thus has a shorter half-life (see Table 40.2).

Measurement of FT_3 or total T_3 is indicated only in rare situations. Total T_3 has been used to further investigate samples that have undergone the TSH reflex outlined earlier (i.e., suppressed TSH and FT_4 within reference limits) to distinguish between patients with suspected subclinical hyperthyroidism and T_3 toxicosis. Rarely, T_3 measurements may provide additional clinical information in cases with abnormal T_4 to T_3 conversion at the peripheral tissue, such as in the case of deiodinase enzyme mutation or NTI. Neither total T_3 nor FT_3 is recommended in the evaluation of hypothyroidism, as it is frequently one of the last measures of thyroid function to be affected in this disease state [9].

Methods

Despite lower concentrations, the methods used to quantify total T_3 and FT_3 are analogous to those used for T_4 and FT_4. Immunoassays are available for determining the total and free concentrations of T_3 in the serum. Similar to the total T_4 assays, measurement of total T_3 also requires liberation of bound-T_3 (e.g., via acidification by ANS) before using T_3-specific Ab to determine the total (free + unbound) T_3 concentration. Likewise, the direct measurement of FT_3 can also be accomplished using ED or UF followed by analytical methods, such as immunoassay or MS. The same indirect methods for estimating FT_4 concentrations may also be used to determine FT_3 concentrations.

Considerations

While indications for measurement are rare, when needed, the decision to use total T_3 or FT_3 measurements is often based on preference and assay availability [10]. Many clinicians default to total T_3 measurements, which predated the availability and validation of FT_3 assays. There is currently no guideline universally dictating the use of FT_3 versus total T_3.

Although the methods used to measure T_3 and FT_3 are similar to those used for T_4 and FT_4, T_3 immunoassays tend to have worse interassay precision. This is thought to be attributed to, at least in part, the fact that serum concentrations of total T_3 are 50−100 times lower than those of T_4.

Reverse triiodothyronine

rT_3 is a metabolically inactive form of T_3 generated from T_4 at the peripheral tissue. Its half-life is even shorter

than that of T_3 (hours instead of days), and its concentrations usually follow those of FT_4. The utility of rT_3 assays is limited; it may help support the diagnosis of NTI but often is not necessary. It has also been proposed that the T_3/rT_3 ratio may be a useful prognostic indicator in patients with NTI. In these patients, the TSH may be normal or high-normal, while the total T_3 and T_3/rT_3 ratio are both low. Although not commonly indicated, both radioimmunoassays and LC−MS/MS assays are available for rT_3 measurement, often in specialty laboratories. LC−MS/MS assays allow the simultaneous quantification of rT_3 and total T_3. At present, the use of rT_3 remains controversial [5].

Thyroxine-binding globulin

In cases where thyroid hormone measurements do not align with the clinical picture, or in patients with abnormal total but normal free thyroid hormone concentrations, further investigation into hormone-binding proteins may be warranted. TBG measurements may aid in determining excess (e.g., during pregnancy) or deficiency (e.g., inherited TBG deficiency), which may affect overall hormone measurements. Historically, TBG along with total T_4 provided an assessment of free hormone concentrations; however, this has been largely replaced with modern FT_4 assays. Currently, immunoassays are the most common methods used to measure TBG concentrations. These assays may be competitive or noncompetitive (i.e., "sandwich"), homogenous or heterogeneous. A variety of detection methods may also be used in these assays, for example, fluorescence, chemiluminescence, or turbidimetry. Overall, TBG measurements are not common and not recommended for routine thyroid screening.

Thyroglobulin

Tg is a particularly important marker in the monitoring of thyroid cancer patients (specifically papillary and follicular cancers). As Tg is produced solely by the thyroid, it is a highly specific marker for this tissue. Tg concentrations become undetectable postthyroid ablation therapy or thyroidectomy. Serial monitoring is then initiated, with increased serum Tg concentrations suggestive of cancer recurrence.

Both competitive and noncompetitive immunoassays are commonly used to measure serum Tg. However, the presence of TgAb can interfere with traditional Tg measurements and underestimate its concentration. Given that TgAb has been reported to be detectable in up to 10% of the general population and as high as 25%−30% of thyroid cancer patients [8], measurement of Tg with automated immunometric assays can be problematic in these patients. Considerable variation is observed among these assays.

Historically, radioimmunoassay has been used to provide a more specific measurement of Tg in these situations [35]. More recently, LC−MS/MS-based methods have been developed to circumvent this interference. Often, enzymatic digestion is used to disrupt Tg and TgAb, if they are present. An Ab is then used to capture peptide fragments that are specific to Tg, and these fragments are then analyzed using LC−MS/MS. By determining the relative amount of endogenous Tg-specific peptides and internal standards, absolute quantification of Tg in the patient sample, even in the presence of TgAb, may be achieved [36,37]. Further studies are needed to fully evaluate the use of this newer technology in the TgAb-positive population.

Due to the possibility for interference in immunoassay techniques, NACB and the ATA have both encouraged that patient samples be tested for TgAb whenever serum Tg is measured. With the advent of LC−MS/MS assays that are not susceptible to TgAb interference, some clinical laboratories have adopted a testing algorithm that is initiated with TgAb testing. If TgAb are present, Tg testing will be appropriately reflexed to an LC−MS/MS method. In contrast, if TgAb testing is negative, automated immunoassays will be used to measure Tg. This testing strategy has been shown to encourage proper test utilization and considerable cost savings, given that the immunoassay performance is comparable with LC−MS/MS in the absence of TgAb [38].

Thyroid autoantibodies

A variety of assays are available for the thyroid autoAbs described earlier in this chapter, including TPO Ab, TgAb, TRAb, and TSI. Some common examples of the methods used include ELISA and radioimmunoassay. Automated immunoassays for TPO Ab and TgAb are routinely available; however, considerable variation is observed between different assays, and care should be used when comparing results between platforms or methods.

As mentioned earlier, TSI and TBII may have overlapping specificities, and both may be present in an individual patient (see "Autoantibodies" section). TRAb assays detect the presence of all autoAbs that interact with the TSHR by measuring their ability to compete with labeled reagents for binding to the TSHR. Therefore these assays do not discriminate between stimulating or blocking activity of the Abs they detect. The second generation assays used labeled TSH to compete with TRAbs in patient sera for binding to a human recombinant TSHR. Instead of TSH, the newer third generation assays substitute a labeled human thyroid-stimulating monoclonal Ab (M22

clone) to compete with patient TRAbs [39]. Naturally, if TRAbs are present, binding of the labeled M22 will be blocked. Therefore modern TRAb assays are often referred to as TBII assays, although it should be noted again that this method does not distinguish between stimulating and blocking autoAb functionalities. These competitive assays are automated and routinely available.

Bioassays have also been used historically for the measurement of thyroid autoAbs, and still are in the case of TSI. In these assays, cell lines have been modified to express a form of the human TSHR. If the receptor is stimulated by the presence of TRAbs in the patient sample, a signaling cascade is initiated within the cell that has a measureable end product (e.g., increased intracellular cAMP). Assay design features, including TSHR makeup and cell lines used, vary by manufacturer or laboratory. Depending on the assay used, the measured response (e.g., cAMP production) is due to stimulation of the TSHR by either TSI alone or the net effect of all TSHR autoAbs. Therefore these TSHR bioassays are a functional measure of TSI activity. By comparing the activity measured in the patient sample with a reference sample (e.g., pooled human serum), the presence of TSI can be expressed as a percentage of basal activity. A high percentage beyond the diagnostic threshold would indicate a positive TSI result. Not surprisingly, these laborious assays are available only in specialty laboratories. Recently, an automated immunoassay specific for TSI has also become available.

Chapter 41

Disorders of the adrenal cortex and medulla

David N. Alter

Department of Pathology and Laboratory Medicine, Emory University School of Medicine, Atlanta, GA, United States

Learning objectives

After reviewing this chapter, the reader will be able to:

- Explain the regulation and actions of aldosterone, cortisol, adrenal androgens, and catecholamines.
- Diagnose conditions involving excesses of aldosterone, cortisol, adrenal androgens, or catecholamines.
- Diagnose conditions involving deficiencies of aldosterone and/or cortisol.

Introduction

The adrenal glands influence several different organ systems. They are located suprarenally, weigh about 4–6 g each, and are structurally and functionally split into cortical (cortex/outer) and medullary (inner) layers. Embryologically, the adrenal cortex arises from the mesoderm and shares biochemical pathways associated with the urogenital system. Similarly, the adrenal medulla is of neuroectodermal (e.g., neural crest) origin and shares biochemical pathways similar to the nervous system. Products of the adrenal cortex consist of mineralocorticoids (aldosterone), glucocorticoids (cortisol), and adrenal androgens [dehydroepiandrosterone (DHEA) and androstenedione]. The adrenal medulla is responsible for catecholamine (e.g., epinephrine) production. Adrenal cortex and medullary hormones and their regulation are listed in Table 41.1.

Similar to other endocrine gland dysfunction, disease can present as adrenal hypofunction, hyperfunction, or a combination of both [e.g., congenital adrenal hyperplasia (CAH)]. Endocrine tumors may present with or without functional changes.

In most situations, biochemical evaluation for endocrine disorders should not be performed unless the history and clinical presentation are compatible with the suspected disorder.

Adrenal cortex

The adrenal cortex is composed of three layers; each responsible for production of specific physiologic steroids, respectively (from outer to inner): zona glomerulosa [mineralocorticoids (aldosterone)], zona fasciculata [glucocorticoids (cortisol) with small amounts of androgens], and zona reticularis (androgens DHEA and androstenedione; see Fig. 41.1 and Table 41.2).

TABLE 41.1 Adrenal gland.

Adrenal layer	Primary hormone(s)	Regulation
Cortex		
Zona glomerulosa	Aldosterone Deoxycorticosterone	Renin–angiotensin–aldosterone system
Zona fasciculata	Cortisol	Hypothalamic–pituitary–adrenal axis
Zona reticularis	Dehydroepiandrosterone Androstenedione	
Medulla	Epinephrine	Sympathomimetic nervous system

Mineralocorticoids

Aldosterone is the primary mineralocorticoid and its secretion/inhibition is associated with sodium concentrations as well as blood pressure/renal perfusion. Aldosterone increases sodium concentrations via the stimulation of sodium reabsorption channels with its secretion controlled through the renin−angiotensin−aldosterone system (RAAS): an interplay of baroreceptors located in the glomerular afferent arterioles working in conjunction with sodium chemoreceptors located in the macula densa of the juxtaglomerular (JG) apparatus. The RAAS is a dynamic process that mediates renin secretion from the JG cells dependent on volume and sodium concentration. In low volume/sodium (physiologic and pathophysiologic) states, basal renin secretion increases leading to increased renin cleavage (as well as all the subsequent steps) of angiotensinogen (485 aa) into angiotensin I (10 aa), which is then converted into angiotensin II (8 aa) via angiotensin-converting enzyme (ACE; located in the lungs). Finally, increased production of Angiotensin II, in turn, stimulates an increase in aldosterone synthesis and release. Aldosterone stimulates sodium reabsorption at the proximal convoluted tubule and vasoconstriction along with increased thirst, increased antidiuretic hormone (ADH) release, and catecholamine release (Fig. 41.2). Ultimately, as described, the RAAS promotes water retention and increases blood volume, with subsequent maintenance of blood pressure. Unsurprisingly, aldosterone excess disorders result in hypertension. In addition, deoxycorticosterone (DOC), an intermediate in the aldosterone synthesis pathway, also possesses systemic mineralocorticoid activity, and in scenarios to be described, DOC excesses will also be presented as hypertension.

Disorders of mineralocorticoid excess

Refractory and/or unexplained hypertension is the underlying clinical feature associated with mineralocorticoid

TABLE 41.2 Mineralocorticoid excess disorders.

Increased aldosterone	*Primary (hyporeninemic)*
	Bilateral IAH (60%–65%)
	Aldosterone-producing adrenal adenoma[APA "aldosteronoma" unilateral (30%–35%)];
	Adrenal hyperplasia (2%)
	Aldosterone producing adrenocortical carcinoma (<1%)
	Familial hyperaldosteronism
	FH Type I GRH <1%
	FH Type II APA or IAH linked to chromosome 7p12 <6%
	FH Type III KCNJ5 massive adrenal hyperplasia of childhood <1%
	Secondary (hyperreninemic)
	Renin-secreting tumors
	Renovascular hypertension
	Compensatory (nephrosis, cirrhosis, and congestive heart failure)
	Renal tubular disorders (e.g., Bartter and Gitelman syndrome)
Normal/low aldosterone	*Hyperdeoxycorticosterone*
	DOC-secreting adrenal adenoma
	11 beta-hydroxylase (CYP11B1) deficiency
	17-hydroxylase (CYP17) deficiency
Glucocorticoid excess	Cushing syndrome
	Cortisol resistance
End-organ defects	Apparent mineralocorticoid excess: HSD11B2 deficiency or glycyrrhizic acid-induced inhibition
	Liddle syndrome (type 1 pseudohyperaldosteronism)

APA, Aldosterone producing adenoma; *DOC*, deoxycorticosterone; *GRH*, glucocorticoid remediable hyperaldosteronism; *HSD11B2*, hydroxysteroid dehydrogenase-11-beta; *IAH*, idiopathic adrenal hyperplasia.

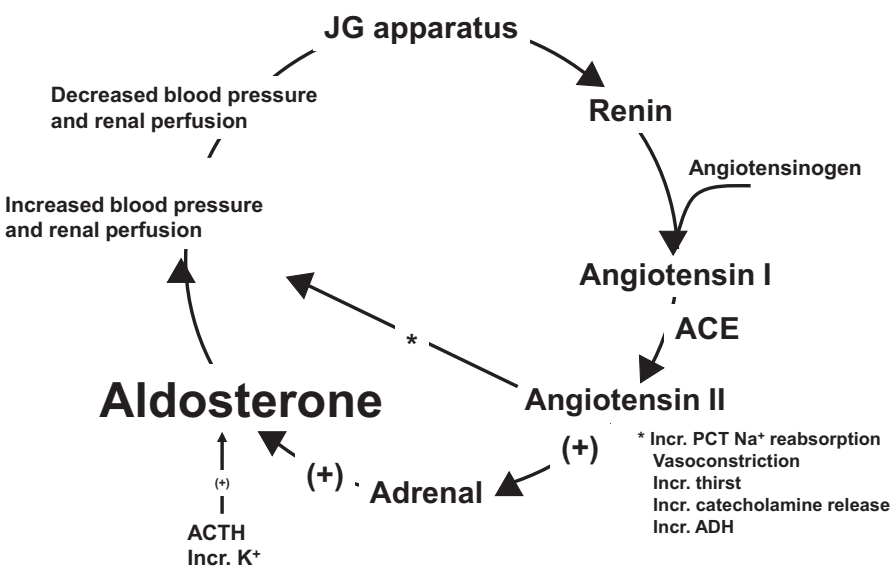

FIGURE 41.2 Aldosterone regulation.

excess or related disorders (Table 41.2). Most are due to aldosterone elevations; however, excess DOC [secondary to 17-alpha hydroxylase and 11-beta hydroxylase (11B-OH) deficiencies] may also be responsible as well as those referred to as apparent mineralocorticoid excess (AME) disorders.

AME disorders are associated with increased mineralocorticoid receptor (MR) activity in the absence of excess mineralocorticoid production. For example, in individuals with 11-beta-hydroxysteroid dehydrogenase (11B-HSD2) deficiency, cortisol is not converted into cortisone with the increased cortisol concentrations stimulating the MR, resulting in aldosterone-like activity. 11B-HSD2 deficiency presents similar to hyperaldosteronism [hypertension, hypokalemia, metabolic alkalosis, and low plasma renin activity (PRA)] but does not have the associated mineralocorticoid elevations. A very rare cause of AME is Liddle's syndrome, an autosomal dominant upregulation of the epithelial sodium channel (ENaC). In this condition, sodium reabsorption occurs regardless of a low/blunted aldosterone response with patient presentation significant for young age of onset, excess sodium retention, and low/normal aldosterone levels. An AME-like disorder involves excess consumption of black licorice containing glycyrrhetinic acid. Lastly, pathologic cortisol elevations from other etiologies not AME (e.g., excess exogenous glucocorticoid intake, endogenous cortisol excess, and cortisol resistance) can also trigger excessive mineralocorticoid activity via activation of the MR.

Disorders of mineralocorticoid excess: laboratory testing

Aldosterone can be measured in plasma or in urine following a timed urine collection. Renin is measured as PRA or plasma renin concentration (PRC). Both assays measure PRA based on renin's ability to convert angiotensinogen into angiotensin I; however, PRA assays utilize endogenous (in vivo) angiotensinogen and PRC assays utilize exogenous (in vitro) angiotensinogen (provided with the assay). Consequently, PRC assays are subject to less variability of result, because a standardized angiotensinogen concentration is used. For the rest of this discussion, "PRA" will be used to represent both assay types. PRA has numerous preanalytic variables such as posture (increased with standing), time of day (diurnal variation), age (PRA decreases with age), dietary sodium (PRA decreases with sodium intake), and other medications (renin is increased if on a patient is on a diuretic). Due to the influence of extra laboratory variables on renin measurements, care must be taken with result reporting and interpretation. An aldosterone/PRA ratio $>20-25$ is considered consistent with primary hyperaldosteronism

Confirmation studies for primary hyperaldosteronism include the failure of aldosterone to be suppressed by one of the following volume expanders: fludrocortisone, oral sodium, or intravenous saline administration. Volume expansion normally suppresses aldosterone levels; therefore failure to suppress aldosterone indicates autonomous aldosterone production. Great care must be taken during saline infusion or oral salt loading as blood pressure may rise and (if preexisting moderate-to-severe hypertension present) can precipitate a hypertensive crisis or the development of pulmonary edema if there is a preexisting marginal cardiac function.

There is also the captopril suppression test, as captopril inhibits ACE; therefore captopril administration should inhibit aldosterone production. Failure to inhibit plasma aldosterone levels using this approach is also consistent with primary aldosteronism, but this test does not appear to carry the same risks as the previously mentioned suppression tests.

When primary hyperaldosteronism is confirmed, CT or MRI in conjunction with R/L adrenal and R/L peripheral vein samplings of aldosterone and cortisol is performed to distinguish bilateral [idiopathic adrenal hyperplasia (IAH)] from unilateral [aldosterone producing adenoma (APA)] disease. Right and left adrenal vein measurements of cortisol and aldosterone are used to confirm adrenal vein cannulation and to determine laterality (if any) of the aldosteronism. Aldosterone/cortisol ratios are calculated to correct for the dilutional effect of blood from the inferior phrenic vein flowing into the left adrenal vein. These measurements are interpreted thusly: unilateral aldosteronism (APA) if the aldosterone/cortisol ratio from side to side is $>4:1$; bilateral (IAH) if the ratio is $\leq 3:1$; and indeterminate if the results are between 3.1 and 3.9 [1–3].

Glucocorticoid remediable hyperaldosteronism (GRH) is suggested by early-onset hyperaldosteronism with a family history of similarly affected individuals in an autosomal dominant pattern. It occurs due to a crossing-over defect between the genes encoding aldosterone synthase and 11B-OH. Both genes are located near each on chromosome 8 such that they can fuse together forming an aldosterone synthase sensitive to adrenocorticotropic hormone (ACTH). The "chimeric" gene converts cortisol into 18-hydroxy and 18-oxometabolites with increased urinary tetrahydro-18-oxocortisol. Therefore in patients with GRH, the ratio of tetrahydro-18-oxocortisol to tetrahydroaldosterone is increased. In practice, reduction in blood pressure secondary to dexamethasone administration supports the diagnosis of GRH. AME is diagnosed by increased ratios of cortisol to cortisone and increased urinary tetrahydrocortisol to tetrahydrocortisone ratios [4].

Disorders of mineralocorticoid deficiency

Hypoaldosteronism biochemically presents as hyponatremia and hyperkalemia with hydrogen ion-retention causing acidosis. Clinically, salt-craving is associated with mineralocorticoid deficiency as a protective response. Aldosterone deficiency is commonly seen in the cases of primary adrenal insufficiency associated with a coexistent cortisol deficiency. Rarely, primary isolated aldosterone deficiency results from loss-of-function mutations in aldosterone synthase (CYP11B2). Renin deficiency is a rare condition, but can be seen in people with long-standing diabetic nephropathy. The syndrome of hyporeninemic hypoaldosteronism (SHH, type 4 distal renal tubular acidosis) occurs in late middle age, and is associated with diabetes and renal insufficiency secondary to tubulointerstitial disease. These patients are hyperkalemic with a hyperchloremic metabolic acidosis. Loss-of-function mutations in the MR cause pseudohypoaldosteronism, where aldosterone is present but there is resistance to its actions [5].

Disorders of mineralocorticoid deficiency: laboratory testing

Hyponatremia, hyperkalemia, acidosis, hypovolemia, hypotension, and possibly shock are the diagnostics for mineralocorticoid deficiency in the setting of suspected primary adrenal insufficiency [Addison disease, autoimmune polyglandular syndrome (APS), Waterhouse–Friderichsen syndrome, etc.]. Aldosterone can be measured in plasma in search of deficiency; however, the clinical findings in the appropriate clinical scenario are usually sufficient to make the diagnosis of mineralocorticoid insufficiency. An elevated PRA and a low aldosterone concentration support the diagnosis of mineralocorticoid deficiency. SHH is notable for its clinical presentation as well as low renin and aldosterone levels that are not responsive to stimulatory testing. Failure of aldosterone to rise in response to standing or furosemide indicates aldosterone insufficiency. Great care must be taken, because acute fluid loss from a furosemide-induced diuresis can precipitate acute hypovolemia and an Addisonian crisis. Although not a test of mineralocorticoid function, the finding of adrenal autoantibodies [either adrenal cytoplasmic autoantibodies detected by indirect immunofluorescence or 21-hydroxylase (21-OH) autoantibodies] identifies that a patient has autoimmune adrenalitis and will be at high risk of adrenal insufficiency due to Addison disease.

Glucocorticoids

Cortisol is the primary glucocorticoid secreted from the adrenal cortex and has numerous actions throughout multiple organs and organ systems with its synthesis and secretion regulated centrally by the hypothalamic–pituitary–adrenocortical–cortisolll axis. Glucocorticoid actions include elevated blood glucose, increased cardiac inotropism/vascular tone, and impaired monocyte/macrophage/CD4-T cell activity. Cortisol has a diurnal release with concentrations highest in the early morning and lowest near midnight; it is released in response to both physiologic and pathologic stimuli. Physiologically, stress situations such as infection, sleep deprivation, and caloric restriction can also trigger release. In contrast, nonpathologic/nonphysiologic stimuli can also affect cortisol release, for example, music (decrease), dancing (decrease), and caffeine intake (increase). Pathologic changes in cortisol release such as Cushing syndrome and adrenal insufficiency will be discussed below.

Under the regulation of neurotransmitters, the hypothalamus produces corticotropin-releasing hormone (CRH; 41 aa) delivered to the anterior pituitary via the hypothalamic–pituitary portal system. CRH binds to anterior pituitary corticotroph receptors, triggering the synthesis of proopiomelanocortin, which upon release is cleaved into ACTH (39 aa; corticotropin) as well as additional fragments that include alpha, beta, and gamma melanocyte stimulating hormones, beta-lipotropin, and beta-endorphins. ACTH release can also be caused by high concentrations of ADH and inflammatory cytokines such as IL-1, IL-6, and tumor necrosis factor-alpha. ACTH binds to receptors on cells of the zona fasciculata and reticularis resulting in increased cortisol production and release.

TABLE 41.3 Cushing syndrome.

Weakness (steroid myopathy especially affecting the proximal muscles)
Back pain (osteoporosis, fractures, and compressed vertebrae)
Bruisability (catabolism of connective tissue)
Psychiatric problems (emotional lability, depression, or psychosis)
Weight gain
Centripetal obesity
Moon facies
Buffalo hump
Supraclavicular fat pad
Plethora
Hypertrichosis
Hirsutism
Acne
Increased susceptibility to infection and hypertension

Disorders of glucocorticoid excess

Cushing syndrome refers to the signs, symptoms, and sequelae (Table 41.3) associated with hypercortisol states, whereas Cushing disease specifically indicates that the source of elevated cortisol is due to an ACTH-producing pituitary adenoma. Cushing syndrome is typically sorted into ACTH-dependent and ACTH-independent causes. ACTH-dependent causes are due to excess ACTH, whereas, ACTH-independent causes are not.

ACTH-dependent (Cushing disease, ectopic ACTH, and ectopic CRH):

- Cushing disease (68%) may occur as a consequence of an anterior pituitary corticotroph adenoma (corticotropinoma). Hyperpigmentation may be present when ACTH levels exceed 300 pg/mL. Additional possible sequelae include hypokalemic alkalotic hypertension, and low eosinophil count and varying degrees of elevated blood glucose concentrations.
- Ectopic ACTH syndrome (6%−15%) is typically seen as a component of certain tumor-related paraneoplastic syndromes, including small-cell lung cancers.
- Ectopic CRH syndrome is very rare and has been associated as a paraneoplastic syndrome of numerous malignancies (bronchial, thymic neuroendocrine, small-cell lung, medullary thyroid, pheochromocytoma, gangliocytoma, prostate carcinoma, and ganglioneuroblastoma).

ACTH-independent [adrenal Cushing syndrome, adrenal carcinoma, pseudo-Cushing, primary pigmented nodular adrenal disease (PPNAD), carney syndrome, McCune-Albright syndrome, and exogenous glucocorticoid administration]:

- Adrenal Cushing's syndrome (8%−19%) occurs when a cortisol-secreting adrenocortical adenoma is present where a single adrenal gland weighs between 25 and 40 g.
- Adrenal hyperplasia (2%) can manifest as bilateral adrenal hyperplasia, with maximum adrenal weights between 30 and 50 g. Bilateral adrenal hyperplasia can be micronodular (<3 mm) or macronodular (>3 mm). Macronodular adrenocortical disease is seen in older adults, whereas micronodular (PPNAD) typically presents as an inherited condition in children, for example, Carney complex. "Pigmented" in that the adrenal gland, in these cases, is studded with dark brown and black nodules.
- Adrenal carcinoma (6%−7%) is similar to its adenomatous cousin except that they typically weigh more than 100 g. Unfortunately, when discovered, they are already metastatic.
- "Pseudo-Cushing" syndrome occurs secondary to elevated cortisol levels from drugs, depression, or underlying illness.
- Exogenous glucocorticoid administration may very well account for most cases of Cushing syndrome because of its endemic use in a variety of medical conditions.

Disorders of glucocorticoid excess: laboratory testing

The diagnosis of Cushing syndrome should proceed stepwise from the clinical suspicion to confirmation of a hypercortisol state to the determination of etiology. Cortisol excess is identified using one of three screening tests: 24-hour urine-free cortisol (UFC) concentrations, the overnight low-dose dexamethasone suppression test (LDDST), or late night salivary cortisol measurements. Due to cortisol's diurnality, random levels are of little clinical value; however, a midnight value cortisol of <2 μg/dL essentially rules out Cushing syndrome with sensitivities in the low 90s and specificities approaching 100%. Some investigators would use a less restrictive cutoff of <5 μg/dL to rule out Cushing syndrome.

UFC (24-hour urine specimen) is an integrated measure of cortisol production and is usually two to three times above the upper limit of the reference interval in Cushing syndrome. Preanalytically, errors in collection (i.e., significantly longer or shorter than 24 hours) can erroneously alter the result. Simultaneous urine creatinine measurements are recommended to ensure completeness of collection with the expected concentrations as denoted (men: 14−26 mg per kg of body mass/24 hour; women: 11−20 mg per kg of body mass/24 hour). Elevated UFC levels have a 95%−100% sensitivity for the diagnosis of Cushing syndrome.

Salivary cortisol levels, like serum cortisol, reach a nadir in the late evening; however, unlike serum specimens, a salivary specimen can be collected at home and does not require refrigeration. Preanalytically, salivary specimens have their own issues. According to one reference laboratory, the sample should not be collected within 60 minutes of eating, no sooner than 12 hours after alcohol intake, and should not be collected immediately after brushing or flossing. An appropriate kit to collect saliva is required (e.g., patients should not simply spit and seal into a cup). Preanalytically, salivary cortisol measurements increase with age, diabetes, and blood pressure. Finally, LC-MS is recommended as the analytic modality, as cortisol immunoassays are subject to false-positive results due to cortisone (converted from cortisol into the salivary glands) cross reactivity. Diagnostically, data suggest that salivary cortisol testing can detect mild hypercortisolism missed by UFC and has reported sensitivities and specificities in the mid to high 90 seconds.

In the overnight LDDST, 1 mg of dexamethasone is taken orally between 2200 and midnight followed by a cortisol measurement the next morning between 0800 and 0900. A normal response would be less than 1.8 μg/dL confirming ACTH suppression, with elevated values indicating nonsuppression, that is, pathologic hypercortisolism. Some investigators use a less restrictive cutoff of <5 μg/dL to rule out Cushing syndrome. Elevated cortisol values (indicating nonsuppression) have a sensitivity approaching 100% for the diagnosis of Cushing syndrome. False-positive and false-negative LDDST results can occur to drug metabolism defects (induction/inhibition of CYP 3A4 system). False-positive results can also be seen in elevated cortisol-binding globulin states (e.g., pregnancy, estrogens, and tamoxifen), and liver disease can result in false-negative results. There is also a 48-hour version of the LDDST. In that test, there is a similar sensitivity, but its specificity approaches 100% (overnight LDDST; specificity approximately 88%). There is also a high-dose variation of the LDDST where 8 mg is administered. The extended LDDST and high-dose variations are used in cases where there are equivocal or unexpected LDDST results. The etiology of confirmed hypercortisolism can be defined using the low-dose–high-dose dexamethasone suppression test, which is described in the chapter discussing pituitary disorders (Table 41.4).

For patients with equivocal physical findings and none/mild biochemical changes, a combined dexamethasone–cortisol releasing hormone test has been proposed. Essentially, dexamethasone is administered every 6 hours for 48 hours followed by one CRH dose at 46 hours with cortisol then measured 5 minutes before, at administration, and 15 minutes afterward. Sensitivity and specificity in the high 90 seconds were reported. Its use has been suggested as a way to sort out pseudo-Cushing and Cushing syndromes. The insulin tolerance test has also been used to sort out Cushing syndrome from pseudo-Cushing states (Chapter 33: Evaluation of exocrine pancreatic function) for more information on insulin-tolerance testing.

In general, when evaluating possible hypercortisolism; if the initial screening test indicates hypercortisolism, confirmatory testing should be performed. If the second test is normal, a third screening test should be performed. If two out of three of the screening tests are abnormal, hypercortisolism is confirmed. The challenge then is to determine the etiology of the hypercortisolism.

After hypercortisolism is confirmed, ACTH testing and radiologic studies should be performed to determine its etiology and location (if necessary). Elevated versus depressed ACTH levels distinguish ACTH-dependent and ACTH-independent etiologies with equivocal results requiring a CRH stimulation test to assess pituitary response. Radiologic studies are key in detecting adrenal tumors or hyperplasia; however, hyperplasia can be seen in ACTH-dependent and ACTH-independent causes.

Bilateral inferior petrosal sinus with peripheral vein sampling (a unique combination of radiology and clinical chemistry) for ACTH with/without the CRH stimulation test can determine if the elevated ACTH is of pituitary or peripheral origin. If the elevation in ACTH concentrations is attributable to the pituitary gland, the ratio of pituitary to peripheral ACTH level is >3:1. In contrast, if the source of elevated ACTH is adrenal or ectopic, the ratio of pituitary to peripheral ACTH levels is <3:1. This test is highly sophisticated and requires interventional radiologists with the appropriate skill and experience to perform the test, because erroneous results will occur if the wrong region is cannulated. Additional complications associated with this sampling include increased blood loss, risk of infection, and sinus perforation. Simultaneous prolactin measurement of these specimens is recommended to confirm pituitary and nonpituitary localization.

As discussed, CRH, released by the hypothalamus, triggers pituitary ACTH release, which stimulates adrenal gland production of cortisol. The CRH stimulation test in combination with the LDDST can be used to sort out pseudo-Cushing from Cushing syndrome. In patients with pseudo-Cushing, serum cortisol would suppress to <1.4 μg/dL, where it would be higher in patients with Cushing syndrome. The CRH test, by itself, can also be used to sort out central versus ectopic ACTH etiologies. In the cases of Cushing disease, there will be elevations in plasma ACTH and cortisol, whereas, in the cases of ectopic ACTH, elevations in ACTH and cortisol levels will not occur. CRH used in conjunction with arginine, vasopressin, and desmopressin will exaggerate the ACTH response allowing for differentiation of central versus ectopic causes of ACTH [6–8].

Disorders of glucocorticoid deficiency (adrenal insufficiency)

Adrenal insufficiency [9] is due to adrenal, central, and exogenous causes. It is also characterized as primary (Addison disease), secondary, and, in some texts, tertiary. For this discussion, primary refers to disorders specific to the adrenal gland, secondary typically refers to pituitary (and in some sources) hypothalamic causes, and tertiary, when used, refers to adrenal insufficiency secondary to suppression from exogenous glucocorticoid use (as well as hypothalamic in other sources). Regardless of cause, adrenal insufficiency clinically presents as weakness, malaise, nausea, vomiting, diarrhea, dehydration, weight loss, hypoglycemia, hyponatremia, hyperkalemia, and acidosis resulting from a combination of coexistent aldosterone and cortisol deficiencies. Acute adrenal insufficiency

TABLE 41.4 Dexamethasone suppression test.

			Abnormal response (failure of suppression)	Sens	Spec
Low-dose DST					
Overnight, 1-mg test	Most common screen; DX of endogenous CS	Dexamethasone 1-mg orally 11 p.m.–12 a.m. Cortisol levels between 8and 9 a.m.	Cortisol 1.8 μg/dL (>50 nmol/L)	95%	86%
Two-day, 2-mg test		Dexamethasone 0.5 mg is administered orally every 6 h (9 a.m., 3 p.m., 9 p.m., and 3 a.m.) for two days (total dose 4 mg). Cortisol level 6 hours after last dose (9 a.m.)	Cortisol 1.8 μg/dL (>50 nmol/L)	97%–100%	>99%
High-dose DST					
Overnight, 8-mg test	Ectopic versus pituitary Overproduction of ACTH in Cushing disease (but not ectopic tumors) can undergo partial or full suppressed by high doses of dexamethasone	Overnight, 8-mg test Baseline a.m. morning cortisol Oral dexamethasone 8 mg between 11 p.m. and midnight Repeat serum cortisol is drawn the next morning (between 8 and 9 a.m.)		60%–100% if 50% suppression	60%–100% if 50% suppression
Two-day, 8-mg test		Day1 Baseline a.m. morning serum cortisol or 24-h urine-free cortisol is obtained Day 2 and 3, oral dexamethasone 2 mg every 6 h (9 a.m., 3 p.m., 9 p.m., and 3 a.m.) is given (total eight doses; 16 mg) with simultaneous collection of a urine sample for urine-free cortisol. Serum cortisol levels are checked 6 h after the last dose (9 a.m.)			
Dexamethasone-CRH test	Glucocorticoid suppression of the HPA axis can be overcome by CRH stimulation in Cushing disease and not in pseudo-Cushing syndrome	Dexamethasone 0.5 mg every 6 h (12 p.m., 6 p.m., 12 a.m., and 6 a.m.) is given orally for 48 h. Two hours after the last dose of dexamethasone, intravenous CRH 1 mcg/kg is administered (8 a.m.). Serum cortisol is drawn 15 min later		Cortisol > 1.4 μg/dL at 15 min CD 90–100 Cortisol > 3.8 μg/dL at 15 min CD 94	Cortisol > 1.4 μg/dL at 15 min CD 50–100 Cortisol > 3.8 μg/dL at 15 min CD 100

(major trauma, surgery, gastroenteritis, and hemorrhage) will present with severe symptoms such as obtundation, hypotension, and shock (Addisonian crisis). Without rapid and appropriate fluid restoration and glucocorticoid replacement, an Addisonian crisis can be fatal.

Historically, and in developing countries, adrenal insufficiency was/is due to infection (first reported secondary to tuberculosis). In developed countries, the most common cause of Addison disease is autoimmune destruction (adrenalitis). It can occur as an isolated condition or as part of an APS. In 90% of recent onset patients, autoantibodies to the 21-OH enzyme were identified and their presence carries a 48% risk of Addison's disease. The remainder of the reported cases of Addison disease is attributed to APS.

APS type I is defined by the presence of at least two out of three of the following findings: hypoparathyroidism, mucocutaneous candidiasis, and Addison disease or adrenal autoantibodies. Associated findings include primary ovarian failure, alopecia, vitiligo, ectodermal dysplasia (e.g., dental enamel hypoplasia and nail dystrophy), red cell aplasia, IgA deficiency, malabsorption, autoimmune hepatitis, progressive myopathy, and type 1 diabetes (T1DM). APS type I is also known as the autoimmune polyendocrinopathy, candidiasis, ectodermal dystrophy syndrome. Onset is usually in childhood with APS type I inherited as an autosomal recessive trait (not gender specific). At the molecular level, it is due to a loss-of-function mutation in the autoimmune regulator (*AIRE*) gene I. AIRE has a role in the expression of self-antigens in the thymus necessary for the development of tolerance to self.

APS type II is identified by the presence of Addison disease or adrenal autoantibodies and either autoimmune thyroid disease (AITD), T1DM, or both T1DM and AITD. In contrast to APS type I, type II disease is inherited in a polygenic fashion and is more common in women than in men with onset later than APS type I. Associated findings include primary ovarian failure, pernicious anemia, hypophysitis, autoimmune hepatitis, vitiligo, alopecia, dermatitis herpetiformis, IgA deficiency, celiac disease, immune thrombocytopenic purpura, myasthenia gravis, stiff person syndrome, and Parkinson disease.

Following autoimmunity, the next most common cause of Addison disease is infections such as tuberculosis, HIV, cytomegalovirus, herpes simplex, syphilis, fungal infections [e.g., blastomycosis (North and South American), *Histoplasma capsulatum*, cryptococcosis, sporotrichosis, and coccidiomycosis], or sarcoidosis. Other causes of Addison disease include adrenoleukodystrophy, CAH, Wolman disease, Smith–Lemli–Opitz syndrome, and adrenal infiltrative diseases, for example, amyloidosis, hemochromatosis, or cancer.

Congenital adrenal hyperplasia

CAH is a number of autosomal recessive disorders characterized by defective genes coding for numerous enzymes in the adrenal corticosteroid biosynthetic pathway. Fig. 41.3 details all of the inborn errors associated with adrenal steroid biosynthesis with those associated with CAH denoted.

21-OH (CYP21A2) deficiency is the most common type of CAH. This enzymatic deficiency occurs in 1 out of 15,000 births and represents up to 95% of all CAH cases. 21-OH is responsible for the conversion of 17-hydroxyprogesterone (17-OHP) into 11-deoxycortisol. Enzyme deficiency will result in elevated levels of 17-OHP and decreases in 11-deoxycortisol concentrations; 75% patients clinically present with mineralocorticoid deficiency. The disorder is categorized into three categories: classic salt wasting, simple virilizing, and nonclassic.

Classic salt-wasting 21-OH deficiency presents at birth or soon after, and can be fatal depending on degree of salt wasting. Females with the disorder display genital ambiguity (i.e., virilization of the external genitalia). Individuals deficient with 21-OH clinically present with hyponatremia, hyperkalemia, and failure to thrive.

Simple virilizing 21-OH deficiency causes virilization of the female fetus and may not be noticed initially in males. Males can show early (2–4 years) virilization and precocious puberty. Nonclassic 21-OH deficiency presents later in life with females showing virilizing features [10,11]. Diagnosis for both classic and nonclassic types depends on clinical presentation (genital ambiguity, salt wasting, and hypotension) and can be confirmed with elevated 17-OHP levels. However, classic 21-OH deficiency will have markedly elevated 17-OHP (>1200 ng/dL with most neonates >3500 ng/dL) levels; whereas, nonclassic not so much. Nonclassic 21-OH deficiency in children is associated with elevated early morning (>200 ng/dL) 17-OHP levels ($>95\%$ sensitivity and specificity). For adults, a 17-OHP value >200 ng/dL strongly suggests the disorder with an exaggerated response (>1500 ng/dL) post-ACTH stimulation considered confirmatory.

Prior to the development of newborn screening programs to detect CAH, more girls than boys were diagnosed with CAH. With current screening programs that measure 17-OHP in dried blood spots, the number of boys and girls diagnosed with CAH is equivalent. 11B-OH deficiency accounts for about 7% of cases of CAH with features similar to the simple virilizing form of 21-OH deficiency. Clinically, it has been associated with excess DOC activity showing hypernatremia, hypokalemia, and hypertension. In addition, rare etiologies of CAH are discussed in the section on androgen disorders.

Disorders of glucocorticoid deficiency (adrenal insufficiency): laboratory testing

When adrenal insufficiency is clinically suspected, the ability of the adrenal gland to secrete cortisol is evaluated by the ACTH (cosyntropin and short synacthen) stimulation test. This test can be performed at any time of the day and involves administration of ACTH after a baseline cortisol level, followed by levels at 30 and 60 minutes. A normal response would be a rise in cortisol greater than 20 μg/dL [9]. Failure to mount an adequate cortisol response indicates primary adrenal insufficiency. ACTH levels should also be measured (prior to stimulation test) to determine whether the defect is at the level of adrenal gland (will be elevated) or "higher" (if due to pituitary disorder, ACTH will be depressed). Additional tests include adrenal autoantibody testing and imaging to determine if there is anatomic disease.

The diagnosis of Addison disease in the ICU setting is controversial yet failure to treat true Addison disease can be fatal especially in the setting of illness. However, there are adverse consequences associated with its treatment as pharmacologic doses of glucocorticoids can result in immunosuppression, hyperglycemia, impaired wound healing, and elevated blood pressure. Adrenal cortical deficiency in the critical care setting has been defined as an increase in the cortisol of <9 μg/dL in response to 250 μg of cosyntropin or a random cortisol of <10 μg/dL.

Adrenal androgens

Adrenal androgens have their greatest effect in women where they are responsible for the development of axillary and pubic hair. In men, the effects of adrenal androgens are minor, because testosterone is primarily produced in the testes with much smaller amounts produced in the adrenals. ACTH stimulates the synthesis and secretion of DHEA and androstenedione; however, physiological control of adrenal androgen synthesis and release is unclear.

Disorders of adrenal androgen excess (hyperandrogenism)

Pathologic increases in adrenal androgens can cause premature adrenarche or hirsutism/virilization in women (with oligomenorrhea, amenorrhea, and infertility as additional possible consequences). Hyperandrogenism is commonly due to CAH but can occur with certain tumors of reproductive system. Androgen producing adenomas and carcinomas are rare. Exogenous adrenal androgens (or other androgens, such as testosterone) in pharmacologic doses produce many adverse health outcomes such as infertility (from gonadotropin suppression), psychological disease (e.g., aggressive behavior), and an increased risk of cardiovascular disease from elevated blood pressure, elevations in low-density lipoprotein-cholesterol, and depressions in high-density lipoprotein-cholesterol.

Premature adrenarche occurs when adrenal androgen production increases earlier than normal (7−8 years of age), leading to axillary and pubic hair in the absence of any other evidence of puberty (e.g., girls do not estrogenize and boys do not display increased size of the penis or testes). Hyperandrogenism in utero in female fetuses causes virilization of the external genitalia resulting in clitoromegaly and labial fusion. The most common cause is CAH in the form of 21-OH deficiency or 11B-OH deficiency.

Such types of CAH result in overproduction of adrenal androgens (DHEA and androstenedione). In very severe cases of CAH, the fetal fetus will be virilized to the point where there is a penile urethra and what appears to be a scrotum with bilaterally undescended testes. In the older literature, CAH was referred to as the "adrenogenital syndrome" [12].

In women of reproductive age, the most common cause of hyperandrogenism is polycystic ovary syndrome (PCOS). Women with PCOS have many features of the metabolic syndrome: centripetal obesity, hirsutism, irregular menses, amenorrhea, or infertility. In this disorder, the ovary secretes excessive testosterone. To measure small, but significant increases in testosterone in women, testosterone should be measured by mass spectrometry (MS) due to a greater analytic sensitivity than testosterone immunoassays. Using this value and a measurement of sex-hormone binding globulin, free testosterone can be calculated. MS assays for free testosterone are available and present a more accurate measurement than the calculated values.

Disorders of adrenal androgen excess (hyperandrogenism) laboratory testing

Excesses of DHEA, dehydroepiandrosterone sulfate (DHEA-S), or androstenedione are investigated by measuring the fasting levels of these hormones in plasma. CAH should be investigated by measuring 17-OHP. Fig. 41.3 illustrates the metabolic blocks in 21-OH (CYP21A2) deficiency and 11beta-hydroxylase deficiency.

Urinary 17-ketosteroids (17-KS) are the metabolites of DHEA and androstenedione and can be measured in a 24-hour urine collection as an integrated measure of adrenal androgen production. In 21-OH-deficient and 11-OH-deficient CAH, 17-KS are elevated and replacement therapy with cortisol (or another appropriately dosed glucocorticoid) will suppress 17-KS to normal. However, affected patients are more easily managed through present-day measurements of serum or plasma 17-OHP or androstenedione. Prior to the development of plasma 17-OHP or androstenedione measurements, 24-hour urinary 17-ketogenic steroids (metabolites of 17-OHP, 11-desoxycortisol, and cortisol) were measured in addition to 17-KS to diagnosis and manage 21-OH (CYP21A2)-deficient CAH.

There is a late-onset form of 21-OH-deficient CAH, where the enzyme defect is relatively mild. There is no virilization in utero of the female fetus. However, at the time of puberty, hirsutism, virilization, and menstrual irregularities develop. Fasting 17-OHP may only be marginally elevated; however, the response of 17-OHP to cosyntropin injection is excessive and identify this form of 21-OH-deficient CAH. Individuals who carry mild mutations in their 21-OH genes are asymptomatic, yet have excessive 17-OHP responses to cosyntropin injection and are classified as having cryptic 21-OH-deficient CAH.

Less common forms of CAH are 3-beta-hydroxysteroid dehydrogenase (3b-HSD) deficiency and CYP17 deficiency. In 3b-HSD deficiency, there is a defective conversion of ^{5}delta to ^{4}delta steroids (e.g., defects in the following conversions: pregnenolone → progesterone; 17-hdroxypregnenolone → 17-OHP; and DHEA → androstenedione) with deficiencies of aldosterone and cortisol. Affected males are incompletely virilized in utero (because there is a block in testosterone

biosynthesis), whereas females are virilized in utero (because of the accumulation of DHEA). Diagnosis is made by examining the increased ratio of ^{5}delta to ^{4}delta steroids. In CYP17 deficiency, there is defective formation of sex steroids and cortisol. Males are undervirilized (or phenotypically female), whereas females fail to feminize at the time of puberty and suffer from primary amenorrhea. The least common form of CAH results from a loss-of-function mutation in steroidogenic acute regulatory protein. This results in deficiencies of all adrenal and gonadal steroids that are usually fatal. The males will display ambiguous genitalia or a frankly female phenotype. In the absence of CAH with elevations in DHEA, DHEA-S, androstenedione, and/or (far less commonly) testosterone, an androgen-secreting adrenal adenoma or carcinoma must be sought [13].

Disorders of adrenal androgen deficiency

Although adrenal androgen deficiency can occur with Addison disease, there are no apparent adverse consequences.

Disorders of adrenal androgen deficiency laboratory testing

There are no readily recognized adverse consequences of isolated adrenal androgen deficiency after birth, and measurements of DHEA, DHEA-S, or androstenedione are not considered part of its diagnostic workup. On the other hand, biosynthetic defects in the overall production of adrenal androgens, for example, 17-hydroxylase/17,20-desmolase (CYP17) deficiency and 3b-HSD, impair testosterone, and estradiol synthesis, will have significant clinical impacts.

In 17-hydroxylase/17,20 desmolase deficiency, males are ambiguous or phenotypically female. There is cortisol deficiency but mineralocorticoids are not deficient, and elevated 11-desoxycorticosterone (DOC) leads to hypokalemia/alkalotic hypertension in childhood. In contrast, females with 17-hydroxylase/17,20 desmolase deficiency do not have maldevelopment of the internal or external genitalia; however, hypokalemia/alkalotic hypertension can develop. At puberty, estrogen deficiency occurs with pubertal failure (e.g., a lack of estrogenization) manifested as primary amenorrhea. Deficiency of 3b-HSD causes sexual ambiguity in males and females. In males, there is insufficient androgen to virilize fully the male fetus. On the other hand, elevated DHEA levels virilize the female fetus. With 3b-HSD deficiency, there is deficient synthesis of cortisol and aldosterone. Adrenal androgen concentrations decline in men and women over time; however, DHEA or androstenedione are not accepted treatments and their therapeutic use is highly controversial.

The adrenal medulla

Located in the center of the adrenal gland, the medulla represents ~10% of the total weight of each adrenal (i.e., 0.4−0.6 g). Despite the small mass of the adrenal medulla, the catecholamine products of the medulla are critically important for survival. Adrenal medullary cells stain brown with chromium salts secondary to catecholamine oxidation to melanin; consequently, they are termed chromaffin cells or pheochromocytes.

Chromaffin cells are a type of modified sympathetic postganglionic neuron that lacks postganglionic processes secreting either epinephrine or norepinephrine. The synthesis of catecholamines is outlined in Fig. 41.4. The medulla secretes epinephrine and lesser amounts of norepinephrine and dopamine. In contrast, peripheral sympathetic nerves only secrete norepinephrine. Epinephrine and norepinephrine are stored in secretory granules along with chromogranin A, ATP, proopiomelanocorticotropin, and adrenomedulin. Interestingly, the systemic effects of catecholamines result from epinephrine secretion, while circulating norepinephrine levels are not sufficiently high to produce systemic effects and the physiologic role of adrenal dopamine is unclear.

The adrenal medulla is an important element of the sympathetic nervous system. The sympathetic nervous system is key to mammals' successful responses to threats that require the "fight and flight" response. Catecholamines raise blood glucose and blood pressure to prepare for the "fight" (e.g., defensive actions) and/or the "flight" (escape). Catecholamines stimulate the liver to increase hepatic glucose output by stimulating glycogenolysis and increased amino acid and lactate uptake to increase gluconeogenesis. Lactate is a product of anaerobic glycolysis from exercising muscle. Rising free fatty acid concentrations provide an alternative energy source to glucose, which will act to maintain or increase blood glucose concentrations. Epinephrine effects on the cardiovascular system include vasoconstriction in the renal, intestinal, and cutaneous circulation, vasodilatation in skeletal muscle and the coronary circulation, venous constriction, increased cardiac inotropism, increased cardiac conduction velocity, and tachycardia. Bronchodilatation and relaxation of intestinal smooth muscle and uterine smooth muscle are other effects of catecholamines.

Medullary epinephrine secretion is controlled by the autonomic nervous system. Splanchic nerve preganglionic sympathetic fibers innervate chromaffin cells via the actions of secreted acetylcholine binding to ganglionic-type nicotinic receptors of the chromaffin cells. This

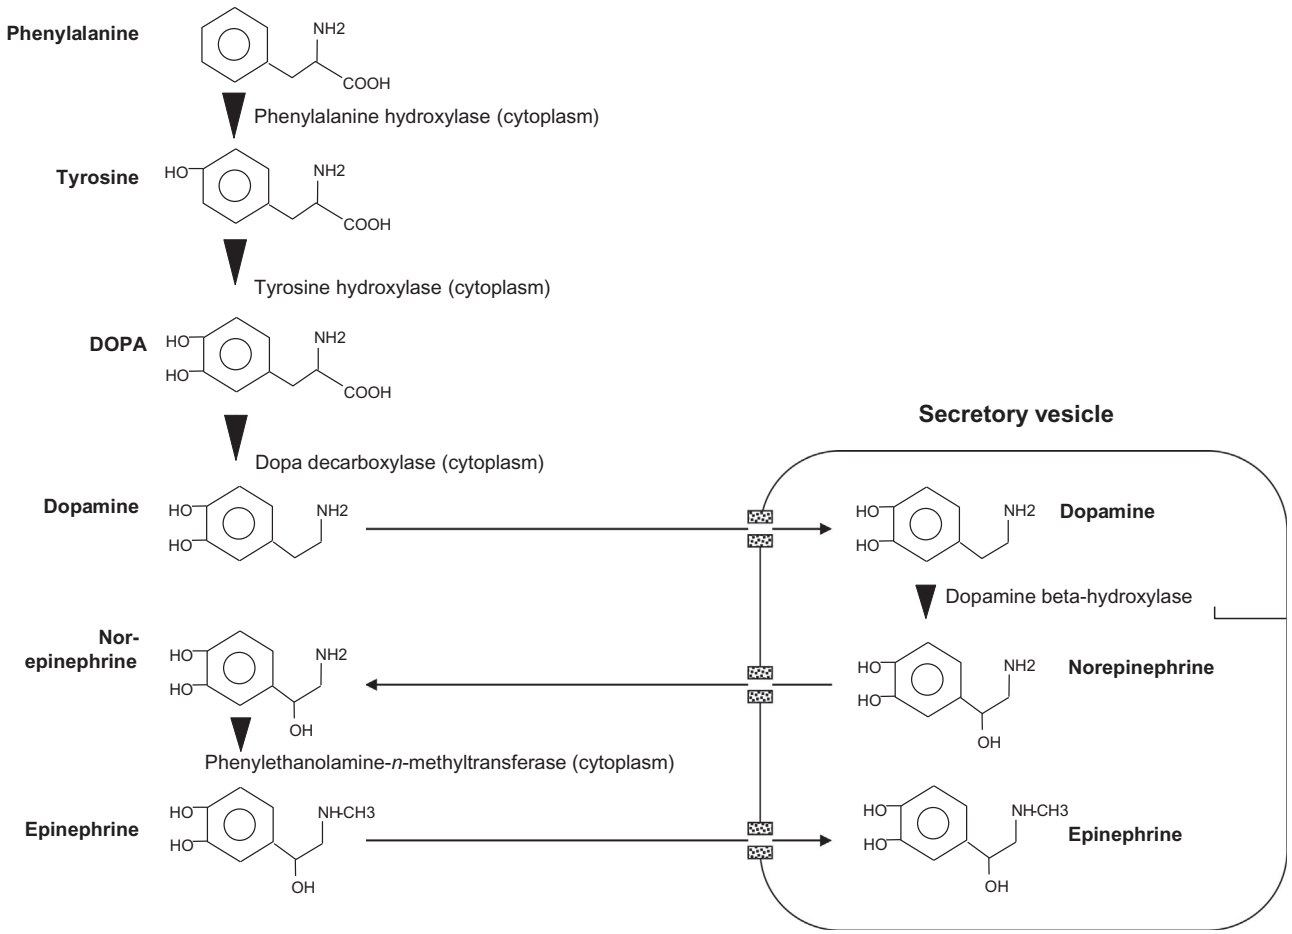

FIGURE 41.4 Catecholamine synthetic pathway.

process triggers the release of chromaffin cell secretory granules, liberating epinephrine and norepinephrine.

Disorders of catecholamine excess

Excessive secretion of catecholamines occurs as a consequence of adrenal medullary chromaffin-cell tumors. Pheochromocytoma is the classic medullary tumor. Clinically, patients experience severe, episodic or persistent hypertension, tachycardia, sweating, pallor, headache, and a "feeling of doom" during times of catecholamine release. Other findings encompass nervousness, nausea, and vomiting, hypertensive retinopathy, fasting hyperglycemia, orthostatic hypotension, and decreased weight. Hypertension can precipitate myocardial infarction or stroke. Pheochromocytoma is most frequently diagnosed in the fourth or fifth decade.

Ten percent of pheochromocytomas are malignant, ~10% are bilateral, ~10% occur in children (where they are more commonly familial and bilateral), and ~10% are located outside of the adrenal medulla (e.g., in the organ of Zuckerkandl). Extra adrenal chromaffin-cell tumors are termed "extra-adrenal" paragangliomas (a pheochromocytoma is an intraadrenal paraganglioma). Histologic examination of pheochromocytomas exhibits cellular features that range from normal to severe atypia and malignancy can only be established by finding metastases. Previously, it was believed that ~10% of pheochromocytomas were familial, but more recent studies report that ~25% of pheochromocytomas are familial. Familial pheochromocytoma can occur as a dominant disorder or as part of von Hippel–Landua type 2 syndrome, Sturge–Weber syndrome, von Recklinghausen neurofibromatosis type 1, tuberous sclerosis, or multiple endocrine neoplasia type 2 (MEN 2).

There are two types of MEN: MEN 1 and MEN 2. MEN 2 has two subtypes: 2A and 2B (formerly known as MEN 3). MEN 1 results from *MENIN* mutations that are inherited in a autosomal dominant fashion and are characterized by pituitary (most commonly prolactinomas), parathyroid (hyperplasia), and pancreatic islet (most commonly gastrinomas) tumors. Tumorogenesis occurs following the loss of heterozygosity in affected tissues that produce hemizygosity for the mutated and dysfunctional

tumor-suppressor gene *MENIN*. MEN 2 results from gain-of-function mutations in the RET protooncogene that encodes a cell-surface receptor of the tyrosine kinase family. Approximately 50% of affected individuals will develop a pheochromocytoma, whereas 100% of affected individuals will develop medullary thyroid carcinoma (MTC). These tumors can develop in childhood with MTC even developing in infancy. See Chapter 44, Tumor markers, of this book for a further discussion of MEN 1, MEN 2, and the distinctive characteristics of MEN 2A versus 2B.

Other tumors of neural crest origin include ganglioneuromas, ganglioneuroblastomas, and neuroblastomas. Neuroblastomas occur in infants or children and may be present at birth. It presents as either an abdominal mass in an infant or child or with widespread metastases. While these tumors may produce catecholamines, there are insufficient elevations of catecholamines to produce clinical symptoms. Nevertheless, catecholamine metabolites measured in timed urine samples can serve as tumor markers (see below).

Disorders of catecholamine excess laboratory testing

Historically, testing was carried out by performing catecholamine measurements in plasma or urine. Test descriptions may vary among reference laboratories, so it is important to clarify which catecholamines are being measured in each assay. Similar test names with different components include "plasma catecholamines" (dopamine plus norepinephrine plus epinephrine), "total" plasma catecholamines (norepinephrine and epinephrine), and "fractionated plasma catecholamines" (specific individual measurements of dopamine, norepinephrine, and epinephrine).

Catecholamine testing is subject to many preanalytic interferences including posture during blood collection, age, placement of samples postcollection on ice, and painful phlebotomy procedure. Use of a butterfly needle with heparin flush to maintain patency with a 20-minute "recovery period" from the needle's insertion is recommended. During this time, the elevated catecholamine levels related to phlebotomy will return to baseline. Biochemical testing for pheochromocytoma is hindered by the fact that catecholamine release is proportional to symptomology, such that if the patient is asymptomatic, catecholamine levels might be falsely depressed.

With the advent of "plasma-free" (nonsulfated) metanephrine measurements, diagnosis has become easier. Plasma-free metanephrines are continuously produced by pheochromocytoma cells, making them less subject to the episodicity of catecholamine release. Plasma-free metanephrine testing is the plasma assay of choice for the diagnosis of pheochromocytoma with a sensitivity and specificity of 97% and 93%, respectively. It is recommended that the patient be supine for up to 30 minutes prior to collection to minimize false-positive results. Twenty-four-hour urine collections can also be performed in search of catecholamine excess. Testing options include "fractionated urine catecholamines," which report specific measurements of dopamine, norepinephrine, and epinephrine per 24 hour [or per gram of creatinine if a random (spot) sample is submitted]. Total urine catecholamines (i.e., norepinephrine plus epinephrine) may also be reported. To preserve urine samples, acid is added to the container (e.g., 20−25 mL of 6 N HCl or 15 g of boric acid).

Initial metabolites of the catecholamines are normetanephrine and metanephrine (collectively referred to as "metanephrines"). Urine metanephrine and normetanephrine can also be individually measured (e.g., fractionated urine metanephrines). Elevated excretion of 24-hour urine metanephrines is superior to the diagnosis of pheochromocytoma compared with other measures of urine catecholamine excretion. However, plasma catecholamine measurements are highly labile and may be elevated to pain and stress leading to false-positive results (i.e., elevated catecholamines in the absence of a pheochromocytoma).

A dynamic test for catecholamine excess is the clonidine suppression test. Clonidine is a centrally acting alpha-2-adrenergic agonist. Blood pressure and plasma catecholamines are drawn at baseline (i.e., 1 hour after insertion of an intravenous line with the patient supine). Three hours after oral administration of clonidine (0.3 mg/70 kg), blood pressure and plasma catecholamines are again measured. Some sources also recommend measuring blood pressure and plasma catecholamines 1 and 2 hours after administration of the clonidine. In normal individuals, blood pressure and plasma catecholamines decline. In pheochromocytoma, plasma catecholamines remain unchanged or rise in concentration. This test is only informative when basal plasma catecholamines increase. Because of the possibility of acute hypertensive crisis, provocative testing with tyramine, glucagon, metoclopramide, or histamine is not advised in the evaluation of suspected pheochromocytoma.

For plasma or urine testing, it is advised that subjects avoid strenuous exercise, tobacco, tea, coffee, and alcohol prior to testing. For urine testing, common drugs used to treat hypertension (e.g., alpha or beta blockers, ACE inhibitors, calcium channel blockers, and diuretics) produce little or no interferences. In the case of urine metanephrine testing, it is recommended that patients be off medications for 3 days prior to testing. Alpha blockers and alpha agonists are not to be taken for 18−24 hours prior the beginning of the urine collection.

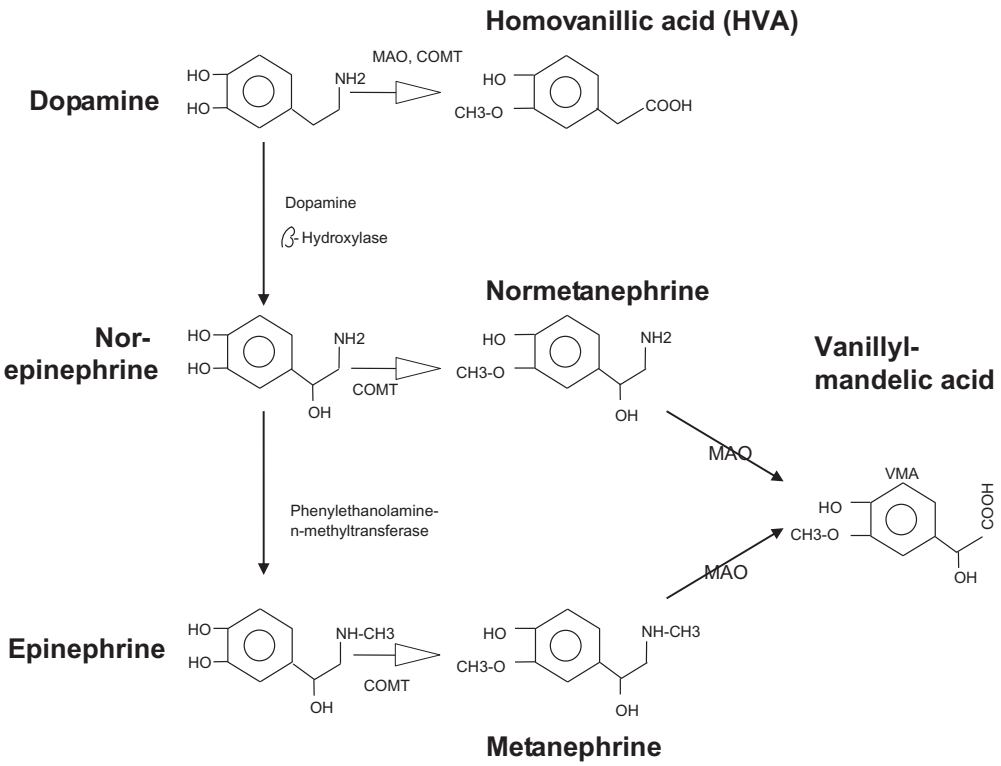

FIGURE 41.5 Catecholamine metabolites.

Homovanillic acid (HVA) and vanillylmandelic acid (VMA) are the metabolites of dopamine and norepinephrine, respectively (Fig. 41.5). Serum and urine levels of HVA and VMA are typically measured to diagnose and monitor children with neuroblastoma, but may also be utilized in pheochromocytoma. Typically, both are assayed using high-performance liquid chromatography [14,15].

Catecholamine deficiency

Inadequate counter regulatory epinephrine and/or glucagon responses to hypoglycemia have been reported in individuals after 5–10 years of diabetes mellitus. This impairs the diabetic patient's ability to recover spontaneously from hypoglycemia that may have resulted from a missed meal, excessive exercise, and/or overdosing of insulin or an oral hypoglycemic agent. While hyperglycemia and its complications are a chronic challenge to patients with diabetes, hypoglycemia is usually an acute problem that can be life-threatening.

Self-assessment questions

1. A lean, nondiabetic 45-year-old hypertensive male who is on no therapies has a potassium concentration of 3.0 meq/L or lower on multiple occasions (reference interval: 3.5–5.0 meq/L). Which one of the following tests is likely to be of the greatest diagnostic assistance?
   a. Cortisol following 1 mg of dexamethasone given the previous evening
   b. Antidiuretic hormone measurement (vasopressin)
   c. Renin and aldosterone measurements
   d. Plasma-free metanephrine measurement
   e. 24-hour urinary HVA and VMA measurements
2. An obese, diabetic 58-year-old hypertensive male who is on no diuretics has a potassium concentration of 3.0 meq/L or lower on multiple occasions (reference interval: 3.5–5.0 meq/L). He has problems with poor wound healing and infections. He has had a collapsed vertebra in the past. Which one of the following tests is likely to be of the greatest diagnostic assistance?
   a. Cortisol following 1 mg of dexamethasone given the previous evening
   b. Antidiuretic hormone measurement (vasopressin)
   c. Renin and aldosterone measurements
   d. Plasma-free metanephrine measurement
   e. 24-hour urinary HVA and VMA measurements
3. Which one of the following assays is least helpful in diagnosing Cushing syndrome?
   a. Cortisol following 1 mg of dexamethasone given the previous evening
   b. Cortisol drawn at midnight
   c. 24-hour urine-free cortisol
   d. a.m. cortisol
4. Which one of the following plasma assays is most helpful in diagnosing pheochromocytoma?
   a. Total catecholamines
   b. Plasma free metanephrines
   c. Epinephrine
   d. Norepinephrine
   e. Dopamine
5. A hyperpigmented patient presents with hypotension, hypoglycemia, hyponatremia, hyperkalemia, and acidosis. What is the most likely diagnosis?
   a. Cortisol resistance
   b. Addison disease
   c. Isolated mineralocorticoid deficiency
   d. ACTH deficiency
   e. Apparent mineralocorticoid excess
6. An infant is born with ambiguous genitalia. Which one of the following tests would be most helpful diagnostically?
   a. Cortisol
   b. Pregnenolone
   c. 24-hour urinary 17-hydroxycorticosterone
   d. Testosterone
   e. 17-hydroxyprogesterone
7. An infant has a palpable abdominal mass. The blood pressure is normal. Which one of the following tests, if normal, would be most helpful in excluding adrenal pathology?
   a. 24-hour urinary HVA and VMA
   b. Aldosterone after salt loading
   c. 24-hour urinary metanephrines
   d. Cortisol after cosyntropin injection
   e. Plasma-free metanephrines
8. Which one of the following tests is most helpful in differentiating an aldosteronoma from bilateral idiopathic adrenal hyperplasia?
   a. Measurement of ACTH in the inferior petrosal venous sinuses and inferior vena cava at baseline and following CRH administration

b. A cortisol measurement following repeated administrations of cosyntropin
c. Failure of aldosterone to increase when the subject is upright
d. Measurement of the aldosterone to renin ratio in a peripheral blood sample
e. An MRI or CT of the pituitary gland

9. A lean, nondiabetic patient is hypertensive, hypokalemic, and alkalotic. They are not treated with any medications. The renin and aldosterone are both decreased. Which of the following disorders is least likely?
a. Glucocorticoid remediable hyperaldosteronism
b. Apparent mineralocorticoid excess
c. Inhibition of 11-beta-hydroxysteroid dehydrogenase-2
d. Gain-of-function mutation in ENaC
e. Gain-of-function mutation in the mineralocorticoid receptor

10. A hyperpigmented patient presents with hypotension, hypoglycemia, hyponatremia, hyperkalemia, and acidosis. What is the most likely cause of the patient's underlying disorder?
a. An anterior pituitary corticotropinoma
b. Autoimmune destruction of the adrenal cortex
c. Administration of high-dose glucocorticoids
d. Failure of HSD11B2 to convert cortisol into cortisone
e. Adrenoleukodystrophy

Learning objectives

After reviewing this chapter, the reader will be able to:

- Explain the changes in physiology and laboratory values associated with normal and abnormal pregnancies.
- Explain the differences among human chorionic gonadotropin assays, their utility, and limitations.
- Describe screening and diagnostic tests for fetal and maternal complications in pregnancy and their limitations and how these are interpreted.

Normal pregnancy

Pregnancy is a healthy state lasting ~40 weeks from the first day of the last menstrual period (LMP) to the expected date of confinement or estimated delivery date. The 40-week time frame is divided into three trimesters of 13 weeks; the first trimester begins with the first day of the LMP. A term pregnancy is any that ends in delivery of the infant between 37 and 42 weeks of gestation. New guidance suggests that a full-term pregnancy is any delivery between 39 and 40 weeks and 6 days, while early term is any pregnancy between 37 and 38 weeks and 6 days, and late and postterm pregnancies are those with deliveries during the 41st and beyond 42nd weeks, respectively. Evidence suggests that full-term pregnancies are associated with the best overall outcome for the infant.

The placenta, umbilical cord, and amniotic fluid (AF) are critical for maintaining pregnancy. The placenta separates the maternal and fetal circulation systems while providing nourishment and eliminating fetal waste. Concentration gradients regulate transport of proteins and small molecules across the placenta. With the exception of maternal IgG, which crosses via receptor-mediated endocytosis, large proteins do not cross the placental membranes. The placenta also produces hormones critical for maintaining pregnancy, such as human chorionic gonadotropin (hCG), human placental lactogen, progesterone, and estrogen. During pregnancy, the fetus is protected and suspended by AF. The volume and composition of AF change over the course of pregnancy through bidirectional flow of molecules along the maternal, fetal, and placental membranes. Analytes detected in AF are used to assess abnormalities in pregnancy including fetal lung immaturity, congenital anomalies, and hemolytic disease.

Physiological changes during pregnancy

Physiological changes in pregnancy affect the hemodynamic, cardiovascular, renal, hepatic, endocrine, and respiratory systems and their associated laboratory tests. Assessment of pregnancy abnormalities requires an understanding of these normal changes. The changes in common analytes that occur during pregnancy, expressed as a percentage of expected nonpregnant reference intervals, are listed in Table 42.1.

Significant hematological changes occur during pregnancy. Maternal blood volume increases by ~45%; of this about 20% is due to red blood cell (RBC) mass and 80% to plasma volume. As a result, hematocrit, hemoglobin, and erythrocyte count are decreased, a combination commonly referred to as "physiological anemia of pregnancy." Pregnancy is a hypercoagulable state associated with increases in several clotting factors and significant risk of deep vein thrombosis. In addition, maternal cardiac output is increased by 30%−40%, resulting in increased blood pressure and flow to organs. Increased blood flow to the kidneys increases glomerular filtration. Renal function tests reveal an elevated eGFR with corresponding decreases in creatinine and BUN.

Pregnancy is marked by significant changes in the endocrine system that are required to maintain gestation, promote labor and delivery of term infants, and facilitate lactation. Increases in the pregnancy-maintaining hormones hCG, progesterone, and estrogen occur early in pregnancy and persist throughout. A combination of

Wittwer (Eds.), Tietz Textbook of Clinical Chemistry and Molecular Diagnostics, sixth ed., Elsevier Inc, St. Louis, MO, 2018, pp. 1655–1696; A. Gronowski, Handbook of Clinical Laboratory Testing During Pregnancy, Humana Press, Totowa, NJ, 2004; and J. Sherwin, G. Lockitch, P. Rosenthal, S. Rhone, L. Magee, E. Ashwood, et al., National Academy of Clinical Biochemistry Laboratory Medicine Practice Guidelines: Maternal-Fetal Risk Assessment and Reference Values in Pregnancy, AACC Press, Washington DC, 2006, pp. 1–75 [1–3].

actions by several hormones results in an insulin resistant/glucose intolerant state characterized by decreased fasting blood glucose and increased insulin synthesis. Increased estrogen stimulates synthesis of hepatic proteins, including cortisol binding globulin, resulting in decreased cortisol clearance and the hypercortisolemic state critical for the labor process. Increased synthesis of thyroid-binding globulin results in elevated total thyroid hormone concentrations. Stimulation of thyroid-stimulating hormone (TSH) receptors by hCG results in downregulation of TSH synthesis.

Estrogen also stimulates synthesis of prolactin (which is essential for lactation), acute phase reactants such as α-1-antitrypsin and ceruloplasmin, and liver enzymes,

such as alkaline phosphatase. Increased angiotensinogen upregulates plasma renin activity and aldosterone, which promotes sodium resorption in the renal tubules. In the third trimester, increases in maternal 1,25-dihydroxyvitamin D and PTH (without corresponding increases in ionized calcium) result in enhanced intestinal absorption of calcium, critical for fetal growth. Progesterone increases during the luteal phase of the menstrual cycle and in pregnancy cause hyperventilation and mild respiratory alkalosis. To compensate for the alkalosis, plasma bicarbonate is slightly decreased; however, blood pH remains mildly alkalemic during pregnancy.

Prenatal laboratory assessment

The health of the fetus and mother is assessed before and throughout pregnancy by collecting an extensive clinical history, as well as performing a physical and prenatal laboratory testing. Currently, common laboratory testing recommended for all pregnant women includes: blood type and antibody screening, infectious disease testing, a complete blood count, immunization checks, gestational diabetes screening, urinalysis, and fetal aneuploidy and neural tube defect (NTD) screening. Women at increased risk based on clinical history are also screened for cystic fibrosis carrier status, thyroid dysfunction, and hemoglobinopathies. Table 42.2 contains a list of routine laboratory testing performed during pregnancy.

Human chorionic gonadotropin

Normal and abnormal pregnancies are detected and followed by monitoring the presence and/or changes in concentration of hCG in serum or urine.

Biochemistry of human chorionic gonadotropin

hCG is a glycoprotein hormone synthesized by the trophoblastic cells of the placenta during pregnancy. It circulates as a heterodimer of α and β subunits that are modified with both *N*- and *O*-linked oligosaccharides. hCG is part of a family of glycoprotein hormones, including LH, FSH, and TSH, characterized by common α and distinct β subunits.

In circulation, hCG has several isoforms. The main isoform in pregnancy is an intact glycosylated hCG heterodimer of ~37 kDa. In addition to intact hCG, the main isoforms found in maternal circulation include both free α and β subunits (hCGβ), nicked hCG dimer (hCGn), nicked free β (hCGβn), and hyperglycosylated hCG (hCGh). The hCGβ-core fragment (hCGβcf) is a major variant in urine. Hyperglycosylated hCG is the main isoform in circulation during early pregnancy, choriocarcinoma, and gestational trophoblastic disease (GTD). Nicked hCG is formed through enzymatic cleavage of the hCGβ between amino acids 44−45 or 47−48, and is common after term pregnancy or abortion. hCGβ is rarely seen in pregnancy, because most is rapidly cleaved and circulates as hCGβn. Some patients with germ cell tumors express hCGβ in circulation. The predominant hCG isoform in urine after 7 weeks of gestation is hCGβcf, which consists of amino acids 6−40 and 55−92 of hCGβ linked by disulfide bridges. The impact and measurement of these various isoforms are discussed below.

Function and expression of human chorionic gonadotropin in normal pregnancy

In early pregnancy, hCG maintains the corpus luteum and stimulates progesterone synthesis. Throughout pregnancy, hCG may act as a proangiogenic factor critical for implantation and maintenance of the blood supply to the fetoplacental unit. Synthesis of hCG begins shortly after implantation of the developing blastocyst into the uterus. Ultrasensitive methods can detect hCG in serum and urine up to 1 week before the predicted menstrual cycle. After implantation, hCG concentrations increase logarithmically, doubling every 1.5 days for the first 5 weeks of pregnancy. It continues to double in concentration, every 40−48 hours until it peaks between 8 and 11 weeks of gestation at ~100,000 IU/L.

Confirmation of a viable pregnancy requires serial measurements of hCG on two separate occasions 2 days apart due to significant variability in concentrations in early pregnancy. In the second and third trimesters, hCG concentrations decrease and remain steady at ~10,000 IU/L until birth. After pregnancy, hCG declines rapidly and is undetectable by 2 weeks postpartum. After an elective or spontaneous abortion in the first trimester, hCG may persist in the serum and urine up to 4 weeks due to increased concentrations and longer half-life.

Expression of human chorionic gonadotropin in abnormal pregnancy

Serial hCG measurements not only confirm normal pregnancies, but also detect abnormal ones. The minimum increase in hCG required for a viable intrauterine pregnancy (VIUP) depends on the initial value measured. Lower initial concentrations (<1500 mIU/mL) are expected to increase by at least 49% in 48 hours in a viable pregnancy, while pregnancies with initial hCG concentrations between 1500−3000 and >3000 mIU/mL are expected to minimally increase by 40% and 33%, respectively. Doubling times less than or greater than described in a VIUP are seen in nonviable and/or abnormal pregnancies. Decreased hCG doubling times are seen in

TABLE 42.2 Routine prenatal laboratory testing by trimester.

Laboratory test name	Reason for test
First trimester conception—13 weeks	
hCG	Confirm pregnancy
Complete blood count	Check for anemia and low platelet count (repeat as needed)
Genetic testing for inherited diseases	Check carrier status for certain genetic diseases
Hemoglobin A1c	Screen for type 2 diabetes (not gestational diabetes)
Hemoglobin variant analysis	Screen for a thalassemia or hemoglobinopathy[a]
Rubella titer	Screen for immunity/vaccination to rubella
HIV screening	Screen for HIV infection (all three trimesters if high risk)
Gonorrhea, chlamydia, and syphilis screening	Screen for STD infections (all three trimesters if high risk)
Hepatitis B and hepatitis C serology	Screen for hepatitis B or hepatitis C infection
Varicella foster virus testing	Screen for immunity to chickenpox
TORCH panel	Toxoplasmosis screen
Urine dip stick/screen	Screen for kidney or bladder infection, undiagnosed diabetes, or preeclampsia (at each visit)
Urine culture	Detect bacterial infection in the urinary tract
Blood typing and antibody screen	Check for blood group incompatibility between mother and fetus
Fetal aneuploidy screen	Combined screening test for trisomies 13, 18, and 21
Noninvasive prenatal testing	Fetal DNA is tested for aneuploidy and Y chromosome
Chorionic villus sampling	Confirmatory testing for positive fetal aneuploidy screening
Tuberculosis	Screen for TB[a]
TSH	Screen for thyroid dysfunction[a]
Zika virus	Screen for exposure to Zika virus[a]
Second trimester—14−26 weeks	
Glucose tolerance test	Screen for gestational diabetes
Maternal serum AFP	Screen for an open neural tube defect
Quadruple screen	Screening test for trisomies 13, 18, and 21 and ONTD
Amniocentesis	Confirmation of fetal aneuploidy by karyotyping
Third trimester—27−40 weeks	
Group B streptococcus	Screen for infection
Blood typing and antibody screen	To check for alloimmunization in Rh-negative mothers
Fetal lung maturity testing	Screen for lung maturity[a]

AFP, α-Fetoprotein; *TSH*, thyroid-stimulating hormone.
[a]*Screening for high risk patients only.*

ectopic pregnancies and miscarriages, while increased doubling time is common in molar pregnancies. Persistent low expression of hCG is seen in GTD; detection of hCGh confirms this diagnosis. Free beta hCG is expressed in malignancies like germ cell tumors, while the glycoprotein hormone alpha subunit is a tumor marker used to monitor progression of pituitary adenoma. Abnormal hCG, hCGβ, and hCGh expression is also seen with fetal aneuploidy.

Human chorionic gonadotropin immunoassays

Most commercially available hCG assays are "sandwich" immunoassays (see Chapter 12, Immunoassays). Both quantitative and qualitative assays detect some or all of the hCG isoforms in blood, urine, and body fluids to diagnose and monitor pregnancy and malignancy. Depending on the antibody epitopes, these assays may differentially recognize the distinct isoforms of hCG.

Qualitative human chorionic gonadotropin assays

Two types of qualitative assays, over-the-counter and point-of-care (POC), are used to detect hCG in urine and sometimes whole blood or serum for pregnancy testing. Most pregnancy tests are based on the principal of immunochromatography. The analytical sensitivity for these types of tests is usually 25 IU/L, a concentration typically seen at the time of missed menses. Although many devices can detect much lower concentrations (<10 IU/L), those cutoff values are less specific for pregnancy. Serum and urine hCG concentrations may be slightly elevated in men and perimenopausal and postmenopausal women due to pituitary expression leading to false-positive pregnancy testing results.

Nonpregnancy-related elevations are also seen in patients with germ cell tumors, GTDs, and heterophilic antibody interactions.

Qualitative hCG kits are also subject to false-negative results caused by multiple factors, including: hCG concentration below the limit of detection, because it was measured too early or in dilute urine (detected in samples with a low specific gravity), operator error (prematurely reading results), the hook effect (see the "Immunoassay" section for details), and/or the hCG "variant hook effect." Qualitative pregnancy testing devices differentially recognize hCG variants. Documented cases of false-negative results have been reported on numerous POC devices in women after 7 weeks of gestation, with a molar excess of hCGβcf in the urine. Some devices also demonstrated false-negative results when hCGβ, hCGβn, or hCGn were in molar excess in urine. Fewer interferences have been seen in serum specimens. Use of qualitative urine hCG testing to rule out pregnancy in emergent patients should be discouraged. While recent advances in POC kit manufacturing have reduced the incidence of the hCG variant effect, older kits are still on the market. Therefore, caution should be taken when interpreting qualitative hCG results in urine from any POC device, as they may be subject to a hook effect due to molar excess of an hCG variant like hCGβcf.

Quantitative human chorionic gonadotropin assays

Like qualitative tests, hCG quantitative assays are primarily sandwich immunoassays with antibody targets directed to different portions of the heterodimer. Most quantitative assays are performed in the clinical laboratory using serum or plasma specimens. Clinical and analytical variability exists among pregnant women and across different assays, making interpretation of results challenging. Analytical variability is due to different specificities for the intact molecule, α or β monomers, and/or other hCG variants. In addition, quantitative assays are not standardized, resulting in significant inter-method variability. While, the majority of assays are calibrated to the WHO Fourth International Standard, these are impure mixtures derived from pregnant urine and based on bioactivity instead of mass units. This mixture contains impurities as well as hCG variants like hCGn and hCGβ causing overestimation of these isoforms in some assays. Furthermore, hCG concentration in the WHO standard is based on bioactivity instead of mass units. Recommendations to correct analytical variability suggest standardization of all assays to the fifth IS, a pure material with fewer contaminating hCG isoforms. Serial hCG determinations from a patient should always be performed on the same assay. Quantitative immunoassays are also limited by interferences from heterophile antibodies or the high-dose hook effect.

Progesterone expression in pregnancy

Progesterone is produced by the corpus luteum for the first 10−12 weeks of gestation, and the placenta and adrenal glands in the remainder of pregnancy. Progesterone is critical for facilitating implantation and maintaining pregnancy and lactation. Progesterone concentrations rise steadily during early pregnancy, and deviations from this pattern indicate a poor prognosis. Serum progesterone concentrations average around 10 ng/mL in nonviable pregnancies. Progesterone concentrations of >25 ng/mL are typically associated with viable intrauterine pregnancies. Patients with ectopic pregnancies or eminent abortions often have progesterone concentrations between 5 and 15 ng/mL.

Abnormal pregnancy

Laboratory testing is critical for the identification and monitoring of abnormalities in pregnancy. The following sections will outline several abnormal conditions for mother and/or fetus and how these are assessed in the clinical laboratory.

Ectopic pregnancy

An ectopic pregnancy (EP) is any extrauterine pregnancy, with most (~97%) occurring in the fallopian tube. They account for ~2% of all pregnancies, but 6% of maternal deaths. EP is dangerous, as growth of the fetus can cause tubal rupture, maternal hemorrhage, and even maternal death. Although the exact cause of EP is unknown, risk factors include: use of assisted reproductive techniques, smoking, tubal damage from pelvic inflammatory disease, a prior sexually transmitted disease or EP, and advanced maternal age.

Clinically, it is difficult to differentiate ectopic from early intrauterine pregnancies and spontaneous abortions. Symptoms including vaginal bleeding, abdominal cramping, and pain occur in women between 5 and 10 weeks of gestation. The diagnosis is often made through a combination of sonographic and laboratory tests. Detection of an intrauterine pregnancy with 100% accuracy is not possible by transvaginal ultrasound (TVUS) until serum hCG concentrations are in the "discriminatory zone" (concentration in which a pregnancy should be seen by ultrasound) for most commercially available assays. Recent studies have challenged the use of the discriminatory zone and have suggested adopting a conservative concentration of 3500 mIU/mL. Given the variability of hCG assays and concentrations in pregnancy, each laboratory should establish its own discriminatory

hCG concentration, in which 100% of pregnancies are detected by TVUS, if a discriminatory zone is utilized in clinical practice.

Up to 31% of women with a suspected EP have an original TVUS in which the location of the pregnancy is unknown (i.e., not detected in the uterus or fallopian tube). TVUS results are correlated with serial hCG concentrations to confirm an EP. Ninety-nine percent of patients with a VIUP show an increase in hCG of at least 53% in 2 days, while 95% of patients undergoing a spontaneous abortion will show a decrease between 21% and 35% in 2 days. The majority of EPs show either hCG increases of $<50\%$ or hCG decreases of $>20\%$ in 2 days. In a minority of ectopic pregnancies, hCG expression falls outside of this expected range, making a rapid and definitive diagnosis difficult. Current research is focused on identifying biomarkers capable of diagnosing an EP at initial presentation. Candidates include markers of abnormal embryonic function (activin A and inhibin A), implantation (activin B), and/or inflammation (cytokines).

EP is treated with expectant management, chemotherapy (methotrexate injection), or surgery. The type of therapy is determined by the concentration of hCG at diagnosis, whether its concentration is increasing or decreasing, and whether there is evidence of fallopian tube rupture. After therapy, serial hCG results are followed until no longer detected in serum. In patients with high hCG and/or evidence of tubal rupture, surgery is the most effective treatment.

Molar pregnancy and gestational trophoblastic disease

There are two types of hydatidiform moles, partial and complete, that mimic pregnancy. A partial mole is often a triploid fertilization (two sperms with a viable egg) with detectable fetal material. A complete mole is typically a fertilized empty ovum with two sperms and no detectable fetal material. Moles account for ~ 1 in 1000 US pregnancies. These are usually diagnosed in the first trimester by ultrasound and/or laboratory evaluation. Partial moles are often asymptomatic and present as missed abortions, while complete moles are associated with clinical symptoms like uterine enlargement, vaginal bleeding, and less often pregnancy-induced hypertension, anemia, and hyperemesis gravidarum (HG). Ultrasound findings for a complete mole show hydropic vesicular changes in the trophoblast, giving them a grape-like appearance. Concentrations of hCG are abnormally high, and doubling times are faster than the typical 48 hours. Both types of molar pregnancies are treated with uterine evacuation and subsequent serial monitoring of serum hCG concentrations until undetectable.

About 20% of complete and 5% of partial molar pregnancies will progress to a malignant disease called GTD. Postmolar malignancies are one type of GTD, which also include noninvasive trophoblastic proliferation, invasive moles, and choriocarcinoma. GTD is most often diagnosed by detecting persistent elevation or increasing hCG in the absence of pregnancy. The predominant isoform in GTD is hCGh. Specific antibody tests for hCGh can confirm disease. GTD is treated with different chemotherapeutic courses depending upon the degree of metastasis. Hysterectomy is necessary in the most severe cases. Response to therapy is monitored by serial measurements of hCG. Persistent elevations of hCG caused by interference from "phantom hCG molecules" (i.e., trypsin cleavage products), heterophile antibodies, or pituitary hCG may occur in the absence of pregnancy and malignancy, and these should be ruled out in cases with low clinical suspicion of cancer.

Hyperemesis gravidarum

HG is a pregnancy disorder characterized by persistent nausea and vomiting (N/V), starvation (i.e., evidence of significant ketonuria), and weight loss ($\geq 5\%$ prepregnancy weight). HG is the most common cause of maternal hospital admission during the first half of pregnancy. HG is associated with extremely high concentrations of hCG, which may induce emesis. Diagnosis of HG also requires ruling out other typical causes of N/V.

Workup of HG begins with a careful clinical history, including time of onset of symptoms and severity of N/V. N/V onset after 9 weeks of gestation is likely unrelated to HG. A laboratory evaluation is helpful in cases of severe N/V. HG is commonly associated with only mildly elevated liver enzymes, bilirubin, and amylase or lipase, while these enzymes are significantly elevated in hepatitis or acute pancreatitis. Although not specific for HG, these patients may also show significant elevations in hCG and free thyroxine (FT_4) and suppressed TSH. Through its homology with TSH, hCG induces thyroid hormone synthesis and, when highly concentrated, transient hyperthyroidism.

Treatment of HG depends on abnormal laboratory results and severity of weight loss and/or dehydration. Hydration and antinausea medications are usually sufficient, although, in severe cases, hospitalization and parenteral nutrition are helpful. Transient hyperthyroidism typically resolves when hCG concentrations decrease in the second trimester and antithyroidal medications are rarely needed.

Preeclampsia

Preeclampsia is a multisystem disorder onset in the second half of pregnancy. It is defined as the presence of two

of the following: hypertension—new (bp $\geq$ 140/90 mm Hg) or worsening (an abrupt change in blood pressure or requirement for additional antihypertensive medications) in pregnancy and proteinuria ($\geq$300 mg/L urine protein/24 hours or $\geq 1+$ on a urine dipstick). In the absence of proteinuria, patients with new onset hypertension and either thrombocytopenia (platelet count $<100{,}000 \times 10^9$/L), renal insufficiency (serum creatinine $>$1.1 mg/dL), impaired liver function (liver transaminases $>$ two times the upper limit of normal), or pulmonary edema also meet the diagnostic criteria for preeclampsia. Hypertensive disorders are present in 6%–8% of all pregnancies and are a major cause of morbidity and mortality to the mother and fetus. Preeclampsia is thought to be caused by poor placentation, leading to an oxidatively stressed placenta. The clinical severity of preeclampsia varies and can present with maternal and/or fetal syndromes (intrauterine growth restriction and poor oxygenation). If left untreated, the maternal syndrome can progress to eclampsia (stroke and seizure) and/or HELLP syndrome (hemolytic anemia, liver dysfunction, and thrombocytopenia).

Preeclampsia is currently diagnosed after onset of clinical symptoms of edema, hypertension, and proteinuria after 20 weeks of gestation. Early prediction of women who will develop preeclampsia may improve maternal and fetal outcomes. However, currently there is no test that can predict preeclampsia prior to onset of clinical signs and symptoms. The most promising predictive markers include a combination of Doppler ultrasonography to monitor placental blood flow and detection of appropriate ratios of circulating proangiogenic and antiangiogenic factors, placental growth factor, and soluble fms-like tyrosine kinase-1, respectively. Despite their promise, guidelines do not recommend any screening tests for early prediction of preeclampsia other than a clinical history to identify risk factors, such as chronic hypertension, renal disease, obesity, diabetes, advanced maternal age, and personal or family history. Treatment of preeclampsia depends on severity and gestational age at onset. In late onset cases, the fetus is delivered, while, in early onset disease, a woman can be treated with antihypertensives and anticonvulsants if necessary. Fetuses that are electively delivered preterm can be treated with corticosteroids prior to delivery to facilitate lung maturity (see "Preterm birth" section) and intratracheal surfactant in the event of respiratory distress after delivery.

Thyroid dysfunction during pregnancy

Thyroid dysfunction in pregnancy can result in increased risks for the mother and fetus. Overt hypothyroidism occurs in $\sim$0.3% of pregnancies and is associated with an increased risk of miscarriage, preterm delivery, and impaired neurological development in the fetus. Subclinical hypothyroidism occurs in 2%–5% of pregnancies and may lead to cognitive deficiencies in neonates. Although controversial, most recommendations suggest screening all high risk and symptomatic pregnant women for hypothyroidism by measuring TSH. Any abnormal TSH result, considered in the context of trimester-specific reference intervals, should be followed with FT_4 testing. Some organizations recommend measuring thyroperoxidase antibodies before pregnancy or in the first trimester, and, if elevated, the mother is at risk for postpartum thyroid disease. Due to the normal decrease in TSH during pregnancy, gestational age-specific reference intervals should be used. Overt hypothyroidism in pregnancy is treated with thyroid hormone replacement therapy.

Hyperthyroidism occurs in 0.1%–0.4% of pregnancies and is associated with increased risk of spontaneous abortion, preterm delivery, preeclampsia, and thyroid anomalies in the newborn. A subnormal TSH test result should be followed with FT_4 testing. An elevated FT_4 in the presence of TSH receptor autoantibodies confirms the diagnosis of hyperthyroidism. Overt hyperthyroidism in pregnancy is treated with antithyroid drugs. In mothers with confirmed thyroid disease, fetal thyroid function can be evaluated with ultrasound to detect a goiter and AF testing for TSH, FT_4, and total T_4. AF-specific reference intervals for thyroid function tests are assay-dependent.

Hemolytic disease of the fetus/newborn

Hemolytic disease of the fetus/newborn (HDFN) is a rare immune-mediated hemolytic disorder in the fetus or neonate caused by maternal antibody attack of antigens on the surface of fetal RBCs. Its prevalence is $\sim$6/1000 live births. HDFN is caused by blood group incompatibility between mother and fetus. ABO and rhesus (Rh) factor incompatibilities are the most common form of HDFN. This is most commonly seen in the United States, when a mother's blood subtype is O while the fetus has the A blood type. Rhesus (Rh) or RhCE alloimmunization most often occurs when a woman lacking blood group antigen D or CE (Rh-negative) encounters RBCs from an RhD or CE-positive fetus. Incompatibility between mother and fetus in the expression of other RBC antigens, like C/c, E/e, A, B, Kell, Duffy, Kidd, or M, N, S, and s, can also trigger severe HDFN.

Pathophysiology

An Rh-negative and/or O blood type mother becomes sensitized to the Rh or other blood group antigens. This occurs most commonly after a blood transfusion or during a fetomaternal hemorrhage in pregnancy or at

delivery, during a spontaneous or elective abortion, or after an EP. After sensitization, antiblood group antibodies can cross the placenta in a current or subsequent pregnancy and attack antigens on the fetal RBCs, inducing hemolysis. Chronic hemolysis leads to severe fetal anemia. Compensation for this anemia involves upregulation of red cell production from the fetal bone marrow, liver, and spleen, leading to damage of these and other organs, a condition commonly referred to as erythroblastosis fetalis. Heart failure due to hypoxic injury and liver damage leading to decreased fetal albumin synthesis and reduced oncotic pressure contribute to the edematous state referred to as hydrops fetalis. If untreated, hydrops is fatal in utero or shortly after birth. After delivery, neonates with HDFN are faced with the additional challenge of removing unconjugated bilirubin without the assistance of the maternal placenta. Typically, bilirubin is conjugated and excreted through the liver; however neonates (particularly those with damaged livers or born prematurely) are not able to adequately conjugate excess bilirubin. Unconjugated bilirubin can cross the blood–brain barrier and cause encephalopathy also called kernicterus, leading to significant morbidity and, in rare cases, mortality.

Prevention

Guidelines recommend that all women should be blood typed and screened for alloantibodies (type and screen) early in pregnancy. An injection of Rh (anti-Rh) immune globulin, RhoGAM (Ortho-Clinical Diagnostics, Inc., Rochester, New York, United States) or a similar product is recommended for all Rh-negative women at 28 weeks of gestation (to prevent sensitization due to a fetomaternal hemorrhage in pregnancy) and postpartum within 72 hours if the newborn is Rh-positive. Since the implementation of routine clinical use of RhoGAM in the 1960s, the incidence of HDN has decreased significantly. Anti-Rh immune globulin should also be administered to Rh-negative women following a molar pregnancy, threatened abortion, intrauterine fetal demise in the second or third trimester, trauma to the abdomen, or a late pregnancy amniocentesis. The half-life of RhoGAM is anywhere between 16 and 30 days and varies based on dose and route, but should be administered in each subsequent pregnancy at 28 weeks.

Diagnosis and management of alloimmunization in pregnancy

Detection of significant concentrations/titers of alloantibodies during the first trimester screening test suggests that the mother is sensitized. Determination of the father's Rh type by serology and genetic testing if he is seropositive is often the next step in assessment of the fetus. The fetus will be Rh-positive if the father is homozygous for RhD and no genotyping of the fetus is necessary. A heterozygous Rh genotype in the father suggests that the fetus is at risk for developing HDFN. Fetal genotyping via PCR testing of AF or free fetal DNA testing in maternal serum is necessary. If the fetal genotype is Rh-negative, there is no risk for development of HDFN. If the fetus is RhD-positive, he or she is at increased risk for HDFN. In rare occasions, false-positive results can occur in the genetic testing of the fetus due to the presence of an RhD pseudogene. If suspected, the RhD-negative mother should be tested genetically for the pseudogene.

In a sensitized woman with an at-risk fetus, titers of alloantibodies in maternal serum are measured by the indirect antiglobulin test every 2 weeks. If the titer exceeds a previously defined cutoff, detection of fetal blood flow through the middle cerebral artery (MCA) by Doppler ultrasonography can help predict fetal anemia. Increased peak systolic blood flow through the MCA compared with a gestational age-specific median is associated with anemia of increasing severity.

In addition to ultrasonography, detection of bilirubin in AF is a sensitive predictor of the severity of fetal anemia. Liley originally determined that, in at-risk pregnancies, increased concentration of bilirubin in AF compared with normal AF of the same gestational age was directly proportional to the severity of hemolytic disease in the fetus. The concentration of bilirubin can be directly measured in AF through absorption spectrometry. The maximum absorbance of bilirubin is at 450 nm. In normal AF, the absorbance spectrum between 350 and 550 nm forms a straight line when plotted on a log–linear graph. However, in the presence of significant amounts of bilirubin, a peak is seen at 450 nm. Measurement of the linear difference between normal spectra at the absorbance of 450 nm (ΔA_{450} or ΔOD_{450} in clinical literature) is proportional to the amount of bilirubin present. The Liley chart (Fig. 42.1) plots the gestational age compared with the change in absorbance or OD at 450 nm. Three zones predicting differing severity of hemolytic disease govern management of patients. Patients whose ΔA_{450} falls within Zone I are minimally affected, while those in the upper third of Zone II or Zone III have severe disease requiring intervention. Decades later, Queenan developed a modified ΔA_{450} curve that more accurately predicts risk at an earlier gestational age, yet its use has not become mainstream. While serial measurements of AF ΔA_{450} are recommended, they are less commonly performed because of the inherent risk of pregnancy loss associated with amniocentesis. MCA Doppler ultrasonography is a noninvasive alternative. Typically, if done, serial ΔA_{450} measurements are performed every 2 weeks until delivery or intervention is necessary in antibody-sensitized women.

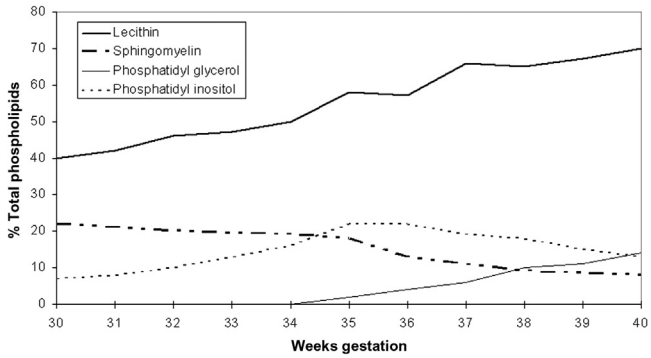

FIGURE 42.1 The Liley chart. Depiction of the relationship between bilirubin concentration as measured by ΔOD_{450} in amniotic fluid and weeks of gestation. Zone I and IIa values are associated with unaffected or mildly affected fetuses. Zone IIb or III values are associated with moderate-to-severe hemolytic disease in the fetus. *Reprinted from A.M. Gronowski (Ed.), Handbook of Clinical Laboratory Testing During Pregnancy, Humana Press, Totowa, NJ, 2004, with kind permission from Springer Science + Business Media.*

AF bilirubin measurements are affected by the presence of fetal blood. If blood is noted in AF, steps should be taken to minimize hemolysis of fetal RBCs (store in the cold and spin down cells). A Kleihauer–Betke (KB) test can be performed to check whether the blood is fetal or maternal. A KB test begins by making a slide with the bloody AF and then treating with acid. Fetal hemoglobin is resistant to acid treatment. After acid treatment, red cells in AF are stained, and fetal red cells will appear pink, while adult red cells appear as ghosts. If the blood is of fetal origin, this should be considered when interpreting results. Blood contamination of the amniotic cavity during amniocentesis takes approximately 2–3 weeks to clear from AF. Meconium contamination increases the peak at 450 nm and takes 3 weeks to clear from AF. Women carrying a fetus with severe anemia are treated with glucocorticoids to induce fetal lung maturity (FLM). These steroids falsely lower the ΔA_{450} values for up to 1 week. In the presence of all of these contaminants, delay of testing is recommended.

The gold standard for assessing fetal anemia is the measurement of hematocrit and other hematologic parameters in fetal blood. Recommendation for an in utero transfusion is based upon the fetal hematocrit, maternal clinical, and laboratory parameters along with clinical judgment. The process of ultrasound-guided fetal blood sampling (percutaneous umbilical blood sampling) is associated with a fetal death rate of 1%–2% and remains the last option when monitoring fetal anemia in a sensitized pregnancy.

Treatment of the symptomatic fetus

Treatment of fetuses with severe anemia is dependent upon gestational age and FLM. Later in pregnancy, delivery may be induced in fetuses with lung maturity and severe anemia. If lungs are immature, antenatal corticosteroids are given to stimulate maturity prior to induction or intratracheal surfactant injections given after delivery. Fetuses of <35 weeks of gestation and severe anemia may undergo an intrauterine transfusion. Perinatal survival rates are $>90\%$ for fetuses in sensitized pregnancies except for those that develop hydrops fetalis, where the survival rate is $\sim 10\%$.

Laboratory testing for fetal anomalies

Fetal congenital, structural, or chromosomal anomalies change the concentrations of certain biochemical analytes in maternal serum or AF. Powerful screening tests employing these biomarkers have been developed to estimate risk of anomalies, such as fetal aneuploidy (trisomies 13, 18, and 21), open neural tube defects (ONTDs), and fetal sex. Prenatal screening (PNS) tests are meant to identify pregnancies at risk for certain disorders that might benefit from invasive diagnostic testing. These are not diagnostic tests and should only be offered in a hospital/clinic where diagnostic testing is available. Laboratories offering PNS should communicate with the clinical care providers and patients about the risks and benefits of such testing.

Open neural tube defects

NTDs are a group of congenital anomalies involving structural defects of the brain and/or spinal cord. These effects occur early in embryonic development, typically by 6 weeks of gestation, when the neural tube fails to close. The severity and defect are dependent upon where the closure fails to occur (i.e., cranial or spinal). Cranial defects occur in the scalp and brain and are typically fatal, while spinal defects, commonly termed spina bifida, vary in severity depending upon the location of the anomaly (i.e., the higher the defect, the worse the prognosis). About 95% of spina bifida cases are open defects in which the spinal column is exposed in utero, and, at birth, 5% are closed (covered by tissue). Closed defects are usually less severe, and are rarely detected in utero by ultrasound or biochemical testing.

NTDs are caused by genetic and environmental factors. Over 90% of affected patients have no family history, suggesting a strong environmental influence. Risk factors include: geographic region, ethnicity, maternal diabetes, and diet. Of these, diet is most important. In particular, adequate intake of folic acid is essential for proper CNS development. Significant reductions in NTDs with folate intake of 400 μg/day is observed when supplementation begins prepregnancy and during the first 4 weeks. Mandatory fortification of US grain products with folate in 1998 saw the incidence of NTD drop to $\sim 1/1000$ births.

ONTDs are characterized by elevated concentrations of alpha-fetoprotein (AFP) in AF and maternal serum. AFP, a fetal protein expressed by the yolk sac and fetal liver, is part of a family of binding proteins that includes albumin. AFP concentrations are greatest in fetal serum in early pregnancy and gradually decline throughout pregnancy. The concentration of AFP in AF mirrors is of fetal serum but is 100-fold lower. In maternal serum, alpha-fetoprotein (MS-AFP) concentrations can be detected after 10 weeks of gestation and are ~4000-fold lower than in AF. MS-AFP increases throughout pregnancy and peaks at 25 weeks of gestation. Maternal serum and AF-AFP concentrations are affected by gestational age, maternal weight, early pregnancy glucose control/diabetes status, race, and the number of fetuses.

There is no clear separation in maternal serum and AF-AFP concentrations between patients with and without an ONTD; therefore it is measured as a screening test to predict women at increased risk. Screening is usually performed between 15 and 23 weeks of gestation. As noted, AFP concentrations increase with gestational age particularly during the recommended testing window. To account for this, screening test results are reported as a multiple of the median (MoM). When AFP testing is set up, laboratory-specific median values are determined for the population being tested for each gestational week.

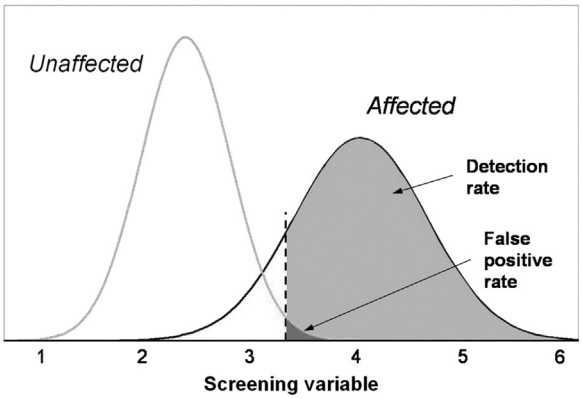

FIGURE 42.2 The effect of an arbitrary screening cutoff value (dotted line) on the detection and false-positive rates for a given disease. *Reprinted from A.M. Gronowski (Ed.), Handbook of Clinical Laboratory Testing During Pregnancy, Humana Press, Totowa, NJ, 2004, with kind permission of Springer Science + Business Media.*

The MoM calculation is as follows:

$$\frac{\text{Patient's AFP Concentration}}{\text{Median AFP Concentration for Gestational Week}}$$

The calculated MoM is adjusted to account for gestational age, maternal weight, race, diabetes status, and the number of fetuses. Prior to implementing the testing, each lab should determine the MoM cutoff for a screen positive result. The ideal cutoff optimizes detection rate while reducing false positives (Fig. 42.2). Typically, cutoffs of 2.0 and 2.5 MoM are used for both maternal serum and AF-AFP. Screening results also contain a relative risk for developing an ONTD calculated from population statistics using the patient's MoM and demographics.

Women with positive screens are referred for genetic counseling and further testing. Gestational age is confirmed by dates or ultrasound. If inaccurate, recalculation of MoM and risk is suggested. Ultrasound may also reveal other potential reasons for elevated AFP like recent fetal demise or twin pregnancy. Most ONTDs are visualized by high-resolution two-dimensional ultrasound in the second trimester. In fact, recent studies suggest that ultrasonography may have a higher detection rate than MS-AFP for NTDs. For this reason, ACOG now recommends NTD detection via high-resolution second trimester ultrasound. AF-AFP testing is often performed when ultrasound is inconclusive. All positive AF-AFP results can be checked for fetal blood contamination with an HbF immunoassay, as blood elevates AFP by 2%−3%. True-positive AF-AFP results should be followed with AF acetylcholinesterase (AChE) testing. A positive AF-AFP and AChE is 99% predictive of an ONTD.

Fetal aneuploidy

Aneuploidy, an abnormal number of chromosomes, is a common cause of miscarriage. Only a few aneuploidies are compatible with life, including trisomies 13, 18, and 21 [Down syndrome (DS)]. ACOG recommends that all pregnant women be screened for fetal aneuploidy. Screening tests identify fetuses at increased risk for DS, trisomy 18 (T18), and sometimes trisomy 13 (T13).

Down syndrome

DS is the most common chromosomal disorder among live born children, with a prevalence of ~1/800 births. DS is caused by the presence of an extra copy of a (complete or partial) chromosome 21. The disease is characterized by moderate-to-severe mental retardation, short stature, and classic facial features, including a flat occiput, upslanting eyes, small ears, congenital heart disease, and GI anomalies. The most commonly cited risk factor for DS is advanced maternal age. After 30 years, a woman's risk at term of having a child with DS is ~1 in 900, and this risk increases rapidly to 1 in 75 by age 40. Other risk factors include a having child with aneuploidy

in a previous pregnancy or detection of the genetic translocation for DS in a previous pregnancy.

In 1984 it was observed that fetal DS was associated with low MS-AFP (0.74 MoM), and this association was independent of maternal age. As with NTDs, there is significant overlap between MS-AFP concentrations in women pregnant with unaffected and DS fetuses; therefore MS-AFP was also measured to screen for DS. When combined with maternal age, MS-AFP screening detects ~50% of DS cases with a 12% false-positive rate (Table 42.3). Maternal serum concentrations of two other analytes are also altered in women with DS fetuses, unconjugated estriol (uE_3), and hCG. uE_3 is the major estrogen produced in the fetoplacental unit. It increases in maternal serum during the second and early third trimesters. Since both analytes change with gestational age, they are normalized with the MoM calculation. MS-uE_3 is lower (0.75 MoM), while hCG is higher (2.06 MoM) in women pregnant with DS fetuses. The serum triple screen (AFP, uE_3, and hCG with maternal age) is performed in the second trimester, ideally between 15 and 23 weeks of gestation, in order to assess risk for DS. Risk estimates are determined by first calculating MoMs for gestational age for each biomarker and then adjusting for interfering factors like maternal age, race, weight, and relevant clinical history. Individual laboratories determine the risk cutoff for a positive test, usually 1:270 at the time of screening. Triple screening detects 69% of DS pregnancies with a screen positive rate of 5% (Table 42.3).

Addition of a fourth analyte, dimeric inhibin A (DIA), to second trimester screening panel increased sensitivity for fetal DS. DIA is elevated in maternal serum of women with DS fetuses (≥1.77 MoM). During pregnancy, DIA is secreted by the placenta and acts to suppress FSH. Its concentrations increase slightly with gestational age; therefore it is expressed as an MoM. The quadruple screen, MS-AFP, HCG, uE_3, and DIA combined with maternal age, is the recommended second trimester test for fetal aneuploidy. Analyte MoMs combined with age and other risk factors are used to calculate risk for FDS. Adjustments in MoMs are made for maternal weight, twin pregnancies, history of prior fetal aneuploidy, and diabetes status. A lab-specific positive risk cutoff is established, which allows for detection of ~80% of FDS cases with a screen positive rate of 5%. The penta screen includes a fifth biomarker, hCGh, but currently there are limited data to support its routine use.

Gestational age should be confirmed on all positive second trimester screens. Quad screening should not be repeated, as this reduces its sensitivity. Depending on gestational age, obstetricians may elect to follow up patients with increased risk for fetal aneuploidy with noninvasive prenatal testing (NIPT)/cell-free DNA testing. AF karyotyping is the preferred confirmatory testing for all remaining screen positive patients. The benefits of diagnostic testing should be weighed against the risks of spontaneous pregnancy loss due to amniocentesis.

TABLE 42.3 Detection and screen positive rates for Down syndrome screening tests.

Screening test	Analytes	Detection rate (%)	Screen positive rate (%)
First trimester			
Maternal age		32	5
Nuchal translucency	NT	70	5
Combined test	NT, PAPP-A, and hCGβ	87	5
Second trimester			
Maternal age		32	5
Double test	AFP and hCG	60	5
Triple test	AFP, hCG, and uE_3	69	5
Quadruple test	AFP, hCG, uE_3, and DIA	81	5
Integrated (Combined test and quadruple test)	NT, PAPP-A, and hCGβ; and AFP, hCG, uE_3, and DIA	96	5
Contingent (Combined test and/or quadruple test)	NT, PAPP-A, and hCGβ; and/or AFP, hCG, uE_3, and DIA	94	5
Noninvasive prenatal testing			
Cell-free fetal DNA	DNA analysis of chromosomes 13, 18, 21, and Y	90%–99%	0.5

AFP, α-Fetoprotein; *DIA*, dimeric inhibin A; *hCG*, human C chorionic gonadotropin; *NT*, Nuchal translucency; *PAPP-A*, pregnancy-associated plasma protein-A; *uE_3*, unconjugated estriol [4].

ACOG recommends the first trimester combined screening test for all pregnant women (Table 42.3). This test combines nuchal translucency (NT) measurements taken by ultrasound and maternal serum biomarkers, hCG or hCGβ, and pregnancy-associated plasma protein-A (PAPP-A). The ultrasonographic measurement of the fluid collection at the back of the fetal neck in the first trimester, NT, is used to assess numerous fetal anomalies. DS fetuses have an increased NT for their gestational age. Alone, NT measurements detect 64%−70% of FDS with a 5% screen positive rate. Any fetus with a NT ≥ 3.0 mm is at increased risk for any aneuploidy as well as other congenital anomalies and should be offered follow-up screening or diagnostic testing. PAPP-A is synthesized by trophoblasts, and its concentration increases with gestational age. Decreased PAPP-A (≤0.43 MoM) with elevated hCG (≥1.98 MoM) and an increased NT are associated with risk of DS. The combined test offers detection rates up to 87% with 5% screen positive rates. Patients with positive screens should receive genetic counseling and diagnostic testing. The preferred confirmation (diagnostic) tests are karyotyping in the first trimester through chorionic villus sampling, performed between 9 and 11 weeks, or second trimester amniocentesis after 15 weeks of gestation. Both procedures are associated with a risk of spontaneous pregnancy loss.

Integrated testing combines both first and second trimester screening tests to assess the risk of FDS as well as ONTD. With integrated testing, the first trimester results are withheld until the second trimester testing is complete, improving DS detection to 96% with a 5% screen positive rate (Table 42.3). The improved detection rate is ideal; however disadvantages to patients are that two samples are needed, there can be significant worry during the testing period, and CVS sampling is not available for confirmation testing. Contingent screening employs a step-wise approach in which the results of the first trimester test are revealed to the patient and the patient is offered diagnostic testing if she screens positive. Intermediate and high risk screening results are followed up in the second trimester with the quad screen. The biochemical marker results are combined to generate an overall risk of fetal DS. When both trimester screening tests are used, the contingent screening approach provides a detection rate of up to 94% and a 5% false-positive rate. Disclosure of the first trimester results obviates the disadvantages of the integrated approach.

Trisomy 18

Both the first and second trimester screening approaches are capable of estimating fetal risk for T18. Screening for T18 is controversial, because the prevalence of disease and survival rate are low, ∼1/8000 live births. Both first trimester maternal serum markers (PAPP-A and hCG) are low in T18, while NT is elevated. AFP, hCG, and uE_3 are low, while inhibin is unaffected in women with T18 fetuses. The detection rate for T18 varies by study and screening test, but is ∼80% with a 0.3% screen positive rate with first trimester screening and ∼60% with a 0.5% screen positive rate when a risk cutoff of 1:100 is used for quad screening.

Trisomy 13

Also known as Patau syndrome, T13 can be detected through cell-free DNA screening. Like T18, the prevalence of T13 in live births is low at ∼1/18,000. While NT is often abnormal, neither the first of second trimester screens can sensitively detect T13.

Multifetal gestations

First and second trimester screening results are unreliable in multifetal gestations due to reduced sensitivities for detection of ONTD or fetal aneuploidy. Interpretation is particularly difficult when only one twin is affected, because maternal serum results are the average to the two fetuses. Most labs do not report risks for twin or other multiple pregnancies. Those that do report an approximate or pseudorisk calculated by dividing the patient's analyte MoM values by averages for unaffected twin pregnancies of the same gestational age.

Cell-free DNA or noninvasive prenatal testing

NIPT utilizing circulating cell-free fetal DNA is a newer screening tool for fetal aneuploidy. While there are data to support use of this testing in both high and low risk populations, it should be noted that the positive predictive value of this testing in a low risk population is decreased due to decreased disease prevalence. As with the other screening tests, decisions to terminate a pregnancy should not be made without a confirmatory diagnostic test. Small amounts of fetal nucleic acid material (3%−13% after 10 weeks of gestation) circulate in maternal serum. Several companies have patented different molecular techniques, all of which utilized next-generation sequencing of isolated cell-free fetal DNA. Along with detection of fetal aneuploidy, NIPT may also determine the sex of the infant. It is recommended that NIPT results be reported in terms of positive predictive values and posttest risks for each aneuploidy tested in the context of the percent fetal fraction isolated. Low % fetal fraction can lead to false-negative results and can occur in patients before 10 weeks of gestation, up to 23% of obese patients, and with fetal aneuploidy. Many laboratories do not report risk estimates in specimens with fetal DNA fractions of <4%, often referred to as a "no call" result. Patients with "no call" results should be offered genetic counseling,

high-resolution ultrasound, and diagnostic testing, because they are at higher risk for fetal aneuploidy. NIPT detects up to 99% of DS cases with a 0.5% screen positive rate in women whose results are reported. Like traditional screening tests, NIPT has limited utility for assessing risk of fetal aneuploidy in twin or other multiple gestations. High risk patients should be counseled on the limitations of NIPT prior to testing. In particular, despite increased sensitivity, specificity, and positive predictive values, NIPT is a screening test and does not replace traditional diagnostic techniques (i.e., karyotyping), and its results should not be used to determine treatment decisions. Furthermore, NIPT only assesses risk of fetal aneuploidy; therefore women should still be screened for an ONTD in the second trimester.

Preterm birth

Preterm birth (PTB), delivery of an infant prior to 37 weeks of gestation, is a major cause of neonatal mortality worldwide. Surviving infants suffer numerous morbidities including: respiratory distress syndrome (RDS), sepsis, neurodevelopmental delay, and behavioral problems. In the United States, approximately 10% of births were preterm in 2018, which has decreased from its peak in 2007 of 12.7%. Despite recent declines, the overall incidence has increased significantly, since the early 1980s despite advancements in prediction and prevention.

There are two types of PTB: spontaneous and induced. Some preterm deliveries are medically necessary to eliminate risk to mother or fetus. Thirty percent are spontaneous with the precipitating factor being premature rupture of membranes, while $\sim$50% of PTBs are spontaneous with intact membranes. The type of PTB depends on the underlying cause of the disease. Preterm labor is a syndrome that may be caused by one of several pathobiological processes (maternal or fetal stress, inflammation, placental abruption/decidual hemorrhage, and uterine distention) with different biochemical or epidemiological triggers. Each converges into a final common pathway involving activation of the myometrium, proteases and prostaglandins, uterine contractions and cervical dilation with or without rupture of membranes, and ultimately PTB.

Prediction of preterm birth

Prediction of spontaneous PTB is difficult, because early clinical symptoms of are typically mild and resolve without intervention. The clinical diagnosis of preterm labor, eight contractions/hour and advanced cervical dilation, often occurs too late for intervention. Epidemiologic and clinical risk factors for PTB include maternal age, socioeconomic status, lifestyle, multiple gestation, history of PTB, genetics, and race. Risk factors alone are neither sensitive nor specific predictors of those who will deliver preterm, because a majority of pregnancies resulting in PTB have no known risk factors. Cervicovaginal fluid (CVF) fetal fibronectin (FFN) is the only ACOG-approved biochemical marker for prediction of PTB in symptomatic women.

Fetal fibronectin testing

FFN is a member of the fibronectin family of matrix proteins. During pregnancy, FFN is expressed in the extracellular matrix between the maternal decidua and the fetal membranes (the choriodecidual junction) and may facilitate implantation. Cervicovaginal secretions contain FFN for the first 22 weeks of gestation until the fetal membranes fuse to the maternal decidua. By 37 weeks, FFN becomes heavily glycosylated, loses its adhesive properties, and is shed into the CVF. The presence of FFN at concentrations of $\geq$50 ng/mL in CVF of women 24−35 weeks of pregnant is associated with increased risk for PTB.

The FFN assay is FDA cleared to predict PTB in women with and without symptoms of preterm labor. In symptomatic women 24−36 weeks of gestation, FFN should be used to assess the risk of PTB within 14 days of specimen collection. Test results for FFN can also be considered in combination with other clinical information to assess the risk of PTB in asymptomatic women with singleton pregnancies of $\leq$35 weeks. Contraindications for FFN use include: advanced cervical dilation ($\geq$3 cm), rupture of amniotic membranes, cervical cerclage, moderate or gross vaginal bleeding, sexual intercourse within 24 hours, twin, or other multiple pregnancy.

The diagnostic strength of FFN lies in its negative predictive value (NPV). Symptomatic women with negative FFN results are at low risk for delivery within 7 days of testing. A positive test is less useful. The prevalence of PTB among women with symptoms of labor is $\sim$5%. The NPV of any test (even a coin flip) for a low prevalence disease is high (95% for a coin flip). Therefore the ideal predictive marker for PTB is one with a high *positive* predictive value. ACOG recommends against using FFN testing alone to determine management strategies for women with symptoms of preterm labor.

Other biochemical markers for the prediction of preterm birth

Besides FFN, the most promising marker for prediction of PTB is interleukin-6 (IL-6) in amniotic or CVF. Since the main underlying cause of PTB is infection or inflammation, cytokines like IL-6 have been implicated in the pathobiological process. The diagnostic utility of CVF IL-6 is similar to FFN (high NPV) at a fraction of the cost. New

studies are investigating panels of biomarkers associated with known genetic or etiological causes of PTB.

Prevention of preterm birth

Traditional therapies for preterm labor include hydration, bed rest, and home uterine-activity monitoring. None of these effectively prevents PTB. Drug therapy with tocolytic agents aimed at stopping contractions has limited utility. Prophylactic antibiotic therapy to prevent infectious causes of PTB showed little benefit and caused adverse effects in fetuses. Intramuscular injections of 17-hydroxyprogesterone reduce the incidence of PTB and are recommended for use in women with a prior history of PTB. While none of these reduces poor outcomes associated with PTB, they are used to prolong pregnancy long enough to treat with corticosteroids. ACOG recommends short-term use of tocolytic therapy aimed at prolonging pregnancy enough to facilitate antenatal corticosteroid treatment. One or two injections (given at least 7 days apart) of corticosteroids reduce morbidity and mortality of PTB if given at least 48 hours prior to delivery. Corticosteroids stimulate FLM.

Fetal lung maturity testing

RDS is the most common morbidity associated with prematurity. RDS occurs with incomplete fetal lung development. The incidence of RDS is increased with decreased gestational age at birth. The fetal pulmonary system is one of the last to completely develop, and risk for RDS is inversely correlated with gestational age at delivery. The final stage of fetal lung development, the alveolar stage, involves production of increasing amounts of pulmonary surfactant. In a normal airway, surfactant coats the alveolar epithelial surfaces. It decreases surface tension of the alveolar wall to prevent lung collapse during exhalation. Surfactant deficiency in RDS patients causes both lung collapse and hyperextension of alveoli, leading to fibrosis and hyaline membrane disease. The alveoli in an RDS lung are perfused, but unventilated, resulting in hypoxia, hypercapnia, and respiratory acidosis.

Pulmonary surfactant synthesis by type II pneumocytes in the fetal lung begins at $\sim$28 weeks of gestation. In type II cells, surfactant is packaged and stored in lamellar bodies (LBs). These platelet-sized vesicles made up of phospholipids (PLs; 90%) and surfactant (10%) are exocytosed to the pulmonary airway, where they coat the epithelium. During lung maturation, the PLs in LB change. Analysis of the change in PL content in AF is used to assess lung maturity.

Prevention of RDS is accomplished by preventing PTB or stimulating surfactant production with antenatal corticosteroids. Assessment of FLM status through one of several AF-based tests may assist in making clinical decisions in women with symptoms of preterm labor and/or women, whose labor is induced prior to 39 weeks of gestation. In recent guidelines, ACOG recommended against any elective induction of labor before 39 weeks of gestation; therefore FLM testing is only necessary in emergent situations (i.e., premature rupture of membranes, severe early preeclampsia requiring delivery of an infant, or HDFN). FLM tests help determine whether an NICU is needed when PTB is required. Despite this, numerous outcome studies have failed to demonstrate improvement in neonatal outcomes when FLM information is known. Furthermore, the advent of intratracheal surfactant therapy has improved outcomes for infants with immature lungs. Improved treatment options and reduced clinical utility of the testing have led to a significant decline in available FLM testing methodologies and FLM testing volumes.

Laboratory assessment of fetal lung maturity

FLM is most often assessed by testing the amount of surfactant, PL, and/or LBs in AF after 32 weeks of gestation. AF is collected through ultrasound-guided amniocentesis. Prior to testing, AF is inspected for contaminants such as blood or meconium. Contamination limits possible FLM methods. Many methods require removal of particulate matter through centrifugation. Short, slow spins are critical to avoid PL precipitation. Despite many available, highly sensitive testing options, the availability of antenatal corticosteroid therapy and intratracheal injections of surfactant has greatly reduced the number of FLM tests requested by providers.

The surfactant–albumin ratio

The surfactant–albumin (S/A) ratio increases throughout gestation proportionally with lung maturity. S/A ratio assays usually employ fluorescence polarization technology. Albumin and surfactant in AF compete for binding of a fluorescent probe. The albumin-bound probe induces a high degree of polarization, whereas the smaller surfactant bound probe has a low degree of polarization. S/A ratios are higher in mature lungs. Blood or meconium-contaminated AF may result in inaccurate results. Since the discontinuation of a commercially available S/A ratio assay, labs must develop their own, which are uncommon and not standardized.

Lamellar body count

Currently, the most common FLM method is the lamellar body count (LBC). Counting LBs in AF is a sensitive and specific alternative to S/A FLM assays. LBs pass into AF in the third trimester, and their numbers increase with FLM. They are similar in size to platelets and can be

counted on a whole blood counter. This fast and simple assay can easily be performed in any lab. LBC of $\geq 50{,}000/\mu L$ generally suggest maturity; however, cutoffs are instrument-specific. Currently, there is no standardized QC material, and LBC cannot be performed on blood or meconium-contaminated AF. Validation of LBC cutoffs is challenging, given the low incidence of RDS.

Lecithin–sphingomyelin ratio

Increases in surfactant-based PLs, like lecithin (phosphatidyl choline) and phosphatidyl glycerol (PG) in the AF compared with consistent concentrations of lipids not originating from the lung, like sphingomyelin, correlate with lung maturity. Usually, a lecithin–sphingomyelin ratio (L/S ratio) of >2.0 indicates FLM, but this is method-dependent. AF PLs are separated by thin-layer chromatography after an extraction step, and quantitated by scanning densitometry. The L/S ratio is a sensitive and specific method for assessing FLM; however, it is time-consuming, technically challenging, and nonstandardized. Availability of L/S ratio testing is uncommon, and this testing is not recommended in the presence of blood or meconium contamination.

Phosphatidyl glycerol

PG is the last surfactant-based PL to be expressed during fetal lung development (after 35 weeks), and it may help in coating the alveolar surface. Semiquantitative detection of PG in AF through an agglutination assay (AmnioSTAT-FLM-PG, Irvine Scientific) is a rapid and sensitive alternative for predicting FLM in late pregnancy. PG measurements are particularly useful in blood and meconium-contaminated AF specimens, as all other tests described above are affected by these contaminants. Because it is not usually present until late pregnancy, it has a high false-positive rate, and interpretation of the test can be inconsistent among technologists.

The appropriate management of indeterminate or immature results is unclear. Clinicians prefer to handle these individually depending on the risk to mother and/or fetus in maintaining the pregnancy. No consensus exists on when and/or whether to repeat FLM testing with an immature or intermediate result. Finally, FLM testing is not associated with improved outcomes for the neonate and has limited clinical utility.

Self-assessment questions

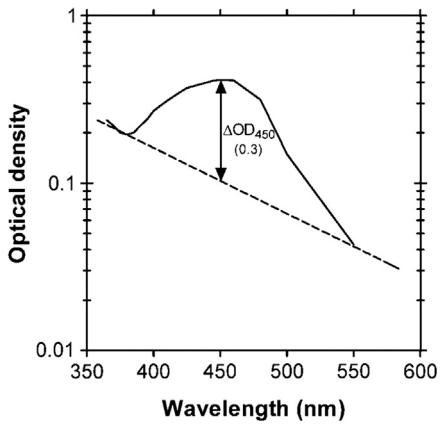
1. All of the following changes in normal laboratory values occur in pregnancy except:
   - **a.** exponential increases in progesterone, estradiol, and cortisol
   - **b.** decreases in BUN and creatinine
   - **c.** increased hemoglobin and hematocrit
   - **d.** increased liver enzymes
2. A 34-year-old female presents to the emergency room with abdominal cramping and vaginal bleeding. Her LMP was ~6 weeks ago. She has a history of an

elective abortion 12 years ago and a chlamydia infection 15 years ago. Her hCG and progesterone values over the course of a week are shown below. What is the most likely scenario?

Date	hCGβ (mIU/mL)	Progesterone (ng/mL)
10/15	493	
10/17	588	3.8
10/19	808	6.3
10/23	1136	

a. Ultrasound reveals the presence of a live intrauterine pregnancy at 6 weeks.
b. Ultrasound reveals the presence of an ectopic pregnancy in the right fallopian tube.
c. Ultrasound reveals the presence of a complete molar pregnancy.
d. Ultrasound shows no pregnancy or masses—the patient is in early menopause.

3. An RhD-negative woman is 32 weeks of pregnant with her second child and was found to have an alloantibody titer of 1:32. The profile derived from ΔOD_{450} testing of her amniotic fluid is pictured below. How should this woman be treated?



A.M. Gronowski (Ed.), Reprinted from Handbook of Clinical Laboratory Testing During Pregnancy, Humana Press, Totowa, NJ, 2004, with kind permission of Springer Science + Business Media.

a. The fetus is mildly anemic, and no intervention is required.
b. The fetus is mildly anemic, treat with antenatal corticosteroids, and induce delivery.
c. The fetus is severely anemic, treat with corticosteroids, and induce delivery.
d. The fetus is severely anemic, and perform an intrauterine blood transfusion.

4. The appropriate follow-up in a 35-year-old pregnant woman whose quadruple screen risk assessment is 1:50 for Down syndrome is:
a. No follow-up is necessary, and this is not a screen positive result.
b. Confirm gestational age with ultrasound and recalculate risk assessment.
c. Redraw maternal serum sample and repeat the quadruple screen.
d. Perform quadruple screen testing in an amniotic fluid sample.

5. Which fetal lung maturity test is most appropriate in the presence of blood contamination?
a. amniostat-FLM-PG
b. L/S Ratio
c. lamellar body counts
d. TDX-FLMII

Learning objectives

After reviewing this chapter, the reader will be able to:

- Describe the main hormones involved in regulating the male and female reproductive systems.
- Describe how clinical laboratory testing is used to diagnose reproductive dysfunction.
- Identify the common etiologies of infertility in males and females and how they are diagnosed.

Introduction

From embryonic development to sexual maturation, the human reproductive system is controlled by hormones. The hypothalamus responds to internal and external cues to regulate pituitary secretion of stimulating hormones that target the gonads. Stimulation by pituitary gonadotrophs signals secretion of steroid hormones that provide negative feedback to the brain. The pituitary and hypothalamus also regulate steroid precursor synthesis by the adrenal glands. The hypothalamus, pituitary, and gonads act as a single unit referred to as the hypothalamic–pituitary–gonadal (HPG) axis along with the adrenal glands to regulate reproductive function.

Hypothalamic–pituitary–gonadal axis

In response to external cues and hormones, such as gonadotropins, neurotransmitters, and steroids, the hypothalamus produces gonadotropin-releasing hormone (GnRH), which signals the pituitary to release the gonadotropins, follicle-stimulating hormone (FSH), and luteinizing hormone (LH). FSH and LH are essential regulators of reproductive function in both females and males. By binding to specific receptors in the gonads, they promote conversion of steroid precursors to estradiol in females and testosterone in males. There are complex sex-specific differences in the type, quantity, and timing of steroid production in response to gonadotropins. It should be noted from the outset that hypothalamic hormones (e.g., GnRH) occur at very low concentrations with very short half-lives, and are thus not readily measurable in peripheral circulation. Consequently, pituitary hormones, such as LH and FSH, are used as surrogates for hypothalamic GnRH in the workup of most reproductive disorders.

Male reproductive endocrinology

The male endocrine sex organs are the testes, which contain two hormone-producing cell types, Leydig and Sertoli. Leydig cells synthesize the male sex steroids (androgens). Sertoli cells make sperm and produce hormones called inhibins that provide negative feedback to the brain. Sertoli cells also establish and maintain the "blood–testes barrier," facilitating a unique luminal fluid composition as compared with blood. The testes rely on signaling and regulation by pituitary hormones, such as GnRH.

Control of testicular function

GnRH is a decapeptide secreted in pulsatile fashion with peaks occurring approximately every 90–120 minutes. Pulses of GnRH are critical for maintaining normal concentrations of gonadotropins. The specificity for release of each is a function of the amplitude and frequency of GnRH signaling. Low-frequency pulses stimulate FSH release, while high-frequency pulses promote LH release. As a consequence, concentrations of GnRH, FSH, and LH are variable at any given time. This secretion pattern is often diagnostic, as pulsatility may be lost in pathophysiological states. Accordingly, interpretation of blood FSH and LH measurements requires an understanding of the

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00043-0

underlying physiological conditions. Structurally, both FSH and LH are secreted as heterodimers consisting of α- and β-subunits with homology to TSH and hCG. Consistent with other pituitary glycoprotein hormones, the α-subunit is the same, while the β-subunit differs and confers the biological specificity.

Once released into circulation, LH binds G-protein-coupled receptors (GPCRs) on the Leydig cell surface, stimulating androgen synthesis [principally testosterone, but also dihydrotestosterone (DHT)]. The increase in circulating testosterone inhibits secretion of GnRH from the hypothalamus and LH from the pituitary (Fig. 43.1). FSH binds to a related GPCR on Sertoli cells and promotes spermatogenesis. Spermatogenesis requires high concentrations of testosterone in the seminiferous tubules, and is maintained by proximity to the Leydig cells and androgen-binding protein from the Sertoli cells (steroids are able to cross the blood–testes barrier). FSH also stimulates Sertoli cells to secrete inhibin. The two isoforms of inhibin (A and B) are heterodimeric in structure and composed of dissimilar subunits. Inhibin B is the predominant isoform produced in males although both inhibins signal the pituitary to downregulate FSH secretion.

Androgens

In males, the testes and adrenal glands secrete several different androgens including testosterone, dihydrotestosterone, androstenediol, dehydroepiandrosterone (DHEA), and dehydroepiandrosterone sulfate (DHEA-S). Like all steroid hormones, androgens are synthesized from cholesterol through a series of compartmentalized enzymatic conversions (Fig. 43.1—male steroidogenesis). The most potent androgen, DHT, is produced largely through peripheral conversion of testosterone. DHT has limited diagnostic utility, because circulating concentrations do not reflect intracellular levels. Functionally, DHT is an important steroid in the development of benign prostatic hyperplasia (BPH). BPH is treated with 5α-reductase inhibitors, which block conversion of DHT from testosterone. Androstenediol and other testosterone precursors have limited bioactivity due to weak affinity for androgen receptors. In clinical and diagnostic terms, testosterone is the most important androgen; in cases of anabolic steroid abuse, other androgens may be important.

Testosterone

Testosterone stimulates differentiation of the male fetal genital tract, establishes and maintains male secondary sex characteristics, and promotes spermatogenesis. The testes secrete ~4–10 mg of testosterone daily, accounting for 95% of total circulating concentration; the remaining 5% is produced by peripheral conversion of the adrenal androgens, such as DHEA. Testosterone exhibits diurnal variation in adult men with the highest concentrations occurring in the morning, followed by a gradual decline throughout the day. Testosterone levels reach their

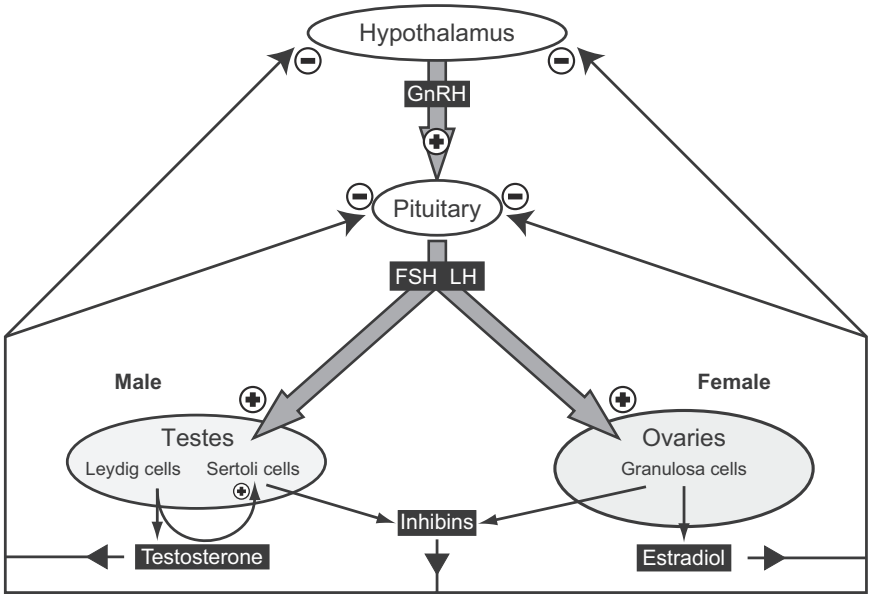

FIGURE 43.1 Hypothalamic–pituitary–gonadal axis. The hypothalamus secretes gonadotropin-releasing hormone in response to environmental and internal cues stimulating gonadotropin (follicle-stimulating hormone and luteinizing hormone) release from the pituitary. In males, luteinizing hormone stimulates testosterone production by Leydig cells. Follicle-stimulating hormone in combination with testosterone promotes spermatogenesis within the Sertoli cell-enclosed seminiferous tubules. In females, follicle-stimulating hormone and luteinizing hormone regulate ovarian production of estradiol in the menstrual cycle. In both males and females, inhibins and sex steroids both provide negative feedback to the hypothalamic–pituitary axis.

nadir in the evening and during the first few hours of sleep. This rhythm is less pronounced with advancing age and in men with testicular failure.

Although a small amount (~2%) of free testosterone is found in circulation, most is bound to carrier proteins including albumin and sex hormone-binding globulin (SHBG). SHBG is synthesized by the liver and binds ~45%–60% of circulating testosterone with high affinity (Kd ~1 nM). The remaining portion of testosterone (35%–55%) is transported bound to albumin with weak affinity (Kd > 1000 nM). SHBG synthesis is increased by estrogen or excess thyroid hormones, and decreased by exogenous androgens, glucocorticoids, growth hormone, and hypothyroidism. Similarly, liver damage may affect synthesis of SHBG and accordingly measurement of total testosterone. Although the free fraction of any hormone is considered to be the biologically active form, there is considerable evidence that the albumin-bound and free portions of plasma testosterone, termed "bioavailable testosterone," represent the biologically active fraction. Provided the affinities above, consider that circulating concentrations of testosterone (Table 43.1) will typically be below the affinity of albumin, such that it will be biologically available.

Measurement of testosterone

There are several different methods available to measure total testosterone including equilibrium dialysis, direct immunoassay (chemiluminescent or radioimmunoassay), and chromatography/mass spectrometry (LC–MS/MS and GC–MS). Isotope dilution mass spectrometry is the reference method for testosterone measurement, although most labs utilize immunoassays. Immunoassays rely on chemical blocking agents that displace testosterone from SHBG and albumin, followed by competitive binding with labeled hormone. There are a number of challenges surrounding measurement of testosterone: (1) assay specificity (cross-reactivity with related steroid hormones); (2) analytical sensitivity (detection of low concentrations of testosterone); and (3) appropriate reference intervals and partitions for men, women, and children. In particular, total testosterone immunoassays are subject to imprecision at low concentrations and when SHBG concentrations are abnormal. Thus detection of androgens in women, children, and some aging men requires more sensitive methods (e.g., LC–MS/MS or second generation immunoassays) to accurately measure testosterone.

Free and bioavailable testosterone

In women and hypogonadal males, second line testing relies on measurement or estimation of free/bioavailable testosterone; these are not widely used in children. The gold standard for free testosterone measurement is equilibrium dialysis/high-performance liquid chromatography–tandem mass spectrometry (ED/LC–MS/MS), although ultrafiltration is a popular alternative used to

TABLE 43.1 Free and bioavailable testosterone measurement limitations.

Method	Limitation
Equilibrium dialysis/high-performance liquid chromatography–tandem mass spectrometry	Expensive and limited availability Results vary with pH, temperature, and dilution Laborious (dialysis alone can take >12 h)
Testosterone analog immunoassays	10-fold negative bias against reference method Not recommended
Free androgen index	Inaccurate due to assumptions about linear relationship between parameters in calculation Not recommended
Calculated free testosterone and bioavailable testosterone	Requires accurate methods unpinning calculation (subject to variation in testosterone and SHBG) Several physicochemical assumptions about dissociation constants (binding affinity, albumin concentrations) Inconsistent reference intervals Many different available equations requiring local validation >50% difference in values reported on proficiency surveys
Ammonium sulfate precipitation	Labor intensive Results vary with temperature Interindividual variation (between staff running assay)

SHBG, Sex hormone-binding globulin.

reduce the amount of time needed for analysis. Direct radioimmunoassay (RIA) testosterone analog methods that rely on competitive binding of a nontestosterone analog to an immobilized antibody have limited clinical utility (Table 43.1). There are also protein precipitation methods, where ammonium sulfate is used to crash protein out of solution leaving behind, in theory, only bioavailable testosterone.

As an alternative to direct measurement, free or "bioavailable" testosterone may also be calculated from total testosterone and SHBG based upon testosterone constant for binding to SHBG using one of several formulae (equations include those from Sodergard, Vermeulen, Nanjee, Sartorius, and Ly). Each of these has limitations in assumptions about binding and kinetics of testosterone and binding proteins (Table 43.1). Of historical note, free androgen index (FAI) calculation (% ratio of testosterone/SHBG) was once used, but is considered inaccurate, because it does not account for the nonlinear relationship between total testosterone and SHBG. Most laboratories have discontinued reporting the FAI.

While the free/bioavailable testosterone methods have their challenges, there have been substantial efforts toward standardization of total testosterone. Currently, the Centers for Disease Control and Prevention (CDC) runs a standardization program, whereby a number of labs with LC−MS/MS methods are certified, provided they achieve results within ∼6% of their reference method. CDC also provides target values for the College of American Pathologists proficiency surveys, which has improved overall agreement of both LC−MS/MS and immunoassays. From a clinical standpoint, practice guidelines recommend measurement of serum total testosterone in a morning collection to screen for deficiency. Bioavailable and/or free testosterone are then used as confirmatory tests.

Dehydroepiandrosterone and dehydroepiandrosterone sulfate

Most DHEA (∼4 mg/day) and DHEA-S (∼10 mg/day) are synthesized by the adrenal glands. Production of these androgens increases just before onset of puberty, peaks in the third decade, and then gradually declines. DHEA-S, a sulfated derivative accounting for >99% of circulating DHEA, is formed largely in the adrenal cortex, but also peripherally through the actions of liver and kidney sulfotransferases.

Both DHEA and DHEA-S are transported primarily bound to albumin. While they are partially influenced by ACTH and the immune system, the regulation of DHEA and DHEA-S is not well understood. Combined DHEA and DHEA-S are the most abundant steroids in the body, where they bind weakly to the androgen receptor and serve as precursors for other steroids. In females, DHEA and DHEA-S contribute approximately half of the total circulating testosterone either directly or through conversion to other testosterone precursors. DHEA-S is preferred for laboratory analysis because of its relative abundance, little to no diurnal variation, and longer half-life (7−10 hours and 15−30 minutes for DHEA-S and DHEA, respectively). DHEA-S measurements are useful when investigating precocious puberty in males, and hirsutism, amenorrhea, or infertility in women.

Male reproductive development

In males, numerous genes on the Y chromosome promote development of indifferent gonads into testes. Embryonic testes control male sexual differentiation through synthesis of various protein and steroid hormones. Testosterone stimulates the Wolffian ducts to develop into the vas deferens, epididymis, and seminal vesicles, and for the differentiation of external male genitalia. After birth, concentrations of the gonadotropins and sex steroids are initially elevated, but then decrease during the first few days of life. Over the next several weeks, plasma concentrations of LH and FSH are higher than during the rest of childhood in both sexes. In males, testosterone is also higher in infants than in older children, suggesting that gonadotropins stimulate its synthesis. Sex steroids, LH, and FSH peak at 2−3 months of age and then decrease to low concentrations that persist throughout childhood. Before puberty, the hypothalamus and pituitary are extremely sensitive to negative feedback from sex steroids and inhibin. Before maturation of the HPG axis, adrenal synthesis of androgens begins to increase. This increase in adrenal androgens (andrenarche) is responsible for the onset of pubic and axillary hair growth.

The increased and intermittent release of GnRH from the hypothalamus causes surges in LH and FSH. The diurnal variation gradually wanes, and the pulsatile release of the gonadotropins occurs at all times during the day. At puberty, the earliest visible sign of increasing LH and FSH secretion is an increase in testicular size. At this time, the hypothalamus and pituitary are less sensitive to the negative feedback allowing the concentrations of gonadotropins and sex steroids to rise steadily, leading to the development of secondary sex characteristics.

The decline of testosterone with advancing age is often referred to as "andropause." Unlike the female menopause where there is a complete absence of estrogen with associated clinical symptoms, andropause involves only a slight decrease in testosterone with less obvious clinical findings. These consist of declines in sexual function, bone mineral density, muscle mass, strength, and cognitive function. Concentrations of SHBG increase with age, resulting in an increase in total testosterone, decreased bioactive testosterone, and increased FSH and LH.

Male reproductive disorders

Reproductive disorders in the male can be divided into five categories including hypergonadotropic (primary) and hypogonadotropic (secondary) hypogonadism, defects in androgen action, impotence, and gynecomastia (Table 43.2). In primary hypogonadism, testosterone is low, and gonadotropins (FSH and LH) are elevated. In contrast, secondary hypogonadism results from low gonadotropins.

Hypogonadism

Male hypogonadism is a clinical diagnosis defined by the inability of the testes to produce testosterone with or without the presence of a low sperm count. Hypogonadism results from disruption of the hypothalamic−pituitary−testicular axis, and diagnosis requires persistent measurably low testosterone output. Clinical features of hypogonadism vary depending on the extent of the disorder. Decreased spermatogenesis is associated with infertility and decreased testicular size. Decreased testosterone synthesis manifests in a variety of symptoms depending on time of onset. A complete deficiency of testosterone in early development results in impaired sexual differentiation in the fetus, where a genotypic male will possess female external genitalia. A partial testosterone deficiency causes incomplete virilization. Males will not develop secondary sexual characteristics at adolescence if testosterone is decreased before puberty. In adults, testosterone deficiency causes decreased libido, muscle mass, and bone mineral density (similar to andropause). Low plasma total testosterone results support the diagnosis of male hypogonadism (Table 43.2). The American Society for Reproductive Medicine (ASRM) Practice Committee guidelines recommend confirmation of low results by repeating morning measurement and/or using free/bioavailable testosterone in cases where SHBG concentrations are abnormal or results are equivocal. The Endocrine Society recommends the testosterone measurement method to be certified by an accuracy-based standard, such as the CDC Hormone Standardization Program for Testosterone. GnRH stimulation testing may also be performed (see hypergonadotropic hypogonadism below).

In hypergonadotropic hypogonadism (primary hypogonadism), there is insufficient steroid production by the gonads. Lack of negative feedback from testosterone leads to increased secretion of FSH and LH by the pituitary. Causes of primary hypogonadism include Klinefelter syndrome (47, XXY karyotype), testicular damage from chemotherapy, radiation, disease, drugs, trauma, and aging. Significant increases in gonadotropins indicate primary hypogonadism even when testosterone is only slightly decreased.

Hypogonadotropic hypogonadism results from low or absent secretion of FSH and LH from the pituitary (secondary hypogonadism) or impaired secretion of GnRH from the hypothalamus (tertiary hypogonadism). Causes include tumors that interfere with hypothalamic−pituitary axis function, panhypopituitarism, hyperprolactinemia, GH deficiency, hypothyroidism, craniopharyngioma, malnutrition, and anorexia. Recently developed immune checkpoint therapies (anti-PD-1/PD-L1 and anti-CTLA-4) are a newer cause of HPA disruption, which can cause secondary hypogonadism. Hypogonadotropic hypogonadism is identified by measuring decreased circulating testosterone in combination with normal or reduced LH and

TABLE 43.2 Diagnosis of androgen excess disorders.

Feature	Comment
Detailed clinical history	Timeline of symptoms
PCOS	Androgen excess
	Oligo or amenorrhea
	Imaging to establish polycystic ovary morphology
Exclusion criteria	Thyroid abnormalities
	Hyperprolactinemia
	Atypical CAH (non-21-OHase deficiency)
Patient-specific exclusion criteria	Acromegaly
	Cushing's syndrome
	Neoplastic secretion of androgens

CAH, Congenital adrenal hyperplasia; *PCOS*, polycystic ovarian syndrome.

FSH concentrations. GnRH stimulation testing may also be performed to determine if the pituitary is responsive. Where LH and FSH increase with GnRH administration, hypergonadotropic hypogonadism may be ruled out. Therapy depends on identifying the underlying condition.

Defects in androgen action

In addition to primary and secondary causes, male reproductive disorders can also result from defective androgen action. These are divided into two categories: (1) defects in the testosterone conversion pathway; and (2) androgen receptor defects.

For testosterone to exert its full biological effect, it must be enzymatically converted to DHT by 5α-reductase. Congenital deficiency of 5α-reductase leads to male pseudohermaphroditism, ambiguous genitalia, and a microphallus. At puberty, normal concentrations of testosterone allow the development of non-DHT-dependent secondary sex characteristics (increased muscle mass, laryngeal enlargement, and enlargement of phallus). In these cases, male children may be raised as females until puberty, necessitating early diagnosis to avoid gender confusion. These individuals are also at risk for development of testicular cancer. Deficiency of 5α-reductase is verified by measuring an increased testosterone:DHT ratio in affected individuals.

Androgen resistance, also referred to as testicular feminization, is the most severe defect in androgen action, and may be caused by any of 150 different mutations in the androgen-receptor gene. These X-linked recessive receptor defects range from partial androgen response to complete androgen insensitivity. Affected individuals have a 46, XY karyotype and bilateral testes, with female external genitalia (a vagina that ends in a blind pouch). The breasts undergo normal (female) development at puberty. A diagnosis of androgen resistance is suggested by normal concentrations of testosterone for a male in a phenotypic female.

Erectile dysfunction

Erectile dysfunction (ED), the persistent inability to develop or maintain an erection, has many causes. Endocrine-related pathologies of ED include diabetes mellitus, hypogonadism, hyperprolactinemia, adrenal insufficiency, feminizing tumors, and both hypothyroidism and hyperthyroidism. Nonendocrine causes of ED include psychological factors, autonomic neuropathy, vascular deficiency, or drug-related side effects. Clinical history is the most effective means to assess the underlying cause of ED and may prompt laboratory evaluation; tests include testosterone, prolactin, and thyroid hormones. As ED is relatively common in men with diabetes mellitus, fasting plasma glucose should also be performed.

Gynecomastia

Benign proliferation of glandular, not adipose, tissue of the male breast, gynecomastia, can occur any time from infancy to old age. It is caused by an imbalance between estrogen and androgen metabolism and results in an increased estrogen:androgen ratio. In neonates, gynecomastia is a side effect of the normally high estrogen concentrations found in pregnancy. Once exposure to estrogen stops at birth, the condition resolves spontaneously. During puberty, gynecomastia occurs when high concentrations of pituitary gonadotropins favor estrogen precursor secretion over testosterone. This condition usually resolves as puberty ends, and steroid synthesis of androgens predominates. In men over 50, gynecomastia is associated with increased aromatase (the enzyme that converts testosterone to estradiol) present in adipose tissue and decreased testosterone synthesis by aging testes.

Gynecomastia can also be induced by several drugs. Prolactin stimulators, such as phenothiazines, methyldopa, and reserpine, suppress gonadotropins and testosterone, whereas spironolactone and anabolic steroids increase aromatization of testosterone to estradiol. Digoxin and phytoestrogens from marijuana act as ligands for the estrogen receptor, such that there is effectively an increased estrogen:testosterone ratio. After excluding pubertal or drug-induced causes, laboratory evaluation for gynecomastia includes measurement of plasma testosterone, estradiol, LH, prolactin, and hCG. In hypogonadic gynecomastia, testosterone is low, and LH and estradiol are elevated. Measurement of hCG is used to detect germ cell tumors that may stimulate estrogen synthesis.

Female reproductive endocrinology

The primary female endocrine sex organs are the ovaries. Ovarian follicles contain oocytes, which are surrounded by several layers of steroid producing cells, the inner granulosa cell layer and the outer theca layers. The theca layers produce steroid precursors, and the granulosa cells convert these precursors to estrogen. Progesterone is produced from the corpus luteum, which develops from ruptured follicles after ovulation. The ovaries function in combination with the hypothalamus and pituitary to regulate the female reproductive system (Fig. 43.1).

Control of ovarian function

As in males, the hypothalamus and pituitary control the primary sex organs in females. Hypothalamic GnRH stimulates the anterior pituitary to release FSH and LH, which promote follicle development and ovulation, respectively; LH also stimulates synthesis of progesterone by the corpus luteum. Ovarian steroids normally inhibit

the secretion of FSH and LH, but, under certain circumstances, exhibit positive feedback, resulting in a release of the pituitary gonadotropins. Ovaries also produce inhibins (A and B), which suppress secretion of pituitary FSH; inhibins may be measured in the context of ovarian tumors and determining ovarian reserve (see below).

Ovarian steroids

The ovaries synthesize sex steroids in a series of enzyme-catalyzed steps from cholesterol (Fig. 43.2). In females, the ovaries are the primary source of estrogens, progestins, and androgens, although the adrenal glands can also produce many of these steroids.

Estrogens

Estrogens are the primary female sex hormones responsible for the development of the secondary sex characteristics, regulation of the menstrual cycle (in conjunction with progesterone), breast and uterine growth, and the maintenance of pregnancy. Although more than 20 different estrogens have been identified, only three have known clinical relevance: estrone (E1), estradiol (E2), and estriol (E3). Of these, estradiol is the predominant estrogen produced by the ovaries, making it a good marker of ovarian function. Estrogen is also produced in small amounts by the adrenal glands and peripheral conversion of androgens by aromatization to estrone. During pregnancy, estriol,

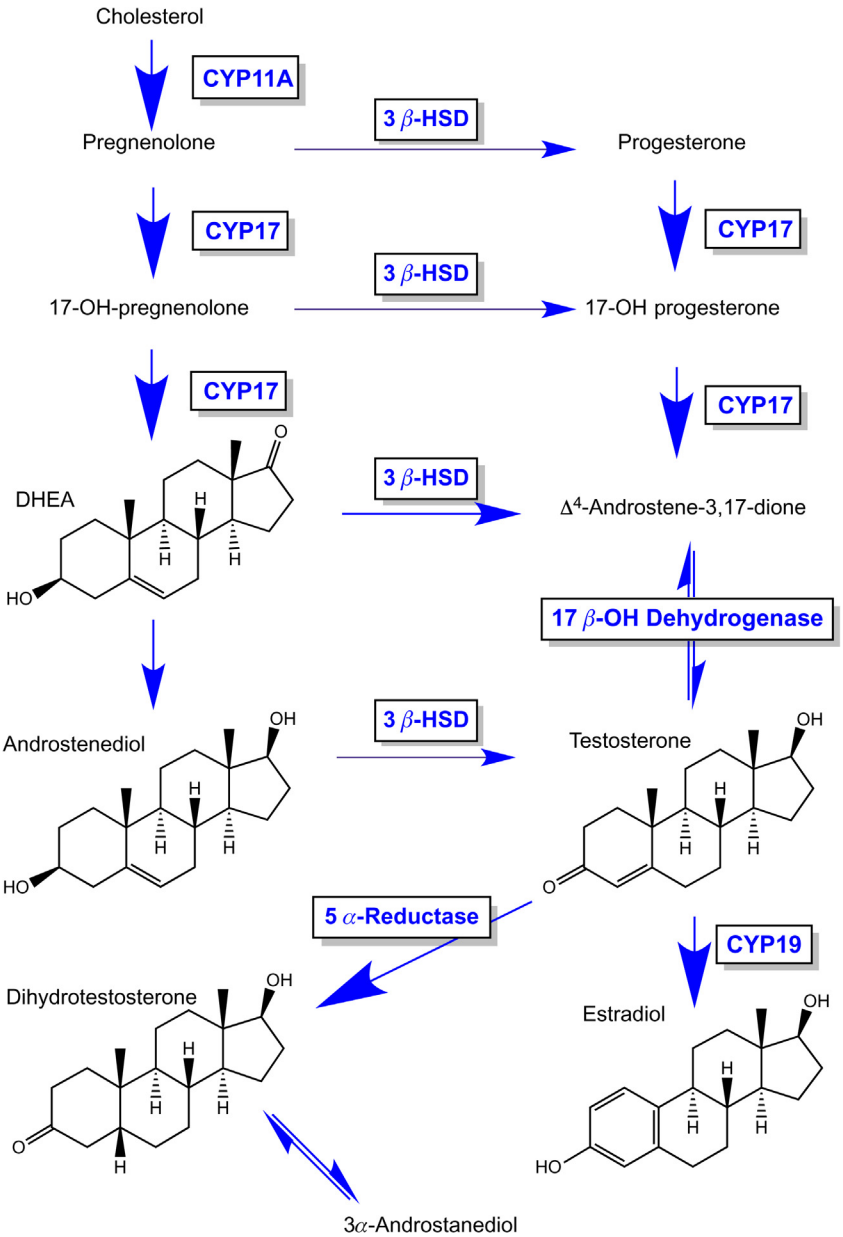

FIGURE 43.2 Overview of androgen synthesis pathway with important converting enzymes.

synthesized in the placenta from fetal 16α-OH-DHEA-S, is present in high concentrations in maternal serum. In nonpregnant, premenopausal women, the concentration of estrogen varies in a temporal pattern throughout the menstrual cycle (Fig. 43.2).

Estrogen exerts its effects by binding to nuclear estrogen receptors. The receptor−ligand complex binds specific response elements in target genes and induces transcription. In addition to nuclear receptors, there are also membrane-bound G-protein-coupled estrogen receptors (mERs). These receptors act nongenomically through complex and incompletely understood mechanisms. Circulating estrogen is metabolized by the liver to estrone, and subsequently to catechol estrogens (2-hydroxyestrone, 2-hydroxyestradiol, and 2-hydroxyestriol) or estriol. Estrogen metabolites are glucuronidated and sulfated rendering them water soluble facilitating excretion in bile or urine.

The majority (97%) of estradiol is bound weakly to albumin (~60%) and tightly to SHBG (~40%) in circulation. Estrogen stimulates the synthesis of binding globulins; thus SHBG concentrations are nearly twice as high in females as in males. Both free and albumin-bound estradiol are considered biologically active, although the clinical significance of this is unclear.

Measurement of estrogen

Circulating estrogens are most commonly measured by immunoassays. As with testosterone, estradiol immunoassays are effective for the majority of cases (infertility assessment in postpubertal females). However, estradiol immunoassays remain insensitive at low concentrations and are ineffective at assessing abnormalities in children and males. RIAs are capable of detecting lower estradiol concentrations, but are slow, labor intensive, and use radioactive reagents. Both RIAs and rapid immunoassays yield variable results between different manufacturers, and measurement methods must accommodate a wide dynamic range (1−3000 pg/mL).

LC−MS/MS methods to measure estrogens have improved low-end sensitivity and are faster than RIAs, but are technically demanding. LC−MS/MS measurement of estradiol is sensitive to interferences, requires extraction, may require derivatization, and is not readily implemented without substantial expertise. The Endocrine Society has called for standardization and improved sensitivity for estradiol assays. Based on the success of testosterone standardization (see "Measurement of testosterone" section), the CDC has defined an HPLC−MS/MS reference method, standard calibrator, and agreement on a certified reference material (SRM-971) for estradiol. A congressionally backed consortium (Partnership for Accurate Testing of Hormones) that includes the American Association for Clinical Chemistry has the goal of standardization and harmonization of estradiol (among other hormone tests).

Progesterone

Progesterone acts in concert with estrogen to regulate the menstrual cycle and prepares the uterine endometrium for implantation of a fertilized egg. Progesterone also regulates glandular development of the breast and maintains the uterus during pregnancy. The adrenal glands, ovaries, and placenta all synthesize progesterone. The circulating concentration of progesterone in nonpregnant, premenopausal women varies throughout the menstrual cycle (Fig. 43.3).

In the corpus luteum, LH and FSH control secretion of progesterone. Once in circulation, progesterone is transported bound to corticosteroid-binding globulin and albumin, with approximately 2%−10% remaining free. Similar to other steroids, progesterone exerts its effects by binding to a specific nuclear receptor in target cells where it modifies gene transcription. Progesterone has a rapid clearance rate and is metabolized in the liver by conversion into one of three classes of compounds: pregnanediones, pregnanolones, and pregnanediols. Conjugation of these metabolites with glucuronate facilitates their excretion by the kidney.

Female reproductive development

In genetic (XX) females, the absence of a Y chromosome allows the gonads to differentiate into ovaries. The absence of testosterone and anti-Müllerian hormone causes the Wolffian ducts to degenerate and the Müllerian ducts to differentiate into the female reproductive tract. At mid-gestation, the developing ovaries contain approximately 7 million oocytes arrested at the first meiotic prophase. An interesting phenomenon related to this early oocyte development is transgenerational epigenetic inheritance, where epigenetic changes (e.g., DNA methylation) in the mother are potentially transmitted to her grandchildren. It is hypothesized that this occurs by differential DNA methylation of the oocytes developing within the female fetus. Oocytes remain in the first meiotic phase until just before ovulation. The number of oocytes declines steadily over a woman's lifetime, and, by menopause, there are few remaining.

As in the males, gonadotropin concentrations in female children are low. These low concentrations of FSH are sufficient to stimulate the granulosa cells to express aromatase, which is required for estrogen synthesis and the follicles to secrete inhibin. LH appears to have little function in female children prior to puberty. Endocrine changes at puberty are initiated by an increase in the frequency and amplitude of the gonadotropins and a corresponding increase in the concentration of ovarian sex hormones. Increased estrogen, the development of the secondary sex characteristics, and onset of menses

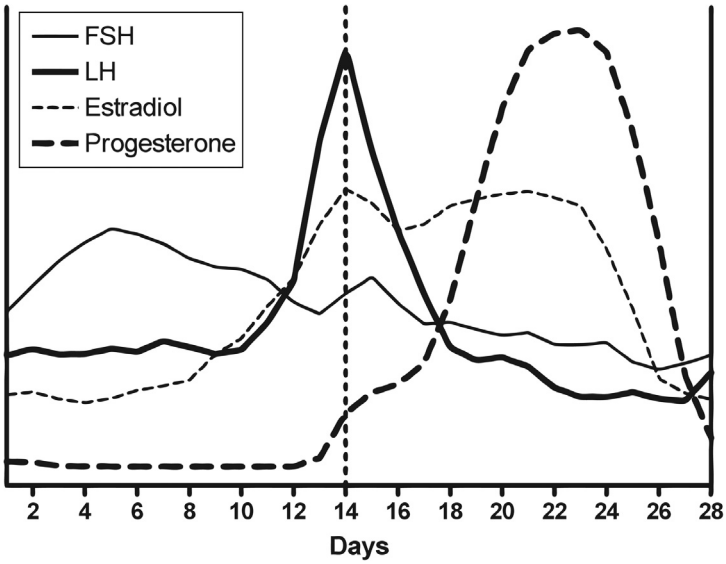

FIGURE 43.3 Relative changes of hormone concentrations throughout the menstrual cycle. Days 1–14: follicular phase. Days 15–28: luteal phase. Ovulation is indicated at Day 14.

(menarche) mark the defining event of puberty in females. The age of puberty onset in females is largely determined through a combination of genes, though other factors contribute. For example, a certain amount of adipose tissue is required to permit puberty to occur (leptin is needed for puberty to occur, but by itself will not induce puberty).

Menstrual cycle

The menstrual cycle is a series of tightly controlled events by the female HPG axis. Its median length is 28 days and consists of two phases (follicular and luteal) divided by ovulation at ~14 days. The hormonal changes observed during the menstrual cycle are shown in Fig. 43.3.

Follicular phase

During the follicular phase, concentrations of ovarian steroids are low, permitting an increase in both FSH and LH. The rapid rise of FSH stimulates maturation of a single follicle. As the follicle develops, synthesis of estradiol increases to stimulate proliferation of the endometrial lining of the uterus. Increasing estradiol concentrations inhibit FSH release by the pituitary, and thus its concentrations decline in the late follicular phase.

A day prior to ovulation, circulating estradiol concentrations peak. At this point, there is a switch from negative to positive feedback control by estradiol, resulting in an LH surge (Fig. 43.3). The LH surge indicates that ovulation will occur within 36 hours and marks the transition from the follicular to the luteal phase of the menstrual cycle. The LH surge can be detected in the urine 24–36 hours prior to ovulation, but does not confirm that ovulation actually occurred.

Luteal phase

In the luteal phase, the ruptured follicle transforms into a corpus luteum. In this process, granulosa cells luteinize (enlarge and appear yellow), as they accumulate cholesterol needed to synthesize progesterone. Negative inhibition by ovarian hormones induces a gradual decrease in FSH and LH. Progesterone and estradiol concentrations peak ~8 days after ovulation. In the absence of fertilization, progesterone concentrations begin declining around day 23 of the cycle, and the endometrium sloughs off as menstruation ensues (Fig. 43.3).

Female reproductive disorders

There are myriad female reproductive disorders, all of which can result in the persistent inability to ovulate. These may manifest as disturbances in the menstrual cycle, infertility, or syndromes of androgen excess. Female reproductive disorders can be broadly classified as hypothalamic–pituitary dysfunction, congenital disorders, and androgen excess (Table 43.3).

Hypothalamic–pituitary dysfunction

Abnormal secretion of hypothalamic or pituitary hormones can adversely affect the female reproductive system. Drugs, physical or psychological stress, tumors, autoimmune disease, and trauma all disrupt the female HPG axis. Diagnosis of hypothalamic–pituitary causes of reproductive dysfunction requires a detailed clinical history and may include imaging studies to rule out neoplasms. Patient history identifies onset of symptoms, comorbidities, and psychosocial and drug-related causes.

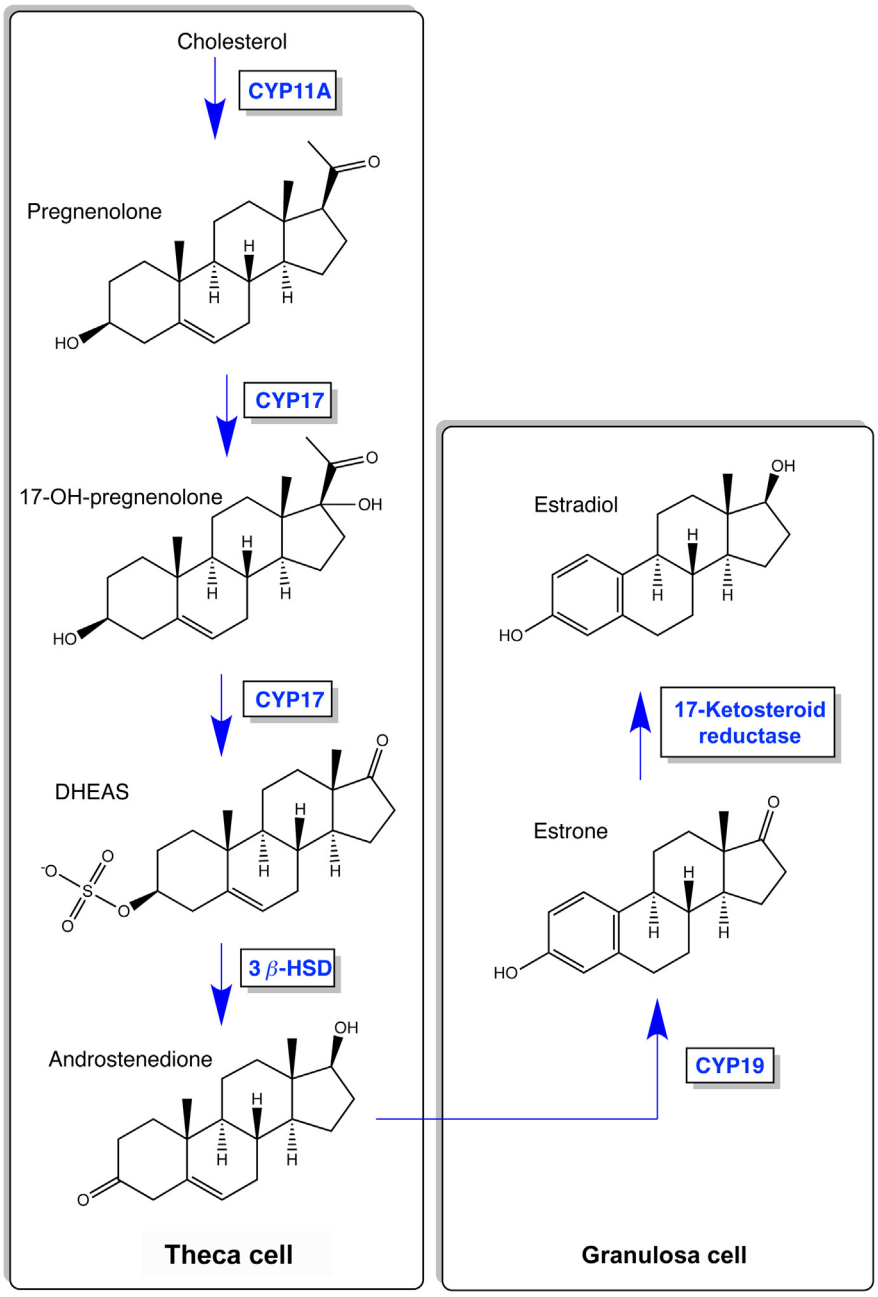

FIGURE 43.4 Estrogen synthesis in granulosa and theca cells that surround oocytes.

Laboratory workup includes measurement of FSH and LH, typically via immunoassay. Concentrations of FSH and LH are typically low with hypothalamic and/or pituitary dysfunction. Follow-up estradiol measurements may help determine the etiology of the hypothalamic/pituitary dysfunction (Table 43.3).

Congenital disorders

A variety of congenital defects can affect reproductive development in women. These range from chromosomal abnormalities, such as Turner syndrome (45, X0), to single-gene mutations in the steroidogenic enzymes, as occur in congenital adrenal hyperplasia (CAH). CAH is caused by deficiency of any of the cytochrome P450 enzymes or 3β-hydroxysteroid dehydrogenase, all of which are required for the synthesis of cortisol and/or aldosterone. The resulting lack of cortisol stimulates pituitary release of ACTH, which drives the steroid pathways causing adrenal hyperplasia. As a consequence, there is a relative excess or deficiency of sex steroids and mineralocorticoids depending on the type of enzyme defect. The most common type of CAH is 21-

TABLE 43.3 Reproductive disorder, etiology, and laboratory results in males and females.

	Abnormality type	Affected sex	Cause	Laboratory results
	Congenital	Females	Turner syndrome	↑FSH, LH ↓Estradiol
		Males	Klinefelter syndrome (XXY) 5α-reductase deficiency Androgen resistance (testicular feminization)	↑FSH, LH ↓Testosterone
	Primary gonadal dysfunction	Females	Menopause Premature ovarian failure Ovarian tumors Chemotherapy or radiation	↑FSH, LH ↓Estradiol
		Males	Trauma Tumors Chemotherapy or radiation Andropause	↑FSH, LH ↓Testosterone
Hypogonadism	Hypothalamic–pituitary dysfunction	Both	Severe weight loss Psychological (eating disorders and stress) GnRH deficiency Cranial irradiation Brain injury Hyperprolactinemia Cushing's syndrome Empty sella syndrome Pituitary infarction	↓FSH, LH ↓Testosterone ↑Prolactin (in cases of prolactinoma)
	Iatrogenic	Both	Prolactin stimulating drugs (reserpine and phenothiazides)	↓FSH, LH ↓Testosterone (male); ↓estradiol (female)
	Physiological	Females	Pregnancy Lactation Lean body weight due to exercise	↑hCG ↑Prolactin ↓FSH, LH ↓Estradiol
Hypergonadism	Congenital	Both	Congenital adrenal hyperplasia	↑Androgens
	Primary gonadal dysfunction	Females	Hormone-secreting tumors • Granulosa cells tumors • Theca cell tumors	↑Total inhibins ↑Estrogen
			Polycystic ovarian syndrome	↑LH/FSH ratio
		Males	Hormone-secreting tumors • Germ cell tumors	↑hCG and/or AFP
	Hypothalamic–pituitary dysfunction	Females	Central ovarian hyperfunction	↑FSH, LH ↑Estradiol
		Males	Hypothalamic hemartoma (ectopic GnRH neurons)	↑FSH, LH ↑Estradiol

GnRH, Gonadotropin-releasing hormone; *FSH*, follicle-stimulating hormone; *LH*, luteinizing hormone.

hydroxylase deficiency, occurring in more than 90% of all cases. This deficiency leads to increased concentrations of 17-hydroxyprogesterone (17-OHP) and adrenal androgens with subsequent virilization. In severe cases (absent 21-hydroxylase) females are born with ambiguous genitalia, whereas in milder forms (nonclassical CAH) women may not undergo sexual maturation. CAH also affects males, who appear phenotypically normal at birth while suffering adrenal insufficiency; newborn screening identifies high 17-OHP concentrations.

A less common form of CAH is 17α-hydroxylase deficiency, an enzyme required for the synthesis of testosterone and estradiol. Deficiency of 17α-hydroxylase causes hypertension and salt wasting due to increased concentrations of deoxycorticosterone (a potent mineralocorticoid), as well as primary amenorrhea (absence of menstruation during adolescence) in females and testicular feminization in males. The laboratory workup for CAH involves measurement of cortisol, aldosterone (to detect mineralocorticoid deficiency), and 17-OHP or other steroid intermediates if 17-OHP is normal. 17-OHP is elevated in classic cases (21-OHase deficiency) and serves as the target analyte in newborn screening tests.

Another congenital cause of infertility in females is Turner syndrome. Turner syndrome results from the absence or dysfunction of one of the X chromosomes. While X-inactivation results in suppression of gene expression from one of the X chromosomes, some genes are not inactivated. Where expression of genes on both X chromosomes is required, XO genotypes cause relative underexpression. This relative genetic underexpression manifests as short stature and sexual infantilism due to a lack of steroid producing follicles at birth. Affected individuals display primary amenorrhea. Identification of a 45, X karyotype is diagnostic for this disorder. Some patients exhibit mosaicism, where only some cells are X0; in these patients, the symptoms may be reduced or absent. Turner patient symptoms are treated with hormonal replacement therapy (e.g., GH and estrogen).

Androgen excess

Affecting 5%−10% of premenopausal women, hirsutism is defined as excessive male-pattern hair growth in woman and is often a sign of androgen excess. Causes of androgen excess include: polycystic ovarian syndrome (PCOS), CAH, ovarian or adrenal androgen-secreting tumors, hyperprolactinemia, and medications. The Endocrine society guidelines suggest measuring plasma androgen concentrations in women with abnormal hirsutism scores (modified Ferriman−Gallwey score) or abnormal hair growth. Androgens in women include testosterone, DHT, androstenedione, DHEA, and DHEA-S. The weakly active adrenal hormones DHEA and DHEA-S can become strong androgens upon conversion to testosterone. Excess androgens in females can result in obesity, acne, and hirsutism (defined as excess hair growth in women in the form of male pattern). The Endocrine Society guidelines recommend against testing androgens in patients with mild hirsutism, as it is unlikely to change treatment. In cases of moderate-to-severe hirsutism, morning testosterone testing is recommended to establish definitive hyperandrogenism. The underlying cause is established through a rule of common symptoms shown in Table 43.2.

PCOS occurs in 8%−13% of women. In women of reproductive age, PCOS is the most common endocrine disorder and most common cause of androgen excess. PCOS presents with a variety of clinical signs including menstrual abnormalities, androgen excess, HPG-axis abnormalities, polycystic ovaries, infertility, obesity, and insulin resistance. Heterogeneity of disease presentation led to disagreement about the definition/diagnostic criteria of PCOS. Recent International Evidence-Based Guidelines for Assessment and Management of PCOS recommend using the Rotterdam criteria to diagnose PCOS in adult women. These criteria require at least two out of the three of the following: ovulatory abnormalities, hyperandrogenism (clinical, biochemical, or both), or polycystic ovarian morphology and the exclusion of related disorders.

The workup for PCOS relies on evidence of androgen excess, menstrual history, and imaging. Imaging of the ovaries is done by ultrasound and reveals the presence of multiple large follicles ($\geq$12) and/or increased ovarian volume. Typically, patients are anovulatory with amenorrhea/oligomenorrhea (established through a careful clinical history and/or low luteal phase progesterone). Hyperandrogenism is established by clinical history and/or clinical exam, and has biochemical evaluation of androgens. Biochemical androgen excess may be identified with total, bioavailable, or free testosterone. Guideline committees have recognized methodological differences, such that there is not a concentration-based cutoff for testosterone for PCOS; guidelines specifically mention preferred use of liquid chromatography−mass spectrometry and extraction chromatography immunoassays for diagnosis. Excess androgens cannot be established in women on oral contraceptives because of the effects on SHBG and gonadotropins. Depending the on the clinical presentation, the laboratory analysis may also include measurement of DHEA-S to identify adrenal androgen excess.

PCOS is currently considered a diagnosis of exclusion, and thyroid dysfunction, hyperprolactinemia, and nonclassical CAH should be ruled out in all adult women with suspected PCOS by measuring TSH, prolactin, and 17-OHP, respectively. In patients with ovulatory dysfunction, pregnancy, hypothalamic amenorrhea, and primary ovarian dysfunction should be ruled out by measuring hCG, FSH, LH, and estradiol. While there is some evidence

supporting anti-Müellerian hormone (AMH) in PCOS, it is not yet recommended for diagnosis because of lack of standardization and robust diagnostic cutoffs. In patients with menstrual abnormalities and/or hirsutism, exclude acromegaly, Cushing's syndrome, and an androgen secreting neoplasm by screening with insulin-like growth factor-1 for acromegaly, one of three tests for Cushing's syndrome (e.g., overnight dexamethasone suppression testing, 24-hour urinary free cortisol, or late night salivary cortisol), and noting a rapid rise and/or significantly elevated testosterone for androgen secreting neoplasm.

Amenorrhea

Clinical history differentiates primary from secondary amenorrhea; primary amenorrhea is the absence of menstruation by adolescence (15−16 years of age), whereas secondary amenorrhea is the absence of menstruation for 6 months in someone who has previously menstruated or its absence for 12 months in those with a history of oligomenorrhea (<9 menstruations/year). Pregnancy is a common cause of secondary amenorrhea. Other causes include premature ovarian failure due to ovarian autoantibodies or prolactinoma. A diagnosis of functional hypothalamic amenorrhea (FHA) is made if organic and anatomical causes are ruled out. FHA is associated with physical or psychological stressors that disrupt normal endocrine function.

Laboratory evaluation of amenorrhea

Measurement of serum LH, FSH, and estradiol is useful in evaluating women with amenorrhea. LH and FSH are increased in primary cases (e.g., genetic causes), but decreased in secondary amenorrhea (e.g., pituitary failure). hCG measurement rules in/out pregnancy, and may be done either in urine or serum/plasma. Prolactin measurement can identify hyperprolactinemia, which causes amenorrhea by disrupting normal pulsatile release of GnRH. The causes of hyperprolactinemia are numerous and include physiological, pharmacological, and pathophysiological causes (see Chapter 39: Disorders of the Anterior and Posterior Pituitary. High TSH concentrations suggest hypothyroidism, which can cause amenorrhea; in primary and secondary hypothyroidism, where thyrotropin-releasing hormone is high, prolactin may be elevated and contribute to amenorrhea. In perimenopause and menopause, waning ovarian function is detected by elevated FSH, decreased estradiol, and slightly increased androgen concentrations.

Assessment of infertility in males and females

A healthy couple attempting to conceive will achieve this at a rate of 20%−25% per month, with 85%−92% occurring within one year. Infertility is defined as the inability to conceive after one year or longer of intercourse without the use of contraception or therapeutic donor artificial insemination. There are numerous causes of infertility in both males and females, necessitating investigation of both partners. Male factors account for 20% of infertility, female factors account for 40%−50%, and 30%−40% of cases are a result of both male and female factors. Endocrine testing and genetic testing (if applicable) are used to identify any of the myriad of causes, which include: anatomical and congenital defects, gonadal failure, malignancies, antisperm antibodies, and psychological, iatrogenic, and endocrine disorders. Guided by the history and physical exam, males typically will have a semen analysis, whereas females will undergo assessment of ovulation and luteal function.

Assessment of infertility in males

Male infertility is divided into four main categories: hypothalamic−pituitary disorders (1%−2%), primary hypogonadism (10%−15%), disorders of sperm transport (10%−20%), and seminiferous tubule dysfunction (60%−80%). Assessment includes a detailed history and physical exam, semen analysis, as well as targeted endocrine and genetic testing.

Semen analysis is considered essential for guiding additional testing to establish a cause of infertility. Though not routinely part of a clinical chemistry menu, semen analysis is subject to the same rigorous regulatory requirements as other testing, and includes quality control and proficiency testing. The Clinical Laboratory Improvement Amendments (and other regulatory bodies in other countries) have defined criteria for semen analysis, and the WHO has defined criteria for volume, pH, viscosity, sperm concentration, count, motility, and morphology. Semen analysis directs subsequent investigations into causes of infertility. Broadly, low sperm counts are divided into pretesticular, testicular, and posttesticular causes. From an endocrine perspective, it is the pretesticular issues that are the focus.

Endocrine evaluation is warranted for men with abnormalities identified by semen analysis (particularly low sperm count) or physical examination findings suggestive of an endocrinopathy. Initially, these findings will prompt measurement of FSH and testosterone at the minimum. Findings of low total testosterone (<300 ng/mL per the ASRM) drive other testing, such as LH and prolactin, to identify primary (gonadal), secondary (pituitary), or tertiary (hypothalamic) causes of infertility. Men with hypothalamic or pituitary failure will have low LH and FSH, which requires a comprehensive investigation and measurement of additional pituitary hormones, such as TSH and prolactin. Men with gonadal failure will display high

FSH and LH with low testosterone. The ability of Leydig cells to produce testosterone can be assessed with an hCG stimulation test. The hCG stimulation test consists of an injection of hCG (5000 IU) with testosterone measurements at baseline and 72-hour postinjection. A healthy response is considered a twofold increase of testosterone from baseline.

Physical examination and imaging may also prompt genetic testing. The congenital bilateral absence of the vas deferens is indicative of a congenital abnormality and a high probability of an abnormal cystic fibrosis transmembrane conductance regulator gene. Karyotypic abnormalities, such as XXY (Klinefelter syndrome), may also be identified as causes of infertility and prompted by physical examination and extremely low sperm count. There are several other rare genetic causes of male infertility, including Y chromosome microdeletions and chromosome translocations. Single-nucleotide polymorphisms in the FSH and LH receptors can also lead to infertility. Collectively, male infertility testing initially involves assessment by a urologist, but may include male infertility specialists, endocrinologists, and clinical geneticists.

Assessment of infertility in females

Female causes of infertility are divided into three categories: anatomic (e.g., congenital abnormalities), ovulatory disorders (e.g., PCOS), and functional problems, such as abnormal cervical mucus. Female assessment of infertility begins with a detailed history and physical examination, which directs the diagnostic evaluation. Investigations may include imaging, biopsy, postcoital testing, ovulation confirmation, endocrine evaluation, and immunological testing.

Approximately 40% of female infertility is the result of ovulatory dysfunction. Ovulatory dysfunction typically manifest as abnormal menstrual cycling. The underlying causes may include PCOS (most common), weight extremes, thyroid dysfunction, and hyperprolactinemia. Ovulatory dysfunction is evaluated with a detailed menstrual history, imaging, biopsy, and endocrine assessment, as well as indirect measurements of ovulation.

Indirect measurements of ovulation are used where the menstrual history does not definitively establish anovulation. Historically, basal body temperature has been used to predict when ovulation occurs, but the American Society for Reproductive Medicine guidelines state that this is not a reliable method to assess ovulatory function, because it does not effectively estimate the timing of ovulation and is tedious for patients. The most accurate assessment of ovulation is a luteal phase progesterone measurement, where a concentration of >3 ng/mL is defined as evidence of ovulation (the ASRM guidelines). Progesterone concentrations begin to rise after ovulation and continue to increase for 5−9 days. In the absence of ovulation, the corpus luteum does not form and cannot secrete progesterone. There are also home testing kits for LH in urine, which can detect the LH peak that occurs 1−2 days prior to ovulation; however, the consistency and reliability of these has been questioned. TSH and prolactin may be measured to establish a treatable cause of anovulation, where thyroid disease and hyperprolactinemia can cause infertility. Imaging may be used to directly assess follicle number and size in complicated cases, whereas endometrial biopsy is now reserved for women with specific endometrial pathology.

In terms of treatment and prognosis, there are a number of laboratory tests that are ordered to assess ovarian reserve. Ovarian reserve is defined by the number and quality of oocytes. Where ovarian reserve is low, so too is the likelihood of fertility. Ovarian reserve is assessed by direct follicle count by ultrasound and/or hormone measurement with or without challenge testing. Clomiphene citrate challenge testing relies on measurement of FSH before and after oral clomiphene citrate (a selective estrogen receptor modulator); elevated postclomiphene FSH levels are consistent with diminished ovarian reserve. More recently, the clomiphene citrate challenge test has been supplanted by measurement of serum AMH. AMH is secreted by granulosa cells of early follicles independent of gonadotropins.

Guidelines state that low serum AMH concentrations (<1 ng/mL, 5.5 pmol/L) predict poor response to ovarian hyperstimulation and low probability of pregnancy success with in vitro fertilization (IVF). Conversely, very high concentrations of AMH (two-to-fivefold higher than the upper reference limit) support a diagnosis of PCOS. Another method for assessing ovarian reserve is "cycle-day 3" serum FSH and estradiol. The prognostic performance of this test is variable, but high FSH on day 3 of the menstrual cycle indicates a low reserve. FSH is elevated when follicles are few and unresponsive, as the hypothalamic−pituitary axis is not suppressed by estradiol. Estradiol is measured to identify if it may be suppressing FSH; high estradiol with low FSH is thus also indicative of low reserve and lower likelihood of successful IVF. Estradiol alone is not effective at assessing ovarian reserve. Overall, female infertility testing is driven by history, where testing is directed based on anatomical and physiological cause factors (Table 43.3).

Self-assessment questions

1. A 32-year-old woman with a history of irregular periods presents to the fertility clinic after being unable to conceive for 2 years. Physical exam shows an obese woman with excess hair growth on the upper lip and chin, and acne on her chin and back. A pelvic ultrasound shows ovaries with multiple small cysts. What pattern of laboratory tests is consistent with this case?
   a. increased estrogen, increased FSH, and decreased LH
   b. increased testosterone, decreased FSH, and increased LH
   c. increased GnRH and decreased FSH and LH
   d. increased prolactin and decreased TSH
2. A baby girl is born at term with ambiguous genitalia. Evaluation reveals female internal organs on pelvic ultrasonography and a 46, XX karyotype. Newborn screening results show elevated 17-hydroxyprogesterone. Endocrine testing reveals a serum androstenedione of 794 (reference interval 25−95 ng/mL) and a cortisol of 1.2 mcg/dL (reference interval 3−20 μg). Other laboratory values: sodium 128 mmol/L, potassium 6.9 mmol/L, chloride 87 mmol/L, bicarbonate 14 mmol/L, and glucose 40 mg/dL. What is the most likely cause of these findings?
   a. 17α-hydroxylase deficiency
   b. Turner syndrome
   c. 21-hydroxylase deficiency
   d. 5α-reductase deficiency
3. Which hormone is associated with galactorrhea, pituitary adenoma, and amenorrhea?
   a. estradiol
   b. progesterone
   c. FSH
   d. prolactin
4. A deficiency of the enzyme 5α-reductase _____.
   a. results in female pseudohermaphroditism
   b. can be identified by a decreased testosterone:dihydrotestosterone ratio
   c. results in individuals with normal physical but impaired mental development
   d. results in intersex genitalia at birth with eventual masculinization at puberty
5. A possible explanation for an adult male with increased concentrations of the gonadotropins and decreased total testosterone is _____.
   a. primary hypogonadism
   b. secondary hypogonadism
   c. tertiary hypogonadism
   d. complete androgen resistance

Tumor markers

Lori J. Sokoll and Daniel W. Chan

Department of Pathology, The Johns Hopkins University School of Medicine, Baltimore, MD, United States

Introduction to cancer

In 2020 it is estimated that approximately 1.8 million new cancer cases will be diagnosed and there will be 606,520 deaths from cancer [1]. For new cancer cases, prostate is the leading site in men while breast cancer is the leading site in women. Lung and bronchus cancer, and colon and rectum cancer are the next leading sites for both sexes. Lung and bronchus cancer leads estimated cancer deaths followed by prostate cancer in men and breast cancer in women. Cancer is the second leading cause of death in the United States accounting for one in four deaths; however, the cancer death rate is on a downwards trend, attributable to reductions in smoking and improvements in early detection and treatment.

A simplified definition of cancer is a relatively autonomous growth of tissue. Cancer is a heterogeneous disease with a genetic basis; often driven by changes to growth-promoting protooncogenes, growth-constraining tumor suppressor genes, and DNA repair genes. Causative factors are likely multifactorial including lifestyle factors such as tobacco use, diet, and obesity, exposure to carcinogenic agents such as radiation and chemicals, and nonmodifiable factors including inherited mutations, hormones, and the immune environment. Early detection of cancer affords a greater chance of detecting cancers at an early stage when cancer is organ confined and curative treatment is possible.

Tumors are described in terms of grade and stage. Grade refers to the extent to which a tumor resembles normal differentiated tissue as opposed to poorly differentiated fetal or embryonic tissue. Typical tumor morphology is described as well, moderately, or poorly differentiated. The stage of a tumor describes the anatomic extent of the disease. In the commonly used TNM system (American Joint Commission on Cancer) it is assessed by three components: T (extent of primary tumor), N (regional lymph nodes), and M (metastasis), each of which is followed by a number indicating the extent of malignant disease with the three components combined into an overall stage (0–IV). Clinical staging is based on evidence acquired before treatment, while pathological staging takes into account clinical evidence plus evidence from surgical and pathological examinations. Staging informs prognosis and aids in treatment plans.

Introduction to tumor markers

Definition

A tumor marker is [2]:

- a substance produced by a tumor or by the host in response to a cancer cell;
- found in cells, tissues, or body fluids; and
- measured qualitatively or quantitatively by methods including chemical, immunological, molecular, and mass spectrometry to identify the presence of cancer.

Characteristics

An ideal tumor marker is specific for a given type of cancer, not present in benign conditions, and is released only by or in response to the tumor [3]. The marker should also be sensitive enough to detect small tumors for early diagnosis or during screening and quantitatively reflect response to treatment. Screening requires a marker with high clinical sensitivity and specificity or the marker is used in a population with a high prevalence of cancer. In reality, however, currently available tumor markers are neither specific nor sensitive enough for screening and are used primarily to evaluate progression of disease status after initial therapy and for monitoring subsequent treatment. An approach to improve the utility of tumor markers for screening in a population with low prevalence is to combine markers with other modalities such as combining cancer antigen 125 (CA 125) and ultrasound to detect ovarian cancer. Combining individual markers and other variables through an algorithm into a score or index, such as an in vitro diagnostic multivariate index assay

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00044-2

(IVDMIA), may also improve the utility of tumor markers for a specific intended use. The potential applications of tumor markers are listed in Table 44.1.

Classes

Classes of tumor markers [2] with examples for each class are listed in Table 44.2 and current tumor markers for solid tumors by specimen type presented in Table 44.3. One class of tumor markers is enzymes. Before the discoveries of oncofetal antigens and monoclonal antibodies, enzymes were commonly used as tumor markers with measurements made as enzyme activity. However, with the exception of enzymes such as prostate specific antigen (PSA), which is now measured using antibody-based techniques, most enzymes are not organ-specific. Hormones are another class of tumor markers that have been in use for many years. Commonly used hormones include human chorionic gonadotropin (hCG) for trophoblastic tumors and nonseminomatous testicular cancers, and calcitonin for medullary thyroid cancer. Hormones are also used as tumor markers for gastrointestinal (GI) endocrine tumors such as gastrinomas, glucagonomas, insulinomas, somatostatinomas, vasoactive intestinal polypeptideomas, etc., as well as pituitary tumors such as prolactinomas and adrenal carcinoma [4].

Proteins constitute another class of tumor markers. The first known tumor marker, discovered over 100 years ago, was the Bence–Jones protein, which is still used in multiple myeloma. More recently, proteins and peptides, such as soluble mesothelin-related peptides (SMRP) and progastrin-releasing peptide (proGRP), have been discovered for use as tumor markers in mesothelioma and small cell lung cancer (SCLC), respectively. Oncodevelopmental or oncofetal are the terms used to describe another class of markers that are produced during fetal development and can also be present in increased concentrations due to transformations in malignant cells. Carcinoembryonic antigen (CEA) and α-fetoprotein (AFP) are the most widely used oncofetal antigens.

Carbohydrate markers consist of antigens secreted by tumor cells or present on tumor cell surfaces and include high-molecular-weight mucins and blood group antigens. Discovery of these markers followed the development of monoclonal antibodies and resulted from detection of antigens in tumor cell lines. Examples of these types of tumor markers include CA 125, a marker for ovarian cancer; CA 15-3 and CA 27.29, markers for breast cancer; and CA 19-9, a marker for GI cancers such as colorectal and pancreatic carcinoma. Other tumor marker types include receptors, such as estrogen and progesterone receptors, which are used as prognostic markers in breast cancer patients in addition to predicting response to therapy.

TABLE 44.1 Potential uses of tumor markers.

- Risk stratification
- Screening or early detection
- Differential diagnosis in symptomatic patients
- Clinical staging
- Estimating tumor volume
- Determine prognosis for disease progression
- Monitoring the response to therapy
- Predicting response to therapy
- Detecting cancer recurrence

TABLE 44.2 Tumor marker classification.

Class	Examples
Enzymes, isoenzymes	PSA, LDH, and neuron-specific enolase
Hormones	hCG, calcitonin, ACTH, gastrin, and VIP
Proteins/peptides	β_2-Microglobulin, NMP22, progastrin-releasing peptide, and thyroglobulin
Oncofetal antigens	AFP and CEA
Carbohydrates	CA 125, CA 15-3, and CA 27.29
Blood group antigens	CA 19-9 and CA 72-4
Receptors	Estrogen and progesterone
Gene mutations and overexpression	*BRCA1*, *BRCA2*, and HER-2/*neu*
Other	Circulating tumor cells, and cell-free nucleic acids

ACTH, adrenocorticotropic hormone; AFP, α-fetoprotein; *BRCA*, breast cancer gene; *CA 125*, cancer antigen 125; *CEA*, carcinoembryonic antigen; *hCG*, human chorionic gonadotropin; *HER-2*, human epidermal growth factor receptor-2; *LDH*, lactate dehydrogenase; *NMP*, nuclear matrix protein; *PSA*, Prostate specific antigen; *VIP*, vasoactive intestinal polypeptide.

TABLE 44.3 FDA-reviewed tumor markers for solid tumors in clinical use.

Tumor marker	Associated cancer(s)
Serum and plasma	
CA 15-3, CA 27.29, and HER-2	Breast
CA 125, HE4, OVA1[a], OVERA[a], and ROMA[a]	Ovarian
CA 19-9	Pancreas
Total PSA, Free PSA, cPSA, p2PSA, and prostatic acid phosphatase	Prostate
CEA	Colorectal, breast, and lung
AFP	Nonseminomatous testicular
Thyroglobulin	Thyroid
AFP-L3% (including AFP) and DCP	Hepatocellular
CYFRA 21-1	Lung
β-Human chorionic gonadotropin (for pregnancy, not cleared/approved as a tumor marker)	None
Soluble mesothelin-related peptides	Mesothelioma
Whole blood	
Circulating tumor cells	Breast, colorectal, and prostate
Urine	
NMP22, bladder tumor associated antigens, and UroVysion	Bladder
PCA3	Prostate
Stool	
Hemoglobin (fecal occult blood) and Cologuard (hemoglobin and DNA alterations)	Colorectal
Tissue	
Estrogen and progesterone receptors, MammaPrint, and Prosigna	Breast
P63 antibody	Prostate
Tissue of origin test	Fifteen tumor types

AFP, α-fetoprotein; *CA 19-9*, carbohydrate antigen 19-9; *CEA*, carcinoembryonic antigen; *cPSA*, complexed prostate specific antigen; *CYFRA 21-1*, cytokeratin 19 fragments; *DCP*, des-γ-carboxy prothrombin; *HER-2*, human epidermal growth factor receptor-2; *NMP*, nuclear matrix protein; *p2PSA*, [-2] proPSA; *PCA3*, prostate cancer gene of antigen 3; *PSA*, prostate specific antigen; *ROMA*, risk of ovarian malignancy algorithm.
[a]*In vitro diagnostic multivariate index algorithm.*

Genes or gene products are utilized as tumor markers through determination of mutations or altered gene expression such as human epidermal growth factor receptor-2 (HER-2)/*neu* for the selection of breast cancer patients for Trastuzumab (Herceptin) therapy. Following the classic example of HER-2/*neu*, in the era of personalized or precision medicine, there are now many companion biomarkers (Table 44.4) that predict response or resistance to specific drugs and are used to support treatment decisions.

DNA testing has traditionally been performed on tissue; however, testing of cell-free circulating tumor DNA (ctDNA) in plasma, so-called "liquid biopsy," allows for minimally invasive sampling, can potentially minimize spatial and temporal tumor heterogeneity and DNA sequencing artifacts, and improve turnaround time [5,6]. In 2016 the first plasma DNA test (Roche cobas EGFR Mutation Test v2) was approved by the FDA to aid in selecting targeted therapies for nonsmall cell lung cancer (NSCLC) patients with specific *EGFR* (epidermal growth factor receptor) variants. To address assay sensitivity, testing in corresponding tissue is recommended for negative results. Despite suggested applications for treatment monitoring, residual disease detection, and cancer screening, preanalytical, analytical, and clinical issues currently limit routine use of ctDNA [5,7].

Circulating tumor cells (CTCs) have also been used as tumor markers following methodological development to

TABLE 44.4 FDA cleared or approved tissue or plasma biomarkers for solid tumors used as companion diagnostics (https://www.fda.gov/medicaldevices/productsandmedicalprocedures/invitrodiagnostics/ucm301431.htm).

Gene and or protein biomarkers	Cancer
ALK	NSCLC
BRAF	Melanoma
BRCA	Breast and ovarian
EGFR[a]	NSCLC
EGFR	Colorectal
Estrogen and progesterone receptors	Breast
HER-2; HER-2/*Neu*	Breast and gastric
c-KIT	Gastrointestinal stromal
RAS	Colorectal
PD-L1	NSCLC, gastric, cervical, and urothelial

ALK, anaplastic lymphoma receptor tyrosine kinase; *BRCA*, breast cancer gene; *EGFR*, epidermal growth factor receptor; *HER-2*, human epidermal growth factor receptor-2; *NSCLC*, nonsmall cell lung cancer; *PD-L1*, programmed death-ligand 1.

isolate, identify, and enumerate epithelial cells, with applications for determining disease progression in patients with metastatic breast, prostate, and colorectal cancers. The CellSearch CTC (Menarini Silicon Biosystems) in vitro diagnostic assay uses a combination of positive (epithelial cell adhesion molecule and cytokeratin) and negative (CD45) selection methods to isolate cells from whole blood. In metastatic breast cancer, for example, a CTC count of ≥ 5 cells in 7.5 mL of blood is associated with shorter progression-free and overall survival.

Measurement and evaluation

Tumor markers can be measured qualitatively or quantitatively in body fluids or tissue by numerous methods depending on analyte type. These may include enzyme assays, immunoassays, immunohistochemistry, receptor assays, flow cytometry, or mass spectrometry, as well as molecular techniques. The discovery and analysis of tumor markers as well as their clinical implementation were significantly enhanced by the introduction of the RIA and ELISA techniques as well as the development of monoclonal antibodies in the 1960s and 1970s. Thus the majority of currently used serum and urine tumor markers are measured using immunoassay.

Reference values

Reference ranges for tumor markers can be established in a similar fashion to other analytes from the mean ± 2 SD of large healthy population for a Gaussian (normal) distribution or percentiles (2.5th and 97.5th) for a nonnormal distribution. Typically, however, only the upper cutoff is clinically useful. Another method commonly used to determine cutoff values or decision levels for tumor markers is to use predictive values. Using this approach, patients with the disease are typically compared with patients with benign diseases as opposed to normal subjects. The context in which the biomarker will be used will guide the populations for clinical studies [8]. Cut points can be determined based on the application of the test and requirements to maximize clinical sensitivity, specificity, or both. Using receiver operating characteristic (ROC) curves, plots of sensitivity (true-positive rate) versus 1-specificity (false-positive rate), the range of decision points and corresponding classification can be presented graphically. The area under the curve (AUC) represents overall diagnostic performance, and thus ROC curves are useful for comparing different methods or analytes. A test with 100% sensitivity and 100% specificity would have an AUC of 1.0, while a test with no discriminatory power would have an AUC of 0.5. In the hypothetical example shown in Fig. 44.1, test A, with a greater AUC, has increased clinical performance compared with test B. The cutoff value with the greatest sensitivity and specificity is the point located closest to the upper left-hand corner of the plot.

Analytical considerations

Although the criteria for the analytical evaluation of tumor marker assays are similar to other assays, there are

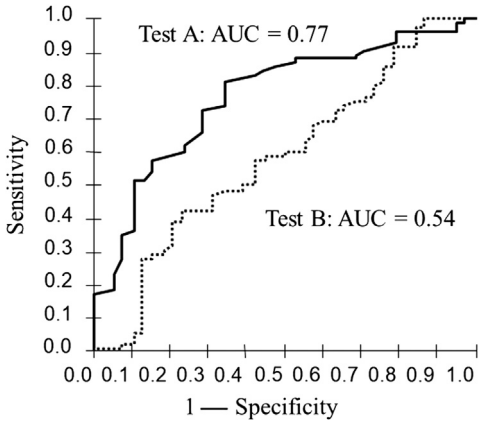

FIGURE 44.1 Receiver operating characteristic curve example.

specific considerations for tumor markers [8,9]. Tumor marker concentrations can span a wide range of values, including undetectable results, and therefore assay linearity is important. When measuring tumor markers, there is potential for a high-dose hook effect (see Chapter 12, Immunoassays) in one-step sandwich assays and for carryover in automated analyzers that do not have disposable sample tips. Heterophilic antibodies and human antimouse antibodies (HAMA) are potential assay interferents although assay manufacturers typically design their assays to minimize HAMA effects. HAMA may also be produced in cancer patients treated with monoclonal antibodies. Test results from patients taking high-dose biotin supplements may be affected in some assays employing biotin−streptavidin designs with false-negative results in sandwich assays and false-positive results in competitive assays.

Interassay precision and lot-to-lot reagent differences are also important since a primary application of tumor markers is monitoring over time. Unlike many assays however, tumor marker assays from different manufacturers may not give the same results, and therefore values are not interchangeable. Typically, reference methods do not exist although international standards and reference materials are available for select analytes (www.nibsc.org). Assay differences may be due to standardization as well as antibody selection and specificity, assay design and kinetics, assay robustness including interferences such as HAMA, as well as variations in reference ranges [10]. When changing assay methods, it may be advisable to offer a crossover period to allow patients being followed to be rebaselined. Including the name of the assay/manufacturer with reported results is also recommended [9].

Clinical considerations

The utility of tumor markers is also evaluated by examining elevations in other disease conditions, both cancerous and noncancerous as well as in the normal population to determine specificity of the test for the type of cancer in question. An example illustrating specificity of risk of ovarian malignancy algorithm (ROMA) for ovarian cancer is shown in Table 44.5.

Tumor markers are most useful for monitoring treatment and progression of cancer [2]. Effective tumor markers should decrease in concentration following initial treatments such as surgery and rise upon disease recurrence following successful treatment. In general, markers used as monitors of therapy should increase with progression, decrease with regression, and remain constant with stable disease. Although there are no standard criteria regarding the relationship between disease status and marker changes, considering analytical and biological marker variability, the following guidelines have been proposed: if no therapy is given, then three consecutive increasing values establish recurrence; if therapy is given, a 25% increase in values indicates progression, a 50% decrease in values indicates partial remission, while complete remission cannot be established using marker values [11].

Specific tumor markers

Despite the large number of potential tumor markers, only a small number have been approved or cleared by the FDA for specific applications (Table 44.3). In contrast, significantly more tumor markers are in use and available commercially worldwide where regulatory requirements are not as rigorous as those in the United States. The FDA review process is described by Fuzery et al. [12]. To follow are the descriptions of primarily protein tumor markers analyzed by immunoassay organized by organ site, primarily focusing on those reviewed by the FDA.

Breast cancer

CA 15-3 and CA 27.29: CA 15-3 and CA 27.29 are tumor markers for breast cancer [2,13]. CA 15-3 and CA 27.29 assays measuring the high-molecular-weight glycoprotein polymorphic epithelial mucin (PEM), also known as episialin, a product of the *MUC1* gene. PEM is shed from the surface of epithelial cells of several tissues, including breast, lung, colon, pancreas, and ovary. PEM is a transmembrane protein (>300 kDa) with a 69 amino acid cellular domain and an extracellular domain consisting of 20 amino acid repeats (1000−2200 amino acids). In each tandem repeat, there are five serine and threonine amino acids that can be glycosylated. In breast cancer, the *MUC1* gene is upregulated with expression 10-fold higher than that in normal cells, and glycosylation is decreased and incomplete exposing epitopes on the core polypeptide backbone, allowing the development of monoclonal antibodies.

TABLE 44.5 Distribution of the risk of ovarian malignancy algorithm in healthy women, and in other malignant and benign conditions for likelihood of malignancy.

		ROMA result interpretation	
	N	Low likelihood (%)	High likelihood (%)
Healthy subjects			
Premenopausal	120	84.2	15.8
Postmenopausal	120	95.0	5.0
Nonovarian malignancies			
Bladder	40	22.5	77.5

ROMA, risk of ovarian malignancy algorithm.
Source: Adapted from ROMA instructions for use, 2011–09, Fujirebio Diagnostics.

CA 15-3 and CA 27.29 detect overlapping epitopes on the PEM molecule. The CA 15-3 assay consists of two antibodies: 115D8 and DF3. The DF3 detector antibody was generated against a membrane-enriched extract from a human breast cancer metastatic to liver and binds to a sequence of amino acids in the tandem repeat region. Antibody binding is independent of carbohydrate. The 115D8 capture antibody was generated against human milk fat globulin membranes. The antibody does not bind in the tandem repeat region and is carbohydrate-dependent. CA 27.29 assays utilize the B27.29 antibody. This antibody is carbohydrate-independent and was generated against ascites from patients with metastatic breast cancer. The antibody also binds in the tandem repeat region with a peptide sequence that overlaps with the sequence of the DF3 antibody. Similar to other tumor markers, the CA 15.3 (cutoff ~35 U/L) and CA 27.29 (cutoff 37.7 U/L) assays may give different values; however, both assays have similar clinical performance.

The FDA indications for use of CA 15-3 and CA 27.29 are as aids in the management of breast cancer patients for the early detection of recurrence in stage II and stage III patients previously treated and clinically free of disease, and for monitoring response to therapy in patients with stage IV breast cancer. These markers can be elevated in benign liver and breast disease as well as other cancers including pancreatic, lung, ovarian, colorectal, and liver, and therefore are not sensitive enough for early detection. They are prognostic indicators and correlate with the stage of disease and tumor volume and, as suggested by their approved applications, are most useful for detecting residual disease following initial therapy and correlate with disease progression or regression. The American Society for Clinical Oncology (ASCO) clinical guidelines confirm the adjunctive role of CA 15-3 and CA 27–29 as well as CEA in the metastatic setting for monitoring treatment response. Rising markers with a 20%–30% change may indicate treatment failure when measurable disease is not present [13,14].

Gastrointestinal cancers

CEA: CEA was discovered in 1965 as a marker for colorectal cancer [2]. It was subsequently discovered, however, that CEA was not specific for colon cancer or for cancer. The CEA family consists of up to 36 cell-surface glycoproteins with CEA as one of the major proteins. CEA has a mass of 150–300 kDa with 45%–55% carbohydrate.

CEA functions as an adhesion molecule and may be involved in tumor invasion and metastasis. The upper limit of CEA is approximately 3 ng/mL for nonsmokers and 5 ng/mL for smokers with exact values method-dependent.

CEA is elevated in a number of primary cancers including colorectal, breast, pancreatic, liver, lung, gastric, ovarian, and uterine and is elevated in the majority of patients with metastatic liver disease. CEA can be elevated in a number of benign diseases such as cirrhosis, emphysema, rectal polyps, ulcerative colitis, and benign breast disease. Because of these elevations, CEA is not useful for screening. In colon cancer, CEA concentrations are associated with increasing tumor burden and correlate with the stage of disease. Pretreatment concentrations are also indicative of prognosis with increased concentrations associated with the risk of recurrence and development of metastatic disease [15]. The most useful application for CEA in colorectal cancer is in monitoring the clinical course of disease and therapy (Fig. 44.2). CEA measurements are recommended at baseline and at 2–3 months for 3 years following surgery and then every 6 months until 5 years.

CA 19-9: CA 19-9 is a sialylated derivative of the Lewis^{a} blood group antigen. Approximately 5% of the population have the Le^{a-b-} genotype, and therefore do not produce CA 19-9. CA 19-9 is elevated in all GI cancers as well as other adenocarcinomas. It is elevated in 70%–95% of patients with pancreatic cancer and is primarily used to monitor the course of disease, its approved indication. Elevated concentrations can also be seen in benign GI diseases including acute and chronic pancreatitis, cholangitis, and cirrhosis. The initial monoclonal antibody employed in the CA 19-9 assay was developed from a human colon carcinoma cell line, and in some assay designs, the antibody is used for both capture and detection [2]. A cutoff of 37 U/mL is typically used. CA 19-9 immunoassays lack harmonization underscoring the need to monitor patients with the same assay.

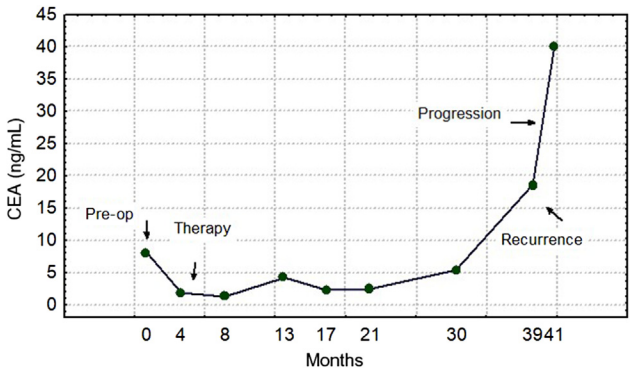

FIGURE 44.2 Carcinoembryonic antigen concentrations for monitoring disease course in a patient with colon cancer.

Genitourinary cancers

Prostate cancer

Prostate specific antigen

PSA is a 28 kDa glycoprotein produced by the prostate epithelium. It is a serine protease and a member of the kallikrein family (hK3) [16]. PSA circulates in the blood in a free form and is bound to protease inhibitors such as α_1-antichymotrypsin (ACT) and α_2-macroglobulin (A2M). PSA is engulfed by the A2M molecule, and therefore PSA-A2M is not measured in total PSA immunoassays. Although PSA is for all intents and purposes organ-specific, it is not cancer-specific and can be elevated in benign prostate diseases such as benign prostatic hyperplasia (BPH) and prostatitis. PSA has replaced prostatic acid phosphatase as a tumor marker for prostate cancer.

Screening for prostate cancer is controversial [17]. Evidence from European randomized trials has shown that PSA screening can reduce metastatic prostate cancer and disease-related death; however, it is acknowledged that screening results in overdiagnosis and overtreatment with potential associated morbidity and mortality. The challenge is to identify men with aggressive disease that will benefit from treatment. It is estimated that approximately half of men diagnosed with prostate cancer have very low-risk disease [18] and are possible candidates for active surveillance. In 2012 the United States Preventive Services Task Force (USPSTF) recommended against PSA screening (grade D), concluding there is more harm from testing than benefit with subsequent decreases in screening, biopsies, and diagnosis of localized disease. In 2018 the recommendations were updated with continued recommendation against screening for men aged 70 or older with acknowledgment that screening may offer a small potential benefit for some men aged 55–69 (grade C), recommending an individualized, informed shared decision-making process between the patient and the physician. Similar to the American Cancer Society and American Urological Association (AUA) recommendations, the USPSTF addresses men at increased risk of prostate cancer including African Americans and men with a family history of prostate cancer.

One of the FDA indications for PSA is to aid in the detection of prostate cancer when used in conjunction with a digital rectal examination (DRE) in men age 50 and older. The associated cutoff of 4 ng/mL has traditionally been used although it is recognized that there is a risk of prostate cancer over all concentrations of PSA [19]. PSA lacks specificity for cancer due to elevations in PSA in men with benign prostate disease, and there is considerable overlap in the PSA range of 4–10 ng/mL, which has been termed the diagnostic gray zone. A number of approaches have been proposed and investigated to

improve the diagnostic accuracy of PSA including age-specific reference ranges, PSA density, PSA velocity, algorithms/nomograms, and the molecular forms of total and free PSA [19]. The concept behind age-specific reference ranges is that by lowering the upper end of the reference range in younger men and extending it in older men, the sensitivity (cancer detection) would be increased in the younger group while specificity (spare unnecessary biopsies) would be increased for the older group. PSA density normalizes PSA concentrations for prostate size using transrectal sonography measurements, while PSA velocity monitors the change in PSA concentrations over time. Nomograms/algorithms look for patterns in variables such as laboratory data and demographic information, and combine information into one index or output measure. An example is the Prostate Cancer Prevention Trial prostate cancer risk calculator (http://myprostatecancerrisk.com/) [20]. Use of the molecular forms of total and free PSA to improve the specificity of PSA, however, has shown the most potential. Biomarkers, including percent free PSA, prostate health index (*phi*), and the 4 kallikrein (4K) score are incorporated into the National Comprehensive Cancer Network (NCCN) prostate cancer early detection guidelines [17] as second line tests for men with specific PSA or DRE results considering first biopsy or repeat biopsy following a negative biopsy.

In the early 1990s it was discovered that the majority of PSA in serum is in the complexed form with only a small portion in the free form and that men with prostate cancer and nonprostate disease differ in proportions of free PSA and PSA bound to ACT. Although the mechanism is unknown, there appears to be a greater percentage of PSA-ACT in patients with prostate cancer than those with benign prostate disease. Measurement of percent free PSA (free PSA/total PSA $\times$ 100) in men with a PSA between 4 and 10 ng/mL is intended to spare biopsies in men with benign disease. Although cutoffs may differ among assays, a recommendation has been made such that if percent free PSA in men with a total PSA between 4 and 10 ng/mL and a negative DRE is greater than 25%, the likelihood of prostate cancer is less than 10%, whereas if percent free PSA is less than 10%, there is a greater than 50% chance of cancer. The test may be most useful in men with an initial negative biopsy.

Subsequently, it was discovered that free PSA consists of the distinct, enzymatically inactive, isoforms benign PSA (BPSA), intact PSA (iPSA), and proPSA [21]. BPSA is a degraded form with two internal peptide bond cleavages found in the transition zone of the prostate where BPH occurs and is associated with benign prostate disease when measured in serum. iPSA is similar to native PSA except that it is enzymatically inactive owing to conformational changes. proPSA is the proenzyme form of PSA with a seven amino acid pro-leader peptide although truncated forms with fewer amino acids exist. proPSA is associated with the peripheral zone of the prostate where the majority of cancers occur. The [-2]proPSA (Beckman Coulter, Inc.) form has been commercialized and is a component of *phi* in combination with total and free PSA. The indication for use is the same as percent free PSA. Ranges of the *phi* index are associated with a probability of prostate cancer on biopsy. A $phi > 35$ is the index defined by the NCCN in men with a PSA of >3.0 ng/mL as informative in the decision for initial or repeat biopsy [17]. The 4Kscore combines PSA, free PSA, iPSA, and hK2 with age, DRE, and prior biopsy status into an algorithm that returns the probability of clinically significant prostate cancer on biopsy [17,20]. Despite inclusion in the NCCN guidelines, the 4Kscore is a lab-developed test (OPKO Health, Inc.) and has not undergone FDA review.

An assay for complexed PSA (cPSA) has been developed that measures PSA-ACT and other PSA complexes irrespective of PSA-A2M. A cPSA concentration of 3.2 ng/mL is equivalent to a PSA cutoff of 4.0 ng/mL, while a PSA concentration of 2.5 ng/mL corresponds to a cPSA concentration of 2.2 ng/mL [22]. cPSA has similar sensitivity for cancer detection compared with total PSA with increased specificity, particularly in the 2−6 ng/mL PSA range. Availability of an automated cPSA assay is limited to one immunoassay manufacturer, Siemens Healthineers.

Serum concentrations of PSA have been found to correlate with tumor volume as well as clinical and pathological stage, with higher levels associated with advanced stages [2]. However, similar to most tumor markers, PSA is most valuable in monitoring the treatment and progression of prostate cancer. PSA can be used to determine the success of initial surgical or radiation treatment. Following radical prostatectomy, PSA concentrations should drop to undetectable levels if the tumor was organ confined and all prostatic tissue has been removed. Detectable PSA levels, determined after a suitable time for concentrations to return to baseline levels, would suggest remaining prostate tissue or the presence of metastases. The PSA cut point for biochemical recurrence defined by the AUA is 0.2 ng/mL. Ultrasensitive PSA and third-generation assays are defined as those with an limit of quantitation (20% CV) of 0.01 ng/mL or lower and many automated assays now achieve this limit. Although cancer recurrence may be detected earlier with lower detection limits, the effect on clinical management, such as for salvage radiation following radical prostatectomy, is unclear and patient-specific. Fourth- and fifth-generation assays with even lower detection limits have been developed although none, including the lab-developed test from Quanterix (AccuPSA) and the FDA-approved NADiA ProsVue assays, are currently available for clinical use.

PSA and its isoforms are measured using sandwich immunoassays. To aid in the standardization of PSA assays, two World Health Organization (WHO) preparations were introduced in 1999. One preparation consists of 100% free PSA, whereas the other consists of 90% PSA-ACT and 10% free PSA. The majority of total PSA assays in use by clinical laboratories are standardized to either the WHO standards or the Beckman Coulter, Inc. Hybritech PSA method. Results from Hybritech standardized assays are approximately 20% higher than WHO standardized assays as a result of different molar absorptivities assigned to PSA.

Prostate cancer gene of antigen 3

Prostate cancer gene of antigen 3 (PCA3) is a molecular urine test for prostate cancer [23]. PCA3 is overexpressed in prostate cancer tissue compared with normal or benign prostate tissue. The PCA3 mRNA is noncoding and has an unknown function. PCA3 is measured in a urine specimen collected after an attentive DRE of three strokes per prostate lobe, which serves to release prostate cells and increase the probability of a sufficient sample. Addition of a stabilization buffer lyses cells and stabilizes the RNA. PCA3 and PSA mRNA are quantitated using transcription-mediated nucleic acid amplification. The PCA3 mRNA copy number is normalized with the PSA mRNA housekeeping gene to generate the PCA3 score (PCA3 mRNA/PSA mRNA $\times$ 1000). The test was approved by the FDA in 2012 (PROGENSA PCA3, Hologic, Inc.) to assist physicians in determining the need for a repeat prostate biopsy in a patient with one or more previous negative biopsies. There is a decreased likelihood of a positive biopsy if the PCA3 score is <25 with a sensitivity and specificity of 77.5% and 57.1% and positive and negative predictive values of 33.6% and 90.0%, respectively. PCA3, with serum PSA and urinary TMPRSS2:ERG (T2:ERG), is part of the lab-developed test from the University of Michigan Mi-Prostate Score for predicting risk of prostate cancer or high-grade prostate cancer on needle biopsy [20,24]. The prostate cancer-specific gene fusion, TMPRSS2:ERG, present in approximately 50% of tumor foci, can be detected in urine using the same methodology as PCA3.

Bladder cancer markers

Urothelial [transitional cell carcinoma (TCC)] bladder cancer presentation includes nonmuscle-invasive, muscle-invasive, and metastatic disease. Seventy-five percent of patients have nonmuscle-invasive disease, which may be treated locally with resection with immunotherapy and/or chemotherapy, while those with muscle-invasive disease initially undergo radical cystectomy with or without perioperative chemotherapy. Bladder cancer has a high rate of recurrence; thus intensive surveillance, generally consisting of cystoscopy and urine cytology, at regular intervals is required. Tumor markers for bladder cancer have been proposed to aid in the management of patients with bladder cancer in order to detect early recurrences of cancer and to complement or replace urine cytology [25].

Several urine tests for TCC of the bladder have been approved for use as aids in the management of bladder cancer patients in conjunction with cystoscopy, including both qualitative and quantitative tests. The bladder tumor antigen *stat* assay is a qualitative test in a point-of-care test format that measures human complement Factor H-related protein (hCFHrp).

The NMP22 assay measures nuclear mitotic apparatus (NuMA), a nuclear matrix protein [2,25]. Nuclear matrix proteins make up the internal structural framework of the nucleus and can function in DNA replication, RNA synthesis, hormone binding, and in regulation of gene expression. NuMA is present in normal and malignant tissues, but can be overexpressed in bladder cancer and, therefore, released into the urine in higher concentrations. Slight elevations above the 10 U/mL cutoff have also been observed in some benign urological conditions as well as in prostate and kidney cancers. In a study of patients resected for TCC, sensitivity of the assay was 70% for detecting recurrence compared with cystoscopy and specificity was 86%. NMP22 assays are available in an ELISA format and an immunochromatographic, point-of-care format (Abbott NMP22 BladderChek) with indications for diagnosis and monitoring.

Hepatocellular cancer

α-Fetoprotein

Another oncofetal antigen, AFP, is a tumor marker for hepatocellular (HCC) and germ cell (nonseminoma) carcinoma [2]. AFP is a 70 kDa single polypeptide chain with 4% carbohydrate. AFP has sequence homology to albumin and is one of the major proteins in the fetal circulation. AFP is produced by the fetal liver and yolk sac with a peak in concentration at 13−14 weeks of gestation. AFP can enter the maternal circulation, and maternal serum concentrations are used in the detection of neural tube defects. AFP concentrations in infants decline to concentrations found in normal adults (<10 ng/mL) by 18 months after birth.

In addition to pregnancy, AFP can be elevated in benign liver conditions such as hepatitis and cirrhosis. A large majority of individuals diagnosed with HCC have cirrhosis with major causes including hepatitis B and C viruses, alcohol, and nonalcoholic fatty liver disease [26]. Ninety-five percent of patients with benign liver disease will have AFP concentrations <200 ng/mL, while

concentrations greater than 1000 ng/mL suggest the presence of cancer in the nonpregnant patient. The American Association for the Study of Liver Diseases recommends surveillance (targeted repeated screening in at risk patients) every 6 months for individuals with cirrhosis using liver ultrasound with or without AFP measurements. Overall survival is improved with the combined modality. The AFP cutoff of 20 ng/mL has a sensitivity of 60% and a specificity of 90%. AFP is also useful in HCC as a prognostic indicator of survival and for monitoring therapy and clinical status.

The glycosylation properties of AFP have been exploited to increase its specificity. Based on the differential binding of AFP to the lectin lens culinaris agglutinin, AFP can be classified into three isoforms: AFP-L1, AFP-L2, and AFP-L3 [27]. AFP-L3 reactivity is associated with liver cancer and AFP-L3%, AFP-L3 as a percentage of AFP, has been developed as a clinical assay with a cutoff of 10% (FUJIFILM Wako Diagnostics). It is indicated for use in patients with chronic liver diseases to assess the risk of developing HCC carcinoma and is prognostic in patients already diagnosed with HCC carcinoma.

AFP, in combination with hCG, is useful for classifying and staging testicular germ cell tumors. Germ cell tumors may be of a single cell type or a mixture of seminomatous and nonseminomatous features. One or both serum markers are elevated in 80%–85% of men with nonseminomatous testicular tumors. In seminomas, hCG is elevated in less than 25% of cases, and in pure seminomas, AFP is not elevated. AFP, hCG, and lactate dehydrogenase have prognostic significance and are used for staging prior to orchiectomy adding on an "S" for serum tumor makers to the traditional T, N, and M staging system [28]. AFP and hCG are most useful for monitoring treatment response and detecting recurrence.

Des-γ-carboxy prothrombin

An additional serum tumor marker for HCC, Des-γ-carboxy prothrombin (DCP) or protein-induced by vitamin K absence or antagonism II (PIVKA-II), is an abnormal form of the coagulation factor prothrombin [27]. In the liver, 10 glutamic acid (glu) residues on prothrombin are posttranslationally modified to γ-carboxy glutamic acid (gla) to form a functional molecule. The γ-glutamyl carboxylase requires vitamin K as a cofactor, and in the cases of dietary deficiency or antagonism, such as by warfarin, DCP is produced. In HCC, gene expression of the enzyme is defective, resulting in DCP.

DCP is most commonly used clinically in countries with a high prevalence of HCC, such as Japan, for early detection, monitoring, and recurrence. In patients with HCC versus those with cirrhosis or chronic hepatitis, sensitivity is 48% and specificity 96%. DCP, and AFP and AFP-L3% are independent markers, and in a case control study of patients with HCC carcinoma or cirrhosis, clinical sensitivity for cancer detection in early stage disease increased to 78% compared with 53% for AFP alone and 61% for DCP alone. DCP correlates with tumor size, although it is less sensitive for detecting small tumors. In the United States, the FUJIFILM Wako microfluidic chip-based immununochemical DPC assay has been FDA cleared as an aid in the risk assessment of patients with chronic liver disease for progression of HCC carcinoma. In a multicenter prospective study in 441 subjects with liver disease, the relative risk of developing HCC carcinoma was 4.8 with a DCP cutoff of 7.5 μg/L.

Thoracic cancer

Lung

The majority of lung cancers are classified histologically as small cell (SCLC), approximately 10%–15% of cases; nonsmall cell (NSCLG), approximately 80%–85% of cases; and, more rarely, carcinoid tumors. NSCLC encompasses adenocarcinoma, squamous cell, and large cell subtypes. A number of nonspecific serum tumor markers have been proposed for lung cancer [29]. Neuron-specific enolase and ProGRP are most associated with SCLC, while CEA and CYFRA 21-1 are most associated with NSCLC. Squamous cell carcinoma antigen is associated with the squamous cell subtype. These markers, in contrast to tissue markers, have less-defined clinical utility and are less likely to be included in clinical guidelines. Availability in the United States is also limited, and only CEA, with a general indication for monitoring in cancer patients, and CYFRA 21-1 are FDA cleared.

CYFRA 21-1

The cytokeratin family consists of approximately 20 proteins that comprise the cytoskeletal intermediate filaments of epithelial cells [2]. Soluble cytokeratin fragments with cancer-associated applications are tissue polypeptide antigen, tissue polypeptide-specific antigen, and cytokeratin 19 fragments (CYFRA 21-1). CYFRA 21-1 is elevated in bladder, lung, and other cancers, and although associated with small cell and NSCLC, it is most sensitive for NSCLC, primarily squamous cell carcinoma. In 2011 an enzyme immunoassay (EIA) for CYFRA 21-1 from Fujirebio Diagnostics was approved for the quantitative determination of soluble cytokeratin 19 fragments in human serum to be used as an aid in monitoring disease progression during the course of disease and treatment in patients with lung cancer. In the 100 patients studied, CYFRA 21-1 serum concentrations reflected change in disease status in 76% of 314 serial specimens. The EIA for CYFRA 21-1 detects cytokeratin 19 fragments with

monoclonal antibodies BM 19.21 and KS 19.1. CYFRA 21-1 concentrations can be elevated in renal disease and other benign conditions and is not affected by smoking status. In 2017 the Elecsys CYFRA 21-1 electrochemiluminescence assay was FDA cleared on Roche immunoassay platforms.

Mesothelioma

Soluble mesothelin-related peptides

SMRP, fragments of the cell-surface glycoprotein mesothelin, can circulate in patients with mesothelial tumors. Mesothelioma is a rare cancer of the mesothelial cells that line the internal organs of the body with the most common form found in the pleura. Mesothelioma is linked to asbestos exposure. The MESOMARK (Fujirebio Diagnostics) assay measures soluble mesothelin-related proteins in an ELISA format and is intended as an aid in monitoring patients diagnosed with epithelioid mesothelioma. A cutoff of 1.5 nM is used, which was derived from the 99th percentile of healthy subjects. It is elevated in 52% of patients with mesothelioma and 10%−15% of patients with ovarian, lung, colon, pancreas, and other cancers. The test has an FDA Humanitarian Device Exemption, which is for medical devices for diseases affecting fewer than 4000 individuals a year; demonstration of test effectiveness is not required.

Ovarian cancer

Cancer antigen 125

Cancer or carbohydrate antigen 125 (CA 125) is a glycoprotein containing 24% carbohydrate with a molecular mass >200 kDa [30,31]. The antigen is so named due to recognition by the OC125 monoclonal antibody. The antibody was developed from a cell line generated from a patient with an ovarian serous papillary cystadenocarcinoma. The antigen is produced by tissues of mullerian duct origin including ovarian epithelium. Secretion of CA 125 is related to the signal transduction pathway of the tyrosine kinase epithelial growth factor receptor.

CA 125 is a tumor marker for epithelial ovarian and endometrial cancers. It is also elevated in pancreatic, lung, breast, and GI cancers as well as in benign conditions such as pregnancy, endometriosis, hepatitis, and others [1,31]. Ovarian cancer is often detected at a late stage with a decreased survival rate compared with early stage disease, and thus sensitive and specific early detection markers are needed. Recent evidence also suggests that high-grade serous carcinoma originates in the fallopian tubes. It is generally accepted that a CA 125 measurement alone is not effective for screening in asymptomatic women, since it is not elevated in early stage disease [19,32]. Approaches to increase the utility of CA 125 for early detection include serial measurements and combining with transvaginal ultrasound. Results from the U.S.US Prostate, Lung, Colorectal, and Ovarian Cancer screening trial showed increased ovarian cancer diagnosis, but did not show a stage shift or reduction in the number of deaths in those randomized to CA 125 and transvaginal ultrasound. The recently reported United Kingdom Collaborative Trial of Ovarian Cancer Screening, which sought to assess ovarian cancer mortality, randomized greater than 200,000 women to no screening, annual transvaginal ultrasound alone, multimodal screening, and triaging with CA 125 testing over time evaluated by risk of ovarian cancer algorithm calculations and ultrasound as a second line test. In the later years of the 14 year study, risk of death was 20% lower in the multimodal screening group and more early stage cancers were detected compared with no screening [31,33]. Early detection in women at high risk for ovarian cancer, such as those with a family history of hereditary disease, is less controversial and screening with CA 125 has been recommended in combination with transvaginal ultrasound [19].

CA 125 may aid in the differential diagnosis of suspicious pelvic masses. A CA 125 > 95 U/L has a high positive predictive value in discriminating malignant and nonmalignant pelvic masses. In the United Kingdom, the risk of malignancy index (RMI) is used for patient management [32]. RMI is calculated from CA 125 concentrations, menopausal status, and ultrasound features. OVA1 is an IVDMIA, the first cleared by the FDA (2009), as aid to assess further the likelihood of malignancy in women with an ovarian adnexal mass with surgery planned who are not yet referred to a gynecologic oncologist. The serum test (Vermillion, Inc.) incorporates CA 125 and four other proteins into a score on a scale of 0−10 with pre- and postmenopausal specific risk cutoffs.

An FDA-approved indication for CA 125 is for monitoring response to therapy for patients with epithelial ovarian cancer. The first approved indication was as an aid in the detection of residual ovarian cancer in previously treated patients considered for diagnostic second-look procedures. However, second-look laparotomy is now considered to be controversial. CA 125 is also useful as a tumor marker for predicting survival pre- and postoperatively and for response to chemotherapy. CA 125 also correlates with disease progression in the majority of cases. The Gynecological Cancer Intergroup has defined response and progression of disease using CA 125. Briefly, a response is described as a 50% decrease in CA 125 from pretreatment that is confirmed and maintained at least 28 days using the same CA 125 assay [34].

The cutoff for CA 125 is 35 U/L. In the initial CA 125 assay, the OC125 monoclonal antibody was used as both capture and detector antibodies owing to multiple binding sites on the antigen. In the CA 125 II assay, the capture

antibody has been replaced with the M11 antibody, which has resulted in improved assay precision.

Human epididymis 4 protein

The human epididymis 4 protein (HE4) is a product of the WAP four-disulfide core domain 2 gene whose function is unknown. The HE4 gene is overexpressed in ovarian cancer, particularly in tumors of serous and endometrioid histology, but is not specific for ovarian tumors. HE4 is also overexpressed in endometrial cancer and as such may be effective as a biomarker [35]. The HE4 protein is measured in serum utilizing 2H5 and 3D8 monoclonal antibodies in a sandwich assay format. The test is cleared by the FDA for monitoring recurrence or progressive disease in patients with epithelial, but not mucinous or germ cell, ovarian cancer. HE4 is available as a manual EIA (Fujirebio Diagnostics) and automated on Abbott, Roche, and Fujirebio (Lumipulse G) automated platforms. HE4 has been incorporated into an algorithm with the CA 125 II assay and menopausal status to aid in assessing likelihood of malignancy in women with an ovarian adnexal mass, an indication similar to OVA1. ROMA was approved by the FDA in 2011. A sensitivity of 93.5% and specificity of 74.9% for ROMA have been reported in 472 women evaluated for an ovarian adnexal mass [35]. The recently FDA cleared second-generation OVA1 test, Overa, incorporates HE4 to improve test specificity.

Thyroid cancer

Thyroglobulin

Thyroglobulin (Tg) is a 660 kDa dimeric glycoprotein synthesized in the follicular colloid of the thyroid gland and is the precursor protein for thyroid hormone synthesis [2]. Tg is regulated by thyroid stimulating hormone (TSH). Serum Tg concentrations are used as a tumor marker to monitor the clinical course of patients with well-differentiated (papillary or follicular) thyroid cancer. Most normal euthyroid individuals have detectable serum Tg concentrations. The majority of patients with elevated Tg concentrations have benign thyroid conditions, since Tg is a nonspecific indicator of thyroid dysfunction. Concentrations can be elevated in Hashimoto's thyroiditis, Graves' disease, thyroid adenoma, and subacute thyroiditis. Therefore Tg is not useful in diagnosing thyroid cancer, and it is used for detecting residual thyroid tissue or recurrent disease.

Tg can be measured by RIA, sandwich immunoassay, or liquid chromatography tandem mass spectrometry (LC-MS)/MS) with immunoaffinity enrichment [36,37]. Second-generation sandwich immunoassays have functional sensitivities of 0.1 ng/mL, allowing monitoring for recurrence postthyroidectomy without the need for recombinant human TSH stimulation. Current RIA and LC-MS/MS assays do not meet the second-generation definition with typical functional sensitivities of 0.5 ng/mL. Tg autoantibodies (TgAb) can cause an interference in Tg immunoassays, most notably in sandwich assays resulting in an underestimation in Tg concentrations. Approximately, a third of thyroid cancer patients have autoantibodies present at some point during their disease and 10% of normal subjects also have TgAb. TgAb should be analyzed with each Tg measurement to aid in the interpretation of results. Similar to other tumor markers, monitoring should be performed with the same Tg assay, irrespective of methodology, facilitating trending, and doubling time calculations. TgAb assay results and cutoffs can also vary among manufacturers and cutoff definition (normal population versus assay sensitivity) can further obscure determination of antibody status. In addition, recognition that trends in TgAb concentrations can reflect response to Tg-secreting thyroid tissue, therefore acting as a tumor marker further emphasizing the need to follow patients with a specific assay as well as the need for assay harmonization [36].

Unlike immunoassays, it is thought LC-MS/MS Tg methods are devoid from antibody interferences although these methods are less well-characterized for their ability to assess accurately disease status in thyroid cancer patients. Mass spectrometry methods may be incorporated into reflex strategies for Tg testing, whereby initial TgAb dictates triage to immunoassay in TgAb-negative specimens and mass spectrometry or RIA in TgAb positive specimens.

Another valuable application for Tg measurement is as an aid to cytology in detecting lymph node metastases in patients treated for differentiated thyroid cancer with total thyroidectomy [38]. Cytomorphologic examination can be nondiagnostic, most often due to insufficient cellularity. Following ultrasound-guided fine needle aspiration of the suspicious lymph node, the needle is rinsed with saline or buffer and the sample tested for Tg. Detectable Tg is suggestive of the presence of metastatic disease; however, there is no uniform diagnostic cutoff for a negative result, as sample collection methods and assays are not standardized.

Guidelines for the use of tumor markers

As cited above, a number of clinical oncology and laboratory organizations develop and publish guidelines, addressing the clinical use of tumor markers. Clinical practice guidelines from The ASCO (https://www.asco.org/practice-guidelines/quality-guidelines/) and The AUA (https://www.auanet.org/guidelines) focus on specific cancers, while the NCCN (www.nccn.org) develops clinical practice guidelines for diagnosis and treatment of a wide range of cancers.

Laboratory medicine contributions include the Laboratory Medicine Practice Guidelines from The National Academy of Clinical Biochemistry (now AACC Academy: www.aacc.org/community/aacc-academy/publications) and publications from the European Group on Tumor Markers (www.egtm.eu), both addressing clinical as well as analytical and quality considerations.

Self-assessment questions

1. Tumor markers _____.
   - **a.** must be produced by the tumor
   - **b.** must be measured in body fluids
   - **c.** must be measured by immunoassay
   - **d.** must be quantitative
   - **e.** none of the above
2. Current tumor markers are most useful for _____.
   - **a.** screening
   - **b.** diagnosis
   - **c.** monitoring disease course
   - **d.** risk assessment
   - **e.** prognosis
3. ROC curves are constructed for two tumor markers for pancreas cancer using patients with cancer compared with normal subjects. The AUCs are 0.75 for test A and 0.54 for test B. What can be concluded about these two tests?
   - **a.** Test A has a better overall clinical performance compared to test B.
   - **b.** Test A is better than CA 19-9 as a tumor marker for pancreas cancer.
   - **c.** These tests are not elevated in patients with benign GI diseases
   - **d.** There is an assay cutoff for test A that provides 100% clinical sensitivity and specificity
   - **e.** All of the above
4. The CA 15-3 breast cancer marker may be elevated in patients with _____.
   - **a.** breast cancer
   - **b.** ovarian cancer
   - **c.** liver disease
   - **d.** lung cancer
   - **e.** all of the above
5. CA 19-9 is analyzed in a patient diagnosed with pancreas cancer prior to surgery. The result is undetectable. Which of the following are true?
   - **a.** The patient does not have pancreas cancer.
   - **b.** The patient has HAMA.
   - **c.** CEA should also be measured.
   - **d.** The marker is not informative for monitoring treatment.
   - **e.** All of the above.
6. A 65-year-old man is referred to a urologist with a PSA of 5.6 ng/mL. His DRE is negative. A 12-core biopsy is performed and no cancer is found. Six months later, his total PSA is 5.4 ng/mL. A percent free PSA is performed. The result is 29%. What can be concluded from this information?
   - **a.** The likelihood of cancer is high.
   - **b.** The likelihood of cancer is low.
   - **c.** This patient has BPH.
   - **d.** This patient has prostatitis.
   - **e.** b and c.
7. Total PSA assays measure _____.
   - **a.** unbound PSA
   - **b.** PSA-ACT
   - **c.** PSA-A2M
   - **d.** a and b
   - **e.** a–c
8. Which of the following is not an approach to improve the clinical utility of PSA for prostate cancer detection?
   - **a.** PSA velocity
   - **b.** Ultrasensitive PSA
   - **c.** Molecular forms of PSA
   - **d.** Molecular forms of free PSA
   - **e.** PSA density
9. Which of the following is true of CA 15-3 and CA 27.29 assays:
   - **a.** Assays cannot be used interchangeably for monitoring disease.
   - **b.** Assays give the some values for a given specimen.
   - **c.** Assays use the same cutoff values.
   - **d.** Assay design and kinetics are similar.
   - **e.** Assays are approved for use in the early detection of breast cancer.
10. Which of the following is/are true for the ROMA and OVA1 algorithms:
    - **a.** They are used to diagnose ovarian cancer.
    - **b.** CA 125 is one of the analytes in the panel of markers.
    - **c.** They are indicated for use only in postmenopausal women.
    - **d.** They have similar indications for use.
    - **e.** b and d.

Chapter 45

Calcium biology and disorders

William E. Winter[1,2], J. Peter R. Pelletier[1,3], and Neil S. Harris[1]

[1]Department of Pathology, University of Florida, Gainesville, FL, United States, [2]Department of Pediatrics, University of Florida, Gainesville, FL, United States, [3]Department of Anesthesia, University of Florida, Gainesville, FL, United States

Learning objectives

After reviewing this chapter, the reader will be able to:

- Explain the regulation of calcium and phosphate.
- List the differential diagnosis of hypocalcemia and hypercalcemia.
- Diagnose conditions involving excesses or deficiencies of calcium.
- Describe the role of calcitonin testing in the diagnosis and monitoring of medullary thyroid carcinoma.
- Choose markers of bone turnover in the evaluation of osteoporosis.

Introduction

In the body, calcium has a major structural role in the formation of bone and is important in blood coagulation, neurological and neuromuscular function, and intracellular signaling. The majority of calcium in the body is localized to bone (e.g., ~99%). Phosphate is involved in many critically important biochemical processes, including energy metabolism (e.g., adenosine triphosphate, ATP), nucleic acid metabolism, cell signaling, bone formation, and maintenance of acid/base balance (especially related to urinary phosphate buffering). Both calcium and phosphate are important in skeletal formation and turnover. Bone provides us (as humans) with form, mobility, and protection. It is also the site of hematopoiesis. In many ways, bone is an extended endocrine target organ, as many hormones regulate bone dynamics to varying degrees, including parathyroid hormone (PTH), 1,25-dihydroxyvitamin D (1,25-OH_2D), calcitonin, thyroid hormones, sex steroids, glucocorticoids, growth hormone, and insulin-like growth factor I. Bone is also the source of many regulatory factors, including fibroblast growth factor-23 (FGF23). The biological action of FGF23 is to produce phosphaturia. FGF23 is produced by osteocytes.

Calcium

Calcium function and distribution

As noted above, the majority of the body's calcium (e.g., ~99%) is localized to bone. Of the remaining 1% of calcium that is not associated with bone, there are two pools of calcium, which are stratified into a slowly exchangeable pool and a rapidly exchangeable pool. The slowly exchangeable pool encompasses calcium in dystrophic sites such as atheromas and damaged cartilage, and in subcellular organelles such as the mitochondria and the endoplasmic reticulum. The rapidly exchangeable pool includes calcium in systemic circulation, interstitial fluid, within cellular cytoplasm, and calcium that has recently been deposited on bone surfaces. Plasma total calcium (not associated with bone) is categorized in the body as: (1) free calcium; (2) protein-bound calcium; and (3) complexed (anion-bound) calcium. Within the circulation, ~40%–50% of calcium is ionized (free). Bound calcium is carried by plasma proteins (predominantly albumin; ~40% of the total calcium) or complexed to anions such as bicarbonate (HCO_3^-), citrate, lactate, and phosphate (~10% of the total calcium).

Ionized calcium is measured using an ion-selective electrode (ISE). The free (unbound) calcium fraction, which is responsible for the electrophysiological actions of calcium, is monitored by the parathyroid gland's cell-surface, transmembrane calcium-sensing receptor (CaSR). The proportion of calcium that is ionized versus bound to plasma proteins is influenced by blood pH. In acidotic states, ionized calcium increases as calcium is "released" by plasma proteins, whereas alkalosis decreases ionized calcium as calcium is bound to plasma proteins. Hyperventilation, for example, through the induction of alkalosis, can produce symptoms of hypocalcemia (e.g., perioral paresthesia and tingling). Ultrafilterable calcium

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00045-4

is the sum of the ionized calcium and anion-complexed calcium that can pass through the glomerular basement membrane of the nephron into the Bowman space. This calcium (and phosphate as well) will be reabsorbed by the renal tubules limiting calciuria (which if excessive can cause renal stones or nephrocalcinosis). Total body phosphate is controlled predominantly by the excretion of phosphate.

In modern laboratories, total calcium is measured using dye-binding assays (e.g., arsenazo III or o-cresolphthalein complexone). Prevention of interference by magnesium is achieved by the addition of 8-hydroxyquinoline to the reaction. Newer generation calcium assays utilize 5-nitro-5′methyl-BAPTA as a substrate for the calcium measurement. On certain analyzers, calcium is measured by ISE after acidification to release protein-bound and complexed calcium into the ionized state. This is important, as ISEs do not show interference from gadolinium, whereas dye-binding methods do display transient negative interferences with some gadolinium formulations [1]. Gadolinium is a contrast agent used in radiology.

Because total calcium levels can be significantly affected by albumin concentrations, if the total calcium is abnormal, either serum albumin or ionized calcium should be measured. Total calcium can be corrected for deficiencies or excesses of albumin as follows: for every decline in albumin of 1 g/dL below 4 g/dL, the total calcium is expected to decline by 0.8 mg/dL assuming there are no disorders of calcium homeostasis. Likewise, for every increase in albumin above 4 gm/dL, the total calcium is expected to rise by 0.8 mg/dL.

$$\text{Corrected total } Ca^{++} = \text{measured total } Ca^{++} + 0.8 * \left[4.0 - \text{measured albumin}(g/dL)\right]$$

Recognizing that these rules are approximations, measurement of ionized calcium is preferred.

Calcium sensing by the parathyroid glands

Ionized calcium is monitored by the CaSR located on the cell surfaces of the parathyroid glands [2] (Fig. 45.1). Four parathyroid glands are normally located behind the thyroid gland. However, the number of parathyroid glands can vary between three and five and ectopic parathyroid tissue can be located elsewhere in the neck, mediastinum, or among the aortic arch. Reduced stimulation of the CaSR because of a low interstitial ionized calcium concentration stimulates the receptor to engage processes that release PTH from the parathyroid cells. On the other hand, increased stimulation of the CaSR because of a high interstitial ionized calcium concentration reduces parathyroid gland PTH release. Although it was initially postulated that the CaSR would function as an ion channel, molecular analysis of the CaSR revealed that this 1078−amino-acid receptor was a member of subfamily C of the G-protein-coupled receptors. Other members of this subfamily include metabotropic glutamate receptors, gamma-aminobutyric acid type B receptors, and pheromone receptors. The CaSR has a large extracellular domain for ionized calcium binding, seven transmembrane domains, and an intracellular domain that couples the receptor to G proteins. The gene for the CaSR is located on chromosome 3q13.3-q21.

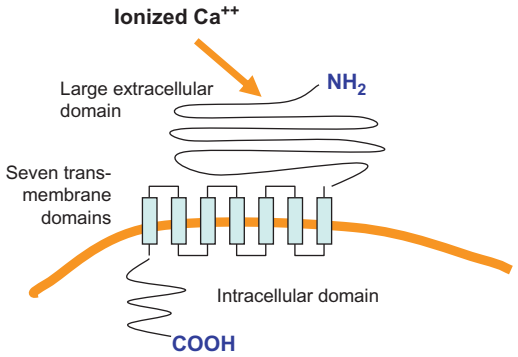

FIGURE 45.1 The calcium sensing receptor has a large N-terminal extracellular domain that binds ionized calcium, a 7-member transmembrane domain, and an intracellular domain.

Parathyroid hormone synthesis, release, and metabolism

A decline in ionized calcium concentrations elicits PTH secretion from the parathyroid glands. The PTH gene is located on chromosome 11p. In contrast, elevations in ionized calcium suppress PTH release. PreproPTH is 115 amino acids in length (Fig. 45.2). Upon entry of preproPTH into the rough endoplasmic reticulum, the 25 amino acid presequence (or leader/signal sequence) is cleaved, yielding proPTH of 90 amino acids. ProPTH is further cleaved to PTH with the removal of another N-terminal, 6 amino acids. This full-length 84−amino-acid form of PTH is termed "1−84 PTH." Either within the parathyroid or shortly after secretion, 6 N-terminal amino acids are removed from ∼50% of the 1−84 PTH molecules, yielding 7−84 PTH within the systemic circulation. In normal individuals, the ratio of 1−84 PTH to 7−84 PTH is ∼1:1. Whereas 1−84 PTH acts to raise calcium concentrations, 7−84 PTH may actually lower calcium concentrations. 1−34 PTH may also be derived from 1−84 PTH [3]. 1−34 PTH also appears to raise calcium concentrations.

In terms of PTH immunoassays, the intact PTH double-antibody (immunometric) assays detect both 1−84 PTH and 7−84 PTH through a standard antibody−antigen−antibody "sandwich" approach. Thus the

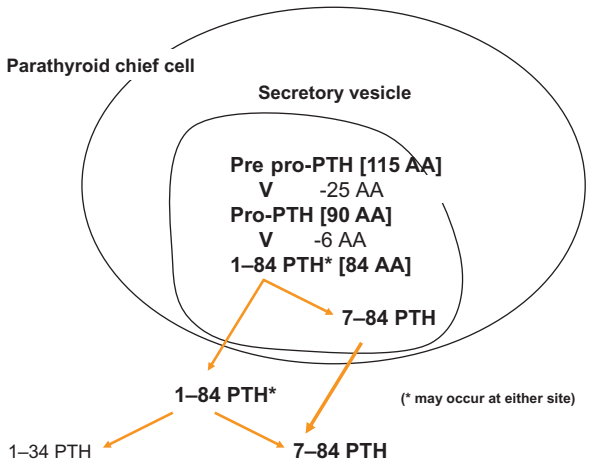

FIGURE 45.2 PTH is initially synthesized as preproPTH (115 amino acids) that is processed to proPTH (90 amino acids) with removal of the pre- or leader sequence (25 amino acids). Removal of a further six amino acids yields 1−84 PTH. Either within parathyroid secretory vesicles or after secretion, the N-terminal 6 amino acids can be cleaved from 1−84 PTH producing 7−84 PTH. A 1−34 PTH fragment can also be produced from 1−84 PTH.

term "intact PTH" assay is really a misnomer, because the intact assay does not exclusively detect 1−84 PTH. In such intact PTH assays, a monoclonal antibody to the N-terminus first recognizes a motif starting at approximately amino acid 7, and thus amino acids 1−6 are not necessary for this assay to detect PTH. A polyclonal antiserum is directed at C-terminus motifs distal to amino acid 34 in PTH.

In response to the recognition that the intact assay does not measure exclusively 1−84 PTH, in the past, several manufacturers developed immunoassays that detected 1−84 PTH but not 7−84 PTH [4,5]. These assays have been variously named "true-intact," "whole," "bio-intact," or "cyclase-activating" PTH assays. These 1−84 PTH assays use an antibody to the N-terminus that binds to the first amino acid in PTH, allowing detection of 1−84 PTH. However, at least some of the whole PTH assays also detect a 1−34 PTH molecule, and thus these assays may not be absolutely specific for 1−84 PTH.

Some investigators have suggested that "whole" PTH assays were superior to intact PTH assays in the assessment of secondary hyperparathyroidism of renal failure [6−12]. Because the intact PTH assays include measurements of 1−84 PTH and 7−84 PTH, a hypothesis was advanced that the whole PTH assays would be superior to the intact PTH assays because of the selectivity of the whole PTH assays for 1−84 PTH. Furthermore, whole PTH assays would not overestimate PTH as would the intact PTH assays. Theoretically, overestimation of the PTH concentration could lead to clinical overtreatment of secondary hyperparathyroidism. Close review of the literature, however, does not support the superiority of the whole PTH assays over the intact PTH assays in this regard. Compared with the intact PTH assay, the whole PTH assay is not a better predictor of bone loss. Furthermore, the ratio of 1−84 PTH to non-1−84 PTH does not correlate with the rate of bone formation.

Presently (November 2018), none of the major reference labs (Mayo Medical Laboratories, LapCorp, Esoterix, Quest, and ARUP) appears to offer true-intact (biointact) PTH assays. Several papers from 2001−05 showed that the correlation of 7−84PTH with 1−84PTH in: (1) primary hyperparathyroidism; (2) uremia; and (3) pediatric dialysis displayed r values of $= > 0.92$. Bone formation rates correlate equally well with 7−84PTH measurements and 1−84PTH measurements regardless of the presence or absence of uremia. These studies lead to the conclusion that 1−84PTH measurements are not clinically superior to 7−84PTH measurements.

Parathyroid hormone actions

Renal tubular cells and osteoblasts respond to PTH via expression of a receptor for PTH. Besides binding PTH, the PTH receptor also binds PTH-related peptide (PTHrP) and is named "PTHR1" or the "PTH/PTHrP" receptor [13]. PTHrP is released by some cancers and can cause hypercalcemia (i.e., humoral hypercalcemia of malignancy). PTHrP is not detected in PTH immunoassays. Intact PTH is 84 amino acids in length versus PTHrP, which is 131 amino acids. PTHrP only shares 8 of its first 13 amino acids with PTH indicating that these proteins are quite different structurally. The N-terminal 14 amino acids in PTH and PTHrP are necessary for the signaling functions of these molecules. There is a separate immunoassay for PTHrP. PTHrP assays are generally offered only in reference laboratories.

The PTH/PTHrP, whose gene (*PTHR1*) is located on chromosome 3p21.1−22, is a member of the group II subgroup of the G-protein−linked receptor (GPCR) superfamily. The PTH/PTHrP receptor has a large extracellular domain, seven transmembrane domains (e.g., heptahelical), and a cytoplasmic tail similar to the thyroid-stimulating hormone (TSH) receptor and CaSR. Other members of the GPCR group II are receptors for calcitonin, glucagon, glucagon-like peptide I, growth-hormone−releasing hormone, vasoactive intestinal polypeptide, and secretin. A second receptor that binds PTH, but not PTHrP, has been identified: PTHR2. Encoded on chromosome 2q33, PTHR2 is expressed in the brain, pancreas, testis, and placenta. The function of this receptor is yet to be fully delineated. PTHR1 appears to be the most important receptor for PTH.

The binding of PTH or PTHrP to the PTH/PTHrP receptor stimulates adenyl cyclase, raising cyclic adenosine monophosphate (cAMP) concentrations, and activating

phospholipase C. PTH stimulates osteoblasts in bone and metaphyseal or cartilaginous growth plates to foster normal bone health; in excess, PTH causes bone resorption. PTH stimulates the renal tubular cells to increase calcium reabsorption from renal tubular fluid while increasing the excretion of phosphate in the urine (e.g., increasing phosphaturia). PTH reduces expression of the sodium-dependent phosphate cotransporter [Npt2; gene name: *SLC34A1*; solute carrier family 34 (sodium phosphate), member 1; chromosome 5q35] at the renal tubular brush border that results in urinary phosphate wasting. These actions of PTH raise circulating calcium concentrations while lowering phosphate concentrations. These actions avoid the development of ectopic calcification.

Vitamin D metabolism and biology

There are two sources of vitamin D: exogenous vitamin D_2 (ergocalciferol) from the diet and endogenous vitamin D_3 (cholecalciferol) from the skin following sun exposure (Fig. 45.3). Most vitamin D comes from the skin. Vitamin D deficiency occurs in the absence of sufficient intake of vitamin D2. Over the counter, both vitamin D2 and vitamin D3 are available. Vitamin D is derived from provitamin D precursors. Provitamin D species (both D_2 and D_3) are bioconverted by ultraviolet (UV) light to form previtamin D molecules. Thermal isomerization then yields vitamin D. Provitamin D_2 is derived from the diet, whereas provitamin D_3 is produced in the skin consequent to UV light exposure. It is controversial whether vitamin D2 is less potent than vitamin D3. Vitamin D2 and vitamin D3 vary only in their R groups. As a fat-soluble vitamin, vitamin D is dependent on normal fat absorption for its absorption. Any cause of steatorrhea (e.g., bile salt deficiency or impaired secretion, or pancreatic insufficiency causing lipase and colipase deficiency) or intestinal disease (with malabsorption) can interfere with vitamin D absorption.

The primary circulating form of vitamin D, 25-hydroxyvitamin D (25-OHD), is produced in the liver via vitamin D-25-hydroxylase (gene name: *CYP27A*; chromosome 2q33-qter) in a PTH-independent manner. However, PTH does stimulate the conversion of 25-OHD to 1,25-OH_2D via 25-hydroxyvitamin D-1 alpha-hydroxylase (gene name: *CYP27B1;* chromosome: 12q1) within the renal tubular cells (Fig. 45.4). The predominant circulating form of vitamin D is 25-OHD, which has lower biological activity than 1,25-OH_2D. While clinicians might request a "vitamin D level," this is not the proper nomenclature for the measurement of 25-OHD.

Vitamin D species act by binding to the vitamin D receptor (VDR). The VDR is 427 amino acids (molecular mass ~48.3 kDa) and is encoded on chromosome 12q13.11. VDR is a member of the NR1I family whose other members include the constitutive androstane receptor and the pregnane X receptor. VDR forms heterodimers with retinoid X receptor family members. The vitamin D species with the highest affinity for the receptor is 1,25-OH_2D. As the most biologically active form of the hormone, 1,25-OH_2D functions as a transcriptional modulator. Physiologically, the active form of vitamin D also increases the absorption of calcium and phosphate from the gastrointestinal tract. 1,25-OH_2D concentrations are controlled through a short, negative feedback loop, in which 1,25-OH_2D suppresses the bioconversion of 25-OHD to the active hormone. In addition, increased phosphate

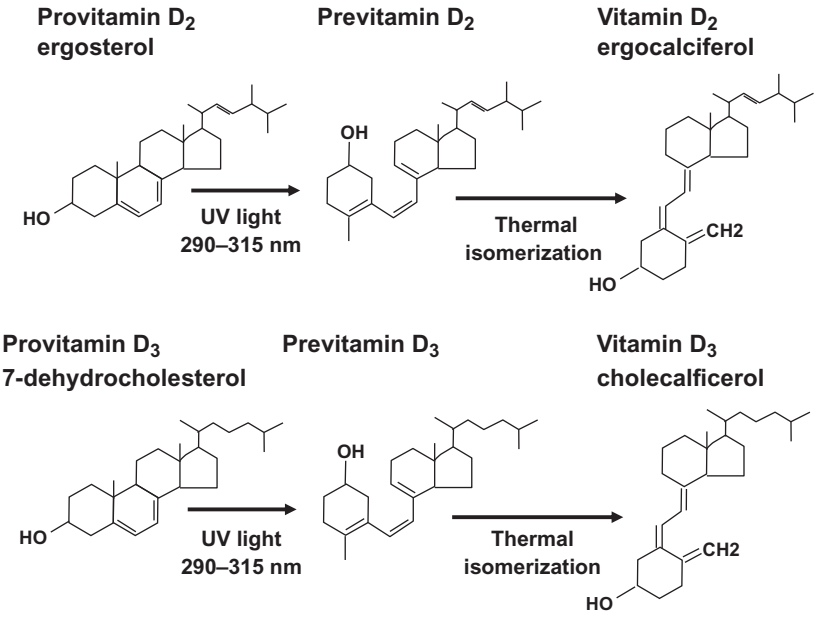

FIGURE 45.3 Provitamin D species (both D2 and D3) are acted upon by UV light to form previtamin D species. Thermal isomerization then yields vitamin D. Provitamin D2 is derived from the diet, whereas provitamin D3 is produced in the skin consequent to UV light exposure.

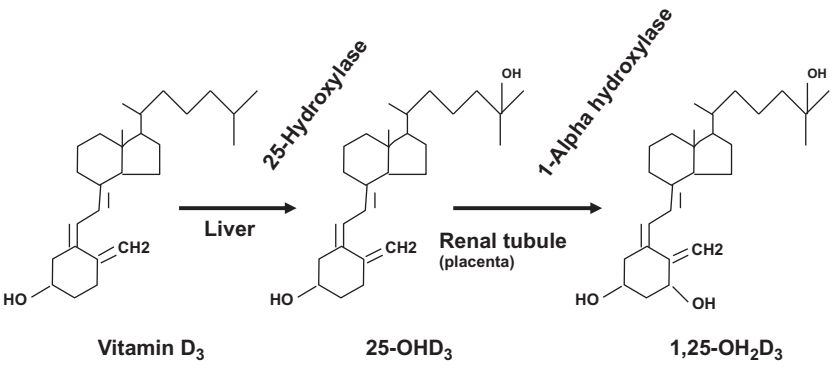

FIGURE 45.4 Vitamin D (in this case vitamin D3) is activated by a 25-hydroxylation in the liver followed by a 25-hydroxylation in the kidney. The placenta can also convert 25-OHD into 1,25-OH_2D.

concentrations and FGF-23 also decrease the conversion of 25-OHD to 1,25-OH_2D. Measurements of 1,25-OH2D are indicated only under special circumstances and such levels require expertise to interpret.

Concentrations of 1,25-OH_2D are also regulated by its conversion to 1,24,25-trihydroxy vitamin D (1,24,25-OH_3D) via the enzyme D-24-hydroxylase ("24-hydroxylase") encoded by *CYP24A1* (cytochrome P450 family 24 subfamily A member 1; chr. 20q13.2) [14]. 24-hydroxylase also converts 25-OH_2D into 24,25-dihydroxyvitamin D. 24-hydroxylase is stimulated by 1,25-OH_2D and FGF23. Loss-of-function variants in 24-hydroxylase can lead to infant hypercalcemia (sometimes referred to as "infantile idiopathic hypercalcemia").

25-OHD and 1,25-OH_2D can be measured by immunoassay or mass spectrometry. The immunoassays do not distinguish the D_2 from D_3 forms of 25-OHD and 1,25-OH_2D. However, mass spectrometry has the potential to distinguish the D_2 and D_3 forms of 25-OHD and 1,25-OH_2D.

To absorb calcium from the diet, three events occur: (1) calcium enters into the cytoplasm of the intestinal brush border cells mediated by CaT1 [a.k.a. ECaC2, an epithelial Ca^{2+} channel /transporter; gene name: *ECAC2 or TRPV6* (transient receptor potential cation channel subfamily V member 6); chromosome 7q34]; (2) calcium diffuses within these cells as mediated by calbindin Ds, which are cytosolic calcium-binding proteins [calbindin D-9K (X-chromosome) and D-28K (chromosome 8)]; and (3) from the basolateral membrane, calcium is pumped out of the cell by a CaATPase (e.g., a Na^+/Ca^{2+} exchanger). The synthesis of CaT1 is ~90% dependent on 1,25-OH_2D, whereas the synthesis of calbindin D is completely dependent on 1,25-OH_2D CaT1 and calbindin D are both rate limiting in the process of calcium absorption. On the other hand, a high calcium diet downregulates CaT1 and calbindin D by downregulating production of 1,25-OH_2D.

Similar to bone resorption, increased gastrointestinal absorption of calcium and phosphate increases both plasma calcium and phosphate concentrations. Although calcium is lost to a minor extent in the stool and urine, the primary control mechanism for total body calcium depends on the appropriate gastrointestinal tract absorption of calcium from the diet. Thus adequate calcium must be present in the diet. If excessive calcium is chronically lost in the urine (i.e., hypercalciuria), urolithiasis (kidney stones) and nephrocalcinosis (kidney calcification) can result. Either condition can lead to renal failure. In adult males, the reference interval for 24-hour urinary excretion of calcium is 25−300 mg/24 h, and in adult females, the reference interval is 20−275 mg/24 h. In adults, a random urine-calcium-to-creatinine ratio can also be used to assess the patient for hypercalciuria. A normal adult calcium-to-creatinine ratio is <0.14 (in English units); ratios >0.20 indicate hypercalciuria. Pediatric reference intervals for calcium excretion (e.g., hypercalciuria: ≥ 4 mg/kg per day) and the calcium/creatinine ratios are available in the literature [15].

Although increased phosphate absorption from the gastrointestinal tract and increased phosphate release from bone act to raise plasma phosphate concentrations, the normal phosphaturic effect of PTH on the renal tubules predominates, leading to an overall decline in plasma phosphate concentrations in response to PTH when renal function is uncompromised. Urinary excretion of phosphate is responsible for the regulation of total body phosphate.

Phosphate biology

The majority of total body phosphate (PO_4^3) resides as organic phosphate complexed with proteins, lipids, and carbohydrates. Inorganic phosphate (noncomplexed phosphate) in plasma is a very small proportion of total body phosphate.

Phosphate is plentiful in the diets of most people in industrialized countries. Gastrointestinal tract absorption of phosphate is not as highly regulated as calcium, with ~70% of dietary phosphate absorbed from the intestinal tract enterocytes (columnar epithelial cells). Excess

phosphate is then excreted in the urine. In renal failure, phosphate retention produces hyperphosphatemia. In turn, hyperphosphatemia can contribute to the development of hypocalcemia. This can be further exacerbated by decreased conversion of 25-OHD to 1,25-OH_2D, further decreasing intestinal calcium absorption. When phosphate is measured in plasma or serum, it is its elemental phosphorus content that is reported.

To summarize, the overall effects of PTH are to raise plasma calcium while lowering plasma phosphate concentrations. These actions are beneficial to avoid inappropriate biomineralization occurring in soft tissues when calcium and/or phosphate are both pathologically increased when the calcium−phosphate product may exceed $\sim 70\ mg^2/mL^2$ (i.e., calcium concentration in mg/dL is multiplied by the phosphate concentration in mg/dL). Examples of ectopic calcification include calcinosis cutis (skin calcification), tendon calcification, and blood vessel calcification. Significantly, calcified blood vessels can be visible on plain-film X-rays and CT scans (e.g., coronary calcium scans). In calcinosis cutis, firm, chip-like deposits can be palpated in the skin. Failure to maintain adequate levels of ionized calcium produces symptoms of hypocalcemia. Vice versa, excessive levels of ionized calcium produce symptoms of hypercalcemia.

Table 45.1 summarizes the major biological effects of PTH, 1,25-OH2D, and FGF23 on the body.

Bone biology

To be discussed in detail below, osteoblasts build bone, osteoclasts resorb bone, and osteocytes are osteoblasts that have encased themselves in bone creating the lacunocanalicular system. The most abundant of these cells in bone is osteocytes that comprise 90%−95% of bone cells. The next most common bone cell is the osteoblast (<5% of bone cells) and the osteoclast is the least common bone cell (1% or more of bone cells but less common than osteoblasts). Bone is in a constant state of remodeling. In adults, approximately 10% of bone turns over yearly. Initially, remodeling involves bone resorption by osteoclasts with the consequent release of calcium and phosphate and degradation of the bone protein matrix. This is followed by new bone formation (i.e., bone accretion), which is carried out by osteoblasts. Type 1 collagen is the major protein component of the bone matrix. Pyridinolines and deoxypyridinolines cross-link collagen strands.

TABLE 45.1 Causes of hypocalcemia.

1. Decreased parathyroid hormone action
2. Deficient vitamin D action
3. Extreme dietary calcium deficiency
4. The healing phase of various forms of bone disease
5. Calcium saponification (e.g., acute pancreatitis)

Osteocalcin (gene located on chromosome 1q2), also known as bone Gla protein, is the major noncollagen protein found in bone that is released from the bone matrix during bone resorption into the plasma. Synthesized by osteoblasts, osteocalcin is a cytosolic calcium-binding protein of 49 amino acids (5.7 kDa). Gla stands for "gamma-carboxy glutamic acid." Via the activity of vitamin-K−dependent carboxylases at positions 17, 21, and 24 of the protein, amino acids are modified to gamma-carboxyglutamyl residues that can bind calcium or hydroxyapatite ($Ca_3(PO_4)_2)_3.Ca(OH)_2$). Between 10% and 30% of osteocalcin produced by osteoblasts is released extracellularly. In systemic circulation, osteocalcin has a short half-life of $\sim$5 minutes. Osteocalcin concentrations can provide an index of bone turnover. Elevated osteocalcin concentrations are observed in conditions such as vitamin D deficiency states (rickets or osteomalacia), osteoporosis, hyperparathyroidism (primary or secondary, e.g., renal osteodystrophy), hyperthyroidism, or in persons with bony metastasis, acromegaly, or fractures. Osteocalcin levels decline with bisphosphonate treatment of osteoporosis or osteopenia.

Intermittent exposure to PTH normally stimulates the mesoderm-derived stromal cells of bone to develop into osteoblasts (Fig. 45.5). By entering the lacunae left by osteoclast-driven erosion of the bone microarchitectural surface, osteoblasts lay down new bone by secreting connective tissue matrix (e.g., type 1 collagen) that is ossified by calcium and phosphate deposition, resulting in the formation of hydroxyapatite. Hydroxyapatite is the hard, mineralized portion of bone. As osteoblasts are encased in this newly formed bone, the osteoblasts become osteocytes. With PTH-mediated osteoblast stimulation, bone cycling will consequently increase osteoclast activity.

Osteoclasts are ultimately derived from bone marrow hematopoietic stem cells (HSCs). HSCs give rise to common myeloid progenitor cells. Under the influence of granulocyte−monocyte colony stimulating factor, the granulocyte−monocyte progenitor arises. Subsequently, under the influence of macrophage-colony-stimulating factor (M-CSF), monocytes develop. Macrophages are formed when monocytes enter into the interstitium upon leaving the circulation.

Osteoblasts secrete M-CSF and express the receptor activator of NF-kB ligand (RANKL; see Fig. 45.5). M-CSF stimulates macrophage proliferation, while RANKL binds to the receptor activator of NF-kB on the developing osteoclast. As a member of the tumor necrosis factor superfamily, RANKL is also recognized as an "osteoclast

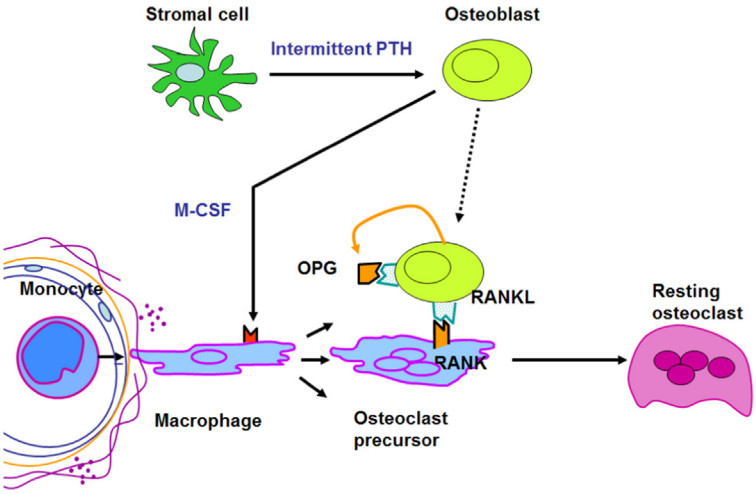

FIGURE 45.5 Under the influence of intermittent PTH stimulation, stromal cells develop into osteoblasts. Via their secretion of macrophage-colony-stimulating factor, macrophages develop into osteoclast precursors. Through the expression of RANKL binding to RANK, the osteoblast precursors develop into resting osteoclasts. Opposing the interaction of RANKL and RANK, osteoblasts secrete osteoprotegerin, which serves as a soluble decoy receptor for RANKL. Therefore the number of "free" RANKL molecules determine the degree to which the osteoblast stimulates the osteoclast.

differentiation factor" or osteoprotegerin (OPG) ligand. Therefore cell-surface proteins on the osteoblast stimulate osteoclast development, thereby fostering bone remodeling. This firmly links osteoblast and osteoclast activity.

RANKL stimulates the differentiation of osteoclasts. This development is also enhanced by intermittent exposure to PTH. On the other hand, osteoblasts secrete OPG, which binds to RANKL and inhibits its action by functioning as a soluble decoy receptor for RANKL. A case study described a young man presenting with osteoporosis who produced an autoantibody against OPG; this process theoretically enhanced osteoclast proliferation, causing his osteoporosis [16]. Deficiency of OPG is one cause of juvenile Paget disease of bone [17]. The expression of RANKL by osteoblasts is increased by cytokines such as IL-1, IL-6, and IL-11, explaining the common finding of osteopenia in chronic inflammatory conditions (e.g., rheumatoid arthritis).

Attachment of the osteoclast to bone occurs via osteoclastic integrins ($alpha_v beta_3$) located on foot-like, actin-containing podosomes that bind to osteopontin and vitronectin on the bone's surface to produce a tight seal (Fig. 45.6). The space between the osteoclast and the bone is termed the subosteoclastic compartment, which is also known as the Howship lacunae. Within the osteoclast, carbon dioxide and water react to form hydrogen (H^+) and HCO_3^- due to carbonic anhydrase II catalysis. At the apical side of the cell, chloride (Cl^-) and HCO_3^- are exchanged via the HCO_3^- −chloride exchanger. At the ruffled border of the osteoclast, a chloride channel allows entry of chloride into the subosteoclastic compartment accompanying H^+ transported into the subosteoclastic compartment by a H^+-ATPase pump (a vacuolar-type ATPase).

Secreted cathepsin k (a cysteine protease; a member of the peptidase C1 protein family; 329 amino acids; ~37 kDa; gene on chromosome 1q21.3) and matrix metalloprotease-9 (707 amino acids; ~78.5 kDa; gene on chromosome 20q13.12) degrade the connective tissue matrix, whereas hydrochloric acid creates an acidic (pH of 4.5) environment to afford solubilization of the mineral content of the bone. Degraded bone components exit the subosteoclastic compartment via transcytosis to the interstitium. The released calcium and phosphate increase calcium and phosphate concentrations in plasma.

Whereas normal concentrations and a pulsatile release of PTH are vital to maintain healthy bone remodeling, persistent excess PTH increases RANKL and decreases OPG production by osteoblasts overall, leading to excessive osteoclast formation. When osteoclast activity exceeds osteoblast activity, bone resorption occurs, resulting in a decline in the mineral content of bone with loss of bone strength. A decline in bone strength predisposes to osteopenic fractures.

Stimulated osteoblasts secrete increased concentrations of bone alkaline phosphatase (BAP). BAP can be measured by immunoassay. Other sources of alkaline phosphatase include [1] the biliary tract with elevations indicative of biliary tract disease and [2] the placenta where alkaline phosphatase is normally elevated in the third trimester of pregnancy. While alkaline phosphatase isoenzymes can be measured by electrophoresis (or the even older inhibition techniques), there are usually better markers of bone or biliary tract disease that can be ordered instead of ordering alkaline phosphatase isoenzyme measurements. Increased BAP is found in childhood and is associated with growth. Further, BAP raises the following fractures in all age groups. Transient hyperphosphatasemia of infancy and childhood describes a condition of unknown etiology, where total alkaline phosphatase activity measurements are inexplicably elevated at least four to five times greater above the upper limit of the reference interval for children (sometimes >10 times the upper limit of the reference interval) [18].

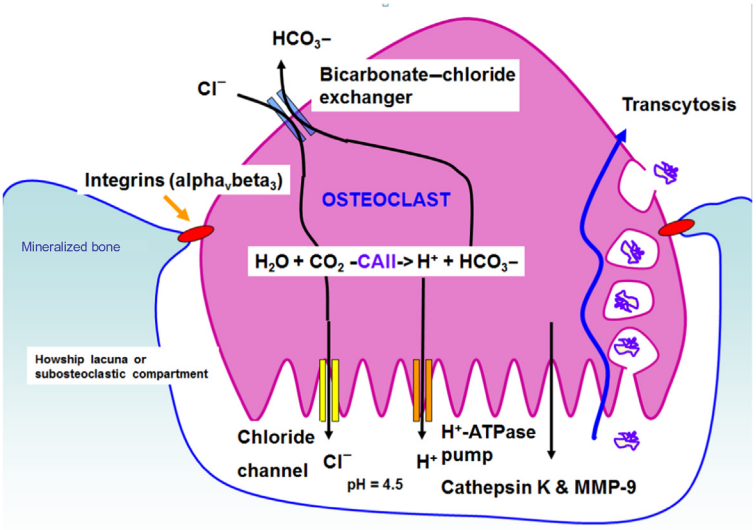

FIGURE 45.6 Once osteoclasts bind to bone, hydrochloric acid, cathepsin K, and matrix metalloprotease-9 enter the subosteoclastic compartment to resorb bone. The released materials transcytose across the osteoclast.

Increased BAP or osteocalcin concentrations signal an increased rate of bone formation although bone loss can exceed bone formation leading to an overall decline in bone mineral density (BMD).

In adults, maintenance of normal bone mass requires proper nutrition in the form of adequate dietary vitamin D and calcium, weight-bearing exercise, sex steroids in pubertal and postpubertal individuals, and growth hormone. Decreased bone density is described as osteopenia. By itself, osteopenia is not a disease. Osteopenia can result in impaired bone strength and a propensity to fractures. Radiologically, osteopenia can be observed with the loss of ~50% of BMD. A more sensitive measure of bone mineral content is dual-energy X-ray absorptimetry (DEXA scanning). DEXA scans are commonly used to measure BMD in perimenopausal and menopausal women.

Disorders that involve the bone connective tissue matrix can also interfere with bone formation, turnover, and strength. Increased bone turnover with type 1 collagen breakdown can be assessed by detecting increased concentrations in the urine and/or serum of pyridinolines, deoxypyridinolines, N-telopeptides, and C-telopeptides [19]. C-telopeptides are measured in serum, N-telopeptides can be measured in serum or urine, and pyridinolines and deoxypyridinolines are usually measured in timed urine collections. It remains controversial whether serial measurements of bone markers improve the diagnosis or management of osteoporosis [20].

The diagnosis of osteoporosis is made clinically and radiologically, where the patient's BMD by DEXA scan displays a T-score of more than 2.5 standard deviations below the mean. In the absence of fractures, routine laboratory testing is normal (e.g., calcium, phosphate, alkaline phosphatase, and creatinine). Causes of secondary osteopenia such as primary hyperparathyroidism, secondary hyperparathyroidism of renal failure, and osteomalacia must be excluded clinically and through laboratory testing.

Hypocalcemia

Electrophysiologically, hypocalcemia lowers the threshold for depolarization of the sodium channel. This accounts for hyperreflexia and tetany in patients with significant degrees of hypocalcemia. The signs of hypocalcemia also include muscle pain or cramps, carpopedal spasm, paresthesias, seizures, and cardiac arrhythmias evidenced in a prolonged QT interval. The Chvostek sign is demonstrated by lightly tapping the face between the ear and temporomandibular joint eliciting an ipsilateral (e.g., the same side) facial contraction. The Trousseau sign of hypocalcemia is elicited by occluding the brachial artery with a blood pressure cuff, leading to spasm of the hand and forearm within 3 minutes. Chronic hypocalcemia can be associated with basal ganglia and corneal calcifications. There are numerous causes for hypocalcemia (Table 45.1).

Decreased parathyroid hormone action

With decreased PTH action, hypocalcemia ultimately results from a failure to absorb sufficient calcium from the gastrointestinal tract, failure to release calcium from bone, and calcium wasting in the urine. The most common cause of decreased PTH action is hypoparathyroidism (e.g., decreased PTH secretion by the parathyroid gland). In the absence of PTH's phosphaturic effect, PTH deficiency causes phosphate retention and hyperphosphatemia.

Hypoparathyroidism

The laboratory diagnosis of hypoparathyroidism is based on the recognition of a low PTH concentration in the setting of hypocalcemia. Hyperphosphatemia supports the diagnosis of hypoparathyroidism. Intact PTH and whole PTH assays are equally effective at identifying low PTH concentrations in plasma or serum. Whereas some research papers report nearly identical reference intervals for intact PTH and whole PTH assays, most research papers report much different reference intervals with the whole PTH reference interval being approximately 40%–50% lower than the intact PTH reference interval.

Hypoparathyroidism has many etiologies including autoimmune parathyroid destruction, parathyroidectomy, irradiation, hypoparathyroidism associated with sensorineural and renal dysplasia, hypoparathyroidism associated with retardation and a dysmorphic appearance [hypoparathyroidism-retardation dysmorphism (HRD)], hypoparathyroidism associated with various other genetic conditions (e.g., DiGeorge syndrome, ring chromosome 16 and ring chromosome 18), and idiopathic hypoparathyroidism. HRD results from a mutation in tubulin cofactor E (del52–55). There are a large number of genetic conditions associated with hypoparathyroidism (Table 45.2).

Chronic hypomagnesemia can impair both PTH release and tissue response to PTH. Familial hypoparathyroidism can display many forms of Mendelian inheritance, such as autosomal dominant (AD), autosomal recessive (AR), and X-linked varieties. AD hypoparathyroidism with normal to increased urinary calcium excretion can result from gain-of-function variants within the *CaSR* gene, leading to inappropriately low PTH secretion due to parathyroid hypersensitivity to ionized calcium concentrations. This is sometimes referred to as "familial hypercalciuric hypoparathyroidism (FHH) type 1." The variants that cause FHH type 1 include missense mutations of the extracellular domain, first extracellular loop, and the fifth and sixth transmembrane domains, or an in-frame 181-bp deletion of the CaSR cytoplasmic tail. FHH types 2 and 3 do not result from CaSR gain-of-function mutations. FHH type 2 is linked to a locus on chromosome 19p13, whereas FHH type 3 is linked to a locus on chromosome 19q13. PTH gene mutations have been described as causes of AD (a signal peptide mutation) and AR (an exon–intron boundary mutation) familial isolated hypoparathyroidism.

DiGeorge syndrome results from a malformation of the third and fourth pharyngeal pouches. In addition to hypoparathyroidism, abnormalities of the aortic arch, thymus, and facial structures (e.g., low-set ears, a beak-shaped mouth) may be observed. Thymic hypoplasia or aplasia leads to mild to severe T-cell immune deficiencies expressed in increased frequencies of viral and fungal infections. A microdeletion of the long arm of chromosome 22 (i.e., 22q11) is the cause of DiGeorge syndrome. If the deletion cannot be detected by karyotypic analysis, the deletion can be evaluated by fluorescence-labeled in situ hybridization. New technologies under study to detect deletions include comparative genomic hybridization [21].

Autoimmune hypoparathyroidism can exist as an isolated condition or can be part of autoimmune polyglandular syndrome type I (APS type I) [22]. Autoantibodies reactive with the parathyroid gland are rare at best [23]. Autoantibodies against the CaSR that stimulate or block the receptor are well described but likely do not identify parathyroid gland destruction [24]. This is discussed again later in this section. APS type I is the concurrence of hypoparathyroidism, mucocutaneous candidiasis, and Addison disease or adrenal autoantibodies. Two of these three conditions must be present to diagnose APS type I. This early-onset AR disorder is caused by mutations in the autoimmune regulator (*AIRE*) gene.

TABLE 45.2 Genetic, syndromic, or familial disorders with hypoparathyroidism.

Hypoparathyroidism associated with sensorineural and renal dysplasia
Hypoparathyroidism associated with retardation and dysmorphic appearance
Hypoparathyroidism associated with ring chromosome 16
Hypoparathyroidism associated with ring chromosome 18
DiGeorge syndrome
Autoimmune polyglandular syndrome type 1
Autosomal dominant hypoparathyroidism, type 1 (CaSR, gain-of-function)
Autosomal dominant hypoparathyroidism, type 2 (chromosome 19p13)
Autosomal dominant hypoparathyroidism, type 3 (chromosome 19q13)
Autosomal recessive hypoparathyroidism
X-linked hypoparathyroidism

CaSR, Calcium-sensing receptor.

The AIRE protein is a transcription factor. AIRE is a 545 amino acid protein with a molecular mass of approximately 58 kDa that is encoded on chromosome 21q22.3. AIRE elicits its function in a dimeric or tetrameric form. The normal action of AIRE relates to the expression of self-peptides in the thymus. At the present time, APS type I is the only known single-gene, autosomal recessive autoimmune disease in humans. Other associated diseases in APS type I patients include gonaditis (producing primary gonadal failure in women) and autoimmune hepatitis. Less commonly associated conditions are type 1 diabetes mellitus, autoimmune thyroid disease, vitiligo, alopecia, fat malabsorption, IgA deficiency, pernicious anemia, red cell aplasia, and progressive myopathy. APS type I has also been named "autoimmune polyendocrinopathy−candidiasis−ectodermal dystrophy syndrome," because associated disorders include nail dystrophy and dental enamel hypoplasia.

Hypocalcemia has been reported infrequently in another immunopolyglandular disorder: the immunodysregulation, polyendocrinopathy, and enteropathy, X-linked (IPEX) syndrome [25]. Disorders in this syndrome include early-onset type 1 diabetes mellitus, severe enteropathy with diarrhea, eczema, autoimmune hemolytic anemia, thrombocytopenia, and thyroiditis or hyperthyroidism. IPEX is usually lethal early in life. Of two IPEX patients reported with hypocalcemia, in one case, the PTH was normal, whereas in the other case, the PTH was increased, suggesting possible PTH resistance. Variants in the transcription factor protein forkhead box P3 (FOXP3) cause IPEX. FOXP3 (chromosome Xp11.23, encoding scurfin) is involved in the development of regulatory CD4 + CD25 + T cells. Such T regulatory cells (Tregs) can form in the thymus ("natural" Tregs) or they can be induced in the periphery ("induced" Tregs).

Currently, there are no readily available clinical tests for parathyroid gland autoantibodies, although target autoantigens have been demonstrated. In the 1960s, parathyroid autoantibodies were detected by indirect immunofluorescence using parathyroid gland as a substrate. However, these findings have been difficult to confirm in subsequent studies. Autoantibodies to NACHT (neuronal apoptosis inhibitory protein, MHC class II transcription activator, HET-E, and TP1) leucine-rich-repeat protein 5 were described in ∼50% of hypoparathyroid patients with APS type 1. NACHT refers to a 300−400 amino acid domain with predicted nucleoside triphosphatase activity [26]. Using Western blotting, autoantibodies to the CaSR protein have been described [27]. Independent of autoimmune parathyroiditis, autoantibodies against the CaSR have been identified that can block this receptor (resulting in hyperparathyroidism) or stimulate the receptor (causing hypoparathyroidism). Because of the current limitations in the availability of autoantibody testing for hypoparathyroidism, to make the diagnosis of autoimmune hypoparathyroidism, the clinician must rely on the presence of associated autoantibodies (e.g., adrenal autoantibodies or interferon-ω autoantibodies in APS I) or autoimmune conditions such as Addison disease to implicate autoimmunity as a cause of hypoparathyroidism [28].

Transient hypoparathyroidism may occur in the settings of prematurity, infants of diabetic mothers, neonatal illness, and children or adults with severe illness or stress such as recent surgery or sepsis. After recovery from the inciting illness, normal parathyroid function and normocalcemia usually returns spontaneously.

Pseudohypoparathyroidism

When hypocalcemia and hyperphosphatemia are present in a patient whose PTH concentrations are above the reference interval, PTH resistance must be considered. Resistance to PTH is termed pseudohypoparathyroidism (PHP). PHP is currently described as decreased activation of the G-stimulatory protein α subunit/cAMP/protein kinase A (Gsα/cAMP/PKA) signaling pathway by PTH (and other hormones) that bind to Gsα-coupled receptors [29].

Historically, PHP has been classified as type 1 or type 2. In type 1 PHP, the defect is in the generation of cAMP, which is a secondary messenger for the PTH/PTHrP receptor. Traditionally, this condition was identified by the inability of an exogenous PTH injection to elicit either increased cAMP concentrations in the urine or concurrent phosphaturia. In PHP type 1a (PHP1A), there is a maternal loss-of-function mutation in *GNAS*, the gene that encodes Gsα. The clinical phenotype of PHP1A includes resistance to PTH, TSH, and gonadotropins, brachydactyly (especially, shortening of the fourth and/or fifth metacarpals), heart-shaped facial features, progressively decreasing growth velocity causing adult short stature, early-onset obesity, neurocognitive impairment, and cerebral calcifications [30]. These features are described as "Albright hereditary osteodystrophy" (AHO).

Isolated resistance to PTH, absence of clinical features of AHO, and normal Gsα activity initially described PHP1B. For example, persons with PHP1B do not display adult short stature or resistance to gonadotropins. However, upon further study, some persons with PHP1B can share various features that overlap with PHPA1, such a brachydactyly, TSH resistance, and cerebral calcifications. Whether a third variety of PHP exists (PHP1C) is controversial and the 2018 Consensus Statement declined to address PHP1C because of a lack of firm data about this entity [30].

In the type 2 variety of PHP (PHP2), the defect is in the cell's response to cAMP. Following injected PTH, increased cAMP excretion in the absence of increased

urinary phosphate excretion was consistent with cAMP resistance. If increased cAMP and phosphate were both recognized after exogenous PTH injection, the possibility of a defective PTH molecule was considered although such inborn errors are very rare. The molecular cause or causes of PHP2 are unknown.

Physical examination and developmental features of AHO, in the absence of disordered calcium/phosphate metabolism, identify pseudopseudohypoparathyroidism (PPHP). Reduced Gsα activity in the absence of PTH resistance has been demonstrated in PPHP. In PPHP, the *GNAS* loss-of-function mutation is inherited from the father (whereas *GNAS* in PHPH1A loss-of-function mutation is inherited from the mother). Families with both PHP and PPHP have been reported but there are no molecular studies of these families [31].

Other defects in the Gsα/cAMP/PKA signaling pathway have been reported. Progressive osseous heteroplasia results from *GNAS* mutations that cause ossification of skin and muscle. However, tissue responses to PTH and TSH are normal. Another rare syndrome, acrodysostosis, is identified clinically by facial dysostosis, nasal hypoplasia, and severe brachydactyly together with TSH and PTH resistance. Acrodysostosis type 1 (ACRDYS1) results from mutations in the *PRKAR1A* (protein kinase cAMP-dependent type I regulatory subunit alpha; chr. 17q24.2) gene, causing decreased PKA activity [32]. Normally, cAMP binds to the regulatory subunits of PKA causing the inactive PKA (composed of two regulatory subunits and two catalytic subunits) to dissociate into two dimers: a dimer of regulatory subunits and a dimer of catalytic subunits. Three different catalytic subunits and four different regulatory subunits of PKA have been described. Active PKA (i.e., the "free" catalytic dimers) phosphorylates various proteins such as phosphodiesterases (e.g., *PDE3A* and *PDE4D*) and cAMP-responsive binding elements. Phosphodiesterases normally lead to degradation of cAMP. Acrodysostosis type 2 (ACRDYS2) results from gain-of-function mutations in *PDE4D* [33] that could result in reduced cAMP levels because of accelerated cAMP clearance. ACRDYS1 and ACRDYS2 are clinically indistinguishable. Because ACRDYS1 and ACRDYS2 share many physical characteristics with PHP such as brachydactyly, obesity, and short stature, ACRDYS1 and ACRDYS2 can be considered phenocopies of PHP.

Individuals who display bone sensitivity to PTH but renal resistance to PTH are also described as having pseudohypohyperparathyroidism. Because of renal resistance, systemic calcium concentrations decline and phosphate concentrations rise, eliciting increased PTH secretion. However, because of bone sensitivity to PTH, bone resorption occurs similar to hyperparathyroid states. There are no reports of molecular studies of this rare disorder [34].

Deficient vitamin D action

In the setting of deficient vitamin D action, there is inadequate absorption of calcium from the diet. Deficient vitamin D action can occur because of dietary vitamin D deficiency, vitamin D malabsorption, and deficient transformation of vitamin D to its most active form (i.e., 1,25-OH2D), VDR defects. Inadequate absorption of calcium causes hypocalcemia. The parathyroid gland's response to hypocalcemia (via the CaSR) is the release of PTH. This stimulates increased conversion of 25-OHD to 1,25-OH_2D, resulting in increased calcium absorption and bone resorption. These actions are usually sufficient to raise extracellular calcium concentrations back into the normal range. In the background of secondary hyperparathyroidism, however, there is increased phosphaturia, resulting in hypophosphatemia leading to inadequate bone matrix mineralization and rickets (in children) or osteomalacia (in adults). In rickets or osteomalacia, total calcium is usually in the lower reference interval.

Increased osteoblast activity, as a consequence of increased PTH concentrations, causes an increase in the bone isoenzyme concentration of alkaline phosphatase. BAP is best measured by immunoassay. Therefore the classic findings of rickets after PTH compensation has occurred (e.g., secondary hyperparathyroidism is present) are a low-normal calcium, low phosphate, increased PTH, and increased total alkaline phosphatase. Inadequate extracellular concentrations of calcium and/or phosphate interfere with normal bone formation in growing children, producing rickets. Rickets is characterized by metaphyseal widening, irregular epiphyseal surfaces, bowing of weight-bearing bones (e.g., the legs), osteopenia, increased prominence of the costochondral junctions (e.g., "rachitic" rosary), and an indentation of the lower rib cage due to bone softening and the pull of the diaphragm on the rib cage (Harrison's groove, a.k.a. Harrison's sulcus).

Vitamin D-dependent rickets result from either defective conversion of 25-OHD to 1,25-OH_2D because of an autosomal recessively inherited error in the renal tubular 1 alpha-hydroxylase enzyme or end-organ resistance to the effects of 1,25-OH_2D. Whereas vitamin D-deficient rickets can be ultimately cured by ensuring that the recommended daily allowance of vitamin D (400 IU/day) is taken in the diet, vitamin D-dependent rickets requires pharmacologic doses of vitamin D (e.g., 2000 IU/day) for correction of rickets or osteomalacia (to be discussed later). Such large doses will overcome the inborn metabolic block in the conversion of 25-OHD to 1,25-OH_2D or the receptor resistance to 1,25-OH_2D. The two forms of vitamin D-dependent rickets can be separated by measuring 1,25-OH_2D concentrations. With decreased conversion of 25-OHD to 1,25-OH_2D, the 1,25-OH_2D

concentration is inappropriately low. However, in the background of 1,25-OH_2D resistance, concentrations are above the reference interval.

Hypophosphatemic rickets arise from a variety of renal tubular disorders where there is excessive phosphaturia, producing hypophosphatemia and insufficient phosphate to ossify bone. Hypophosphatemic (vitamin D-resistant) rickets is most commonly inherited as an X-linked dominant disorder caused by mutations in *PHEX*, and less commonly as an AD disorder caused by *FGF23* mutations, an X-linked recessive disorder (XLR) caused by *CLCN5* mutations, or as an AR disorder caused by mutations in *GNAS*, dentin matrix acidic phosphoprotein (*DMP1*), or *SLC34A3*.

In X-linked dominant familial hypophosphatemic rickets (XHR), a variant in the cell-membrane Zn-metalloendopeptidase *PHEX* (phosphate regulating gene with homologies to endopeptidases on the X chromosome; 749 amino acids; molecular mass ~86.5 kDa; gene location: chromosome Xp22.11) is the etiology. *PHEX* mutations elevate FGF23, which produces hyperphosphaturia. XHR can also be referred to as XHR. Normal sources of PHEX are osteoblasts, muscle, lung, liver, and the gonads. PHEX structurally resembles the neutral endopeptidases endothelin-converting enzyme-1 and Kell antigen. A normal function of PHEX is to inhibit cleavage of matrix extracellular phosphoglycoprotein (MEPE). When MEPE is cleaved, an acidic serine aspartate-rich MEPE-associated motif (ASARM) is produced that inhibits NPT2, similar to the action of FGF23. With less inhibition of MEPE cleavage, higher ASARM levels are achieved, causing more phosphaturia. Because elevated FGF23 impairs the conversion of 25-OHD into 1,25-OH2D, XHR produces a state of vitamin D deficiency.

X-linked recessive hypophosphatemic rickets results from *CLCN5* loss-of-function mutations. *CLCN5* (chloride channel, voltage-sensitive 5; 746 amino acids, molecular mass ~83.1 kDa; chromosome Xp11.23) encodes a voltage-gated proximal renal tubular chloride channel that is expressed in intracellular endosomes. Other conditions caused by *CLCN5* loss-of-function mutations include X-linked nephrocalcinosis, nephrolithiasis, renal failure, and Dent disease (a type of chronic kidney disorder in males).

The autosomal dominant form of hypophosphatemic rickets is caused by *FGF23* mutations. FGF23 is 251 amino acids (molecular mass ~30.0 kDa) and is encoded on chromosome 12p13.32. The mutated FGF23 is resistant to degradation and FGF23 concentrations rise causing hyperphosphaturia and hypophosphatemia. Similar to XLR, there is impaired conversion of 25-OHD into 1,25-OH2D because of the elevated FGF23 concentrations. The specific enzymes degrading FGF23 are unknown at the present time.

In general, FGFs affect cell survival and cell division involving the development and differentiation of tissues, healing, and carcinogenesis. The FGF family includes more than 20 members. FGFs bind to FGF receptors (FGFR), including FGFR1, FGFR2, FGFR3, and FGFR4. FGF19, FGF21, and FGF23 (the endocrine FGFs) represent one of the seven subfamilies of FGFs based on amino acid composition, sequence similarity, and implied evolutionary similarities. The hypophosphatemic action of FGF23 is mediated by its binding to FGFR1 with interaction involving the protein Klotho (to be discussed later). Of the AR forms of hypophosphatemic rickets (ARHR), *GNAS* gain-of-function mutations increase the effects of FGF23. In addition to ARHR, gain-of-function GNAS mutations can cause fibrous dysplasia of bone and McCune-Albright syndrome.

DMP1 loss-of-function mutations increase FGF23 concentrations [35]. DMP1 is a noncollagenous tooth and bone protein and belongs to a class of proteins termed small integrin-binding ligand, N-linked glycoproteins that include osteopontin and bone sialoprotein. DMP1 is 513 amino acids (molecular mass ~55.8 kDa) and is encoded on chromosome 4q22.1. *SLC34A3* [solute carrier family 34 (type II sodium/phosphate cotransporter), member 3; a.k.a. sodium-dependent phosphate cotransporter type IIC] loss-of-function mutations impair renal tubular phosphate reabsorption, causing hyperphosphaturia. SLC34A3 is 599 amino acids (molecular mass ~63.6 kDa) encoded on chromosome 9q34.3. *SLC34A3* mutations also cause hypercalciuria.

Deficient extracellular phosphate concentrations cause hypophosphatemic rickets. This disorder cannot be healed through the administration of vitamin D alone. Because of excessive phosphaturia, patients with this disorder must take supplemental oral phosphate up to six times per day. Unfortunately, such medications are of low palatability. Nevertheless, if sufficient oral phosphate is ingested, along with a modest dose of vitamin D to support phosphate absorption from the gastrointestinal tract, rickets can be substantially treated when plasma phosphate concentrations exceed ~3 mg/dL between the doses of oral phosphate.

Any renal tubular disorder that results in hyperphosphaturia can also produce rickets. One such example is Fanconi syndrome. In Fanconi syndrome affecting the renal tubules, in addition to phosphate loss, electrolytes, glucose, amino acids, and HCO_3^- are also lost in the urine. Urinary glucose loss in the absence of hyperglycemia is termed "renal glycosuria," which results from *SGLT2* mutations [SLC5A2; solute carrier family 5 (sodium/glucose cotransporter), member 2 encoded on chromosome 16p11.2]. HCO_3^- loss produces renal tubular acidosis, in which there is a normal anion gap and hyperchloremia.

Rickets can develop in the cases of obstructive biliary tract disease for several reasons. With hepatocyte dysfunction, there may be decreased conversion of vitamin D

to 25-OHD. However, the major reason for vitamin D deficiency in biliary tract obstruction (with reduced bile delivery to the intestine) is fat malabsorption that leads to malabsorption of fat-soluble vitamins. Persons with biliary tract disease may also suffer from deficiencies in vitamin A, E, and K. Although controversial, drugs that stimulate the P450 enzyme system appear to be associated with vitamin D deficiency, possibly by increasing the metabolism of vitamin D [36]. Classic drugs to cause "toxic hepatic hydroxylation" include phenytoin and phenobarbital.

Vitamin D deficiency in adults may lead to osteomalacia, which can cause osteopenia, bone pain, bone tenderness, proximal muscle weakness, bone deformations, and fractures. However, compared with children with rickets, osteomalacia causes less severe bony deformities. While there is tremendous interest in the nonskeletal effects of vitamin D, there is no firm evidence that vitamin D, as a treatment, is useful for any disorders other than states of vitamin D deficiency affecting the skeleton [37]. Until recently, dietary deficiency of vitamin D was thought to be very uncommon in industrialized countries. However, a rising frequency of vitamin D deficiency is being observed. For example, in the absence of vitamin D supplementation, exclusively breast-fed infants are at risk of nutritional rickets. Low concentrations of 25-OHD are detected in conditions of dietary vitamin D deficiency. Adjusting the reference interval for 25-OHD according to the PTH level may be necessary.

When selecting an assay to measure 25-OHD, the assay should measure total 25-OHD (e.g., 25-OHD2 plus 25-OHD3) or the assay can measure each analyte uniquely. However, there are no data to suggest that separate monitoring of 25-OHD2 and 25-OHD3 is helpful in the diagnosis or follow-up of vitamin D deficiency. Analytic problems with 25-OHD measurements persist. Bias exists between assays, in part, because of a lack of standardization [38]. Various laboratories can report twofold differences in 25-OHD concentrations for the same sample. A 2013 paper from the National Institute of Standards and Technology [39] recommended using Standard Reference Material 972a and Standard Reference Material 2972 for vitamin D measurements. These materials have certified concentration values for vitamin D metabolites. Some assays are insensitive and are poorly able to detect 20% changes in 25-OHD concentrations in serially measured samples. Assays may not be equipotent in measuring 25-OHD_2 versus 25-OHD_3. Many laboratories have turned to mass spectrometry to measure 25-OHD_2 and 25-OHD_3.

What constitutes a sufficient 25-OHD level remains controversial [40–43]. Whereas reference intervals for 25-OHD are reported in the teens or lower (e.g., 13–67 ng/mL for children and 9–54 ng/mL in adults), maximal absorption of dietary calcium is achieved with 25-OHD levels near 30 ng/mL. This suggests that a healthy 25-OHD level should be at or above 30 ng/mL. Some aggressive clinicians are routinely prescribing up to 2000 IU of vitamin D per day to achieve higher 25-OHD levels in the hope that this will lead to improved bone strength, resistance to fractures, and less osteoporosis. On the other hand, if hypercalcemia were to develop as a consequence of high-dose vitamin D therapy, significant morbidity could ensue.

The Institute of Medicine [44] concluded in 2011 that the minimum 25-OHD concentration sufficient to meet the needs of 97.5% of the population was 20 ng/mL (50 nmol/L). Clinical practice guidelines from the Endocrine Society describe 25-OHD concentrations of <20 ng/mL as deficient, whereas concentrations between 21 and 29 ng/mL are insufficient [45]. Mayo Clinical Laboratories defines severe vitamin D deficiency as 25-OHD concentrations as <10 ng/mL and mild to moderate vitamin D deficiency as 10–19 ng/mL [46]. Quest Laboratories provides a 25-OHD reference interval of 30–100 ng/mL for chromatography/mass spectrometry [47]. LabCorp uses the same reference interval [48]. Finally, ARUP Laboratory describes vitamin D deficiency as a 25-OHD concentration of <20 ng/dL and insufficiency is 20–29 ng/mL [49].

The condition "tumor-induced" osteomalacia (a.k.a. oncogenic osteomalacia) results from tumors that produce FGF23 that induce hypophosphatemia because of hyperphosphaturia. Causes of this condition include hemangiopericytoma, phosphaturic mesenchymal tumor of the mixed connective tissue type, osteoblastoma-like tumors, and fibroma-like tumors (ossifying and nonossifying). In such cases, the identification of an elevated FGF23 concentration is diagnostically helpful.

Other causes of hypocalcemia

In order for vitamin D to serve its purpose, there must be sufficient dietary calcium for absorption. Thus a rare cause of hypocalcemia is inadequate calcium intake. Another uncommon cause of hypocalcemia is hemorrhagic and edematous pancreatitis. In cases of pancreatitis, lipase is released extracellularly due to acinar cell necrosis. Increased lipase activity can lead to increased breakdown of fats to free fatty acids and glycerol. Increased concentrations of free fatty acids can bind plasma calcium, reducing circulating total calcium concentrations. This extraction of calcium from the bloodstream by the tissues (e.g., saponification) causes hypocalcemia. Another rare cause of hypocalcemia is observed following the treatment of hyperparathyroidism, hyperthyroidism, or hematologic malignancies, where healing bone consumes increased amounts of calcium for

new bone formation. This can be referred to as "hungry bone syndrome."

Certain drugs can cause hypocalcemia. Bisphosphonates used in the treatment of osteoporosis reduce bone turnover by inhibiting osteoclasts. With a decline in calcium concentrations, PTH release is triggered, subsequently increasing the conversion of 25-OHD into 1,25-OH_2D, increasing urinary calcium reabsorption, and increasing urinary phosphate excretion. The newest bisphosphonates are taken monthly; once-yearly intravenous (IV) bisphosphonates were approved in 2007. An uncommon but serious complication of bisphosphonates is osteonecrosis of the jaw. Bisphosphates can also cause adynamic bone disease.

Adynamic bone disease is a type of renal osteodystrophy with decreased numbers of osteoblasts and osteoclasts, no increased osteoid, and very low bone turnover [50].

During medical procedures such as apheresis (whether for collection or therapy), calcium concentrations can decrease transiently [51]. For instance, during a plateletpheresis procedure, there may be a 6%−25% reduction in ionized calcium. Dilution, redistribution, metabolism, and excretion of infused citrate used as the anticoagulant during the procedure are important factors protecting against immediate extreme levels of hypocalcemia. Supplemental calcium may also be given during these procedures to mitigate the physiologic effects of hypocalcemia. PTH rises quickly in the first 5−15 minutes then more slowly during the next 30−90 minutes of these procedures. Serum and urine citrate levels ordinarily return to baseline within 4 hours after infusion ceases.

In the treatment of secondary hyperparathyroidism, a family of drugs have been developed that bind to the CaSR to reduce PTH concentrations. These CaSR agonists suppress PTH secretion (which could uncommonly induce hypocalcemia). The first oral drug in this family was cinacalcet hydrochloride (Sensipar in the United States, Australia, New Zealand, and Canada and Mimpara in Europe). By reducing PTH secretion, cinacalcet hydrochloride lowers calcium, phosphate, and the calcium−phosphate product (also reducing ectopic calcification).

Clinical approach to hypocalcemia

If a patient's total plasma calcium is decreased, plasma albumin or, preferably, ionized calcium should be measured to confirm that the hypocalcemia is not due to hypoproteinemia (e.g., hypoalbuminemia). Next, phosphate, magnesium, and PTH should be measured and renal function assessed (e.g., creatinine, BUN, and urinalysis), because renal dysfunction can have a profound effect on calcium and bone metabolism.

Clinically, the causes of hypocalcemia can initially be divided into those conditions associated with increased PTH and those conditions with low PTH (Fig. 45.7). Hypocalcemia and hyperphosphatemia are most consistent with functional hypoparathyroidism. If the PTH is indeed low, hypoparathyroidism is diagnosed. Chronic hypomagnesemia must also be excluded. Hypomagnesemia is usually associated with normal or, in 20% of cases, low phosphate concentrations, although chronic hypomagnesemia does decrease both PTH release and PTH response. If PTH is paradoxically normal or high in the face of hypocalcemia and hyperphosphatemia, PTH resistance is identified and PHP and its varieties should be considered.

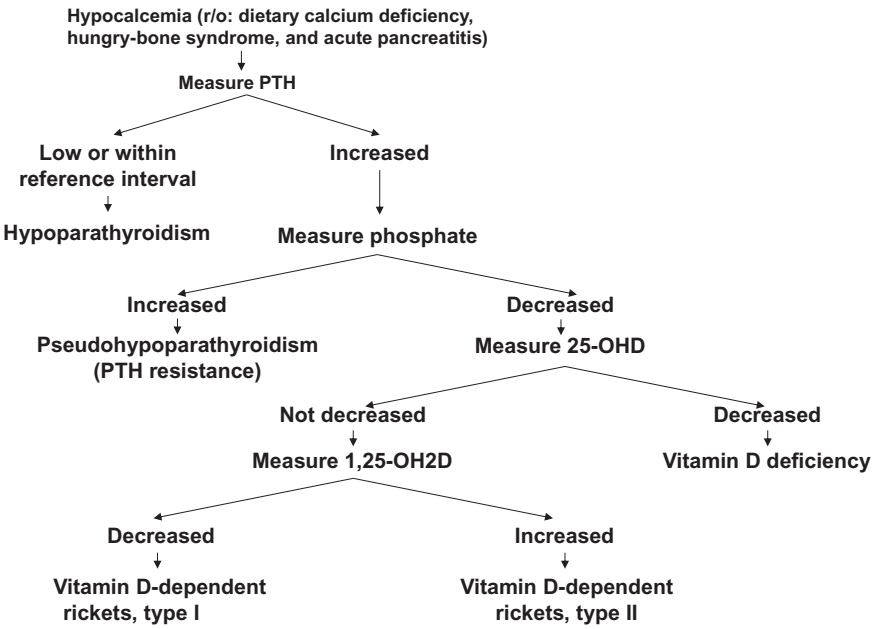

FIGURE 45.7 Diagrammed is an approach to the evaluation of hypocalcemia. See the text for details.

Low or low normal calcium, hypophosphatemia, and an increased PTH level are consistent with rickets in children or osteomalacia in adults. A depressed 25-OHD level and a history of poor vitamin D intake or lack of exposure to sunlight establish the diagnosis of vitamin D deficiency. Cure of the rickets or osteomalacia with 400 IU of vitamin D daily supports the diagnosis to vitamin D deficiency. However, physicians will usually give higher doses of vitamin D or vitamin D analogs for a short period of time to enhance initial bone healing in vitamin D deficiency. When routine doses of vitamin D do not heal a child's rickets, vitamin D-dependent rickets should be considered. Radiologic healing with ~2000 IU of vitamin D daily supports the diagnosis of vitamin D-dependent rickets.

Failure of vitamin D alone (despite increased doses) to heal rickets is consistent with vitamin D-resistant rickets. Because this is most commonly an X-linked dominant disorder, evidence of mild rickets/osteomalacia in the child's mother strongly supports the diagnosis of vitamin D-resistant rickets. The treating physician must always evaluate the rachitic child for liver disease and examine the child's medication history. Pancreatitis sufficient to produce hypocalcemia should be blatantly evident and not cause any diagnostic dilemmas. Because of the increasing recognition of vitamin D deficiency in the general population, requests for 25-OHD measurements continue to increase. This increasing prevalence of vitamin D deficiency is likely related to less time spent outdoors, increased coverage of the skin, and increased use of sunscreen to prevent skin cancers (such as melanoma).

Hypercalcemia

Modest hypercalcemia (e.g., total calcium between ~10.5 and ~11.9 mg/dL) may be asymptomatic. Symptomatic hypercalcemia may cause vague complaints such as fatigue, malaise, weakness, depression, apathy, and an inability to concentrate. Other disturbances can include bone pain and gastrointestinal tract disturbances.

The kidney is adversely affected by hypercalcemia through the formation of nephrolithiasis (i.e., kidney stones) with consequent renal colic (i.e., the pain experienced when a stone is passed through the ureter or urethra), mild nephrogenic diabetes insipidus, or renal failure from nephrocalcinosis (i.e., kidney calcification). Other possible findings in hypercalcemia encompass ectopic calcification of the cornea, conjunctiva and blood vessels, cystic bone lesions, pathologic fractures, and osteopenia from bone breakdown. Patients with hyperparathyroidism classically present with "moans" (e.g., CNS complaints), "bones" (e.g., bone pain), "groans" (e.g., gastrointestinal tract disturbances), and "stones" (e.g., kidney stones). Subperiosteal bone resorption noted in the fingers and around the teeth is a classic finding in hyperparathyroidism. There are many potential causes of hypercalcemia (Table 45.3) [52].

TABLE 45.3 Causes of hypercalcemia.

6. Immobilization and other miscellaneous causes

Primary hyperparathyroidism

In the setting of hypercalcemia with a normally functioning parathyroid gland, PTH should be suppressed below the reference interval. On the other hand, hypercalcemia accompanied by a low normal to depressed phosphate concentration and an inappropriately normal to increased PTH is consistent with primary hyperparathyroidism. Elevations in PTH can elevate 1,25-OH_2D concentrations that will also contribute to hypercalcemia. Typically, in hyperparathyroidism, the filtered calcium load is so great that despite increased PTH and its effect on increasing urinary calcium reabsorption, hypercalciuria results.

The differential diagnosis of hyperparathyroidism includes parathyroid adenoma (~80% of cases of primary hyperparathyroidism), parathyroid hyperplasia (15%–20% of cases of primary hyperparathyroidism), and parathyroid carcinoma (<5% of cases of primary hyperparathyroidism). Some sources report that parathyroid carcinoma causes <1% of all cases of primary hyperparathyroidism. In parathyroid adenomas, there is a capsule, possible compression of adjacent tissue and a reduction in the fat content of the adenoma. Adenomas usually occur in a single gland. In parathyroid hyperplasia, all four glands are usually enlarged with a possible reduction in fat cell content of the hyperplastic tissue. The diagnosis is assisted by weighing the four surgically removed parathyroids and finding that each hyperplastic parathyroid gland is increased in weight (normal parathyroid glands weigh <40 mg).

Histologically, the diagnosis of parathyroid carcinoma is not straightforward. Invasion of the capsule supports the diagnosis of carcinoma (versus adenoma), and evidence of metastases is pathognomonic of carcinoma. Besides local invasion, metastatic sites encompass bone, lung, liver, and the adrenal gland. Hypercalcemia in parathyroid carcinoma can be more severe than in other forms of primary hyperparathyroidism with calcium

concentrations possibly exceeding 14−16 mg/dL; PTH also tends to be greatly elevated. In summary, a palpable, firm neck mass in the setting of hypercalcemia is suggestive of a parathyroid carcinoma. If hyperparathyroidism is present and not otherwise explained in a person with a persistently normal calcium concentration, the term "normocalcemic primary hyperparathyroidism" is applied [53,54]. Over time, this condition evolves to display overt hypercalcemia.

Cases of primary hyperparathyroidism are treated surgically. Indications for surgical parathyroidectomy include: (1) serum calcium >12 mg/dL; (2) marked hypercalciuria (e.g., >400 mg/day in adults); (3) any overt clinical manifestation of hyperparathyroidism (e.g., nephrolithiasis); (4) age <50 years; (5) reduced glomerular filtration rate (GFR) not otherwise explained; and (6) cortical bone density radius z-score less than—2 SD below the mean. Indications for surgery in asymptomatic patients with primary hyperparathyroidism include: (1) a markedly increased serum calcium; (2) a history of an episode of life-threatening hypercalcemia; (3) reduced creatinine clearance, presence of kidney stone(s) detected by abdominal radiograph; (4) markedly increased 24-hour urinary calcium excretion; or (5) a substantially reduced bone mass. If any one of these criteria are met (and likely confirmed), parathyroidectomy is indicated in asymptomatic primary hyperparathyroidism [55].

Regarding surgical management of parathyroid adenomas, with surgical removal of the adenomatous parathyroid gland, the three remaining parathyroids can be left in place. Using nuclear medicine sestamibi scans, the adenomatous gland can often be identified preoperatively. If this is the case, in place of a wide-neck incision required for a neck dissection, the surgeon can make a small incision on the side of the neck where the adenoma is anticipated and selectively remove the single adenomatous gland. New technologies for localization of adenomatous parathyroid glands when a sestamibi scan (99mTc-sestamibi parathyroid SPECT) is negative include ^{11}C-methionine positron-emission tomography (PET) with sensitivities and specificities of 86% [56]. ^{18}F-fluorocholine PET/CT exhibits correct rates of 90% or better for the identification of hyperfunctioning parathyroid glands [57].

By measuring PTH intraoperatively and observing a minimum 50% decline in PTH concentrations, successful removal of the parathyroid adenoma is confirmed [58−60]. Such procedures can be performed even in outpatient settings. The baseline PTH should be measured after the induction of anesthesia but before any manipulation of the gland externally or surgically. Squeezing or stimulating a parathyroid gland can result in the rapid release of PTH [61]. Ten minutes after removal of the suspected adenoma, PTH should be reassessed, because PTH has a short half-life of <5 minutes. Intraoperative PTH can be measured in the surgical suite or in a central laboratory if rapid sample transport is coupled with rapid immunochemical analysis. Another proposed approach to identifying a single adenomatous gland (without frozen section diagnosis or intraoperative PTH testing) is to administer sestamibi preoperatively (e.g., within 2.25 hours of surgical removal of tissue) and determine the radioactivity of the surgically removed tissue [59]. This procedure requires validation by other surgical centers.

With parathyroid hyperplasia, usually all of the parathyroids are surgically removed with one-half of one parathyroid gland implanted in the forearm for easy surgical removal in the future should hyperparathyroidism recur [62]. Because the parathyroid glands can exist in ectopic locations, localization by venography with PTH sampling may be necessary following a failed surgical attempt at complete parathyroidectomy. Theoretically, there is no reason why PTH assays during such radiologic procedures cannot be performed in real time using intraoperative technologies.

Lithium can produce hyperparathyroidism in 10%−15% of patients so treated for bipolar disorder. Chronic lithium therapy may raise the set point in the parathyroid gland for negative feedback, thereby eliciting hypercalcemia. This appears to also occur in the kidney tubules as hypocalciuria may be present [63]. Hyperparathyroidism is not uncommon in patients with acromegaly or Zollinger−Ellison syndrome. Hypercalcemia and increased PTH may occur in thiazide-treated patients. Many such patients eventually exhibit primary hyperparathyroidism. However, thiazides must be withdrawn for 2−3 months to determine if hypercalcemia abates, thus attributing increased calcium concentrations to the drug class.

Familial forms of hyperparathyroidism

An asymptomatic, AD familial form of mild, chronic hypercalcemia results from a loss-of-function mutation in the *CaSR* that is expressed on the parathyroid chief cells and on renal tubular cells. Because the parathyroid glands are relatively insensitive to negative feedback from calcium in this case, mild hypersecretion of PTH occurs relative to the patient's calcium. PTH may be increased, although in most cases it is within normal reference limits; phosphate and 1,25-OH_2D concentrations are also normal. Serum calcium usually does not exceed 12 mg/dL. In contrast to other forms of hyperparathyroidism, urinary calcium is not increased, because the renal tubules, which normally express a CaSR, perceive a state of calcium deficiency, leading to high levels of urinary calcium reabsorption and actual hypocalciuria. Therefore this disorder is termed FHH or benign familial hypercalcemia (FHH

type 1; FHH1). Additional causes of the FHH phenotype include inactivating mutations of the G-protein subunit α11 (*GNA11* gene; chr.19p13.3; FHH2) and inactivating mutations of the adaptor-related protein complex 2, sigma 1 subunit (*AP2S1* gene; chr. 19q13.32; FHH3). GNA11 is involved in CaSR signaling as the CaSR employs G-protein-cAMP-adenyl cyclase signaling. AP2S1 plays a role in clathrin-mediated endocytosis of the CaSR, which effects signaling [64]. Mutations in AP2S1 reduce intracellular cycling of CaSR, increasing the expression of the CaSR [65].

Individuals heterozygous for any type of FHH do not display bone pain or gastrointestinal or psychiatric complaints, nor do these individuals develop kidney stones or nephrocalcinosis. However, the clinical differentiation from mild primary hyperparathyroidism may be difficult. In infants homozygous for FHH, severe neonatal hypercalcemia results, which can be life-threatening. Emergency parathyroidectomy may be required to control hypercalcemia in such infants.

Hyperparathyroidism can occur in patients with multiple endocrine neoplasias (MEN). There are two major forms of MEN: MEN1 and MEN2. Furthermore, there are two subtypes of MEN2: MEN2A and MEN2B (note: some authors refer to MEN2A and "MEN2" while referring to MEN2B as "MEN3." This terminology is not preferred because MEN2A and MEN2B result from mutations in the same gene). MEN is inherited as an AD trait, indicating that MEN1 and MEN2 result from germline variants. Mutations in the *MEN1* gene [encoding multiple endocrine neoplasia I gene (MENIN) on chromosome 11q13.1] cause MEN1, and mutations in the *RET* proto-oncogene (on chromosome 10q11.21) cause MEN2. In approximately 5%−10% of persons with the clinical phenotype of MEN1, *MEN1* is not mutated. In some persons that were *MEN1*-negative, heterozygous mutations in the cyclin-dependent kinase inhibitor 1B (*CDNK1B* gene, on chromosome 12p13.1) have been described, resulting in the designation MEN4 [66].

MEN1 is clinically characterized by tumors of the anterior pituitary gland, parathyroid glands, and the pancreatic islets (the "3 Ps"). The parathyroids usually are hyperplastic in MEN1. The most common anterior pituitary tumor is a prolactinoma. Next most common are nonfunctioning pituitary adenomas followed by ACTH-secreting anterior pituitary tumors causing Cushing disease. Less common anterior pituitary tumors secrete growth hormone or TSH.

The most common pancreatic islet cell tumor is a gastrinoma producing a Zollinger−Ellison clinical phenotype. Gastrin serves as a tumor marker for gastrinomas. Next most common are insulinomas (hypoglycemia is discussed in Chapter 33, Evaluation of exocrine pancreatic function). Rare islet cell tumors include somatostatinomas, glucagonomas, and VIPomas. Somatostatinomas, glucagonomas, and VIPomas can produce a secretory, watery, cholera-like diarrhea. Glucagonomas can also produce mild hyperglycemia and a unique skin rash termed "migratory necrolytic epidermolysis."

MEN1 develops when, as part of tumorigenesis, a cell line becomes monosomic for at least a portion of chromosome 11q13.1 containing the *MEN1* gene. The result is that only a defective copy of the tumor-suppressor gene *MEN1* persists. Before loss of heterozygosity, the chromosome 11q13.1 that carried the functional *MEN1* gene prevented cancers. With loss of the normal *MEN1* gene, there is insufficient tumor-suppressor gene activity to prevent cancer. MENIN is a 610−amino-acid, 67-kDa protein. It is expressed throughout the body and is predominantly identified in the nucleus. MENIN has two nuclear localization sequence motifs and interacts with various transcription factors, DNA repair proteins, DNA processing factors, and cytoskeletal proteins including FANCD2, GFAP, junD, NF-kB, NM23beta, nonmuscle myosin heavy chain IIA, PEM, RPA2, and SMAD3. Loss of function of MENIN changes the downstream action of its junD partner from growth suppression to growth promotion. This may explain the neoplastic role of MENIN mutations.

MEN2 manifests as medullary thyroid carcinoma (MTC) and pheochromocytoma in a subset of cases. MTC occurs in ~100% of MEN2 cases, and pheochromocytoma occurs in ~50% of MEN2 cases. MEN2B is distinguished from MEN2A by the presence of neuromas of the tongue, oral mucosa, lips, and eyelids; ganglioneuromatosis of the salivary glands, gall bladder, pancreas, and alimentary canal; evidence of corneal nerve thickening on slit lamp examination; and a marfanoid habitus with skeletal deformities in MEN2B patients. Hyperparathyroidism in MEN2A results from adenomas or hyperplasia. Hyperparathyroidism is possible but uncommon in patients with MEN2B.

MEN2 results from inheritance of a mutated *RET* proto-oncogene. The normal function of the RET proto-oncogene involves signal transduction for glial-derived neurotropic factor (GDNF). The protein that results from the transcription of the *RET* proto-oncogene is a member of the tyrosine-kinase receptor family. There are extracellular domains, a transmembrane domain, and intracellular domains. Normally, GDNF initially binds to a specific cell-surface receptor (GDNF receptor alpha) that then cross-links two copies of the RET proto-oncogene protein (Fig. 45.8). Disulfide bonds form between cysteines present in the paramembrane extracellular domains (encoded by exons 10 and 11) of the two RET proto-oncogene receptors. With cross-linking of the two RET proto-oncogene proteins, tyrosine kinase activity develops within the two intracellular domains, allowing for downstream autophosphorylation and phosphorylation.

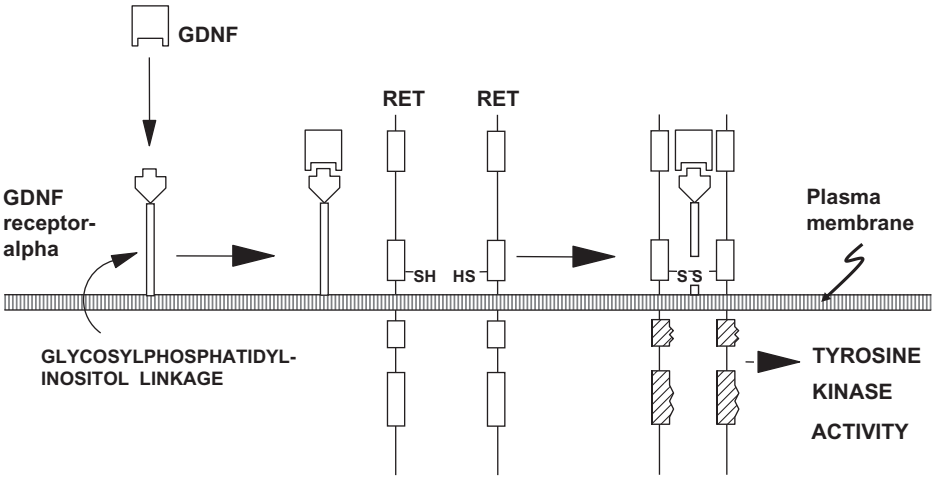

FIGURE 45.8 The normal function of the *RET* proto-oncogene is to interact with glial cell-derived neurotrophic factor receptor-alpha after it has bound GDNF. Two *RET* proto-oncogene proteins cross-link upon binding the GDNF-GDNF receptor alpha complex to initiate signal transduction via the development of tyrosine kinase activity in *RET*.

The locations of mutations in the RET proto-oncogene differ between the two forms of MEN2. In MEN2A, the mutations are located in the extracellular, paramembrane, cysteine-rich domains that foster spontaneous dimerization in the absence of ligand binding. In MEN2B, there is a gain-of-function mutation in either of the two cytoplasmic tyrosine kinase domains (Fig. 45.9). Activation then occurs in the absence of RET proto-oncogene protein dimerization. Tyrosine kinase domain 1 is encoded by exons 13, 14, and 15, whereas tyrosine kinase domain 2 is encoded by exon 16. MEN2B is caused by mutations in exon 16 more commonly than in exons 13, 14, or 15. Of interest, there is one report of the coexistence of MEN2 and APS type 2 [67]. However, the patient described did not have adrenal disease, suggesting that the patient's APS was not APS type 2.

If there is a family history of MEN2 and the proband (a person serving as the starting point for the genetic study of a family) has been studied on a molecular basis, relatives can be specifically studied for the same mutation. However, if the proband has not been studied on a molecular basis, then relatives will require study of their entire RET proto-oncogene for mutations in the exons known to harbor mutations causative of MEN2. Once one mutation is recognized, other first-degree relatives can be studied selectively for this mutation. Specific MEN2 mutations can help guide therapy (e.g., in the timing of elective thyroidectomy in MEN2) [68,69].

Regarding MEN4, *CDNK1B* encodes the 196 amino-acid CDK1 p27Kip1 that is activated by H3K4 methylation [70]. Failure of normal CDK1 p27Kip1f function appears to allow activation of cyclin E-CDK2 or cyclin D-CDK4 complexes, permitting cell cycle progression at the G1 cell-cycle phase (Fig. 45.10). Progression to S phase involves the *RB1* (retinoblastoma 1) gene [encoding the RB Transcriptional Corepressor 1 (chr. 13q14.2)] modifying the gene from a hypophosphorylated state to a hyperphosphorylated state. A novel role for CDKN1B as a tumor susceptibility/suppressor gene is supported by the detection of CDKN1B mutations (either germ line or somatic) in some patients with breast cancer, nonfamilial primary hyperparathyroidism, lymphoma, and small intestinal neuroendocrine tumors.

Still another familial cancer syndrome involving the parathyroid glands is the hyperparathyroidism-jaw tumor syndrome (HPT-JT) [71]. Hyperparathyroidism most often results from a parathyroid adenoma but can result from a parathyroid carcinoma. Other tumors can occur (e.g., fibroosseous tumors of the jaw or maxilla) but uterine tumors are particularly common in women with HPT-JT. This AD condition results from HRPT2 [hyperparathyroidism 2 homolog (human); chromosome 1q24-q32] loss-of-function mutations. HRPT2 has also been named CDC73 (cell division cycle 73; a.k.a. parafibromin). CDC73 normally functions as a tumor suppressor gene. HPT-JT may occur sporadically where such CDC73 mutations are believed to occur somatically. HPT-JT should be considered in cases of early-onset hyperparathyroidism to inform the choice of surgical management (e.g., removal of all parathyroids in HPT-JT) [72]. Familial isolated hyperparathyroidism may represent incomplete expression of FHH, MEN1, and HPT-JT, while some patients have an activating glial cells missing homolog 2 (*GCM2*; chr. 6p24.2) mutation. GCM2 is involved in parathyroid gland development. In summary, there are now at least eight familial syndromes potentially causing hyperparathyroidism (Table 45.4) [73].

Another rare form of primary hyperparathyroidism is autoimmune hypercalcemia. This condition results from the production of a CaSR autoantibody that blocks the

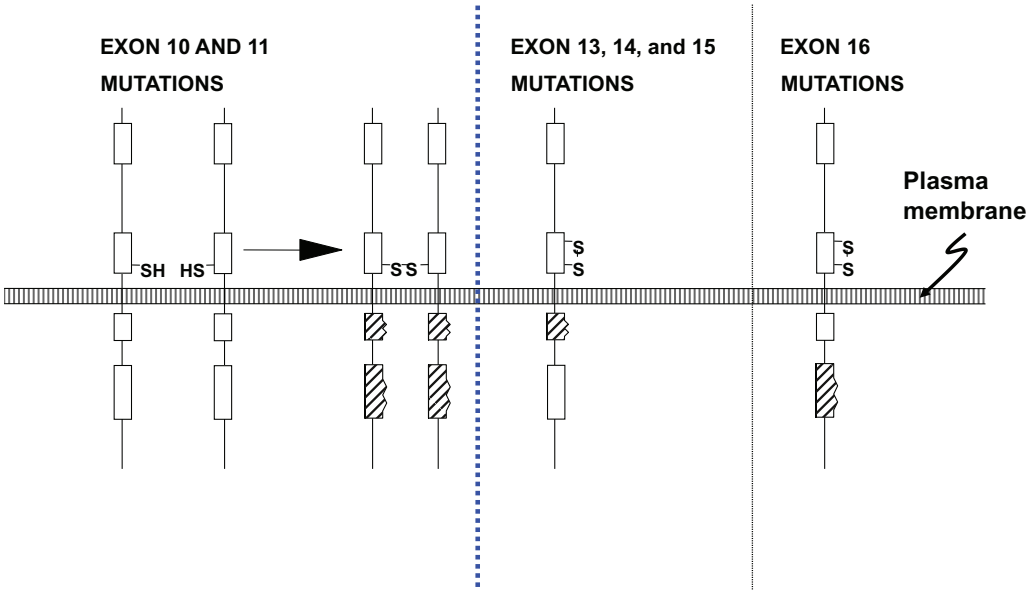

FIGURE 45.9 MEN2A is caused by mutations in exons 10 or 11 that allow spontaneous homodimerization of RET in the absence of the GDNF-GDNF receptor alpha complex. In MEN2B, mutations in exons 13, 14, or 15 produce gain-of-function mutations in the either of the tyrosine kinase domains.

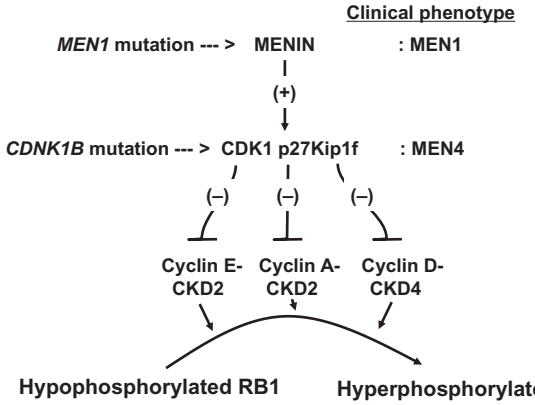

FIGURE 45.10 MENIN normally stimulates CDK1 p27Kip1f. In turn, CDK1 p27Kip1f suppresses cyclin/chronic kidney disease (CKD) complexes. Cyclin/CKD complexes advance cells through the G1 stage by phosphorylating RB1 (Retinoblastoma transcriptional corepressor 1; chr.13q14.2). Mutations in *MEN1* cause MEN1. Mutations in *CDNK1B* that encode CDK1 p27Kip1f cause MEN4.

receptor's perception of ionized calcium, producing increased and pathologic PTH secretion. Similar to FHH and lithium-induced hyperparathyroidism, hypocalciuria can be present.

Secondary hyperparathyroidism

Although not usually a cause of hypercalcemia, secondary hyperparathyroidism is included because of its adverse effect on bone biology. Secondary hyperparathyroidism is a normal response to hypocalcemia. Deficient vitamin D action was also described previously as a cause of secondary hyperparathyroidism.

Secondary hyperparathyroidism is a major consequence of chronic renal failure. Several factors contribute to secondary hyperparathyroidism in chronic renal failure. First, the kidneys' failure to excrete phosphate produces hyperphosphatemia. Hyperphosphatemia then lowers calcium concentrations with the development of ectopic calcification. Hyperphosphatemia also inhibits renal 1 alpha-hydroxylase activity, impairing the conversion of 25-OHD to 1,25-OH_2D in the renal tubule. Declining 1,25-OH_2D concentrations impair calcium absorption from the diet. In addition, renal tubular disease or destruction can also lead to a deficiency of 1,25-OH_2D. With a decline in calcium concentrations, PTH is secreted (i.e., secondary hyperparathyroidism). The calcium consequently rises back into the lower reference interval but at the expense of bone destruction from bone resorption. Such renal bone disease is histologically referred to as "osteitis fibrosa cystica." Secondary hyperparathyroidism of renal failure is treated by administering vitamin D (usually the active form of vitamin D: 1,25-OH_2D) and oral phosphate binders that inhibit phosphate absorption from the gastrointestinal tract. Routine monitoring is undertaken through measurements of calcium, phosphate, alkaline phosphatase, and PTH.

As noted above, in general, true-intact PTH assays are not superior to intact PTH assays [74,75]. In the cases of patients with secondary hyperparathyroidism undergoing parathyroidectomy for a pathologic excess of PTH, there are data suggesting that PTH measured intraoperatively

TABLE 45.4 Familial causes of hyperparathyroidism.

with the whole (1−84) PTH assays will decline more rapidly as than the PTH that is measured with the traditional intact (7−84) PTH assays [76]. The degree to which this proves valuable in clinical practice is unproven.

Tertiary hyperparathyroidism

In patients with secondary hyperparathyroidism of renal failure, renal transplantation with subsequent normal production of 1,25-OH_2D and normal phosphate excretion should permit the return of normal parathyroid function. However, if hyperparathyroidism continues despite renal transplantation, the parathyroid glands have become hyperplastic to the point that they are autonomous. This is termed "tertiary hyperparathyroidism." Hypercalcemia can occur. Like primary hyperparathyroidism, surgical removal of the glands is required. Typically, 3.5 parathyroids are surgically removed and the remaining one-half of 1 parathyroid is implanted in the forearm. Forearm placement of this parathyroid tissue will allow easy surgical removal should hyperparathyroidism recur in this autotransplanted tissue.

Malignancy

Excluding hyperparathyroidism, malignancy is the most common cause of severe and/or persistent hypercalcemia. There are several mechanisms, whereby cancer can cause increased calcium concentrations. One mechanism involves the secretion of PTHrP. PTHrP has actions similar to PTH. However, PTHrP is not detected in the PTH immunoassays. A separate assay specific for PTHrP is available. Three isoforms of PTHrP (139, 141, and 173 amino acids) with N-terminal homology to PTH are encoded by the PTHrP gene (PTH like hormone; *PTHLH*; chr. 12p11.22). Another term for this form of paraneoplastic hypercalcemia is "humoral hypercalcemia of malignancy."

The second mechanism of hypercalcemia in malignancy is local bone destruction by the secretion of cytokines or other osteoclast-activating factors by tumor metastases. This is referred to as "local osteolytic hypercalcemia of malignancy." Numerous tumors cause this type of hypercalcemia including multiple myeloma, leukemias, lymphomas, and breast, colon, and lung cancers. Wilms tumor in children is another cause of this form of hypercalcemia. One interesting feature of multiple myeloma is that alkaline phosphatase measurements are not elevated (assuming a fracture is not present) [77]. Osteoblasts also appear to be suppressed in myeloma-bone lesions by cytokines (e.g., IL-3, IL-7, TNF-α, dickkopf 1, and soluble-frizzled receptor-like proteins 2 and 3) and via surface contact from stromal cells (e.g., activin A and growth factor-independent 1 transcriptional repressor).

A third form of cancer-related hypercalcemia has been observed in certain cases of lymphoma. The lymphoma appears to be able to convert 25-OHD into 1,25-OH_2D. Increased 1,25-OH_2D then produces hypercalcemia through increased calcium absorption from the gut and bone. This is similar to hypercalcemia resulting from granulomas. Rarely, PTH is produced ectopically.

Endocrine disorders

Both hypothyroidism and hyperthyroidism have been associated with hypercalcemia. In hypothyroidism, the proposed mechanism is prolonged action of vitamin D because of slowed metabolism. Increased bone turnover with bone loss is the proposed cause of hypercalcemia in hyperthyroidism. Alkaline phosphatase may also be increased in such cases of thyrotoxicosis.

Although glucocorticoids acutely suppress bone turnover and can lower calcium, glucocorticoid deficiency (e.g., Addison disease) can lead to increased calcium in the setting of Addisonian crisis. Volume contraction and hemoconcentration may also contribute to the hypercalcemia by elevating the relative concentration of albumin, the major calcium-binding protein. VIPomas can produce hypercalcemia independently of hyperparathyroidism; however, the mechanism causing hypercalcemia is unclear [78].

Granulomatous diseases

Any form of granulomatous disease can cause hypercalcemia through the production of 1,25-OH_2D. Normally, the major site of conversion of 25-OHD into 1,25-OH_2D is the renal tubule. However, in granulomatous diseases, the macrophages may acquire the ability to convert 25-OHD into 1,25-OH_2D. The list of possible granulomatous

diseases includes sarcoidosis, histoplasmosis, coccidioidomycosis, cryptococcosis, leprosy, berylliosis, and silicosis.

Drugs

Vitamin D excess causes pathologic elevations in both calcium and phosphate through increased intestinal absorption and increased bone mobilization [79]. Because vitamin D is fat-soluble, toxicity can be prolonged for weeks to months. Vitamin A excess has been reported to cause hypercalcemia. In some of these cases, there is coexistent vitamin D excess. Vitamin A itself in high doses appears to be able to cause bone resorption. Thiazides increase calcium absorption from the urine ultrafiltrate but rarely cause significant hypercalcemia. Because of thiazides' effects on increasing urinary calcium reabsorption, thiazides were studied as therapeutic agents intended to benefit osteoporosis. However, they were clinically ineffective.

Toxic doses of PTH administered in the treatment of osteoporosis can cause hypercalcemia. An FDA-approved drug for the treatment of osteoporosis is teriparatide, which contains the first 34 amino acids of PTH. Studies in rats demonstrated an increased risk of developing osteosarcoma.

Immobilization and other miscellaneous causes of hypercalcemia

Especially in growing teenagers, prolonged immobilization will raise calcium as calcium is released from the skeleton. Although weightlessness in outer space does not cause hypercalcemia, accelerated bone resorption in weightless conditions will be a major hazard of extended-duration space missions or travel to distant planets such as Mars.

Milk-alkali syndrome resulting from large intakes of calcium and alkali leads to both increased calcium absorption (and subsequent hypercalcemia) and metabolic alkalosis. The typical patient who develops milk-alkali syndrome is treating him or herself with milk and HCO_3^- for peptic ulcer disease. In hospitalized patients, total parenteral nutrition must be considered as a cause of hypercalcemia.

Approach to hypercalcemia

Once dehydration or hemoconcentration has been excluded as causes of hypercalcemia through measurements of albumin or ionized calcium (the preferred measurement), PTH is measured to differentiate hyperparathyroidism from all other causes of hypercalcemia (Fig. 45.11). Phosphate and alkaline phosphatase should be measured as well. If hyperparathyroidism is documented (e.g., the PTH is inappropriately normal or elevated in the setting of true hypercalcemia), familial causes should be excluded. The evaluation should include an assessment of the 24-hour urinary calcium excretion.

When PTH is suppressed in the face of hypercalcemia, non−PTH-dependent hypercalcemia is pursued. A thorough search for malignancy must be undertaken. Measurement of serum phosphate concentrations is informative in cases of non−PTH-dependent hypercalcemia. For example, with normal renal function, the presence of hypercalcemia and hyperphosphatemia is suggestive of vitamin D toxicity or granulomatous disease. Assuming

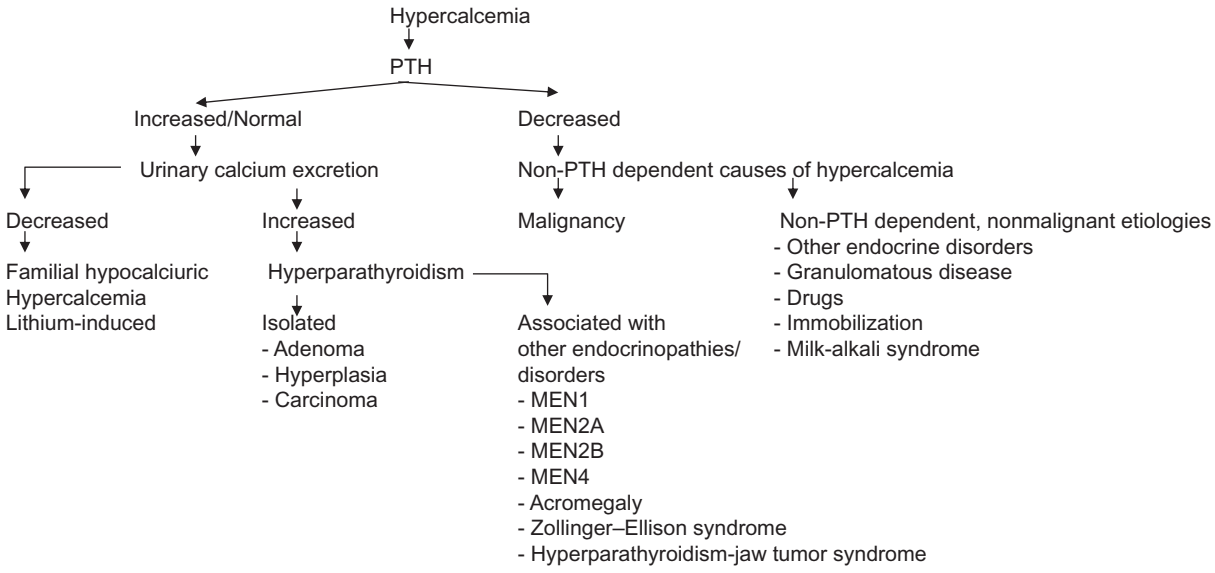

FIGURE 45.11 Diagrammed is an approach to the evaluation of hypecalcemia. See the text for details.

that malignancy is ruled out, endocrine, drug, and various miscellaneous causes of hypercalcemia are then stepwisely investigated.

Mutations in the parathyroid hormone/parathyroid hormone-related peptide receptor

PTH/PTHrP receptor mutations cause rare genetic bone disorders. A gain-of-function mutation in the PTH/PTHrP receptor results in Jansen metaphyseal chondrodysplasia [80]. This AD disorder is characterized by short-limbed disproportionate short stature and abnormal regulation of enchondral bone formation, hypercalcemia independent of either PTH or PTHrP, and increased bone turnover. PTH/PTHrP receptor mutations have also been reported in a few cases of enchondromatosis (Ollier disease) in the absence of hypercalcemia. Isocitrate dehydrogenase [NADP(+)] 1, cytosolic (IDH1; chr. 2q34), and isocitrate dehydrogenase [NADP(+)] 2, mitochondrial (IDH2; chr. 15q26.1) have been reported in some patients with Ollier disease [81].

Loss-of-function mutations in the PTH/PTHrP receptor are reported to cause Blomstrand chondrodysplasia. This rare, AR disorder is manifested in early death and advanced bone maturation with accelerated chondrocyte differentiation.

Calcitonin

Calcitonin is a product of the C-cells (a.k.a. parafollicular cells) of the thyroid gland. Less than 0.1% of the thyroid epithelial mass is C cells. The calcitonin gene family has five members: *CALC-I* encodes calcitonin and calcitonin gene-related peptide-I, *CALC-II* encodes calcitonin gene-related peptide-II, *CALC-III* is a pseudogene; *CALC-IV* encodes amylin (a.k.a. islet-associated polypeptide), and *CALC-V* encodes adrenomedullin. Preprocalcitonin is cleaved to a signal peptide plus procalcitonin (116 amino acids; 12.8 kDa). Procalcitonin is further cleaved to aminoprocalcitonin (N-terminal procalcitonin) plus conjoined calcitonin: calcitonin carboxypeptide-I. Cleavage of calcitonin: calcitonin carboxypeptide-I yields immature calcitonin plus calcitonin carboxypeptide-I. Finally, immature calcitonin (33 amino acids; terminal glycine) loses one amino acid and is modified to mature amidated calcitonin (32 amino acids; terminal amidated proline).

Calcitonin lowers serum calcium by stimulating bone accretion. Calcitonin plays only a minor physiologic role in humans: complete thyroidectomy has no adverse effect on BMD or bone strength if the subject is appropriately replaced with thyroid hormone. In clinical medicine, calcitonin is measured as a tumor marker for MTC. Procalcitonin is a marker used for the diagnosis of bacterial infections [82]; however, procalcitonin measurements have no role in endocrine testing.

Because MTC is derived from the C cells of the thyroid gland, elevated calcitonin concentrations serve as a tumor marker for MTC. Most experts consider basal calcitonin concentrations ≤ 20 pg/mL as normal. Such values do not require further study. A basal calcitonin ≥ 100 pg/mL is frankly elevated. If the basal calcitonin is >20 pg/mL but less than 100 pg/mL, calcitonin should be measured following stimulation, e.g., following the IV injection of calcium. In this test, 2 mg/kg of elemental calcium is infused intravenously as calcium gluconate over 50–60 seconds. Calcitonin is then measured at +1, +3, +5, and +10 minutes. Previously, pentagastrin (dose: 0.5 mcg/kg IV push over 5–10 seconds) was used as a calcitonin-secretagogue alone or together with IV calcium. However, pentagastrin is not presently available for diagnostic testing in the United States. An elevated calcitonin (e.g., ≥ 100 pg/mL) in a patient with a thyroid mass (e.g., nodule or nodules) is presumptive evidence of MTC. However, the final diagnosis of MTC is dependent on the gross and microscopic examination of the surgically excised tissue.

As noted above, MTC can occur sporadically (75% of cases) or as part of a familial cancer syndrome (25% of cases). Because the likelihood of MTC occurring in MEN2 is nearly 100% in affected subjects, prophylactic complete thyroidectomy should be performed. The specific *RET* proto-onocgene mutation can inform the medical staff as to how aggressive they should be in thyroidectomy (e.g., early versus later thyroidectomy). The preoperative diagnosis of familial cancer syndromes associated with MTC can be performed by testing for mutations in the *RET* proto-oncogene. The preoperative diagnosis specifically of MTC can be made by fine needle aspiration biopsy of a thyroid lesion or, more effectively, by measuring calcitonin as described above. Once thyroidectomy has been accomplished, calcitonin can be measured serially as a tumor marker.

Calcitonin measurements are available as radioimmunassays and as two-site immunoenzymatic or immunoradiometric assays. The differential diagnosis of elevated calcitonin includes MTC, C-cell hyperplasia (a precursor of MTC), certain nonthyroidal cancers (e.g., small-cell carcinomas, oat cell carcinomas, and other malignancies), acute or chronic renal failure, hypercalcemia, hypergastrinemia and other gastrointestinal disorders, and pulmonary disease.

Phosphate

Traditionally, phosphate has been viewed as subordinate to calcium concentrations: the body primarily regulates calcium and in the process of regulating calcium, phosphate is regulated. However, with the discovery that FGF23 has a role in phosphate homeostasis, independent control of phosphate has emerged as an important issue [83].

FGF23 is derived from bone, and together with the membrane bound protein Klotho, FGF23 has the following actions: (1) induction of renal phosphaturia by reducing the activity of Npt-2 (NaPi-2a and NaPi-2c; note: NaPi-2b is regulated by calcitonin); (2) reduced expression of renal 1 alpha-hydroxylase; and (3) increased clearance of 1,25-OH_2D via stimulation of 24-hydroxylase. Thus the overall effect of FGF23 is to lower plasma phosphate concentrations. Klotho associates with the receptor for FGF23. Klotho is encoded by the *KL* gene on chromosome 13q13.1. Klotho is composed of 1012 amino acids and weighs ~116 kDa.

Plasma phosphate concentrations represent the balance of phosphate entering the body through the gastrointestinal tract or IV route, the distribution of phosphate inside and outside of cells and its deposition into bone, and the renal clearance of phosphate (Fig. 45.12). Total body phosphate is predominantly controlled by controlling the degree of phosphaturia, with both PTH and FGF23 increasing phosphate excretion.

Elevations in phosphate occur for the following reasons: (1) increased phosphate burden [e.g., increased phosphate intake from any source (oral, rectal, cutaneous, parenteral) or increased phosphate absorption from the gastrointestinal tract]; (2) phosphate redistribution within the body (e.g., increased cellular release of phosphate from cell injury, dysfunction or cell lysis, or increased bone turnover or release from bone); and (3) decreased renal phosphate clearance (e.g., reduced renal excretion or increased renal tubular reabsorption) (Table 45.5). The causes of hypophosphatemia are essentially the inverse of hyperphosphatemia: (1) inadequate intake; (2) phosphate redistribution into cells; and (3) excessive renal loss (Table 45.6).

Magnesium

Although magnesium is the fourth most abundant cation in the body (following sodium, potassium, and calcium) and is the second most abundant intracellular cation (following potassium), there is no "primary" hormone that controls circulating magnesium concentrations. Nevertheless, magnesium is important in cellular metabolism. Acutely, PTH appears to have some regulatory effect on magnesium as acute hypoparathyroidism will reduce magnesium concentrations. On the other hand, chronic hypomagnesemia impairs PTH release and reduces target tissues' responses to PTH.

The most common cause of hypermagnesemia in clinical practice is iatrogenic: the intended infusion of magnesium sulfate in the treatment of preeclampsia or eclampsia in pregnant women. Infants born to magnesium-treated mothers can also be hypermagnesemic. Other causes of hypermagnesemia include excessive oral intake, increased gastrointestinal tract absorption (e.g., hypomotility and milk-alkali syndrome), cellular release (e.g., tumor lysis syndrome and rhabdomyolysis), and contraction of the circulating blood volume.

Transient hypomagnesemia is not uncommon in severe acute or critical illnesses. This may result from transient hypoparathyroidism that is self-limited but also common in such states. The most common causes of chronic hypomagnesemia are malabsorption, malnutrition, and renal magnesium wasting from drugs (e.g., loop or thiazide diuretics; cisplatin; cyclosporine, or tacrolimus), endocrine disorders (e.g., primary hyperaldosteronism, hypoparathyroidism, and hyperthyroidism) or osmotic diuresis.

Markers of bone turnover

Osteoporosis is a major medical problem for postmenopausal women and the elderly in general [84]. The costs associated with the consequences of osteoporosis run into the billions of dollars per year. There is controversy concerning the role of laboratory testing in the assessment of bone turnover during osteoporosis treatment [50]. If any

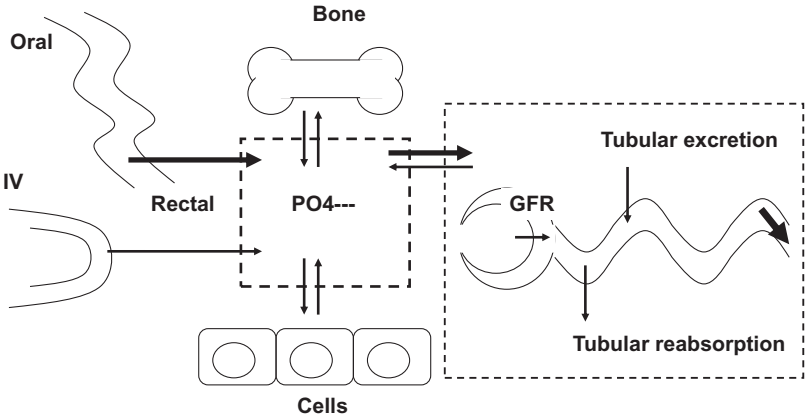

FIGURE 45.12 Phosphate is plentiful in normal diets and phosphate balance is maintained by the urinary excretion of phosphate. Appropriate excretion is a function of a normal glomerular filtration rate and tubular excretion, and the lack of excessive tubular reabsorption of phosphate. Phosphate exchanges with pools in the cells and bone.

TABLE 45.5 Causes of hyperphosphatemia.

Increased phosphate burden
Increased phosphate intake
Oral/rectal
- Noncompliance to phosphate binders in renal insufficiency
- Phosphate salts (e.g., oral/rectal laxatives and enemas)
Cutaneous: white phosphorous burns
Parenteral
Transfusion of outdated blood
Liposomal amphotericin B
Intravenous phosphate
Hyperalimentation (including lipid administration)
Increased phosphate absorption from the gastrointestinal tract
Vitamin D excess[a] (multiple causes including sarcoidosis)
Milk-alkali syndrome
Phosphate redistribution within the body
Increased bone turnover or release from bone
Thyrotoxicosis
Prolonged immobilization
Glucocorticoid withdrawal or deficiency
Increased cellular release of phosphate: cell injury, dysfunction, or cell lysis
Cancer (tumor lysis syndrome)
Trauma (including crush injures; rhabdomyolysis)
Burns
Ischemia or infarction (e.g., involving the bowel)
Thermal injury (heat or hypothermia)
Infection
Shock
Diabetic ketoacidosis, lactic acidosis, acute respiratory acidosis, and alcoholic ketoacidosis
Hemolysis
Inborn errors (e.g., malignant hyperthermia)
Exhaustive exercise
Decreased renal phosphate clearance
Increased tubular reabsorption of phosphate
Growth hormone excess (e.g., acromegaly)
Bisphosphonates
Tumoral calcinosis (mutations in FGF23 or uridine diphosphate-*N*-acetyl-alpha-D-galactosamine:polypeptide *N*-acetylgalactosaminyltransferase 3 or Klotho)
Decreased renal excretion:
Reduced glomerular filtration rate
Renal disease (acute or chronic)
Normal glomerular filtration rate: reduced tubular excretion of phosphate
Hypoparathyroidism
Pseudohypoparathyroidism
Alkalosis (acquired PTH resistance)

FGF23, Fibroblast growth factor-23; *PTH,* parathyroid hormone.

[a]*Also causes increased bone turnover.*

bone marker is going to be used to monitor the rate of bone turnover, it should be measured at baseline prior to the institution of any antiresorptive therapy. This allows each patient to serve as their own control.

Bone markers are breakdown products of collagen or are products of bone cells such as osteoblasts (e.g., BAP; a.k.a. skeletal alkaline phosphatase and osteocalcin) [85].

Osteocalcin (encoded by the bone gamma-carboxyglutamate protein gene on chr. 1q22) is a cytosolic 5.7-kDa calcium binding protein (49 amino acids). Osteocalcin is the major noncollagen protein found in bone and represents ~1% of total protein. Via the action of vitamin-K–dependent carboxylases, amino acids are modified into gamma-carboxy glutamyl residues that can

TABLE 45.6 Causes of hypophosphatemia.

Inadequate intake
Inadequate dietary intake
Malabsorption of intestinal phosphate
Phosphate binding by the antacids
Vitamin D deficiency (inadequate absorption)
Phosphate redistribution into cells
Acute respiratory alkalosis or hyperventilation
Insulin administration
Epinephrine injection
Cytokine-induced
Hungry bone syndrome (healing bone)
Vitamin D replenishment
Excessive loss
Renal phosphate wasting (genetic or acquired renal disorders)
Rickets with secondary hyperparathyroidism
Familial forms of hypophosphatemic rickets
Diseases of or injury to proximal renal tubule: heavy metal poisoning, various drugs, and monoclonal gammopathies
Drug-induced renal phosphate wasting (e.g., loop diuretics)
Increased glomerular filtration rate (including diuretics and osmotic agents)
Alkalosis
Tumor-induced osteomalacia (FGF23 secretion)
Following kidney transplantation (transient)

bind calcium or hydroxyapatite. Osteocalcin has a short half-life (~5 minutes). Between 10% and 30% of osteocalcin produced by osteoblasts is released extracellularly.

Increased osteocalcin or BAP levels signal an elevated rate of bone formation. Because bone building and bone breakdown are interrelated and because in the postmenopausal woman and in the elderly bone breakdown usually exceeds bone formation, elevated BAP or osteocalcin are undesirable suggesting an overall decline in BMD. In addition to osteoporosis, other causes of elevated BAP or osteocalcin include osteomalacia, rickets, renal osteodystrophy, Paget disease of bone, hyperparathyroidism, acromegaly, and thyrotoxicosis. Increased BAP also occurs with osteolytic metastases.

With bone resorption, osteoclasts degrade type 1 collagen. Type 1 collagen, which represents ~90% of the organic matrix of bone, is composed of three individual procollagen chains: two α1 procollagen chains and one α2 procollagen chain. The procollagen chains are composed of three regions: the amino-terminal propeptide, the helical domain and the carboxy-terminal propeptide. For the α1 procollagen chains, the amino-terminal propeptides include a globular domain. The procollagen chains are modified following translation with the addition of sugars and formation of intrachain disulfide bonds and the addition of hydroxyl groups on proline and lysine residues.

A triple helix of the three procollagen chains (two α1 and one α2) is formed within osteoblasts (Fig. 45.13) and is then secreted outside the cell (Fig. 45.14). The secreted

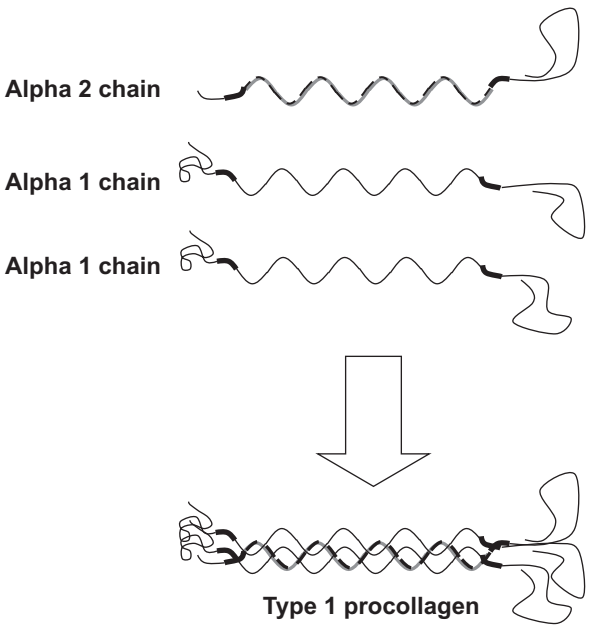

FIGURE 45.13 Within osteoblasts, three procollagen chains (two α1 and one α2) from a triple helix constituting type 1 procollagen.

type 1 procollagen undergoes removal of propeptides via the action of procollagen amino proteinase and carboxy proteinase. This releases the amino and carboxyl terminal propeptides yielding the mature triple helix type 1 collagen (Fig. 45.14). Cross-linking of the collagen triple helices occurs extracellularly (Fig. 45.15). The pyridinium

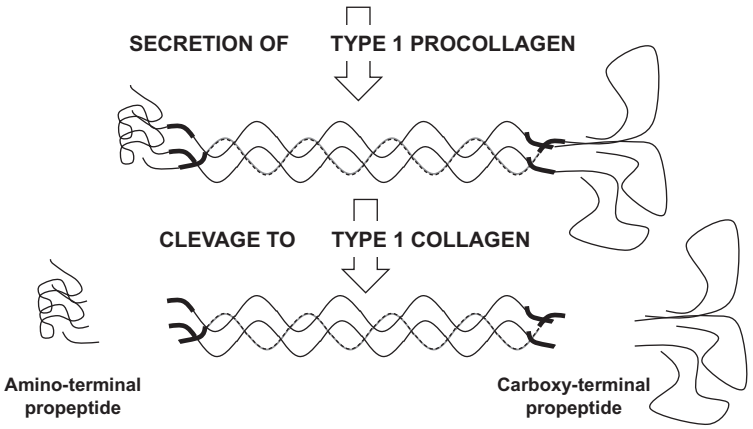

FIGURE 45.14 The secreted triple helix of type 1 procollagen undergoes removal of propeptides via the action of procollagen amino proteinase and carboxy proteinase releasing the aminoterminal and carboxyterminal propeptides to form type 1 collagen.

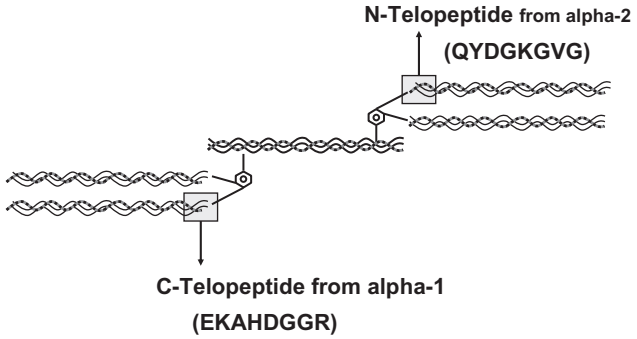

FIGURE 45.15 The cross-linking of the type 1 collagen triple helices occurs extracellularly. The pyridinium cross-links (i.e., the hexagons in the figure) bridge 2 N-telopeptide or 2 C-telopeptide portions of two strands to the helix of another collagen strand. When type 1 collagen is broken down as part of bone resorption, N-terminal telopeptides (N-telopeptides) and C-terminal telopeptides (C-telopeptides) are released.

cross-links (i.e., pyridinoline or deoxypyridinoline) bridge 2 N-telopeptide or 2 C-telopeptide portions of two strands of 2 helices. Lysyl oxidase converts 3-amino acids (i.e., lysines and hydroxylysines) into one trivalent amino acid (deoxypyridinoline and pyridinoline) producing the cross-linking. These cross-linked triple helices account for the very high tensile strength of collagen.

As part of bone resorption when collagen is degraded, pyridinolines, deoxypyridinolines, C-terminal telopeptides, and N-terminal telopeptides are released (Fig. 45.15). An immunoassay for serum C-telopeptides recognizes the following amino acid sequence within the $\alpha 1$ molecule C-telopeptide: EKAHDGGR. An immunoassay for N-telopeptides recognizes the following amino acid sequence within the $\alpha 2$ chain N-telopeptide: QYDGKGVG.

N-telopeptides can be measured in serum or urine. C-telopeptides are measured in serum. Using high-pressure liquid chromatography, ELISA, or radioimmunoassay techniques, deoxypyridinolines or pyridinolines are usually measured in timed urine collections. Deoxypyridinoline is believed to be a more specific marker of bone collagen turnover than pyridinoline.

Whereas monitoring BMD and bone markers in the treatment of osteoporosis is logical, there are few data to demonstrate improved compliance or outcome with treatment when either BMD or bone markers are serially measured [67]. If BMD decreases or bone marker concentrations increase, it is not recommended that therapy for osteoporosis be discontinued. Thus our discussion on the clinical use of bone markers ends as it began: the effectiveness of bone marker monitoring is controversial [86].

Summary

Bone is a tissue scaffolding that grows as we progress from infants to children to teenagers to adults. Bone is amazing in its complexing and ability to self-heal (within certain limits). However, bone is just one aspect of calcium and phosphate biology that demands our attention. Understanding PTH, vitamin D, FGF23, and the many other factors that help maintain homeostasis forms the basis for medically related practices. Most medical activities relating to calcium and PTH biology and disease diagnosis and management require appropriate and prudent laboratory testing.

Self-assessment questions

1. Where is 25-hydroxyvitamin D normally converted into 1,25-dihydroxyvitamin D?
   - **a.** liver
   - **b.** intestine
   - **c.** parathyroid gland
   - **d.** C cell
   - **e.** kidney tubule
2. What is the etiology of hypercalcemia in sarcoidosis?
   - **a.** excess PTH acting on the renal tubule to increase Ca and phosphate absorption
   - **b.** depressed calcitonin production by the C cells
   - **c.** increased conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D by macrophages
   - **d.** increased vitamin D action on the intestine
   - **e.** increased albumin concentrations
3. In biliary atresia, rickets results from:
   - **a.** decreased bile flow and decreased vitamin D absorption
   - **b.** decreased conversion of vitamin D into 25-hydroxyvitamin D
   - **c.** both
   - **d.** neither
4. 4. The pathogenesis of renal osteodystrophy involves all of the following processes except:
   - **a.** phosphate retention, depressed calcium, and increased PTH.
   - **b.** decreased conversion of 25-hydroxyvitamin D into 1,25-dihydroxyvitamin D.
   - **c.** hyperparathyroidism.
   - **d.** resistance to the effects of PTH on bone.
   - **e.** decreased intestinal calcium absorption.
5. A 5-year-old girl's parents bring their adopted daughter to the pediatrician because she has suffered periodic episodes of what the parents call "stiffening." The intellectual development of this girl is significantly delayed. As well, she has short stature. Physical examination reveals a "heart-shaped" face, mild obesity, delayed development, and short fourth metacarpals. The Chvostek sign and Trousseau sign are elicited on physical examination. When parathyroid hormone was isolated from this child by immunoaffinity chromatography, purified, and injected into a normal mouse, a transient hyperphosphaturia was produced. The following laboratory studies are obtained on the child (see below). What is the most likely diagnosis?

	Result	Reference interval
Ca^{++}	6.5 mg/dL	8.4–10.4
PO_4^{---}	6.1 mg/dL	2.5–4.5
PTH	85 pg/mL	10–65
Albumin	4.0 g/dL	3.5–5
Cr	0.5 mg/dL	0.4–1.2
BUN	10 mg/dL	5–20

   - **a.** PTH/PTHrP receptor loss-of-function mutation
   - **b.** hypoparathyroidism, etiology not otherwise specified
   - **c.** loss-of-function mutation in the parathyroid calcium receptor
   - **d.** renal failure with secondary hyperparathyroidism
   - **e.** PTH loss-of-function mutation

Chapter 46

Vitamins: functions and assessment of status through laboratory testing

Emile Levy[1,2] and Edgard Delvin[1,3]

[1]*Division of Gastroenterology, Hepatology and Nutrition, CHU Sainte-Justine Research Centre, Montreal, QC, Canada,* [2]*Department of Nutrition, Faculty of Medicine, University of Montreal, Montreal, QC, Canada,* [3]*Department of Biochemistry, Faculty of Medicine, University of Montreal, Montreal, QC, Canada*

Learning objectives

After reviewing this chapter, the reader should be able to:

- Recognize clinically important lipid- and water-soluble vitamins.
- Describe situations in which their assessment status is necessary to prevent deterioration in health status of individuals and/or populations.
- Apply vitamin testing to situations requiring the investigation of their status utilizing methods available to clinical and research laboratories.
- Discuss the methodological approaches used to measure the wide variety of lipid- and water-soluble vitamins.

Introduction

According to the National Institute of Health (NIH; Bethesda, MD, United States), "the science of nutrition interprets the interaction of nutrients and other substances in food in relation to maintenance, growth, reproduction, health, and disease of an organism [1]. It covers food intake, absorption, assimilation, biosynthesis, catabolism, and excretion." Nutritional biochemistry per se encompasses the study of the chemistry and biology of nutrients. Societies such as the American Society for Nutrition (www.nutrition.org), the Academy of Nutrition and Dietetics (www.eatright.org), and the European Society for Clinical Nutrition and Metabolism (http://www.espen.org) publish either in print or online a vast repertoire of literature, making this science and the metabolism and measurement of nutrients more accessible both to health professionals and lay public. Furthermore, government-sponsored panels of nutrition leaders produce consensus statements and materials to guide nutrition thought that could be consulted in internationally well-known nutrition-related journals. As the micronutrient market, *claiming beneficial effects in preventing deficiencies or enhancing physical and intellectual capacities*, is a multi-billion dollar business, it must be underlined that all online materials may not be authoritative, and can even be deceptive or even fraudulent. Therefore it is the obligation of the professionals in the fields to guide consumers in distinguishing the oat from the chaff. This requires the development of tools for sturdy and reproducible nutritional status assessment schemes.

Nutrients are compounds or elements that the body must use for essential metabolic processes including growth. They are broadly classified into two categories: the macronutrients and the micronutrients. Macronutrients, which include protein (Chapter 22, Proteins: analysis and interpretation of serum, urine, and cerebrospinal fluid), carbohydrates (Chapter 33, Evaluation of exocrine pancreatic function), and lipids and lipoproteins (Chapter 27, Diagnostic body fluid testing), consumed in amounts of >1 g/day, are sources of energy required for metabolism and for synthesis of cell structural and functional components. Micronutrients (consumed in amounts of <1 mg/day) include vitamins, minerals, trace elements, and ultra-trace elements. Their physiologic requirements change according to statuses related, among others, to growth, pregnancy, lactation, activity, aging, and disease. This chapter covers the lipid- and water-soluble vitamins.

Nota bene.[1]

1. *Nota bene*: Reference intervals *provided* in the text for each vitamin are obtained from studies that include variable number of subjects; some having fewer than 100 participants, and some based on population studies. Hence, the values cited should be interpreted with caution and are mainly suggestive.

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00046-6

Vitamins

Three criteria define the term vitamin: (1) vitamin deficiency produces symptoms or a disease that can be corrected by returning the micronutrient to adequate levels; (2) vitamins have organic structures; and (3) vitamins are required in small amounts and are normally not synthesized by the body. Classically, vitamins have been classified as lipid- and water-soluble compounds, a characteristic that dictates their cellular uptake and metabolism.

Fat-soluble vitamins

Intestinal uptake and transport

The lipid-soluble vitamins A, D, E, and K must associate with mixed micelles, consisting of phospholipids, lysophospholipids, monoacylglycerol, cholesterol, and bile salts, or with vesicles in order to be absorbed at the enterocyte apical brush border and transported to the basolateral membrane to be distributed to the various target organs in order to exert their biological effects. Although initial studies led to the conclusion that fat-soluble vitamins were absorbed by passive diffusion, more recent evidence, reviewed comprehensively [2–4], shows that, while passive diffusion occurs at pharmacological doses, absorption at physiological or dietary doses requires protein carriers, such as Niemann-Pick C1-like 1, cluster determinant 36, ATP-binding cassette subfamily A member 1, and scavenger receptor class B type 1, all involved in lipid transport and trafficking. Fig. 46.1 schematizes this process. It is well-known that congenital lipid malabsorption diseases, such as chylomicron retention disease, familial abetalipoproteinemia, or familial hypobetalipoproteinemia, involving genes related to intestinal lipoprotein assembly and secretion, and also to lipid-soluble uptake, lead to severe conditions such as retinopathy, myopathy, neuropathy, cardiomyopathy hepatic steatosis, steatorrhea, and acanthosis (Table 46.1) [5]. It can be argued that these conditions could be due, at least in part, to deficiency in fat-soluble vitamins. The presence of cholesterol transporters, facilitating also the transport of lipid-soluble vitamins, could lessen the severity of the deficiency. If deficiencies impact on health status, so do excesses. Table 46.2 summarizes the effect of lipid-soluble vitamin deficiencies and excesses on the health status in the general population. Thorough evaluation of the vitamin statuses is thus warranted in those conditions.

Vitamin A

According to the IUPAC-IUB Joint Commission on Biochemical Nomenclature recommendations of 1981, the term vitamin A is a generic descriptor for retinoids, exhibiting the biological activity of *all-trans* retinol [6]. To exert its role as activator of nuclear transcription factors, *all-trans* retinol must be converted to *all-trans* retinoic acid by ubiquitous cytochrome P450s [7,8]. Preformed vitamin A is derived from animal sources, particularly fish liver oils and liver. Plants, principally yellow-pigmented vegetables and fruits, provide α-carotene, β-carotene, and β-cryptoxanthin that must be converted, in the intestine and liver, to vitamin A-active compounds. Some retinoids, such as 11-*cis* retinaldehyde, have very specific functions. This retinoid covalently binds with, the rod outer segment photoreceptor protein, rhodopsin through a protonated Schiff-base link. Photoactivation of this complex requires the isomerization of the bound 11-*cis* retinal moiety to the all-*trans* retinal, which, in turn, induces major structural changes of the receptor [9].

Vitamin A deficiency is a significant worldwide problem for public health, as it contributes significantly to the global disease burden that includes xerophthalmia and decreased resistance to infections, both of which are preventable [10,11]. *Vitamin A may however be a double-edged sword, having a higher potential for toxicity than water-soluble vitamins*. Indeed, intakes marginally above the recommended dietary intake have been associated with teratogenic effects [12]. In other clinical settings, neuromuscular adverse effects have been reported for

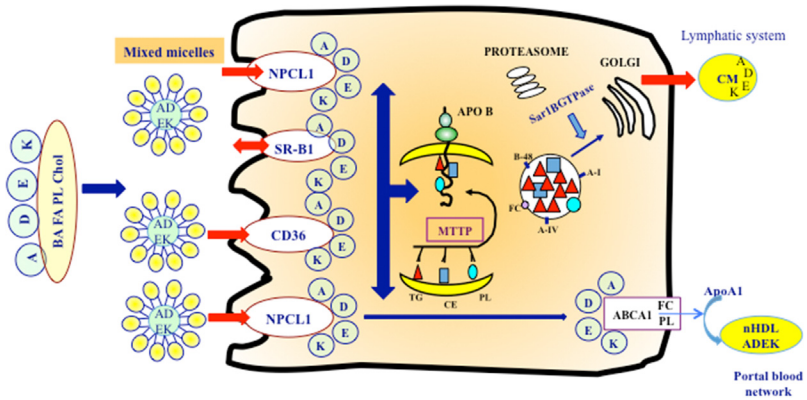

FIGURE 46.1 Simplified scheme of the uptake, transport, and secretion of vitamins A, D, E, and K by the enterocyte. At physiological doses, vitamins A, D, E, and K are captured from the mixed micelles by apical membrane transporters and transported across the cytosol to be secreted into the lymphatic system associated with chylomicrons or in the portal blood network associated with nascent HDL particles. A, D, E, and K: vitamins A, D, E, and K, respectively. *ABCA1*, ATP-binding cassette subfamily A member; *CD36*, cluster determinant 36; MTTP, microsomal triglyceride transfer protein; *NPC1-L1*, Niemann-Pick C1-like 1; *SR-B1*, scavenger receptor class B type 1.

TABLE 46.2 Selected illnesses related to improper intake of lipid-soluble vitamins.

Vitamins	Deficiency	Excess
Vitamin A	Xerophthalmia, night blindness, and immunity disorders	Hypervitaminosis A (teratogenicity, myalgia, polyneuropathies, liver fibrosis, cholestasis, and hypercalcemia)
Vitamin D	Rickets, osteomalacia, and osteoporosis	Hypercalcemia and nephrocalcinosis
Vitamin E	Ataxia	Coagulopathies
Vitamin K	Coagulopathy and hemorrhagic disease of the newborn	Rare condition. High doses of vitamin K_3 (menadione) may produce red blood cell fragility

isotretinoin and acitretin, two commonly oral potent retinoids used in systemic dermatotherapy that have led to the development of neuromuscular algorithm for appropriate monitoring of patients treated with these two compounds [13]. The use of over-the-counter supplements is also a source of concern, as a case of vitamin A intoxication translating into deranged liver function tests consistent with a cholestatic process has been reported [14]. Hypercalcemia leading to nephrocalcinosis and renal impairment is yet another potential adverse effect of hypervitaminosis A as described by Safi et al. [15] in a 4-year-old cystic fibrosis patient. Although anecdotal, these case reports call physicians and clinical laboratory to vigilance when assessing nutritional status of patients.

Biochemical assessment of vitamin A status

Dietary preformed vitamin A, resulting from the obligatory hydrolysis in the intestinal lumen of long-chain fatty acid retinol esters, and retinol resulting from the cleavage of β-carotene are taken up by the mucosal cells, reesterified and incorporated with other neutral lipid esters, assembled into chylomicrons and secreted into the lymphatic system, and ultimately delivered to the liver where it is stored mainly as retinyl palmitate [16]. Vitamin A from the liver, providing the needs of the body, is stochiometrically bound to and transported by the retinol-binding protein (RBP) to the different target tissues [8]. When considering central clinical laboratories, the measurements of serum retinol and RBP concentrations are the standard methods to assess the vitamin A status. For specialized laboratories or for research purposes, relative dose response, modified relative dose response, and the deuterated retinol isotope dilution tests, reviewed by Tanumihardjo et al. [17], are also available.

A number of methods for the measurement of serum retinol have been developed in the last 40 years. The early methods involved fluorometric measurement with or without extraction and chromatography [18]. They were later replaced by high-performance liquid chromatography (HPLC) with ultraviolet (UV) detection systems. Methods for the measurement of retinol standardized based on the use of Standard Reference Material (SRM) have been reported [19,20]. However, at the present time, there is no international reference method available, although the Micronutrients Measurement Quality Assurance Program

(M2QAP) of the National Institute of Standards and Technology (NIST; Gaithersburg, MD, United States) is available [21]. The recent development of accessible mass spectrometric methods offers the advantage metabolic profiling of the different circulating retinoids and hence enables to measure retinoic acid, the active component of the vitamin [22]. Serum RBP has also been used as a surrogate for serum retinol concentrations. Although RBP has the advantage of being more stable than retinol, this protein exists in multiple forms. Immunoassays have so far not been standardized, and there are no international methods available with which a standardization or harmonization could be performed. Blood plasma retinol concentrations are typically 1−2 μM and are not affected by daily intake [8].

Vitamin D

The widespread term vitamin D makes no distinction between vitamin D_3 (cholecalciferol) of human or animal origin, and vitamin D_2 (ergocalciferol) of plant origin. The term "vitamin," that is, a "vital" product that the organism cannot produce is inappropriate for vitamin D, as the skin can synthesize vitamin D_3 from 7-dehydrocholesterol under the action of UVB radiation. The role of vitamin D in bone health is well established, and its suspected role in other systems has been addressed [23,24]. Despite major national public health campaigns since the late 1960s, Vitamin D insufficiency remains a common problem, particularly in high latitudes [25−27], leading to increased incidence of rickets, osteomalacia, and osteoporosis [28,29]. Vitamin D toxicity, also known as hypervitaminosis D, remains anecdotal despite an increased risk with vitamin D supplementation practices [30]. However, advocacy of high vitamin D intakes in the order of 10,000 IU/d warrants caution, and rather guidelines published by the Institute of Medicine should be applied [31,32].

Vitamin D intoxication is a serious condition. It presents with hypercalcemia, poor appetite, weight loss, abdominal pain, vomiting, constipation, polyuria, and polydipsia, and in severe situations, life-threatening dehydration. In some cases, the concentration of calcium phosphate salts in the glomerular filtrate may exceed its solubility threshold, resulting in nephrocalcinosis, and in extreme cases to renal tubular acidosis and insufficiency [33−36].

Biochemical assessment of vitamin D status

Vitamin D nutritional status is evaluated by the measurement of serum 25-hydroxyvitamin D (25OHD), and not by the parent vitamin D or the hormonal form 1α,25$(OH)_2$D. In cases of vitamin D deficiency, serum 1α,25$(OH)_2$D may be normal, low or high depending on the secretion of parathyroid hormone (PTH) and FGF-23 [37,38]. Lips [29,39] suggested defining vitamin D deficiency as that serum 25OHD concentration below which there are detrimental effects on health, particularly on bone because of hyperparathyroidism. The relationship between circulating 25OHD and PTH concentrations is of interest, as it theoretically allows defining "functional vitamin D deficiency." The results from the locally weighted scattered plot smoothing (Loess) model, as shown in Fig. 46.2, exemplifies that this relationship may not be as clear as wished with a natural breakpoint 25OHD concentration ranging from 40 to 50 nmol/L [41]. Furthermore, Steingrimsdottir et al. [42] reported a calcium intake−optimal 25OHD interaction for an effect on circulating PTH levels, which was confirmed by Aloia et al. [41]. Patel et al. [43] recently confirmed the calcium dependency of the 25OHD−PTH relationship in healthy adolescents. Fig. 46.3 adapted from their study shows that circulating intact PTH levels are lower in participants with calcium intakes of >520 mg/day independently of serum 25OHD concentration. Furthermore, free-hand drafting of asymptotes for the respective axes suggests that the threshold for defining "functional" vitamin D deficiency (inflexion point of increased PTH levels) is situated at ≈12 ng/mL (30 nmol/L).

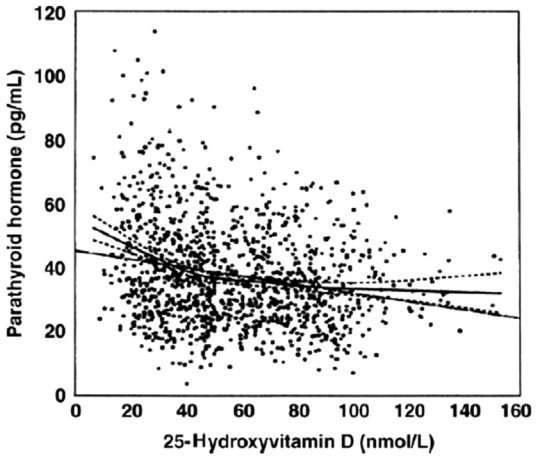

FIGURE 46.2 Relationship between circulating parathyroid hormone and serum 25-hydroxyvitamin D concentrations. Loess plot (solid line) and 95% confidence interval of the Loess plot (dotted lines) of parathyroid hormone as a function of 25-hydroxyvitamin D ($n = 124$). The linear regression line (dashed line) is outside the 95% confidence interval for 25-hydroxyvitamin D concentrations of <30 or >110 nmol/L. *Reproduced with permission from J.F. Aloia, S.A. Talwar, S. Pollack, M. Feuerman and K.K. Yeh, Optimal vitamin D status and serum parathyroid hormone concentrations in African American women,* Am J Clin Nutr. ***84*** *(3), 2006, 602−609.*

The observed widespread differences in circulating 25OHD concentrations across epidemiological studies restrain from concluding on the circulating 25OHD concentrations required for optimal health status, and confuse

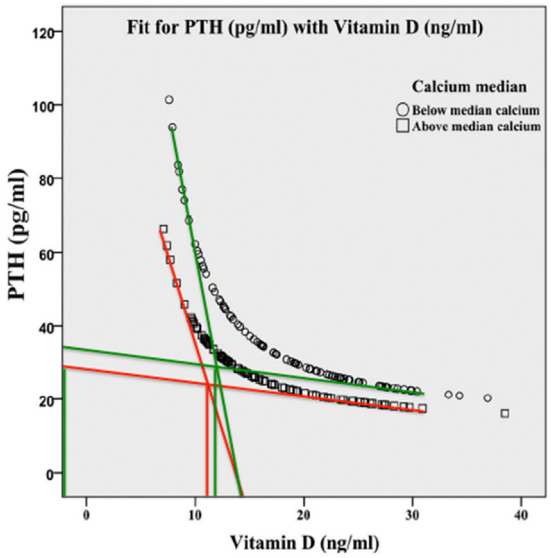

FIGURE 46.3 Relationship between plasma parathyroid hormone and 25-hydroxyvitamin D as a function of calcium intake. Red lines: above median calcium intake. Green lines: below median calcium intake. The respective intercepts represent the estimate of the serum 25-hydroxyvitamin D concentrations for functional vitamin D deficiency. At high calcium intake, the serum 25-hydroxyvitamin D threshold is lower than that at low calcium intake. *Adapted with permission from P. Patel, M.Z. Mughal, P. Patel, B. Yagnik, N. Kajale, R. Mandlik, et al., Dietary calcium intake influences the relationship between serum 25-hydroxyvitamin D3 (25OHD) concentration and parathyroid hormone (PTH) concentration, Arch. Dis. Child. 101 (4) (2016) 316–319.*

the efforts in developing international evidence-based public health guidelines. Despite recent technological advances, the measurement of circulating 25OHD remains a challenge, and many important issues have still to be resolved to obtain an accurate measure of serum 25OHD concentration. To solve this issue, the consortium composed of the NIH Office of Dietary Supplements, the Center for Disease Control National Center for Environmental Health, the NIST, and Ghent University (Ghent, Belgium) have established the Vitamin D Standardization Program having as mandate the promotion of methodological consistency for the measurement of 25OHD [44]. This consortium is thus advocating, based on the recommendations of Stockl et al. [45], an imprecision (CV) of $\leq 10\%$ and a bias of $\leq 5\%$ as current goals for the analytical performance of vitamin D assays in routine clinical laboratories [46]. The impact of this standardization progress is exemplified in the recent report of the Canadian Health Measure Survey, showing that prevalence of vitamin D insufficiency (20 ng/mL or 50 nmol/L) in the Canadian population, based on serum 25OHD concentrations observed after the standardization process, increased from 29% to 36.8% [47]. Le Goff et al. [48] reviewed the main elements and the difficulties of the automated and semiautomated methods for 25OHD measurement, from sample preparation to the analytical phase, as well as those related to mass spectrometry, and emphasized the need for standardization to better define the clinical decision thresholds of vitamin D nutritional status [49–51]. Mass spectrometry is now considered the state-of-the-art method for accurately measuring vitamin D metabolites. Several methods have been published in the recent years [52–55].

As mentioned in the "Introduction" section, there is mounting evidence indicating that the measurement of serum vitamin D binding protein, and *in fine* the definition of its polymorphisms, should be part of the vitamin D nutritional assessment workup. The Endocrine Society defines vitamin D deficiency as serum 25OHD values of <50 nM, and insufficiency as values between 52.5 and 72.5 nM [56].

Vitamin E

The generic term vitamin E represents a family of eight naturally occurring complex compounds that include α-, β-, γ-, and δ-tocopherols and tocotrienols, differing in the position and number of methyl groups on their benzene rings C5, C7, and C8 of the chromanol structure. Tocopherol differs from tocotrienols by having a trimethyltridecyl residue side chain with chiral carbons at C4', C8', and C12' rather than a phytyl side chain unsaturated at C4, C7, and C11 [57–59]. The natural α-tocopherol stereoisomer is (2'R, 4'R, 8'R)-α-tocopherol, which is the one preferentially incorporated into liver lipoproteins for peripheral export [58] and recognized by the α-tocopherol transport protein, responsible for maintaining circulating α-tocopherol concentrations [60,61].

Human vitamin E deficiency symptoms mainly include progressive peripheral neurologic disorders, which, if not treated, may ultimately result in ataxia [62,63] and cardiomyopathies [64]. The disparity of biomarkers and cutoffs used in the definition of vitamin E deficiency prevent an accurate measure of the prevalence of its dietary inadequacy. It is, however, accepted that symptomatic nutritional vitamin E deficiency is rare in the general population, although there are groups at risk particularly in developing countries [65–67]. Vitamin E is moderately toxic compared with vitamin A or D [36,68]. However, when used at very high doses, it can potentially lead to harmful effects by antagonizing leukocyte and platelet 5-lipoxygenase activity, resulting in inadequate thromboxane and leukotriene synthesis, decrease in blood coagulating capacity, and disruption of granulocyte and phagocyte antiinfective function [69]. Vitamin E has been reported to interact with vitamin K metabolism particularly in individuals at risk for vitamin K nutritional or iatrogenic deficiency [70]. The mechanisms underlying this deleterious interaction elude

explanations, although competitive inhibition of the vitamin K metabolism has been suggested [70].

Biochemical assessment of vitamin E status

There are a variety of published methods available for the measurement of vitamin E. The Emmerie–Engel chemical method based on the oxidation of total tocopherols to tocopherol quinine by $FeCl_3$ and the reaction of the resulting $FeCl_2$ with $\alpha-\alpha$-dipyridyl to a red color, and the functional test based on the red blood cell (RBC) hemolysis index have been used for decades, but are now considered outdated. The current recommended methods are HPLC-based and involve an initial organic extraction step, followed by the separation and either using UV (292 nm) or fluorescent (excitation wavelength of 205 nm and with an emission filter of 340 nm) detection systems. Vitamin E is often measured concurrently with vitamin A [19,20,71]. Hinchliffe et al. [72] recently described a method allowing the simultaneous quantification of vitamins A and E by liquid chromatography–tandem mass spectrometry. As for vitamin A, standardization of vitamin E is possible through the M2QAP at the NIST, and no reference-standardized method has yet been accepted. Proposed reference values for vitamin E lie between 14 and 40 μM, while values of <21 μM can be considered unhealthy [73].

Vitamin K

The term vitamin K represents a collection of homologous fat-soluble compounds derived from the core molecule 2-methyl-1,4-naphthoquinone. The naturally occurring phylloquinone (2-methyl-3-phytyl-1,4-naphthoquinone), termed vitamin K_1, the major dietary form of vitamin K, mainly originates from plants. Its absorption depends largely on protein-mediated mechanisms, shared with other fat-soluble vitamins [74]. Krzyzanowska et al. [75] recently reported a higher prevalence and severity of vitamin K deficiency in cystic fibrotic patients for which the presence of the F508del CFTR mutation constituted an independent risk factor. This observation implied that this transmembrane conductance regulator is involved directly or indirectly in vitamin K transport.

Menaquinones, collectively known as vitamin K_2, are a large series of compounds containing an unsaturated side chain with differing numbers of isoprenyl units linked to the C3 of the 2-methyl-1,4-naphthoquinone nucleus. They are produced by the normal jejunum and ileum Gram (+) flora and represent a substantial portion of the daily requirements [76]. Contrasting with the other fat-soluble vitamins, vitamin K has a rapid turnover, resulting in comparatively low tissue stocks [40].

The pleiotropic roles of vitamin K are mostly channeled through a common pathway involving the γ-carboxylation of the glutamyl side-chain residue of specific protein factors, thereby known as GLA-proteins. These GLA-proteins are involved in diverse biological systems, such as blood clotting (prothrombin), bone formation (osteocalcin), mobilization, and deposition of calcium in bone hydroxyapatite (GLA-bone matrix protein), and kidney GLA-proteins involved in the tubular calcium reabsorption and solubilization of calcium salts in urine [77,78]. Vitamin K-dependent proteins are also thought to have roles in cell signaling and brain lipid metabolism [79]. Hence, vitamin K deficiency is likely to affect those systems to varying degrees depending upon the level of deficiency. However, impairment of the coagulation pathway is certainly the most overt symptom [77]. In a search of the NIH PubMed database using "vitamin K toxicity" with case reports as filter, no toxicity case emerged.

Biochemical assessment of vitamin K status

The initial measurements of vitamin K depended upon bioassays based on the reduction of prothrombin time (PT) in anticoagulant stressed chicken [80]. PT and the international normalized ratio are the main tests currently used in clinical homeostasis laboratories to monitor vitamin K antagonists and also to indirectly assess vitamin K status [81]. Reversed-phase HPLC methods with postcolumn reduction and fluorescent detection have been described and are the usual biochemical method to measure serum or plasma phylloquinone [82,83]. However, more recently available mass spectrometry-based methods allow the measurement and metabolic profiling of phylloquinone [84,85]. The Mayo Clinic reports normal values for vitamin K_1 in serum to be from 0.10 to 2.20 μg/L [86].

Water-soluble vitamins

Transport and absorption

Despite their different structures, water-soluble vitamins are central to various cellular functions where they are essential for normal cellular functions, growth, and development. Their deficiency causes diverse clinical entities spanning from growth retardation to neurological syndromes. Table 46.3 summarizes the conditions related to improper intake of water-soluble vitamins. Although water-soluble vitamins are obtained from dietary sources, the bacterial source via the gut microbiota should not be underestimated. Whereas vitamins obtained from the diet are mainly absorbed in the jejunum and the ileum, the colon absorbs those produced by the microbiota. They are, however, all transported by carrier-mediated mechanisms. An exception

TABLE 46.3 Selected illnesses related to improper intakes of water-soluble vitamins.

Vitamins	Deficiency	Excess
Vitamin B_1 (thiamin)	Subclinical deficiency include headache, tiredness, anorexia, and muscle wasting. Frank deficiency causes beriberi, Wernicke's encephalopathy, and Korsakoff psychosis.	Rare and usually follow long-term parenteral nutrition. High doses cause headaches, nausea, insomnia, and tachycardia.
Vitamin B_2 (riboflavin)	Dermatitis, photophobia, itching, glossitis, dizziness, insomnia, muscle weakness, and anemia associated with reticulocytopenia.	No toxic or adverse reactions were reported.
Vitamin B_3 (niacin)	Pellagra, dizziness, vomiting, constipation or diarrhea, neurological disorders, fatigue, memory loss, and visual deficiency.	Stems essentially from its use in treating hypercholesterolemia. Symptoms include flushing, itching, nausea, and gastrointestinal disorders. Few cases of liver dysfunction following high-dose nicotinamide treatment.
Vitamin B_5 (pantothenic acid)	Extremely rare. Provoked experimentally. Fatigue, apathy, sleep disturbance, gastrointestinal disorders, numbness, paresthesia, and staggering gait.	No toxic or adverse reactions were reported.
Vitamin B_6 (pyridoxal phosphate)	Extremely rare in humans. Children fed overheated milk display weakness, irritability, weight loss, and insomnia. Inherited pyridoxine dependency translates into neonatal seizures. Large doses of pyridoxine are required to avoid severe mental retardation.	Reports of paresthesia, somnolence, stumbling gait, lack of muscle coordination, and sensory loss.
Vitamin B_7 (biotin)	Desquamating dermatitis, skin rash, hair loss, and ataxia, conjunctivitis. Deficient infants show hypotonia, lethargy, developmental delay, and withdrawn behavior. Inherited biotinidase deficiency creates the similar disorders.	No toxic or adverse reactions were reported.
Vitamin B_9 (folic acid)	Megaloblastic and macrocytic anemia, and moderate hyperhomocysteinemia. In utero developmental defects: spina bifida. Decreased since folate supplementation.	No toxic or adverse reactions were reported.
Vitamin B_{12} (cobalamin)	Megaloblastic and macrocytic anemia. Neurological disorders and moderate hyperhomocysteinemia.	No toxic or adverse reactions were reported. Anecdotal cases of allergic reactions.
Vitamin C (ascorbic acid)	Scurvy, fatigue, muscle weakness, aching joints, and advanced deficiency lead to anemia, gum bleeding, and delayed wound healing.	Gastrointestinal disorders, metabolic acidosis, renal acidosis (megadoses), and renal lithiasis.
Choline*	Rare occurrence. hepatocarcinoma and hepatosteatosis.	Body fishy odor, gastrointestinal disorders, anorexia, and mild cholinergic toxicity.

Based on *Standing Committee on the Scientific Evaluation of Dietary Reference Intakes and Its Panel on Folate OV, and Choline and Subcommittee on Upper Reference Levels of Nutrients, Food and Nutrition Board, Institute of Medicine, Pantothenic Acid. Dietary Reference Intakes for Thiamine, Riboflavin, Niacin, Vitamin B6, Folate, Vitamin B12, Pantothenic Acid, Biotin, and Choline, The National Academies Press, Washington, DC, 1998.

being made of niacin of limited endogenous synthesis; water-soluble vitamins must be obtained from either the diet or the colonic microbiota; hence, the body depends on their intestinal absorption. The mechanisms regulating their luminal absorption, cellular transport, and basolateral secretion are subjects of excellent reviews [88–91]. Table 46.4 lists the source and known carriers for the various water-soluble vitamins.

The B vitamin complex

The water-soluble vitamin B complex consists of eight vitamins all involved in cell function and survival. They are thiamine (vitamin B_1 and vitamin F), riboflavin (vitamin B_2 and vitamin G), niacin (vitamin B_3, vitamin P, or vitamin PP), pantothenic acid (vitamin B_5), pyridoxine and pyridoxamine (vitamin B_6), biotin (vitamin B_7, vitamin H, and Vitamin BW), folic acid (vitamin B_9), and cyanocobalamin (CNCbl; vitamin B_{12}). The magnitude of body stores varies for each vitamin; hence, the impact of dietary restriction changes, for example, from 4 to 10 days for thiamine to 3–5 years for vitamin B_{12} [92]. Water-soluble vitamin deficiencies are observed in a number of conditions, such as chronic renal insufficiency patients, in whom peripheral neurological disorders and anemia, documented in the early 1990s, have partly been corrected by vitamin supplements [93,94]. Whereas the small intestine and the pancreas absorb dietary and

TABLE 46.4 Sources and transporters of water-soluble vitamins.

Vitamin	Source	Transporter	Associated genes
Thiamine	Dietary	THTR1/THTR2	*SLC19A2/SLC19A3*
Riboflavin	Dietary	RFVT1/RFVT2	*SLC52A1/SLC52A2*
Niacin	Dietary/microbial	OAT10?	*SLC22A13?*
Pantothenic acid	Dietary/microbial?	SMVT	*SLC5A6*
Pyridoxine/pyridoxamine	Dietary/microbial	?	*?*
Biotin	Dietary/microbial	SMVT	*SLC5A6*
Folic acid	Dietary/microbial	FOLT/PCFT/HCP1/FOLR1	*SLC19A1/SLC46A1*
Cyanocobalamin	Dietary/microbial	Cubam (cubilin/amnionless)	*?*
Choline	Dietary/endogenous	OCT1/CTL?	*SLC22/SLC44?*
Ascorbic acid	Dietary	SVCT1/SVCT2	*SLC23A1/SLC23A2*

Notes: Cubam is composed of two proteins, cubilin (intrinsic factor-cobalamin receptor) and amnionless (amnion-associated transmembrane protein). Cubilin harbors ligand-binding capabilities, while amnionless provides membrane anchorage and potential endocytic capacity.
CTL, Choline transporter; *CVCT1/SVCT2*, specific vitamin C transporter, members 1 and 2; *FOLR1*, folate receptor 1; *FOLT*, folate transporter; *HCP1*, heme carrier protein 1; *OAT*, organic anion transporter; *OCT*, organic cation transporter; *PCFT*, proton-coupled folate transporter; *RFVT1/RFVT2*, riboflavin transporter, members 1 and 2; *SLC*, solute carrier; *SMVT*, Na^+-dependent specific vitamin carrier system; *THTR1/THTR2*, thiamine transporter, members 1 and 2.

supplement water-soluble vitamins, those produced by the microbiota are absorbed in the colon. The mechanisms involved in each process have recently been reviewed [90].

Thiamine

Thiamine, with the IUPAC name of 3-((4-amino-2-methyl-5-pyrimidinyl)methyl)-5-(2-hydroxyethyl)-4-methylthiazolium chloride, is synthesized by bacteria, fungi, and plants. It is present in the rice grain envelope. It is for that reason that, in the late 19th century endemic beriberi, manifesting as cardiovascular disease, central nervous system disorder (Wernicke-Korsakoff encephalopathy syndrome), or peripheral neuropathy, was described in the Dutch Indonesian people who, contrary to the indigenous people, were consuming exclusively polished rice. Interestingly, Chinese medical literature described the symptoms of beriberi as early as of the 10th century [95]. Thiamine plays key roles as a cofactor in several biochemical pathways, such as the respiratory chain in oxidative metabolism, the regulation of carbohydrate metabolic flux through α-ketoglutarate dehydrogenase, a highly regulated enzyme of the Krebs cycle, the biosynthesis of the neurotransmitters acetylcholine (ACh) and γ-aminobutyric acid, and myelin production. Oxidative-dependent organs such as the nervous system and the heart are particularly sensitive to thiamine deficiency that results in mitochondrial uncoupling [96]. Activation of thiamine requires sequential phosphorylation steps to thiamine pyrophosphate (TPP) that accounts for 80% of the thiamine in tissues [97].

Erythrocyte TPP concentration is influenced by a number of physiological (erythrocyte age and alcohol consumption), pathological [diabetes, liver disorders, polyneuritis, uremic neuropathy, gastrointestinal (GI) disorders, and obesity], and iatrogenic factors (drugs used to treat cancer) [98].

Biochemical assessment of thiamine status

Free thiamine is the main form in the circulation, while TPP predominates in the erythrocytes. The method based on the activation coefficient or ratio (α) of erythrocyte transketolase activity without and with added thiamine developed by Vuilleumier et al. [99] has extensively been used to assess vitamin B_1 nutritional status, and is still a valid "bioassay." An ratio of [enzyme activity (with excess coenzyme)]/[basal enzyme activity (without enzyme)] of 1 or a percentage of zero indicate an adequate thiamine status. The greater the thiamine depletion, the higher the ratios and percentages.

The erythrocyte TPP concentration is recognized as being an adequate indicator of body stores, as its depletion closely parallels those of other principal organs [100]. However, the clinical utility of the EKT functional test is weakened by factors other than the thiamine deficiency per se, including altered enzyme kinetics or levels, compounded with standardization issues and sample storage instability [101,102]. Hence, direct determination of RBC TPP is a more sensitive index of thiamine status. Sensitive, specific, precise, and robust HPLC methods for erythrocyte TPP have been developed over the last 30 years with results correlating to the EKT assay [103]. Urine, easy to collect and noninvasive, can also be considered for assessing recent dietary thiamine intake [98]. Tears have also been used to measure thiamine as well as other water- and fat-soluble vitamins by mass spectrometry [104]. Being a minimally invasive

available biological fluid, it is likely that its use could increase in clinical practice. Total thiamine concentration is expected to be within 60−120 μg/L, where 10% is found in plasma and the remaining 90% as the phosphate ester form in erythrocytes and leukocytes [103].

Riboflavin

Riboflavin (7,8-dimethyl-10-ribityl-isoalloxazine), originally extracted from milk whey by the chemist Wynter-Blyth in 1879, plays a pivotal role in the proper functioning of aerobic cells. Flavin adenine dinucleotide (FAD) and flavin mononucleotide (FMN), its active forms, participate in mitochondrial electron transfer processes and in energy production by acting as cofactors for a variety of enzymes, such as glutathione reductase, L-gulonolactone oxidase, xanthine oxidase, L-amino oxidase, and nicotinamide adenine dehydrogenase [105]. Flavins also contribute to oxidative stress by producing superoxide radicals and yet are responsible for the reduction of hydroperoxydes and are linked to cell death programing [106].

Despite their wide distribution in meat, fish, vegetables, and fruits, endemic deficiency defined by biochemical analysis has been documented in different groups [107−109]. While insufficient riboflavin intake results in primary deficiency, anorexia, intestinal malabsorption syndromes, liver diseases, chronic alcoholism, advanced age, use of diuretics, and repeated hospitalization are some of the contributory risk factors for secondary dietary riboflavin deficiency. Of importance, riboflavin deficiency is rarely isolated. While inflamed oral mucosal tissue and dry scaly skin represent the common dermatological deficiency symptoms, sensorimotor peripheral neuropathy is the main neurological manifestation [110]. However, as riboflavin deficiency is rarely isolated, the above signs and symptoms are likely to reflect multiple deficiencies of the vitamin B complex. Indeed, severe riboflavin deficiency alters the conversion of vitamin B_6 to its coenzyme forms and of tryptophan to niacin. Furthermore, riboflavin deficiency can possibly cause hyperhomocysteinemia through an abated methylenetetrahydrofolate reductase (MTHFR) activity, an FAD-dependent enzyme [111].

Biochemical assessment of riboflavin status

Originally, riboflavin nutritional status was assessed using microbiological assays to indirectly measure the amount of the vitamin in different biological fluids (plasma, whole blood, and urine). However, these methods were perceived to reflect recent vitamin intake not the body stores. Hence, the in vitro stimulation of the erythrocyte glutathione reductase with exogenous FAD, expressed as an erythrocyte glutathione reductase activation coefficient, was developed in the early 1970s and is still being used in population surveys [112,113]. However, care in interpreting results should be applied, as a lack of standardization has been reported, leading to misleading evaluation of riboflavin deficiency in some populations [114]. Care must also be applied before transposing data obtained from a presumably healthy population to subjects with pathologies. Since erythrocyte glutathione reductase activity depends on the cellular FAD concentration, it follows that the direct measurement of FAD in red cells would be a reliable biomarker for a longitudinal assessment of the riboflavin nutritional status, as shown by Hustad et al. [115]. Riboflavin status may also be assessed by measuring urinary excretion of the vitamin in either a random specimen or 24-hour collection, particularly in replete individuals, as it is not a sensitive marker at low vitamin intakes [105,116]. Moreover, there is a call for caution, as there are few data on the effect of kidney malfunction on water-soluble vitamins.

A number of methods for measuring plasma, whole blood and urine riboflavin, FMN, and FAD based on HPLC coupled to fluorometric detection or tandem mass-spectrometry have been published [117−119]. None, however, are based on international reference material as standard, thereby weakening the transferability of results between laboratories and methods. Petteys and Frank [119] using an HPLC−UV method reported a range of riboflavin values in plasma from 6.7 to 50.1 nM.

Niacin

Association of niacin deficiency, referring collectively to nicotinic acid (pyridine-3-carboxylic acid) and its nicotinamide derivative, to pellagra became apparent by the mid-20th century, in populations consuming low-quality protein corn-based diets. The explanation lies in that the preformed nicotinic acid, present in corn, is tightly bound to a protein, preventing its absorption by the small intestine [120]. The classical symptoms of pellagra include sun-sensitive dermatitis, diarrhea, neurological disorders, accompanied by anxiety, insomnia, disorientation, hallucinations, and delirium [121]. Niacin is peculiar among the "vitamin B complex," as it can be obtained with poor efficiency through the conversion of tryptophan, an indispensable amino acid and precursor of serotonin [122]. This process requires multiple factors (pyridoxine, riboflavin, iron, and copper). Hence, conditions in which conversion of tryptophan to nicotinic acid is impaired, such as in isoniazid treatment for tuberculosis that depletes pyridoxine and pyridoxamine stores, or malignant carcinoid syndrome in which tryptophan is preferentially converted to serotonin, or still in Hartnup's syndrome in which tryptophan absorption is impaired, may all lead to niacin

deficiency. Niacin deficiency is also associated with Crohn's disease and chronic alcoholism [123].

Nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP) are the major active components of niacin, acting both as cofactors for multiple enzymes involved in redox reactions and energy metabolism and as substrates for poly (ADP-ribosylation) of nuclear proteins. In addition to its action as a vitamin, nicotinic acid (rather than nicotinamide) at pharmacologic doses lowers total cholesterol, LDL-cholesterol, triglyceride, and lipoprotein(a) concentrations, while raising HDL-cholesterol concentrations. These effects, however, have a downside, such as skin flushing, GI distress, hepatotoxicity, gout, and decreased insulin sensitivity [124,125].

Biochemical assessment of niacin status

Early assessment of niacin status involved the determination of the urinary metabolites *N*-methyl-2-pyridone-5-carboxamide and *N*-methylnicotinamide and expressing them as a ratio, the *N*-methyl-2-pyridone metabolite being more sensitive to a low dietary intake than the *N*-methylnicotinamide. In this context, a ratio of <1.0 is indicative of niacin deficiency [126]. It was later demonstrated that the RBC NAD pool decreased rapidly during niacin deficiency, whereas the NADP pool was quite stable. This led Jacobson et al. [127] to suggest NAD/NADP, referred to as the niacin number, as an index of niacin deficiency in humans. Methods for measuring nicotinic acid and its metabolites have evolved with time from the microbiological bioassay using *Leuconostoc mesenteroides*, an obligate user of nicotinic acid [128]. A few years later Huff and Perlzweig [129] developed a sensitive fluorometric assay for *N*′-methylnicotinamide based on its condensation with either acetone or acetophenone, thus producing a fluorescent adduct. HPLC coupled to UV detection [130] or mass spectrometry [131] and electron-capture negative-ion gas chromatography–mass spectrometry [132] have replaced these time-consuming methods with the advantage of being able to provide a metabolic profile of the niacin derivatives. According to the Mayo Clinic, normal ranges for niacin range from 0.50 to 8.91 mg/L [133].

Pantothenic acid

Pantothenic acid, consisting of pantoic acid linked to β-alanine through an amide linkage, is inactive as such. It must be sequentially metabolized to pantothenic acid-4′-phosphate, whose condensation with a cysteine moiety in an ATP-dependent reaction forms 4′-phosphopantothenoylcysteine. Following a decarboxylation and addition of adenosine 5′-monophosphate to 4′-phosphopantetheine, followed by phosphorylation of the ribose 3′-hydroxyl, the active form of the vitamin is produced: coenzyme A (CoA) [134], acting as an acyl carrier for a variety of enzymes involved in lipid synthesis and intermediate metabolism [135].

In humans, pantothenic acid supply depends on the diet and the colonic microflora. Dietary pantothenic acid consists mainly of CoA, from which it has to be hydrolyzed prior to a sodium-dependent multivitamin transporter (SMVT)-mediated absorption in the ileum and the colon [88,136]. Clinically, overt pantothenic acid deficiency has been observed experimentally in individuals fed a low pantothenic acid diet virtually devoid of pantothenic acid. The subjects exhibited varying degrees of irritability, low blood pressure, fatigue; apathy; malaise; sleep disturbances; nausea, vomiting, and abdominal cramps; and numbness, paresthesia, muscle cramps, and staggering gait [137]. Inadequacy of vitamins and minerals, including pantothenic acid, based on food recall diaries, has recently been reported among Moroccan high-school pupils. However, no clinical data were recorded [138].

Biochemical assessment of pantothenic acid status

Reports on the assessment of pantothenic acid nutritional status in humans are scarce and are often related to clinical trials or epidemiological nutritional studies rather than to clinical settings. Pantothenic acid nutritional status is best reflected by whole blood or erythrocyte concentrations, although urine concentration is also highly correlated with dietary intake [87]. It must be borne in mind that pantothenic acid, in cells containing mitochondria, is present mostly as CoA [135]. Therefore an enzymatic digestion is required if total pantothenic acid was to be measured. On the contrary, mature RBC, plasma, and urine pantothenic acid are essentially in the free form. The first record of a microbiological assay for blood and urine pantothenic acid dates back to 1962 [139]. Guilarte [140] later developed a radiometric microbiological assay based on the measurement of $^{14}CO_2$ generated from the metabolism of a ^{14}C-labeled pantothenic acid by yeast *Kloeckeru brevis* in proportion to the amount of vitamin present. This microorganism has an absolute requirement for pantothenic acid for its growth.

Wyse et al. [141] described a radioimmunoassay based on a rabbit polyclonal antibody against pantothenic acid–bovine serum albumin conjugate. The assay demonstrated good specificity, but only moderate correlation with Hatano's microbiological assay, referred to above. It was later used to assess the pantothenic acid nutritional status of a small group of adolescents [142]. More recently,

Takahashi et al. [143] described a rapid, accurate, and precise isocratic reversed-phase ion-pair HPLC method coupled to postcolumn derivatization for the determination of pantothenic acid in human urine. This method was successfully applied for the assessment of the pantothenic acid nutritional status of a group of Japanese pregnant women [144]. Methods using gas chromatography coupled to mass fragmentation of trimethylsilyl derivatives and multiple ion detections have also been published [145,146]. Rychlik [147], on his part, developed a gas chromatography−stable-isotope dilution−mass spectrometry method for quantification of total and free pantothenic acid trimethylsilyl derivatives in food and plasma. These methods being time-consuming and labor-intensive may, however, not be applicable for routine testing in clinical laboratories. There are no reports on the measurement of pantothenic acid in biological samples by HPLC−tandem mass spectrometry, although methods have been developed for its measurement in food and supplements [148,149]. Adaptation of this approach to plasma and urine is an attractive alternative to the other methods, as it would require less intensive sample preparation. Wittwer et al. [150] reported a normal range from 1.57 to 2.66 μmol/L for whole blood pantothenic acid.

Vitamin B_6 (pyridoxine, pyridoxamine, and pyridoxal)

3-Hydroxy-2-methylpyridine is the cyclical core of all B_6 vitamers: pyridoxine, pyridoxamine, pyridoxal, and their phosphorylated counterparts: pyridoxine-5′-phosphate, pyridoxal-5′-phosphate (PLP), pyridoxamine-5′-phosphate, and 4-pyridoxic acid (4-PA). The coenzyme form of vitamin B_6, PLP, is found covalently bound to enzymes through a Schiff base with a specific ε-aminolysine group (close to or within the active site) [151,152]. PLP is the principal active cofactor for amino acid transferases, decarboxylases, and dehydratases. In addition, it is involved in heme biosynthesis through the δ-aminolevulinate synthase, glycogenolysis through the phosphorylase, brain glutamate metabolism, and sphingoid base biosynthesis. Leklem [153] and Chawla and Kvarnberg [154] have extensively reviewed its natural sources, metabolism, absorption mechanisms, and multiple roles in metabolic processes.

As a summary, in view of its central role in numerous biological functions, deficiency in vitamin B_6 usually occurs in combination with the other B vitamins. Restricted intake (particularly infants and the elderly), intestinal malabsorption conditions, such as celiac disease, Crohn's disease, and ulcerative colitis, and chronic alcoholism are the most frequent reasons for its deficiency. Chronic renal insufficiency, hemodialysis, liver disease, sickle cell anemia, rheumatoid arthritis, hyperoxaluria types I and II, and certain types of medications (interference with its bioavailability) are also risk factors for pyridoxine deficiency. Riboflavin deficiency also negatively impacts vitamin B_6 status, since the conversion of pyridoxamine-5′-phosphate and pyridoxine-5′-phosphate to PLP necessitates the FMN-requiring oxidase [155]. PLP deficiency may include cardiovascular, neurologic, GI, dermatologic, and immunological disorders. The cardiovascular risk link can be explained by the fact that PLP is a central cofactor in the one-carbon metabolic pathway and is a coenzyme for cystathionine β-synthase and cystathionine γ-lyase in the transsulfuration pathway [156], thus a deficiency state could impair homocysteine turnover, leading to hyperhomocysteinemia, which is recognized as an independent risk factor for reversible coronary heart disease [157]. Toxicity symptoms related to pyridoxine are rarely reported. They occur upon long-term ingestion of large doses of pyridoxine, and usually consist of motor and peripheral sensory neuropathy, unsteady gait, and photosensitivity expressed as vesicular dermatosis upon sun exposure [153].

Biochemical assessment of vitamin B_6 status

A variety of direct, indirect, and dietary methods have been developed to assess vitamin B_6 nutritional status in humans. Direct indices define those in which one or more of the vitamin B_6 metabolites are measured in plasma, erythrocytes, or urine samples. Indirect methods refer to those requiring measurement of PLP-dependent enzyme activities in biological fluids, usually plasma in the presence and absence of excess PLP. Dietary methods must be interpreted with caution, as they are the least reliable because of the inherent problems in obtaining accurate dietary recalls.

Keeping clinical laboratories in mind, direct methods should be prioritized and circulating PLP concentration is to be considered. Alternatively, 24-hour collection or spot sample urinary 4-PA can also be a useful biomarker. However, these indices are to be interpreted in the proper context; dietary intake of vitamin B_6 and protein, and physiological and pathological variables influence the fasting plasma PLP concentration and urine 4-PA [158−161]. Other indices include the measurement of urinary xanthurenic acid excretion following a tryptophan load test, most useful for monitoring an individual's response to pyridoxine supplementation, and the indirect erythrocyte aspartate aminotransferase activity coefficients (ratio of stimulated/basal activity), and plasma homocysteine [162]. Recently published methods for measuring PLP and 4-PA are based on HPLC coupled to fluorescence detection or mass spectrometry.

Different microbiological and enzymatic methods have been described for the measurement of plasma PLP [163,164]. More recently, HPLC-based methods with fluorescence detection are preferred. However, these methods classically required derivatization of PLP to enhance the fluorescence signal. Cabo et al. [165] recently published an HPLC method without postcolumn derivatization, coupled to a fluorescence detector for the measurement of plasma or serum PLP and 4-PA after precipitation of proteins with trichloroacetic acid. The authors reported a 100% recovery and interassay coefficient of variations of $\leq 6\%$ for both compounds. The development of user-friendly tandem mass spectrometers, coupled to HPLC systems, enables clinical laboratories to use this technology. van Zelst and de Jonge [166] have developed a high-throughput method using this technology. Its advantages are the short chromatography runtime, the high sensitivity and specificity, and the wide concentration spectrum. In this study, reported values ranged from 35 to 110 mM using 120 whole blood samples.

Biotin

Biotin, playing an essential role in the expression of genes involved in intermediate metabolism immune function and cell proliferation [167,168], is required by all classes of living organisms. Biotin (IUPAC name: 5-[(3a*S*,4*S*,6a*R*)-2-oxohexahydro-1*H*-thieno[3,4-*d*]imidazol-4-yl]pentanoic acid) is composed of a tetrahydroimidizalone ring fused with a tetrahydrothiophene ring in a boat conformation with a valeric acid attached to carbon 4 of the tetrahydrothiophene ring. Prior to the Goldberg−Sternbach stereospecific synthesis pathway [169], the chemical synthesis of biotin yields eight enantiomers. Of these, only one designated **d**-(+)-biotin is enzymatically active. Humans, like other mammalians, cannot synthesize biotin and thus must obtain it from exogenous sources. As for a number of other water-soluble vitamins, two sources of biotin are available: a dietary source, biotin being widely distributed in foods; and the normal microflora present in the colon. Dietary protein-bound biotin, converted by GI proteases, peptidases, and biotinidase to free biotin [90,170], is absorbed in the small and large intestines through a saturable and Na^+-dependent carrier-mediated process, exclusively expressed at the apical membrane of enterocytes, that is shared with pantothenic acid and lipoic acid [88]. The human intestinal biotin uptake process is adaptively upregulated in biotin deficiency via transcriptionally mediated mechanisms that involve Kruppel-like factor 4 sites [170].

Biotin is a coenzyme for at least six biotin-dependent carboxylases, two decarboxylases, and one transcarboxylase that include pyruvate carboxylase, methylcrotonyl-CoA carboxylase, propionyl-CoA carboxylase, and acetyl-CoA carboxylase [171]. Biotin is conjugated to these apoenzymes through the action of the enzyme holocarboxylase synthetase, driven by the transfer of the adenylate portion of ATP, with the formation of biotinyl-5′-adenylate and pyrophosphate that is immediately hydrolyzed by pyrophosphatase [168]. Dietary deficiency is rare; however, it can occur in individuals chronically consuming raw egg whites that contain avidin, a high-affinity biotin-binding protein, patients on total parenteral nutrition given formulas without biotin, and in inborn errors of metabolism causing multiple carboxylase deficiencies or biotinidase deficiency. Biotin deficiency includes organic aciduria associated with neurologic abnormalities comprising developmental delay in infants, hypotonia, impaired consciousness, seizures, ataxia, depression, and cutaneous lesions (rash and alopecia) [168,172,173]. However, the clinical presentation and age of onset of symptoms are variable.

Biochemical assessment of vitamin biotin status

Traditional methods of quantifying biotin in biological fluids include microbiological assays and bioassay, and have already been reviewed [173,174]. Other methods depend on competitive binding assays of biotin to either avidin or streptavidin after a prior purification of biotin and its metabolites by HPLC [175]. Circulating biotin (serum or plasma) has also been proposed as an index of the biotin status. However, it proved not to be a predictable biomarker, because biotin deficiency was not always reflected by low circulating biotin [174]. More recently, quantification of urinary 3-hydroxyisovaleric acid (3-HIA), an intermediate that accumulates and is excreted upon decreased methylcrotonyl-CoA carboxylase activity during biotin deficiency, has furthered the advancement of the assessment of biotin status in the early process of biotin deficiency [176,177].

Different methods have been developed to measure urinary 3-HIA and related compounds, including gas chromatography−mass spectrometry analysis after di-trimethylsilyl derivatization [178], reversed-phase HPLC and UV detection at 230 nm of the 2-nitrophenylhydrazine derivative [179], and ultrahigh-performance liquid chromatography−tandem mass spectrometry (UPLC−MS/MS) [177]. Urinary biotin average values of 0.74 and 0.52 nM biotin/μM creatinine were reported by Eng et al. [176] using avidin-binding assay for biotin sufficient and biotin insufficient, respectively.

Folic acid

Folic acid is a collective term designating pteroylglutamic acids and their oligoglutamic acid conjugates: *N*-[p-[[(2-amino-4-hydroxypteridin-6-yl)methyl]amino]benzoyl]-L

(+)-(n)-glutamic acid. Commonly, the number of glutamic acid residues varies between 3 and 7. It is an important cofactor, which, together with vitamin B_{12}, plays a key role in the utilization of methyl groups, essential in cell division and multiple metabolic reactions [180]. Furthermore, folic acid is involved in DNA biosynthesis, and hence participates in the regulation of gene expression and transcription, chromatin structure, and genomic stability [181]. In the one-carbon cycle, MTHFR catalyzes the reduction of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate, the main circulating form of folate. Transference of the 5-methyltetrahydrofolate methyl group to homocysteine, mediated by methionine synthase, yields methionine to which an adenosyl residue is added to form S-adenosylmethionine, a universal methyl donor [180].

In addition to folate, the metabolism of homocysteine and methionine requires vitamin B_{12}, vitamin B_6, and vitamin B_2 as cofactors for the numerous enzyme reactions. Adequate supply of these vitamins and fully operational enzymes assure normal homocysteine levels. Elevated circulating homocysteine concentration is an independent risk factor for cardiovascular disease and colorectal cancer [182]. Delvin et al. [183] have shown that plasma homocysteine concentration correlates negatively with folate and vitamin B_{12} concentrations and that MTHFR genotype plays a significant role in determining homocysteine concentrations, particularly in nutritionally stressed children older than 10 years. The mechanisms of folate absorption, metabolism, and excretion have already been reviewed [87]. In brief, dietary folate polyglutamates are hydrolyzed in the gut by a γ-glutamyl hydrolase to a monoglutamate form before being actively transported across the proximal small intestine by a saturable pH-dependent process. A nonsaturable passive diffusion takes over when pharmacological doses of folate monoglutamate are consumed. The liver, where it is metabolized to polyglutamate derivatives and retained or released into the blood or bile, takes much of the folate present in the portal circulation. Approximately, two-thirds of the folate in plasma is protein-bound, with albumin accounting for 50% of protein binding. Cellular transport of folate is mediated by membrane carriers and folate-binding proteins. Before being stored in tissue or used as a coenzyme in single-carbon transfer reactions, folate monoglutamate must be converted to the polyglutamate form and reduced enzymatically. When released from tissues into circulation, it is reconverted to the monoglutamate form [180].

Megaloblastic anemia, defined by RBC macrocytosis and abnormal nuclear maturation, is a cardinal feature of folate deficiency and is indistinguishable from that caused by vitamin B_{12} deficiency, since the two vitamins are substrates or cofactors for the methionine synthase reaction and other pathways, leading to DNA precursor synthesis. Discrimination between the two is crucial for an effective treatment. Although folate deficiency symptoms are usually due to a dietary insufficiency, chronic excessive alcohol consumption, malabsorption syndromes, or iatrogenic causes must be considered in the clinical workup. Also, an increased requirement may be due to genetic variation including women who require increased folate in early pregnancy to reduce the risk of neural tube defects [184]. The fortification of cereal and grain products, required in the United States since 1998, resulted in a documented rise in the serum and RBC folate levels, and successfully decreased the incidence of neural tube defects in neonates and of megaloblastic anemia. Widespread food fortification, and the between-laboratory and intermethod analytical variations question the clinical utility of folate measurements to detect folate deficiency. Gilfix, examining the literature, revealed that, in clinical situations, in general, $<1\%$ of the subjects will have folate deficiency regardless of the assay method used and of potentially predisposing factors [185].

Biochemical assessment of vitamin folate status

Assessment of folate falls into two categories: short- and long-term nutritional statuses. Whereas plasma folate (essentially monoglutamate) relates the recent intake, RBC polyglutamate, however, reflects the average content of the circulating red cell population, and thus could be considered the "glycated hemoglobin" equivalent to diabetes monitoring. Caution should be exercised in interpreting results in the presence of abnormal hemoglobin with shorter half-life, such as in sickle cell anemia. As for plasma folate, adequately spaced serial plasma measurements are needed to allow the distinction between acute and chronic folic acid deficiencies. Whereas a single plasma folate measurement is not reliable in a nutrition intervention, particularly short term, it, however, provides a fitting assessment in population surveys. Plasma folate consists almost entirely of 5-methyltetrahydrofolate (5-methyl-THF), and RBC of long-chain polyglutamates of 5-methyl-THF. Microbiological assays, classified as "functional assays" using *Lactobacillus casei*, were used first to assess folate status and served to establish the present-day reference values and cutoffs, defining the deficiency status. Methods based on HPLC coupled to electrochemical detection have also been developed [186] and have been used in clinical settings. However, due to their relative simplicity of use, assays, using high-affinity folate-binding proteins to compete with endogenous and labeled folic acid (or methyltetrahydrofolate), and using either radioactive, enzyme-linked, or chemiluminescent detection systems, have gradually supplanted microbiological assays in clinical laboratories [187].

The question raised by Yetley and Johnson [188] as to whether differences in folate concentrations observed from one study to another are due to population changes or are methodology artifacts has been answered by Colapinto et al. [189] who have shown that the difference between the Canadian and American RBC folate concentrations was assay method-dependent. An interlaboratory "round robin" comparison study published in 1996 that included 20 participants revealed, for serum and whole blood, overall within-method coefficients of variation of 27.6% and 35.7%, respectively, and two- to ninefold differences in concentrations between methods, with the greatest variation occurring at critical low folate concentrations [190]. These studies clearly show the need for harmonization, and preferably standardization of the assay methods against an international reference method traceable to the SRM 1955 developed by NIST [191]. As a number of such methods, based on HPLC or UPLC−MS/MS, have been published in the last 10 years [192−194], a second "round robin" study would be timely. Also, worthy of note, the preanalytical conservation protocols are crucial, since delayed processing and freezing of the plasma samples result in clinically unacceptable folate losses [195,196]. Fazili et al. [193] reported a range of total folic acid (including five folate vitamers) ranging from 10 to 100 nM in serum, where average folic acid levels were 2 nM.

Vitamin B_{12}

As already mentioned, vitamin B_{12} and folic acid have common metabolic pathways that define the size of the methyl donor pool utilized in multiple metabolic pathways. Vitamin B_{12} in its natural form is present only in foods of animal origin, explaining why its deficiency is more common among strict vegetarians and populations consuming little animal food. Detailing the chemistry pathways and the physiology of vitamin B_{12} is beyond the scope of this chapter; more detailed reviews can be consulted [197−199].

The generic term cobalamin (vitamin B_{12}) refers to structures, named corrin, consisting of one central cobalt (Co) atom coordinated with four equatorial nitrogen atoms donated by pyrrole residues. The fifth Co coordination site (α), below the planar structure, is occupied by a 5′, 6′-dimethyl benzimidazole residue linked to an α-ribosyl-3-phosphate. The sixth Co coordination site (β), above the corrin ring, is occupied either by a methyl [methylcobalamin (MeCbl)], 5′-deoxyadenosyl [5′-deoxyadenosylcobalamin (AdoCbl)], or a cyanide group (CNCbl) that has no biological activity. MeCbl is the cofactor of several methyltransferases, such as methionine synthase, which catalyzes the conversion of homocysteine to methionine; AdoCbl is the cofactor of enzymes such as L-methylmalonyl-CoA mutase that catalyzes the reversible isomerization of L-methylmalonate into the succinate.

Cobalamin synthesis is a complex process restricted to certain strains of bacteria, such as *Lactobacillus rossiae* and *Lactobacillus reuteri*, which, present in the human gut microbiota, are sources of the vitamin [200,201]. Red meat is another source of cobalamin, accounting for 20%−40% of the dietary intake [202]. Paradoxically, epidemiological studies recommend a limited consumption of red meat to reduce risk of obesity, cancer, and other chronic diseases, as they contain a fair content of saturated fat. To circumvent the health risk, the consumption of lean red meat has been proposed as a healthy alternative because of its low saturated fat content [203]. After intestinal uptake, cobalamin circulates in the bloodstream bound to two carriers: 20% to one of three transcobalamins (TCs I, II, and III) named holotranscobalamin (holoTC), and the remainder to the metabolically inert haptocorrin [199]. Holo II is the form that has biological function allowing the delivery of the vitamin to the target cells. Having a short serum half-life, it is accepted as being the earliest indicator of negative vitamin B_{12} balance, its concentration falling before serum total vitamin B_{12}.

Following ingestion, the release of vitamin B_{12} from food is dependent upon stomach acidity, explaining in part the higher prevalence of vitamin B_{12} deficiency in the elderly population. Other conditions such as intestinal malabsorption, postgastric/intestinal surgery, or the loss of the distal ileum can also contribute to vitamin B_{12} deficiency. Since vitamin B_{12} absorption is dependent on binding to the protein intrinsic factor (IF) in the small intestine, its absence leads to malabsorption and pernicious anemia [199]. Megaloblastic anemia is the prevalent effect of vitamin B_{12} (and folate) deficiency, followed by neurological effects that include tingling and numbness, abnormalities in walking, and cognitive changes ranging from simple memory loss to severe dementia [204]. Decreased energy, shortness of breath, loss of appetite, constipation, glossitis, and papillary atrophy of the tongue are also associated with vitamin B_{12} deficiency.

Biochemical assessment of vitamin B_{12} status

No single test adequately allows the diagnosis of vitamin B_{12} deficiency. The Schilling test was the first to be described to measure vitamin B_{12} absorption. However, the administration of radioactively labeled cobalamin that is needed to follow the vitamin in the circulation and in the urine has limited its use in recent years. Present-day biochemical tests used to assess vitamin B_{12} status include serum total vitamin B_{12}, TC II, and methylmalonic acid (MMA). Despite its low sensitivity and specificity, serum vitamin B_{12} is the first-line test when vitamin

B_{12} deficiency is suspected. As for other vitamins, serum vitamin B_{12} was initially measured by microbiological methods using, for example, *Lactobacillus leichmannii*, for which cobalamin is an obligate nutrient. These methods, being functional assays, had the advantage of measuring the biologically active cobalamin fraction, and hence were more accurate. They, however, suffered from interlaboratory variability, interference by antibiotics, and extended turnaround time inherent to the assay principle [205]. The microbiological assays were gradually replaced by nonspecific R-protein-binding assays. However, the values obtained with these were markedly higher than those obtained with the microbiological functional assay, as they measured cobalamin analogs that are not biologically active [206]. This problem has been resolved by the introduction of IF-based radioassays that compared well with the microbiological assays [207]. The development of immunochemistry analyzers led clinical laboratories to opt for high-throughput automated competitive binding chemiluminescence assays, using purified IF as reagent, that measure total cobalamin after its release from the endogenous binding proteins. Some caution should be observed, however, in interpreting results, as reports have shown that some of these assays are vulnerable to the presence of interfering anti-IF antibodies, particularly in patients with pernicious anemia, thereby providing spuriously elevated serum cobalamin concentrations in otherwise vitamin B_{12}-deficient patients [208,209].

The long-standing lack of standardization against internationally accepted reference materials for serum vitamin B_{12} measurements has led to intermethodology variability that complicates interstudy comparisons. The World Health Organization Expert Committee on Biological Standardization established, in 1992, a first international standard for serum vitamin B_{12} (coded 81/563) that was assayed using a variety of methods [210]. Also, the NIST is currently developing an isotope dilution−liquid chromatography−tandem mass spectrometric (ID−LC−MS/MS) method for vitamin B_{12} (and vitamin B_6), to validate the standard reference material SRM 3951, consisting of three levels of vitamin B_{12} spanning the range usually found in patient samples. This initiative will improve the accuracy of marketed routine cobalamin tests and reduce differences in laboratory proficiency [211]. Aside from the analytical dilemma, cutoffs are customarily derived from reference intervals obtained from different groups, representative or not of a specific population, and as these are method- and population-dependent, it follows that characterizing cobalamin status remains challenging. This is of public health interest, as the prevalence of "cobalamin deficiency" will vary with different cutoff points. Bailey et al. [212] proved the point by reporting that, in NHANES surveys, the prevalence of cobalamin deficiency ranged from 2.9% at a cutoff of <148 pmol/L to 25.7% at <258 pmol/L.

HoloTC II, the biologically active form of vitamin B_{12}, has been proposed as a replacement of total cobalamin. A high-throughput automated two-step sandwich microparticle enzyme immunoassay allows its measurement in clinical settings [213]. However, its clinical utility has been challenged in a thorough review reporting a marginally better receiver operating curve analysis when MMA, a functional indicator of vitamin B_{12} status, is taken as reference [214]. The problem is compounded by the variable MMA cutoff points accepted as indicative of vitamin B_{12} deficiency [215]. The same argument holds for total cobalamin, and, in both cases, the variable cutoffs led to a wide variation in the prevalence of vitamin B_{12} deficiency. Recently, Bailey et al. [216] modeled the relationship between the serum vitamin B_{12} and MMA concentrations. Fig. 46.4 shows that the cutoff for vitamin B_{12} deficiency is at ≈ 120 pmol/L.

Plasma homocysteine has also been proposed as a functional indicator for vitamin B_{12} and folate status, although its sensitivity is questioned [214]. As it can be appreciated, any biomarker has its own limitation, and none qualifies as a single diagnostic standard. Hence, a combination of biomarkers is needed to delineate vitamin B_{12} nutritional status, and an evaluation of algorithms is needed to circumscribe this issue. According to the NIH MedlinePlus [217], the expected reference intervals for vitamin B_{12} range between 200 and 900 ng/L, values that Bailey et al. [212] argued could lead to significant misclassifications.

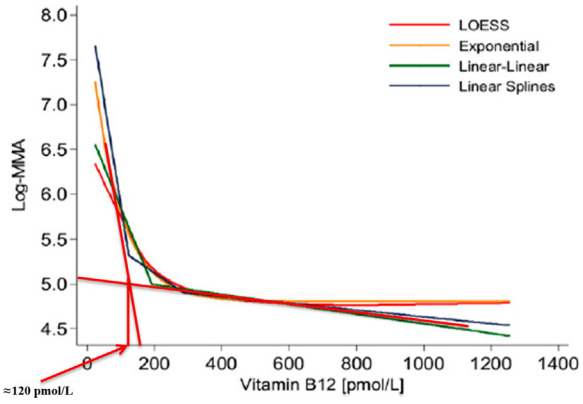

FIGURE 46.4 Relationship between serum methylmalonic acid and vitamin B_{12} concentrations. Loess, exponential, linear−linear, and linear−spline models of the relation between serum vitamin B_{12} and log-methylmalonic acid concentrations among US adults aged >19 years, 1999−2004. Tangent lines were hand free drawn. The intercept and projection lines to the *x*-axis give a threshold estimate for vitamin B_{12} deficiency of 120 pmol/L. *Adapted with permission from R.L. Bailey, R.A. Durazo-Arvizu, R. Carmel, R. Green, C.M. Pfeiffer, C.T. Sempos, et al., Modeling a methylmalonic acid-derived change point for serum vitamin B-12 for adults in NHANES, Am. J. Clin. Nutr. 98 (2) (2013) 460−467.*

Choline

Although described in the late 19th century, choline was officially recognized as an essential micronutrient for humans in 1998 when the Food and Nutrition Board of the United States of America Institute of Medicine of the National Academy of Sciences issued guidelines on its daily intake [218]. Choline (trimethyl-beta-hydroxyethylammonium) is widely distributed in plants and animals. Choline is essential for the synthesis of methionine and carnitine and ACh, and is a building block of phosphatidylcholine and sphingomyelin, important elements of cell membranes. As a methyl donor choline is the third member of the triumvirate that includes folic acid and vitamin B_{12} involved in epigenetic gene regulation through DNA and histone methylation [219]. In terms of bioavailability, choline can be obtained endogenously through de novo synthesis, although this pathway is not sufficient to sustain an adequate supply [218]. Water-soluble choline, phosphocholine, and glycerophosphocholine are absorbed via the portal circulation, and the widely food-distributed lipid-soluble phosphatidylcholine and sphingomyelin are absorbed into lymph as chylomicrons. Although most individuals have adequate choline intake, pregnant and lactating women, infants, cirrhotic and anorexic patients, and those on parenteral nutrition are at higher risk of deficiency. Choline deficiency has been associated with nonalcoholic fatty liver disease and muscle dysfunction [220]. Excessive choline intake from food has been associated with body odor, sweating, salivation, hypotension, and hepatotoxicity in humans [218].

Biochemical assessment of choline status

Although methods for measuring free and phospholipid-bound choline are available, requests for choline measurement addressed to clinical laboratories are infrequent. The first radiolabelling labor-intensive method for measuring free choline developed by Wang and Haubrich [221] from the Squibb Institute was rapidly replaced by nonisotopic methods. Takayama et al. [222] published an enzymatic method to measure choline-containing phospholipids that was used once to assess serum-free choline and phospholipid-bound choline concentrations in pregnancy and in newborns [223]. Other methods described were based on micropyrolysis gas chromatography [224], and more recently on stable-isotope dilution–ultraperformance liquid chromatography–mass spectrometry (UPLC–MS/MS), which allows a metabolic profiling by simultaneous quantifying ACh, betaine, choline, and dimethylglycine [225]. Although sensitive, precise, and rapid, the use of these methods has so far been limited in clinical investigation. However, the development of increasingly user-friendly mass spectrometers will allow application of these methods for clinical evaluation. This is of importance, since high frequency of inadequate choline intake has recently been reported in pregnant women enrolled in the Programming of Intergenerational Stress Mechanisms study [226]. Kirsch et al. [225] reported plasma choline values of 6.99–12.35 μM and 1.14–4.7 mM choline/mol creatinine in urine in 54 adults of >50 years.

Vitamin C

The biosynthetic pathway of vitamin C (ascorbic acid) differs in plants and fungi from mammals. In the first group, it is initiated from mannose and in the second from glucose. Both pathways, however, need the oxidation of L-gulonolactone by L-gulonolactone oxidase, which is not functional in primates, including the human species [227,228]. Vitamin C is involved in biological systems as varied as neurotransmission, peptide hormone synthesis and secretion, and extracellular matrix integrity. It is an obligate cofactor for dopamine beta-hydroxylase that catalyzes norepinephrine synthesis, and of peptidylglycine amidating monooxygenase that catalyzes the conversion of proenkephalin to metenkephalin in chromaffin vesicles. It is also an essential actor in collagen fibril maturation, through the hydroxylation of lysine and proline residues required for collagen chain and fibril crosslinking in a variety of connective tissues. It also acts as a cofactor for nucleic acid and histone demethylation, proteoglycan deglycanation, and acts as both a prooxidant and an antioxidant [229].

Scurvy is the hallmark of severe and prolonged vitamin C deficiency, of which the, first “Modern” description, is attributed to Lind in his treatise published in 1753 [230], leading to supplementation through lime consumption. Despite its early recognition, scurvy remained a problem for explorers into the beginning of the 20th century. While frank scurvy, characterized by subcutaneous and intramuscular hemorrhages, leg edema, neuropathy, and cerebral hemorrhage, is uncommon in industrialized countries, vitamin C insufficiency may be more prevalent than generally assumed despite the widespread availability of vitamins. A UK Low Income Diet and Nutrition Survey based on a representative sample of the low-income population estimated that 25% of men and 16% of women had plasma vitamin C concentrations indicative of deficiency [231]. Persons with excessive alcohol consumption, those consuming diets containing little or no fruits and vegetables, who present with skin rashes and oral lesions, and complain of muscle weakness and pain are likely to be vitamin C-deficient [230]. The symptoms associated with scurvy are explained by the central role that ascorbic acid plays in the numerous biological systems mentioned earlier.

Early reports have associated long-term vitamin C megadose treatment with nephrolithiasis (oxaluria), diarrhea, nausea, dental erosion, and hemolysis in the presence of glucose-6-phosphate dehydrogenase deficiency, an X-linked enzymopathy [232,233]. However, other reports and pharmacokinetic studies challenge these observations [234]. Finally, as pointed out by Lucock et al. [235], the possible synergetic interaction between dietary ascorbic acid and folate should not be overlooked when large doses of vitamins are administered. Cigarette smoking, oral contraceptive, and chronic aspirin use, as well as age, gender, pregnancy, and infection, all influence circulating ascorbic acid concentration and tissue stores [236].

Biochemical assessment of vitamin C status

Vitamin C nutritional assessment is most frequently based on the measure of serum and urine (preferably 24-hour collection) ascorbic acid concentrations. Fasting conditions are essential, because foods are commonly supplemented with the ascorbate epimer erythorbic acid, which is not antiscorbutic. Serum and urine ascorbic acid concentrations reflect the most recent intake of vitamin C, which for leukocytes correlates well with tissue stores. However, white blood cells, as well as erythrocytes, whole blood, saliva, and oral cavity ascorbic acid contents, are used essentially in research protocols, these assays being more complex and time-consuming [236]. Stable isotope-labeled ascorbic acid (^{13}C) dilution has been shown to be useful for the measurement of vitamin C absorption and body pool size in human subjects [237] but is of little use in clinical settings.

Vitamin C can be measured by a variety of methods, including spectrophotometry, colorimetry, capillary electrophoresis, and microdialysis. Independently of the method, preanalytical precautions are, however, paramount for reliable results. Ascorbic acid measurement in biological samples is highly dependent on the type of sampling method (EDTA versus heparin vacuum tubes), rapidity of processing (immediate centrifugation and plasma acidification), storage conditions, and length of time (avoiding light, $-70^{\circ}C$ without delay, and <80 days) [238,239]. After 1980, the use of HPLC-based assays followed by UV, fluorescence, or electrochemical detection became the standard, improving analytical specificity and sensitivity [240–242]. Fluorescence detection offers higher sensitivity but requires postcolumn derivatization with a fluorophore (O-phenylenediamine). Electrochemical detection is thought to provide the best measurement, because it differentiates between ascorbic acid and Derythorbic acid when nonfasting samples are inadvertently used [243]. Jansen and Ruskovska [73] reported plasma vitamin C reference intervals ranging between 4.1 and 20 mg/L.

Self-assessment questions

1. Which of the following are lipid-soluble vitamins? 1) vitamin A; 2) vitamin B12; 3) vitamin D; 4) folate; and 5) vitamin K.
a. 1, 2, 4, 5
b. 1, 3, 5,
c. 2, 3, 4, 5
d. 1, 3, 5
e. All

2. Which statements are true regarding lipid-soluble vitamins? They are 1) absorbed by passive diffusion in all circumstances; 2) absorbed by specific carriers at physiological concentrations; or 3) absorbed by passive diffusion at pharmacological doses?
   a. 1
   b. 2
   c. 3
   d. All

3. Xerophthalmia is due to 1) vitamin D deficiency; 2) folate deficiency; 3) vitamin K deficiency; and 4) vitamin A deficiency.
   a. 1
   b. 2
   c. 3
   d. 4

4. Which of the following statement is false?
   a. The Endocrine Society defines vitamin D deficiency as $25OHD_3$ serum concentrations ≤ 50 nmol/L;
   b. Vitamin E at very high doses may lead to harmful effects such as decreasing blood coagulating capacity, and disrupting granulocyte and phagocyte anti infective function;
   c. Proposed references values for circulating vitamin E lie between 14 and 20 μM;
   d. Patients with cystic fibrosis present with a higher prevalence of vitamin K deficiency.

5. Which of the following statements are true?
   a. The water-soluble vitamin B complex consists of eight vitamins: thiamin, riboflavin, niacin, pantothenic acid, pyridoxine and pyridoxamine, biotin, folic acid and cyanocobalamin;
   b. The small intestine and the pancreas absorb dietary and supplement water-soluble vitamins;
   c. The colon absorbs water-soluble vitamins produced by the microbiota;
   d. Plasma TPP concentration is recognized as being an adequate indicator of body stores.
      1. a, b, c
      2. a, c, d
      3. b, c, d
      4. a, c
      5. all

6. Which of the following statements are true?
   a. Pantothenic acid nutritional status is best reflected by whole blood or erythrocyte concentrations;
   b. Pantothenic acid, in cells containing mitochondria, is present in majority as coenzyme-A;
   c. Pyridoxal-5′-phosphate (PLP) is the principal active cofactor for amino acid transferases, decarboxylases and dehydratases;
   d. Restricted intake, intestinal malabsorption conditions, and chronic alcoholism are the most frequent reasons for PLP deficiency;
   e. Megaloblastic anemia, defined by RBC macrocytosis and abnormal nuclear maturation, is distinguishable from that caused by vitamin B_{12} deficiency.
      1. a, b, c, d
      2. a, b, d, e
      3. b, c, d, e
      4. a, c, d, e
      5. all

Answers

Chapter 47

Trace elements: functions and assessment of status through laboratory testing

Edgard Delvin[1,2] and Emile Levy[1,3]

[1]Division of Gastroenterology, Hepatology and Nutrition, CHU Sainte Justine Research Centre, Montreal, QC, Canada, [2]Department of Biochemistry, Faculty of Medicine, University of Montreal, Montreal, QC, Canada, [3]Department of Nutrition, Faculty of Medicine, University of Montreal, Montreal, QC, Canada

Learning objectives

After reading this chapter, the reader will be able to:

- Recognize clinically important trace elements.
- Describe situations in which the assessment of trace element status is necessary to prevent deterioration in health status of individuals and/or populations.
- Apply trace element testing to situations requiring the investigation of their status utilizing methods available to clinical and research laboratories.
- Discuss the methodological approaches that are used to measure trace elements.

Introduction

In the context of human nutrition, elements can be classified as bulk elements (calcium, magnesium, phosphorus, sulfur, sodium, potassium, and chloride, the last three being the main electrolytes), and trace elements, needed in minute quantities for the proper growth and development, and present in parts per billion (ppb) in the circulation [1−4]. Care must be taken in distinguishing trace elements originating from environmental contamination of public health concerns (lead, cadmium, cobalt, and mercury) that have toxic effects, even at low concentrations, and functional trace elements (iron, iodine, zinc, selenium, copper, manganese, cobalt, molybdenum, boron, and fluorine) that participate actively in various biological processes. Deficiency and excess in these elements lead to impairment of health status, examples being given in Table 47.1. For the purposes of this chapter, we will review, with varying emphasis, the 10 trace elements that are essential in humans, of which iron, iodine, zinc, selenium, copper, and manganese are the most important. Chromium perceived as a trace element and as a contaminant having toxic properties will also be addressed.

Iron

Iron (Fe), a transition metal with a high redox potential, ubiquitously distributed in biological systems, exists in solution as ferrous (Fe^{2+}), and ferric ions (Fe^{3+}). The majority of Fe is present in hemoglobin, myoglobin, cytochromes, and flavoproteins involved in oxygen transport and the mitochondrial oxidoreduction pathway, and in other enzymes such as catalase and peroxidase. Fe's high redox potential is a double-edged sword, as it can damage cellular components such as fatty acids, proteins, and nucleic acids by an excessive free-radical production in adverse conditions. This characteristic is shared with other trace elements such as copper (Cu) and chromium (Cr), with which Fe may interact [6]. However, the ability of Fe to cause oxidative stress is dampened by being bound to carrier proteins and molecules with antioxidant properties. Body iron stores are mainly regulated through the feedback modulation of iron intestinal absorption that involves iron-regulatory proteins and hepcidin gene regulation [7,8]. Studies on human subjects have shown that calcium, irrespective of its form, can inhibit Fe absorption. However, this interference seems to be of short duration, as adaptation mechanisms develop with time [9]. Ascorbic acid increases absorption by maintaining iron in solution but care should be taken as the combination ascorbic acid−Fe leads to the production of reactive oxygen species (ROS) and the creation of an oxidative stress [6].

Iron deficiency is the most frequent micronutrient deficiency worldwide, particularly in infants, children, adolescents, and women [10]. It generally goes unnoticed until body stores are depleted resulting in iron-deficiency anemia (IDA). Acute iron toxicity occurs most frequently in children causing constipation, vomiting, and diarrhea. Chronic overload is rare in the general population and is

TABLE 47.1 Selected illnesses following improper intakes of trace elements.

Element	Deficiency	Excess
Iron	Anemia	Gastrointestinal effects (constipation, nausea, and vomiting) and genetic hemochromatosis
Iodine	Acquired goitrous hypothyroidism (myxedema), fetal iodine deficiency (mental retardation and deaf mutism), and delayed growth	Chronic and subchronic excess: impairment of thyroid function (hypothyroidism with or without goiter), hyperthyroidism, and thyroid gland malignancies
Zinc	Poor prenatal development, growth retardation, impaired nerve conduction, reproductive failure, dermatitis, alopecia, diarrhea, loss of appetite, anemia, susceptibility to infections, and macular degeneration	Chronic exposure: hypocupremia, impaired iron mobilization, anemia, leukopenia, neutropenia, metabolic disorders, and abnormal cardiac function
Selenium	Kashin–Beck disease (musculoskeletal disorder) and Keshan disease (cardiomyopathy)	Chronic exposure: selenosis (hair, nails, skin lesions, neurological disorders, pain, convulsion, and paralysis)
Copper	Acquired anemia, neutropenia, bone abnormalities, stunting, and congenital Menkes syndrome	Rare occurrence, epigastric pain, nausea, vomiting, diarrhea, childhood cirrhosis (First Nations), Wilson Disease, and increased prevalence of hepatoma?
Manganese	Reported only in experimental conditions, coagulopathy, and dermatitis	Occupational exposure: manganism, a neurotoxic condition similar to Parkinson's disease
Cobalt	Not reported in human populations	Cardiomyopathy in heavy beer drinkers (interaction with ethanol), secondary to associated conditions? Hypothyroidism and poiter, decreased iodine uptake
Molybdenum	Not reported in human populations	Low toxicity index, associated with diarrhea and anemia, and hyperuricemia
Boron	Not officially reported in human populations. Associated with Kashin–Beck disease? Impairment of cognitive functions?	Instability, seizures, and gastrointestinal disturbances
Chromium	Observed in patients on long-term parenteral nutrition, impaired glucose tolerance and utilization, weight loss, neuropathy, dyslipidemia, and abnormalities in nitrogen metabolism (associated with other primary conditions)?	Chronic exposure: renal failure, anemia, hemolysis, liver dysfunction. Symptoms reversible when exposed to Cr^{+3}
Fluorine	Not documented	Fluorosis and osteosclerosis

essentially due to autosomal recessive hereditary hemochromatosis in which the hemochromatosis protein gene (High Fe), a member of the major histocompatiblity complex Class 1 family, is inactivated, thereby causing a dysregulation of Fe uptake [11].

Assessment of iron status

Hemoglobin is the most commonly used parameter in the evaluation of the iron status due to its simplicity and accessibility. However, when used alone, it lacks specificity as it is influenced by vitamin B_{12} and folate status, as well as by infections and hemoglobinopathies. Modern flow cytometry allows accurate and precise measurement of red blood cell morphometry [12]. Mean corpuscular volume reduction (microcytosis) is a reliable index that develops late in severe iron deficiency and when thalassemia and anemia of chronic disease (ACD) have been ruled out. Anisochromia and anisocytosis are also observed in IDA but are not specific to this condition [13].

Biochemical tests to investigate iron deficiency include total serum iron, total iron binding capacity (TIBC), transferrin, soluble transferrin receptor (sTfR), serum ferritin, and erythrocyte zinc protoporphyrin. Their individual value and limitations have been reviewed in the scope of the differential diagnosis of IDA and ACD [14]. In summary, the plasma iron (PI)/TIBC ratio reflecting the transferrin saturation [15] is easily obtained from PI and TIBC routinely analyzed spectrophotometrically on automated platforms. In the presence of iron deficiency, transferrin synthesis is upregulated to maximize iron delivery to target cells, resulting in low transferrin saturation. However, inflammatory and protein-energy wasting conditions may lead to transferrin downregulation that could yield a normal or even high PI/TIBC ratio even in the presence of true iron deficiency state, thereby masking an impairment of iron delivery to hematopoietic cells. Direct measurement of transferrin has been proposed as a better biomarker, and automated immunochemical methods have been developed [16,17] but are not extensively used in clinical laboratories. An LC-MS/MS method using synthetic transferrin peptides has recently been described

for the measurement of serum transferrin [18]. It could become the basis for a reference method that would allow improving the accuracy of immunological methods.

sTfR measurement, a more recently described assessor of iron status, typically distinguishes between IDA and ACD, and is particularly useful in identifying IDA in patients affected by concurrent inflammatory diseases in which ferritin, an acute phase protein, is increased. Measurement of sTfR is of particular clinical interest, as the concentration increases rapidly when iron stores are deficient, falls before other biomarkers upon normalization of the iron status, and is not influenced by acute phase responses [19]. ELISAs and automated immunoturbidimetric and chemiluminescent sTfR assays have been described. They are, however, not harmonized, thereby impeding the definition of a common diagnostic threshold and decreasing its clinical sensitivity and specificity [19–21]. The establishment, in 2010 of a Reference Reagent to standardize immunoassays for sTfR by the WHO Expert Committee on Biological Standardization should help in solving this issue [22].

Serum ferritin was thought to be a better biomarker to detect early iron deficiency. However, being an acute phase reactant, its serum concentration is influenced by inflammatory conditions and may be elevated by chronic alcohol use, thereby limiting its utility in the diagnosis of IDA [23–25]. Furthermore, the heterogeneity of ferritin isoforms, the panoply of antibodies used in immunoassays, as well as the absence of an internationally recognized method have impaired the clinical interpretation of the results. This problem has partially been solved by the use of the third International Standard to assure the traceability of the different automated chemiluminescent and electrochemiluminescent assay standardization [26].

Erythrocyte zinc protoporphyrin, a product of abnormal heme synthesis, is particularly valuable in the primary screening of uncomplicated iron deficiency (iron-deficiency erythropoiesis) and, together with sTfR, for monitoring iron supplement therapy, when lead toxicity (rare nowadays) is ruled out [27]. Low costs and ability to measure the erythrocyte zinc protoporphyrin/heme ratio directly on a drop of blood with a point-of-care hematofluorimeter are the major advantages of this test. The difficulty in automating the assay, however, limits its use by central clinical laboratories. In last recourse, bone marrow may be examined to assess the amount of hemosiderin in the reticulum cells. However, this technique is invasive, semiquantitative, and observer-dependent and cannot be used routinely in clinical pathology laboratories.

Iodine

Hypothyroidism can be classified as goitrous, the most visible sign of endemic iodine deficiency and of goitrogenic foods consumption, and nongoitrous, the congenital form of hypothyroidism [28]. Despite massive iodination of salt, the 2009 UNICEF survey revealed that more than 200 million globally distributed school-age children suffered from iodine deficiency [29]. Iodine (I_2) deficiency disorders are major public health concerns, as they lead to brain damage and mental retardation, particularly in children and to goiter in adults. Furthermore, severe in utero I_2 deficiency retards fetal growth and brain development. The recognition of the universality of iodine deficiency highlights the need to develop and apply new strategies to establish and maintain iodine dietary status monitoring programs.

Dietary I_2, absorbed in the small intestine, reaches the circulation in the form of iodide (I^-), from which it is cleared by the Na^+/I^- symporter (NIS) into the thyroid gland, where it is concentrated in the follicular cell as I_2 for thyroid hormone biosynthesis [28]. It is also transported into other tissues such as mammary gland to provide I^- to the neonate or cleared by the kidney. In euthyroid adults, the thyroid gland contains approximately 70%–80% of the body I_2, and I_2 uptake varies greatly according to the nutritional status [30]. Pituitary thyrotropin [thyroid stimulating hormone (TSH)] stimulates all stages of thyroid iodine metabolism, including NIS-mediated iodine transport into the thyroid gland, and the synthesis and secretion of thyroxin (T_4) and triiodothyronine (T_3). Approximately 90% of the unnecessary I^- is excreted in urine, and the remaining 10% in the feces and perspiration. Iatrogenic iodine toxicity may be due to exposure to radiological contrast media, drugs, and iodine-containing sterilizing solutions. It usually results in high plasma iodine concentrations, derangement of thyroid hormone synthesis accompanied by brassy taste, increased salivation, gastric irritation, and acne-like lesions.

Assessment of iodine status

The global nature of iodine deficiency warrants the need to maintain and strengthen I_2 nutritional surveillance programs. Their efficient management and evaluation require good quality data on urine I_2 concentrations. The 2001 WHO shift from goiter prevalence as the indicator of I_2 deficiency to the spot-urine median I_2 excretion level, the principal marker of recent I_2 intake, was a pivotal decision that dramatically improved the accuracy of the prevalence data [31]. However, as individual I_2 intakes vary from day to day, interpretation of spot-urine I_2 values warrants some caution [32]. Although I_2 concentrations measured on 24-hour collections are more accurate, such an approach is more demanding, particularly in population studies.

The alternative, the age- and sex-adjusted iodine/creatinine ratio, is more accurate than the casual reporting based on concentration per liter, but may lead to

overestimation in the presence of low protein intake (low urinary creatinine) and underestimation in conditions of high creatinine excretion [33]. Knudsen et al. [33] have reported a median (5%–95%iles) 24-hour iodine urinary excretion 143 (75–297) μg/day in a small group of apparently healthy adults.

The spectrophotometric measurement of Sandell–Kolthoff reduction reaction based on iodide-catalyzed reaction between arsenic (III) and cerium (IV), stopped by the addition of diphenylamine-4-sulfonic acid, is the method mostly used to measure urinary I^- [34]. This method has been adapted to a microplate robotic system, allowing the measurement of large numbers of samples [35]. A more technological advanced method using the inductively coupled plasma mass-spectrometry method (ICP-MS) has also been described [36]. Its analytical qualities and stability make this approach particularly valuable for long-term monitoring of populations. ICP-MS can also be coupled to multielement analyses, offering an additional advantage.

Serum TSH and serum thyroglobulin (Tg) are complementary "functional" biochemical indicators of the iodine status, reflecting intermediate time response to the nutritional status. Their use is, however, limited by the cost and technology needed in the perspective of a national screening program, particularly in developing countries in which the iodine deficiency is endemic. Whereas TSH is a sensitive indicator of iodine status in the newborn period, it is relatively insensitive in older children and adult, as values could remain within reference intervals especially in the presence of a borderline iodine deficiency. Furthermore, data must be interpreted with some caution, since normative values are age-, physiological state-, and analytical platform-dependent [37,38]. Tg is a storage protein providing the substance for thyroxin synthesis. In normal conditions, serum Tg concentration is low. It increases when the thyroid becomes hyperplastic, is correlated with urinary I_2, and declines rapidly upon iodine repletion, making it a sensitive indicator of iodine homeostasis [39,40]. Automated immunochemical assay methods for measuring Tg in serum or dried blood spots have been published [41–43]. Although they have a high throughput potential, their use in epidemiological surveys is limited by cost and because of the potential presence of Tg heterophilic antibodies that can artificially decrease the Tg concentration, which would require a reflex test after neutralizing the antibodies.

Zinc

Zinc is an essential Group IIB posttransition element of public health importance. Based on food availability data and on the 2002 WHO report, zinc deficiency affects approximately 1/3 of the world population [44]. Also based on the 2004 Canadian Community Health Survey and the 2003–2006 NHANES survey, the standardized prevalence of inadequate zinc intakes in Canadian and American food-secure and food-insecure households was 13% and 29%, and 12% and 17%, respectively [45]. Zinc deficiency may also be observed in the presence of high phytate content diets due to poor intestinal absorption. Zinc and copper mutually interfere with the gastrointestinal (GI) uptake of the other, thus potentially leading to zinc imbalance in the presence of high copper-containing diets. Similarly, zinc and iron compete for absorption.

Zinc is an essential constituent of zinc-dependent endopeptidases that play key roles in the remodeling of extracellular matrices and of nuclear transcription factors that regulate the transcription of genes involved in metabolic and immune processes, and cell life cycle [46–49]. Zinc deficiency is characterized by poor prenatal development and intrauterine growth retardation, short stature, hypogonadism, impaired immune function, skin disorders, cognitive dysfunction, anorexia, and loss of taste and smell, and is responsible worldwide for approximately 16% of lower respiratory tract infections, 18% of malaria, and 10% of diarrheal diseases [44]. Intracellular Zn homeostasis mainly depends on two species of Zn transporters (ZnTs): Zrt- and Irt-like proteins, known as solute carrier family 39A, ZnTs, known as SLC30A proteins, and metallothioneins (MTs) [50].

Rare genetic loss of expression and activity of ZnTs has been involved in the pathogenesis of acrodermatitis enteropathica, Spondylocheiro dysplastic Ehlers–Danlos syndrome, transient neonatal zinc deficiency, Type II diabetes, and hepatic cirrhosis [51]. Acute zinc salt toxicity, accidental or iatrogenic, is accompanied by variety of symptoms, including abdominal pain, nausea vomiting, lethargy, anemia, and dizziness. Chronic overexposure to zinc can result in secondary hypocupremia, by the inhibition of intestinal copper absorption, which symptoms include impaired iron mobilization, hematological disorders, decreased ROS detoxification superoxide dismutase (SOD) activity, decreased ceruloplasmin, decreased cytochrome c oxidase, and impairment of lipid metabolism [5].

Assessment of zinc status

Despite its limitations in detecting marginal deficiency, its responsiveness to acute and chronic inflammation, and its circadian fluctuations, serum zinc concentration remains the most commonly used biomarker for zinc status. Although urinary zinc excretion declines in parallel to zinc body stores, it is an insensitive measure of zinc status. Several precautions must be observed during phlebotomy, as zinc contamination can occur if zinc-containing ointments are used. Hemolysis must be avoided, since the erythrocyte zinc concentration is greater than serum or

plasma. The type of collecting tube is also of importance; glass "trace metal" vacuum tubes (glass) are most frequently used. Although the utilization of plastic tubes has not been advised because of potential environmental contamination, Boeynaems et al. [52] polyethylene terephthalate tubes were suitable alternatives to glass tubes. Serum/plasma zinc is customarily measured by either flame atomic absorption spectroscopy or ICP-MS [53,54]. MT monocyte messenger RNA, which is downregulated in zinc deficiency and upregulated with zinc supplementation, has been proposed as a surrogate "functional marker" of zinc deficiency. Its use is, however, limited as it is not within reach of all clinical laboratories, lacks reference intervals, and is influenced by inflammatory processes. Furthermore, one study has demonstrated its poor predictive value for poor zinc nutritional status [55].

Selenium

Selenium is an essential trace element for the production of selenoproteins that act either as structural proteins or as enzymes. The mechanisms involved in their synthesis are unique in that selenium is incorporated through the opal UGA stop codon, usually read as a translation stop signal, and is there perceived as a sense selenocysteine (Sec) codon. This phenomenon requires a conserved Sec insertion sequence, located in the 3′-untranslated region, which then recruits a binding protein (SBP2) to serve as a scaffold for mobilizing a Sec elongation factor [56]. Selenoenzymes are catalysts for a number of metabolic pathways related to antioxidant balance, thyroid hormones, and immunity [28,57]. The mechanisms involved in the intestinal selenium absorption are not completely understood. However, an in vitro transport model using human Caco-2 cells shows that selenium is absorbed from the apical pole as selenomethionine and methyl selenocysteine through saturable systems [58]. Hepatic production of methylated selenium compounds and their urinary excretion regulate body selenium content. Selenium is primarily transported in the plasma to the organs via Sepp1, a apolipoprotein E receptor-2 [57].

Selenium deficiency is thought to be a risk factor for several chronic conditions linked to oxidative stress and inflammation involving the GI tract, muscles, and the neurological system [59,60] among others. Selenium has also been associated with the endemic Keshan disease, a congestive cardiomyopathy, resulting from an interaction between its deficiency and the presence of a mutant strain of Coxsackie virus, as well as Kashin−Beck disease, an endemic osteochondropathy thought to result from the combined selenium deficiency, and the presence of mycotoxins in grain high levels of humic acid in drinking water [61,62]. Like other micronutrients, selenium deficiency has also been suspected in patients receiving total parenteral nutrition, in which cardiomyopathy, muscle pain, and muscle weakness are resolved by selenium supplementation. The range between selenium deficiency and toxicity is narrow. Frequent symptoms associated with acute toxicity include diarrhea, fatigue, alopecia, joint pain, nail discoloration or brittleness, and nausea. Longer exposition to excessive selenium peripheral neuropathy and dermatitis is observed [63,64].

Assessment of selenium status

Circulating selenium increasing quickly with intake, plasma, or serum selenium concentration is the most frequently used assessor of short-term selenium dietary consumption. Several techniques for the measurement of serum/plasma/urine selenium have been described. Although older methods utilized fluorometry, the present-day methods are based on atomic absorption spectrophotometry (AAS) with Zeeman correction or ICP-MS without digestion [65].

The study of Meplan et al. [66] opened the possibility of using the circulating Selenoprotein P (SePP) concentration and its polymorphism to evaluate longer term selenium status. They showed, by Western blot analysis, that the serum concentration of SePP-1 depended on the genotype and the selenium concentration and that a 6-week selenium supplementation produced a shift in the proportion of two SePP-1 isoforms. An immunoassay for one specific polymorphic SePP-1 could possibly be developed and used as a "functional" biomarker of selenium status. Plasma glutathione peroxidase-3, erythrocyte glutathione peroxidase-1, and blood cell selenoperoxidase activities, all dependent on selenium are also potential biomarkers. However, their specificity is lacking, as they may be modulated by numerous health conditions.

Copper

Copper (Cu) is a transition metal, widely distributed in nature with cupric ion (Cu^{2+}) being the most important oxidative state. It is ubiquitously distributed in cells and tissues with highest concentrations in brain and liver. In essence, the body's copper reserve is almost totally bound to enzyme prosthetic groups or to chaperone proteins that assure its delivery to specific target proteins such as superoxide dismustase-1 and Cu(1) P_{1B}-type ATPases [67]. Copper is absorbed from the intestinal lumen through the highly conserved apical enterocyte membrane copper-transporter family (Human Ctr1 transporter) and picked up by specific chaperones [68]. Copper is a cofactor of enzymes involved in several metabolic processes required for the development of tissue structures. It is also important in ROS control through ceruloplasmin (ferroxidase I), cytochrome c oxidase, SOD, tyrosinase, lysyl

oxidase, amine oxidases, dopamine-beta-monooxygenase, and peptidylglycine monooxygenase reactions. Because of its central role in biological processes, copper deficiency leads to hematological, musculoskeletal, dermatological, neurological, immunological, and developmental problems. Copper deficiency is fortunately rare, but has been observed in malnourished infants, premature and low birth weight infants fed cow's milk, and patients on copper-free total parenteral nutrition [69].

Copper, similarly to iron, is a double-edged sword as it can also be a toxic element, as it is observed in hepatic, neurodegenerative, and cardiovascular diseases. Its destructive potential is attributed to its ability, as is iron, to take part in Fenton-like reactions yielding extremely harmful ROS [70]. Fortunately, the efficiency of the copper homeostatic control allows a low incidence of chronic copper toxicosis. Copper poisoning can nevertheless develop under certain conditions. The clinical features include vomiting, diarrhea, GI bleeding, hemolysis, oliguria, hematuria, seizures, coma, and eventually death if not treated [71].

Two well-known genetic diseases involve copper transport. The first, Menke's disease or kinky-hair syndrome, could be perceived as a copper pseudodeficiency syndrome due to an ubiquitous (except liver) inactivating mutation of the copper-transporter P-type ATPase (P_{1B} ATP7A) preventing the copper, taken up at the enterocyte luminal membrane of being secreted into the portal circulation, thereby reducing copper bioavailability and decreasing copper-dependent enzyme activities. The second is Wilson's disease picturing a copper toxicity syndrome resulting from an inactivating mutation of the copper-transporter P-type ATPase (P_{1B} ATP7B), preventing copper from being transported to the Golgi apparatus for secretion, and thus accumulating in the hepatocytes. Of importance in both situations, serum/plasma copper and ceruloplasmin, common biomarkers of copper status, are decreased, as they are in nutritional copper deprivation. In Wilson's disease, urinary copper excretion and liver content are increased [72].

Assessment of copper status

Total Serum or plasma copper ($>80\%$ ceruloplasmin-bound), and ceruloplasmin are both widely utilized as biomarkers of the copper status. Their validity, however, may not as reliable as originally ascertained. Although they are decreased in the presence of severe copper deficiency, their concentrations may vary in the cases of mild deficiency. Furthermore, both demonstrate variability in their circulating concentrations related to age, sex, and pregnancy, and are increased by conditions such as inflammatory or infectious processes, cancer, and estrogen therapy, which can hide copper deficiency [73].

Other markers of copper status have been evaluated including 24-hour-urine copper and several cuproenzymes including leukocyte cytochrome c oxidase, erythrocyte SOD, serum diamine oxidase, and plasma peptidylglycine α-amidating monooxygenase. However, the lack of standardization, the absence of normative values, and high interindividual variability limit their use for diagnostic purposes. The recent observation of the increased abundance of the peripheral mononuclear cell copper chaperone for superoxide dismutase (CCS) in malnourished children supports the theory that CCS may be a copper biomarker [74]. Future research may result in the addition of these potential markers to the more traditional plasma copper and ceruloplasmin measures. In addition, as contamination is of particular concern in trace metal analysis; plasma copper measurement must be performed using trace element-free vacuum tubes. The two methods of choice for measuring this element are with AAS with Zeeman correction and ICP-MS [54,75].

Manganese

Manganese, a transition element for which $+2$ oxidative state is the most stable, is a cofactor for a variety of enzymes including oxidoreductases, dismutases, transferases, hydrolases, lyases, isomerases, and ligases [76]. It also modulates the affinity of some carbohydrate-binding lectins and transmembrane receptors (integrins) for their respective ligands [77–79]. Manganese and other trace elements (copper, zinc, fluorine, magnesium, iron, and boron) play a role in bone metabolism, being a cofactor for enzymes synthesizing bone matrix glycoproteins. Although manganese could not be singled out, a double-blind placebo-controlled supplementation study in osteoporotic women that included this element plus calcium, zinc and copper resulted in a net increase in spinal bone mineral density [80]. These data argue in favor of an active role for manganese and the other nutrients in preserving bone density and preventing osteoporosis. The divalent metal ion transporter-1 transports only a small percentage of dietary manganese through the intestinal apical membrane [81]. The integrity of the enterohepatic cycle is essential as the absorbed manganese is excreted very rapidly into the gut via concentration gradient into the bile duct [82]; hence, the risk of manganese toxicity is higher in neonates, in whom this cycle is immature, and also in obstructive liver disease.

No clinical deficiency has been reported in healthy individuals with poor dietary intakes. In a depletion study, seven adult volunteers who were fed a low manganese-containing diet for 35 days developed dermatological lesions accompanied by a decline in serum cholesterol, which resolved quickly upon repletion. Manganese toxicity is a well-recognized occupational risk for miners who are likely to inhale manganese dust if not properly protected. Manganese overload affects the extrapyramidal

motor system in particular, leading to lesions and symptoms close to those of Parkinson's disease and to psychiatric conditions [79].

Assessment of manganese status

The assessment of manganese nutritional status remains problematic. Although plasma/serum manganese concentrations are often cited as reflecting dietary manganese intake, they tend to react only to wide intake variations. Urinary excretion follows the same pattern when usual amounts of manganese are consumed and seems to be responsive only to severe depletion [79,83]. Hence, further studies are needed to evaluate their usefulness as indicators of manganese status. A recently proposed cohort study to be conducted among apprentice welders to determine if blood could be a useful biomarker for manganese status in the context of an occupational health surveillance program will help solving the problem [84].

Liver arginase activity has been shown to be depressed in manganese-deficient animals and lymphocyte Mn-SOD activity increased in supplemented women [79]. These functional tests could in the future potentially be biomarkers for manganese status, providing that simplified methods are developed. As with the other trace elements, serum and urinary manganese can be measured by ICP-MS in samples collected in trace element-free tubes, and in whole blood or erythrocytes by graphite furnace AAS [54,75].

Cobalt

Cobalt, a transition metal for which oxidative states +2 and +3 are the most common, is the key constituent of cobalamin, which is its reservoir in the body (see the section on Vitamin B_{12} in Chapter 46, Vitamins and Nutritional Testing). Cobalt toxicity is not frequent and is more likely to result from occupational exposure in industries where its concentration in ambient air is high. The use of cobalt–chromium hard-metal alloys in arthroplasty is also a potential source of internal cobalt exposure, as slow corrosion and deterioration create nanometric-size metal debris that are systemically disseminated [85]. Finally, the use of cobalt salts by high-level athletes for enhancing their aerobic performance is another potential cause of cobalt contamination [86,87]. These improper intakes of inorganic cobalt salts can cause severe GI tract, thyroid, heart, and sensory system damages [88,89].

Assessment of cobalt status

It is generally accepted that plasma or serum cobalt includes both free cobalt (Co^{2+}) and protein-bound soluble cobalt ions, which reflects the recent exposure, and that red blood cell cobalt content reflects the long-term exposure to Co^{2+} [86,90]. A urinary and fecal excretion study demonstrated that Co^{2+} was primarily eliminated in urine the first 2–8 days after administration, showing that urine could serve for biomonitoring a recent exposure [91]. ICP-MS is the method of choice to measure total cobalt content in biological samples [92]. Trace element-free tubes with strict sampling procedures should be used to avoid environmental contamination.

Molybdenum

Molybdenum (Mo), an essential trace element and crucial for the survival of animals, shuttles between the oxidation states Mo^{+2} and Mo^{+6}. Four Mo-dependent enzymes are known in humans: sulfite oxidase, xanthine oxidase, aldehyde oxidase, and mitochondrial amidoxime reductase, each containing a pterin-based molybdenum prosthetic group acting as cofactor [93]. The mechanisms involved in molybdenum absorption from the human intestinal lumen and in its transcellular transport and release into the lymphatic system have not yet been characterized. However, presence of the molybdate transporter CrMoT2 in human embryonic kidney cell line HEK-293T may allow to further our understanding of the transport process [94].

To date, molybdenum deficiency due to an inadequate intake has not been reported in healthy individuals. Adult patients and preterm infants on long-term parenteral nutrition without supplementation may, however, develop a deficiency. Multielement deficiency usually accompanies this nowadays-rare deficiency. Human molybdenum cofactor deficiency is a rare recessive inborn error of metabolism (incidence below 1:100,000), which results in the loss of activity of sulfite oxidase, xanthine dehydrogenase, and aldehyde oxidase. Symptoms that develop soon after birth include seizures, progressive encephalopathy and other progressive neurological damage, and, in most cases to, early childhood death [95]. There is limited evidence for molybdenum toxicity in humans. Hyperuricemia and arthralgia have been associated with increased dietary molybdenum intake and with increased serum molybdenum concentration. However, no other study has confirmed this observation [93]. The rapid urinary excretion of molybdenum could possibly explain its low toxicity. However, occupational exposure, by inhalation, to molybdenum containing dusts, such as molybdenum trioxide (MoO_3), has been associated with induced subclinical alveolitis [96]. Finally, Meeker et al. [97] have provided evidence for molybdenum being a male reproductive toxicant.

Assessment of molybdenum status

In plasma, molybdenum circulates bound specifically to α2-macroglobulin. In terms of excretion, experimental data from healthy volunteers show that, in repletion states,

>70% of the absorbed amount is excreted via urine and <8% in the feces [98]. As with other trace minerals, molybdenum is measured by ICP-MS and inductively coupled plasma optical emission spectroscopy [54].

Boron

Boron is a metalloid element found in nature and foods, principally nuts, fruits, and green vegetables, mainly as boric acid and salt. It is readily absorbed from the human gut through mechanisms that are yet to be defined. In addition to passive diffusion, in vitro results suggest the existence of a boron-specific membrane transporter in murine monocyte cell lines [99] and aquaporin channel-mediated transport in plants [100]. The human counterpart of these pathways have, however, not been confirmed.

The exact function of boron is elusive. There is, however, some suggestion that it is beneficial to bone growth, musculoskeletal health, and central nervous system function, among other systems. Several lines of evidence suggest that boron activity manifests through the formation of boroesters, biomolecules such as S-adenosylmethionine, diadenosine phosphates, as well as nicotinamide adenine dinucleotide, phosphoinositides, glycoproteins, and glycolipids [101]. The high bone boron content supports the hypothesis that it may be an important element in bone growth and function by contributing to the metabolism and fixation of calcium [102].

Boron deficiency is rare or poorly documented in human population studies. However, it has been suggested that it could be, together with germanium and selenium, a contributing factor to Kashin–Beck disease [62,103]. Boron compounds have a low order of toxicity and accidental lethal poisoning is nowadays extremely rare. Acute boron poisoning generally presents with GI (nausea, persistent vomiting, abdominal pain, and diarrhea) and neurological symptoms (headache, irritability, delirium, seizures, and occasionally coma and death) [104]. The most frequently cited consequence of chronic exposure to boron relates to male reproductive toxicity. The few epidemiologic studies that have examined human reproductive health related to environmental or workplace borates diverged in their conclusions, with some reporting no adverse effects and some reporting sterility [105]; this question remains pending.

Assessment of boron status

Reports on boron homeostasis are scarce. Sutherland et al. [106] demonstrated that urinary boron excretion changed rapidly with modifications in boron intake, suggesting that the kidney was the primary site for regulating its homeostasis and that urine was thus a sensitive indicator of its intake. The preferred methods for the analysis of boron are inductively coupled plasma atomic emission spectroscopy and more commonly ICP-MS [1].

Chromium

Chromium is a metallic element that exists in a variety of oxidation states, of which trivalent (Cr^{3+}) and hexavalent (Cr^{6+}) ions are the biologically most important, with (Cr^{6+}) containing compounds being considered toxic and mutagenic [107]. Grain products, fruits, and vegetables provide most of the dietary chromium [108] at variable levels. Chromium deficiency in the general population, although suggested, is poorly documented lack of sensitive nutritional indicators. This might be a false problem, since the status of chromium as an essential element, and even as a pharmacologic agent, is being challenged and its alleged beneficial effect on insulin sensitivity not having been conclusively demonstrated in type 2 diabetic patients [109–111]. Chromium deficiency has been reported in total parenteral nutrition patients who manifested impaired glucose tolerance, hyperglycemia, weight loss, and neuropathy.

Chromium is absorbed by passive diffusion when taken orally and its uptake from the intestine is increased when the paracellular channels are disturbed (increased permeability) such as in type 2 diabetes [109,112]. Once absorbed and transported to the portal system, chromium is bound to transferrin, the major iron blood transport protein [113]. Chromium toxicity is valence-dependent, with Cr^{+6} having a much higher degree of toxicity than Cr^{+3}. However, given that the latter is poorly absorbed, its toxicity is low. The adverse effects of exposure to high Cr^{+6} containing environment include renal failure, genotoxicity, hepatic dysfunction, and rhabdomyolysis [79]. Irritation of skin, lungs, and GI tract and perforation of the nasal septum have also reported in the cases of suspected chromium overload.

Assessment of chromium status

Reliable biomarkers of dietary chromium and chromium status are lacking, as normal plasma levels are close to the limit of detection of currently available assays. However, elevated plasma chromium may be a good indicator of recent dietary of or excessive exposure to chromium. Graphite furnace AAS with Zeeman correction and ICP-MS are the two common methods for measuring chromium in serum or urine [92,114].

Fluorine

Fluorine, a strongly reactive halide, is widely available in the environment as the ion fluoride (F^-). Primary sources are tea, water (particularly supplemented), and dental products; it can also be absorbed as a contaminant in pesticides (cryolite and sulfuryl fluoride) [115]. Fluoride is not

considered an essential nutrient, because its deficiency has not been defined, and clinical signs of deprivation have not been reported [116]. Given that the basis for assessing a low fluoride status is nonexistent, fluoride deficiency has not been defined. Dental fluorosis expressed as porous enamel is the most overt sign of fluoride toxicity. Excess fluoride consumption may also increase the number of osteoblasts and generate osteosclerosis [117]. The Expert Committee on fluoride in drinking water of the National research Council has identified young children, patients with diabetes and chronic renal disease, elderly persons, hypersensitive individuals, pregnant women or lactating mothers, and individuals deficient in specific micronutrients such as calcium, magnesium, iodine, and selenium at risk of adverse effects for fluoride excess [115]. Experiments conducted in confluent-differentiated Caco-2 cells indicate that the paracellular pathway leads the bidirectional fluoride transport (absorption and secretion). However, the participation of a F^-/H^+ cotransporter or a F^-/OH^- antiporter cannot be excluded [118].

Assessment of fluorine status

Serum, saliva, and urine have all been used to evaluate recent fluoride exposure. Urine being the prime vehicle for fluoride excretion, 24-hour collections are particularly useful in assessing current fluoride exposure for population studies [119]. Serum fluoride concentration has also proven to be useful in monitoring bone turnover in postmenopausal osteoporosis treatment with alendronate [120]. Nail clippings is an unusual biologic material that proved its utility in evaluating long-term exposure to fluoride ions. Since fluoride enters fingernails at the growth end and reaches the distal end by approximately 3 months, its concentration in the clipping reflects the average fluoride intake concentration during the period when the clipping was obtained [121]. Potentiometry using ion-selective electrodes is the most frequently used technology to measure fluoride ions [122]. Gas chromatography-mass spectrometry after derivatization with 2-(bromomethyl)-naphthalene has also been described [123]. This method is, however, technologically more demanding and not practical for most first-line clinical laboratories. Using the ion-selective electrode approach, Zohoori et al. [122] have reported urinary fluoride excretion values ranging from 0.03 to 0.476 mg/days. Table 47.2 provides a sample of reference intervals for the serum concentration of each trace element covered in this chapter [124–130].

Self-assessment questions

1. Which elements other than Fe share the potential of excessive free-radical production in adverse conditions?
2. Which statements are true regarding the concentration of soluble serum transferrin receptor (sTfR)? Its level (i) increases rapidly when iron stores are deficient; (ii) falls long before additional biomarkers upon normalization of the iron status; and (iii) is influenced by acute phase responses?
   - **a.** i
   - **b.** ii
   - **c.** iii
   - **d.** All
3. What statement is true? Goiter is the sign of (i) endemic iodine deficiency and (ii) congenital hypothyroidism.
   - **a.** 1
   - **b.** 2
   - **c.** both
4. Which of the following statement is false?
   - **a.** Zinc, copper, and selenium are classified as essential elements.
   - **b.** Zinc deficiency can be observed in the presence of high phytate contained in diets.
   - **c.** Selenoenzymes are catalysts for metabolic pathways related to antioxidant balance.
   - **d.** Selenium deficiency is a risk factor for chronic conditions linked to oxidative stress and inflammation.
   - **e.** Measurement of serum selenium is used for assessing long-term selenium intake.
5. Which of the following four statements are true?
   - **a.** Manganese is a cofactor for oxidoreductases, dismutases, and transferases.
   - **b.** Manganese, copper, zinc, and fluoride play important roles in bone metabolism.
   - **c.** Cobalt toxicity is frequently observed in rural environment.
   - **d.** Sulfite oxidase and xanthine oxidase are molybdenum-dependent enzymes.
   - **e.** Plasma chromium reflect recent dietary intake.
   - **1.** a, b, c, d
   - **2.** a, b, c, e
   - **3.** a, b, d, e
   - **4.** b, c, d, e
6. Which of the following statements are true?
   - **a.** Chromium is a metallic element that exists in a variety of oxidation states of which trivalent (Cr^{3+}) and hexavalent (Cr^{6+}) ions are the biologically most important.
   - **b.** The preferred methods for analysis of boron are inductively coupled with plasma atomic emission spectroscopy (ICP-AES) and more commonly inductively coupled with plasma mass spectrometry (ICP-MS).
   - **c.** In plasma, molybdenum circulates as a free element.
   - **d.** Red blood cell cobalt content reflects the long-term exposure to Co^{2+}.

Answers

1. a, b, c, d
2. a, b, d
3. b, c, d
4. a, c, d

Chapter 48

Newborn screening and inborn errors of metabolism

Khushbu Patel[1] **and Stephen R. Master**[2]

[1]Division of Pediatric Pathology, Department of Pathology, UT Southwestern Medical Center, Dallas, TX, United States, [2]Division of Laboratory Medicine, Children's Hospital of Philadelphia, Department of Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA, United States

Learning objectives

After reviewing this chapter, the reader will be able to:

- List the major groups of inherited metabolic disorders and associated laboratory findings.
- Discuss the role of newborn screening and the methodology used for detecting metabolic diseases.
- Describe commonly used analytical methodologies for evaluation of inborn errors of metabolism.

Introduction to inborn errors of metabolism

Approximately one quarter of pediatric hospital admissions are due to genetic diseases, a large subset of which are a class of metabolic diseases known as inborn errors of metabolism (IEMs). While individually these are classified as rare diseases, collectively their incidence approaches 1:500. Most IEMs are inherited in an autosomal recessive manner and occur due to defects in biochemical pathways involved in metabolism and energy production. They arise from either a loss of function of an enzyme directly involved in a metabolic step or deficiencies in proteins, vitamins, or cofactors required for enzyme stability and/or in vivo activity. The age of onset and severity of symptoms often depends on the type of IEM and other factors such as mutation status and external triggers of metabolic decompensation (e.g., fasting, infection, and fever). While in some cases IEMs are not compatible with life, there are other instances where signs and symptoms of disease may be completely absent even in the presence of a biochemical abnormality.

Newborns affected with an IEM often have a nonspecific clinical presentation or a long asymptomatic period. Most signs and symptoms of IEMs are due to either accumulation of toxic metabolites or metabolite deficiencies that are important for energy production. Clinically, IEMs can be grouped accordingly: (1) disorders that give rise to intoxication; (2) disorders involving energy metabolism; and (3) disorders involving complex molecules (Table 48.1). In disorders of intoxication, metabolites proximal to the metabolic block accumulate to toxic concentrations. Biochemical measurement of these metabolites forms the basis for diagnosis of most IEMs. Deficiencies of energy production involve the Krebs cycle, fatty acid oxidation, or mitochondrial respiration. Disorders involving complex molecules arise from defects in synthesis or catabolism of complex molecules, and include lysosomal and peroxisomal disorders, as well as disorders of intracellular processing and trafficking. These defects lead to the accumulation of metabolites within various cellular compartments.

The laboratory plays a vital role in diagnosis of IEMs, which requires performing the correct test on the most appropriate sample type and properly interpreting test results. IEMs may be diagnosed through routine and specialized tests. Many of the screening tests used in the evaluation of metabolic disease use instrumentation similar to that available in many clinical chemistry laboratories. What distinguishes metabolic testing from routine testing are the compounds analyzed and their correlation to IEMs. Most physicians requesting metabolic testing are not familiar with the metabolic abnormalities seen in various IEMs. For this reason, most metabolic tests require an interpretation in addition to any quantitative results. Test reports should ideally include the result (with age-appropriate reference intervals for quantitative results), a differential diagnosis based on the pertinent abnormal and normal findings, recommendations for further testing,

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00048-X

TABLE 48.1 Categories of inborn errors of metabolism and their associated clinical and biochemical findings.

IEM category	Clinical features	Associated laboratory findings	IEM types
Intoxication	Neurological distress Seizures Lethargy/coma Liver/other organ failure Unusual urine odor/color	Metabolic acidosis High anion gap Hyperammonemia Ketonuria	Organic acidurias Amino acid disorders Urea cycle disorders Galactosemia
Energy deficiency	Cardiomyopathy Hepatomegaly Lethargy/coma Exercise intolerance	Hypoglycemia (nonketotic) Lactic acidosis Ketosis	Fatty acid oxidation defects Glycogen storage diseases
Disorders of complex metabolism	Hydrops fetalis Hepatomegaly Hypotonia Seizures Neurological abnormalities Severe growth and mental retardation		Lysosomal disorders Peroxisomal disorders Congenital disorders of glycosylation

IEM, Inborn errors of metabolism.

information regarding additional recommended testing, and contact information for the person writing the report should questions arise. Results are interpreted most accurately when clinical and relevant laboratory information is included with the test requisition. When results point to a number of IEMs, correlation with the patient's clinical and laboratory findings is necessary to narrow the differential diagnosis and suggest the most appropriate follow-up testing.

Newborn screening

In the United States, most common IEMs are detected through newborn screening programs. Newborn screening is a population-based screening method to identify newborns with metabolic, endocrine, and other disorders for which timely detection and treatment prevents severe complications and manifestations of the disease. A number of criteria must be met for a condition to be included on the screening panel. These criteria are based on the Wilson and Jungner principles developed in 1968 on behalf of the World Health Organization. For a condition to be included on a screening panel, a test with appropriate sensitivity and specificity must be available, and clear benefits through early detection and timely intervention must be demonstrated. Careful consideration must be given to each criterion, weighing its impact on both affected and unaffected individuals.

In 2006 the American College of Medical Genetics recommended a list of 29 core conditions, which was approved by the Secretary Advisory Committee for Heritable Diseases in Newborn and Children (SACHDNC) and formed the Recommended Uniform Screening Panel (RUSP). The SACHDNC periodically updates the RUSP using an evidence-based protocol for proposing and approving a condition. To date, there are 35 core conditions and 26 secondary conditions on the RUSP. Though not all disorders on newborn screening panels are IEMs, a vast majority of these conditions (~80%) are metabolic disorders. Table 48.2 lists the IEMs that are currently included on the RUSP, as well as the estimated incidence of the core conditions. It is important to note that screening is not nationally mandated in the United States; individual state public health departments guide the number of disorders included in the screening, and the methods used for screening.

Methods used in newborn screening programs are geared toward direct measurement or detection of metabolites, measurement of enzyme activity, or DNA analysis. This testing is typically performed at a centralized laboratory. Screening for other conditions, such as critical congenital heart disease and hearing loss, requires functional tests, performed at the birthing facility. The first method used for newborn screening dates back to the 1960s, which started with screening for phenylketonuria (PKU) using a bacterial inhibition assay known as the Guthrie test. Advances in tandem mass spectrometry have now replaced this method and have allowed for expansion of current newborn screening programs. Currently, over 40 metabolic disorders can be screened for from blood spotted on a filter paper card or "Guthrie card" by measuring a combination of amino acids and acylcarnitines with only 2–4 minutes of instrument time.

Newborn screening is recognized as one of the most successful public health programs. Newborn screening

TABLE 48.2 Metabolic conditions included on the Recommended Uniform Screening Panel and their estimated incidence.

	Core conditions	Incidence	Secondary conditions
Organic acid disorders	Propionic acidemia	1:200,000	Malonic acidemia
	Methylmalonic aciduria	1:100,000	Isobutyrylglycinuria
	Isovaleric acidemia	1:80,000	2-Methylbutyrylglycinuria
	3-Methylcrotonyl-CoA carboxylase deficiency	1:50,000	3-Methylglutaconic aciduria
	HMG-CoA lyase deficiency	<1:100,000	2-Methyl-3-hydroxybutyric aciduria
	Holocarboxylase synthase deficiency	<1:200,000	
	ß-Ketothiolase deficiency	<1:200,000	
	Glutaric aciduria type I	1:100,000	
Fatty acid oxidation disorders	Carnitine uptake defect/carnitine transport defect	1:22,000	Short-chain acyl-CoA dehydrogenase deficiency
	Medium-chain acyl-CoA dehydrogenase deficiency	1:15,000	Medium/short-chain L-3-hydroxyacyl-CoA dehydrogenase deficiency
	Very long-chain acyl-CoA dehydrogenase deficiency	1:85,000	Glutaric acidemia type II
	Long-chain L-3 hydroxyacyl-CoA dehydrogenase deficiency	<1:250,000	Medium-chain ketoacyl-CoA thiolase deficiency
	Trifunctional protein deficiency		2,4-Dienoyl-CoA reductase deficiency
			Carnitine palmitoyltransferase type I deficiency
			Carnitine palmitoyltransferase type II deficiency
			Carnitine acylcarnitine translocase deficiency
Amino acid/urea cycle disorders	Argininosuccinic aciduria	1:220,000	Argininemia
	Citrullinemia type I	1:250,000	Citrullinemia type II
	Maple syrup urine disease	1:185,000	Hypermethioninemia
	Homocystinuria	1:450,000	Benign hyperphenylalaninemia
	Classic phenylketonuria	1:10,000	Biopterin defect in cofactor biosynthesis
	Tyrosinemia type I	1:100,000	Biopterin defect in cofactor regeneration
			Tyrosinemia type II
			Tyrosinemia type III
Other IEMs	Biotinidase deficiency	1:100,000	Galactoepimerase deficiency
	Classic galactosemia	1:60,000	Galactokinase deficiency
	Glycogen storage disease	1:20,000	
	Pompe disease	1:40,000	
	Mucopolysaccharidosis type 1	1:100,000	
	X-linked adrenoleukodystrophy	1:17,000

programs are not only limited to biochemical testing, but also responsible for coordination of follow-up activities, including clinical care, education, and quality assurance. For a program to be successful, it must constantly evaluate its protocols and procedures to ensure its effectiveness. This involves engagement of various stakeholders, including government and nongovernment agencies, hospitals, academic centers, and private partners.

Metabolic testing

Laboratory evaluation of the IEMs includes both routine and specialized testing. Routine testing includes measurement of glucose, electrolytes, ammonia, lactate, pyruvate, renal function tests, liver function tests, urinalysis, and basic hematology tests. Most pediatric centers that offer specialized metabolic testing include amino acid, acylcarnitine, and urine organic acid analysis on their test menu to cover the most commonly detected IEMs on a state's newborn screening panel. The purpose of offering such services in-house is often to provide confirmatory testing on screen-positive infants, expanded coverage of disorders not included on the newborn screening panel, and faster results in cases where prompt therapeutic intervention is necessary. Some patients can be missed by newborn screening, especially for disorders that present later in life. Therefore a symptomatic patient at any age, regardless of newborn screening results, should be investigated for a potential IEM.

Specialized testing typically includes a combination of chromatography and mass spectrometry for the analysis of amino acids, carnitines (including free and total) and acylcarnitines, and organic acids. A combination of these tests is often needed to support a biochemical diagnosis of an IEM. Liquid chromatography−tandem mass spectrometry (LC−MS/MS) is commonly used for targeted analysis of small molecules including amino acids, acylcarnitines, and organic acids. Typically, compounds are separated by hydrophobicity with liquid chromatography and then filtered by unique mass-to-charge (*m/z*) ratios in mass spectrometers in tandem. Please refer to Chapter 10, Mass spectrometry, for a more detailed discussion on mass spectrometry. LC−MS/MS analysis is suitable for a wide variety of specimen types, including plasma, urine, cerebral spinal fluid (CSF), dried blood spots, and postmortem specimens. Gas chromatography−mass spectrometry (GC−MS) offers a broader coverage of metabolites.

Amino acid analysis

Amino acid analysis is helpful in evaluation of hyperammonemia, developmental delay, seizures, and metabolic acidosis. Specialized HPLC systems have been used to measure amino acids since the 1950s. Detection of amino acids by absorption or fluorescence requires deproteinization and derivatization that may be performed before or after separation. Fig. 48.1A illustrates an amino acid chromatogram generated by an ion-exchange chromatography method. Amino acids are separated based on their pK_a with a buffer gradient of increasing ionic strength. With this method, acidic amino acids are eluted first, followed by neutral and then basic amino acids. Ninhydrin is the most common postcolumn derivatization reagent for amino acids. It reacts with primary amino groups to produce a purple compound with an absorption maximum at 570 nm. The peak area for each compound is compared with an external calibration standard. Additionally, an internal standard is added to both the patient sample and calibrator to adjust for any variation in injection volume or reagent reactivity.

Amino acid analysis detects all amino-containing compounds, including nonamino acid compounds such as urea and ammonia. A number of other amino acids that are not found in proteins, but that aid in diagnosis of IEMs, are also identified. These include alloisoleucine, ornithine, citrulline, and argininosuccinic acid (ASA). Dietary artifacts and medications, as well as abnormal amino acids characteristic of various IEMs, may also be identified using this method. Identification of eluting compounds is based on retention time and relative elution order. Amino acid analysis with visible or fluorescent detection does not provide absolute identification of any compound. This is generally adequate for samples containing only normal physiologic amino acids, but the presence of medications or unusual amino acids due to an IEM complicate interpretation. Ion-exchange chromatography is the most commonly used method for amino acid analysis; however,

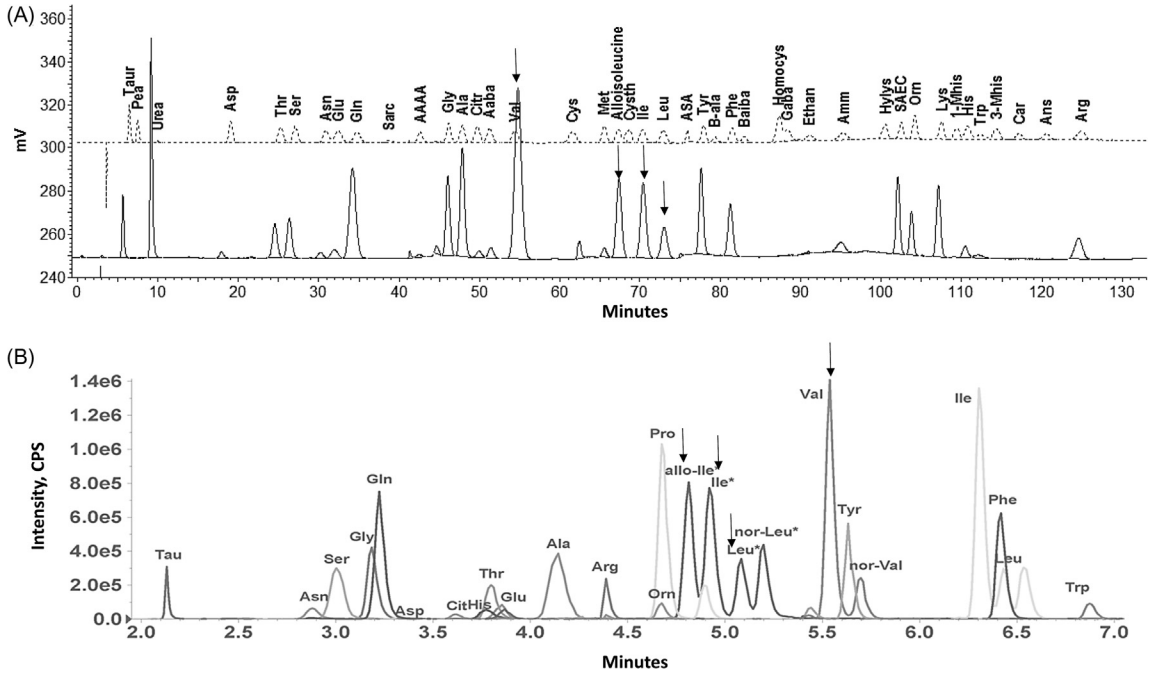

FIGURE 48.1 (A) Plasma amino acid analysis of a patient with maple syrup urine disease using an ion-exchange chromatography method. *Dotted line*: calibration standard. *Solid line*: patient sample. (B) Multiple reaction monitoring liquid chromatography−tandem mass spectrometry method. *Arrows*: diagnostic amino acids (alloisoleucine, isoleucine, leucine, and valine).

many laboratories are now starting to adopt LC−MS/MS methods [1,2]. LC−MS/MS assays for amino acid analysis offer more analytical specificity and sensitivity, as well as faster analysis time (Fig. 48.1B).

Plasma is the preferred sample for amino acid analysis for the diagnosis of most disorders. When possible, the blood should be collected in the fasting state (at least 3−4 hours postprandial) or after holding parenteral nutrition for 30−60 minutes. Plasma should be separated as soon as possible and frozen if analysis is delayed. If serum is used, the sample should be immediately centrifuged after clotting [3]. Cysteine and homocysteine attach to proteins in plasma samples and can be falsely decreased with improper storage conditions. Hemolysis will result in falsely increased concentrations of aspartate, glutamate, and taurine.

Urine amino acid analysis is usually less informative than analysis of plasma samples due to the wide reference intervals for urinary excretions of most amino acids. Reference intervals for urine amino acids are usually normalized for creatinine. Excretion of amino acids is especially high during infancy and decreases with age. In general, urine amino acid analysis should be reserved for assessment of renal tubular transport abnormalities and disorders of amino acid transport, such as lysinuric protein intolerance (characterized by an increase of lysine and other dibasic amino acids in urine), Hartnup disease, and cystinuria. Generalized dysfunction of proximal tubular reuptake (Fanconi syndrome), which results in elevations of many urine amino acids, may be seen in a number of IEMs, including mitochondrial disorders. CSF amino acid analysis is essential in the diagnosis of neurotransmitter disorders such as NKH, serine deficiency disorders, and pyridoxal-phosphate-dependent epilepsy.

Age-related reference intervals have been published for various sample types. Table 48.3 lists IEMs typically diagnosed by an amino acid profile and their associated amino acid abnormalities. Generally, glutamine, alanine, and valine are the largest peaks in the chromatogram. In urine, ammonia and urea predominate, whereas glycine and histidine are the amino acids usually present in the highest concentrations. Glutamine is the most abundant amino acid in normal, acellular CSF. Analysis of amino acids should be performed quantitatively, as qualitative analysis is not sufficient to identify some of the subtler changes in amino acid concentrations that characterize some disorders. Once an IEM is diagnosed, plasma amino acid analysis may be an important part of management, especially for urea cycle disorders (UCDs) and those conditions requiring restriction of selected amino acids.

Acylcarnitine analysis

Acylcarnitine analysis is helpful in the evaluation of hypoglycemia, hypotonia, cardiomyopathy, rhabdomyolysis, and metabolic acidosis. Analysis is commonly performed by MS/MS directly after derivatization to either butyl or methyl esters. Acylcarnitines arise from the conjugations of acyl-coenzyme A (CoAs) with carnitine for the transport of long-chain fatty acids across the innermitochondrial membrane for β-oxidation. Additionally, carnitine binds acyl residues and aids in their excretion. This mechanism is also important in the removal of organic acids that accumulate in some organic acidemias. For this reason, a plasma acylcarnitine profile can aid in the diagnosis of organic acidemas in addition to fatty acid oxidation disorders (FAODs). In certain IEMs, carnitine supplementation is employed to aid in the elimination of the toxic metabolite. Table 48.4 lists the acylcarnitine abnormalities that characterize various organic acid and FAODs.

Plasma is the preferred sample type for acylcarnitine analysis, although analysis of urine acylcarnitines can be useful in the workup of glutaric academia type I (GA1) when other tests have led to equivocal results. Hydrolysis of acylcarnitines in unfrozen samples can result in falsely decreased concentrations; therefore plasma samples should be processed immediately and kept frozen

TABLE 48.3 Inborn errors of metabolism associated with amino acid abnormalities.

IEM	Abnormal amino acid[a]
Maple syrup urine disease	↑Alloisoleucine, isoleucine, leucine, and valine
Lysinuric protein intolerance (low in serum)	Arginine, lysine, and ornithine (↑urine/↓serum)
Urea cycle defects	↑Glutamine (see Table 48.6)
Glycine encephalopathy	↑Glycine (serum and CSF)
Homocystinuria	↑Methionine and ↑homocysteine
Phenylketonuria	↑Phenylalanine and ↓tyrosine
Tyrosinemia types 1−3	↑Tyrosine
Hartnup disease	↑Neutral amino acids (urine)

IEM, Inborn errors of metabolism; *CSF*, cerebral spinal fluid.
[a]*Abnormality of amino acid found in serum unless indicated.*

TABLE 48.4 Acylcarnitines characteristic of fatty acid oxidation disorders.

Enzyme deficiency	Abnormal acylcarnitines (increased unless indicated)
Carnitine palmitoyltransferase I	Increased free carnitine (C0) and decreased C16 and C18 species
Carnitine transporter	Decreased C0, decreases in most acylcarnitines
Propionic acidemia	C3
Methylmalonic aciduria	C3, usually C4DC
SCAD	C4
SCHAD	C4-OH
Beta-ketothiolase	C5:1
Isovaleric acidemia	C5
Methylbutyrylglycinuria	C5
Glutaric acidemia type 1	C5DC
3-Methylglutaconic aciduria type I	C5OH and C6DC
MCAD	C6, C8, C10:1
VLCAD	C14:1, C14:0, C14:2, C16:0, C16:1, C18:1, C18:2, and C18:0
LCHAD	C16-OH, C16:1-OH, C18-OH, and C18:1-OH
Carnitine-palmitoyltransferase II	C16:0, C16:1, C18:1, C18:2, and C18:0; often normal
Carnitine-acylcarnitine translocase	C16:0DC, C18:0DC
Multiple acyl-CoA dehydrogenase deficiency	C4, C5 and C6-C18 acylcarnitines with and without double bonds; very low C2-carnitine
Mitochondrial disease	Elevations of multiple acylcarnitines in a nonspecific pattern
Renal insufficiency	Elevations of multiple acylcarnitines in a nonspecific pattern, more normal with hemodialysis, and unchanged by peritoneal dialysis
Fasting	Increased C2, C4−OH, and possibly other acylcarnitines

Notes: Acylcarnitines are named according to the number of carbons, the number of double bonds, and the presence or absence of a hydroxyl group as part of the acyl group. For example, octadeca-di-enoylcarnitine (18 carbons and two double bonds) is noted as C18:2. DC indicates the acylcarnitine derivative of the dicarboxylic acid of the corresponding number of carbons.
CoA, Coenzyme A; *LCHAD*, long-chain hydroxyacyl-coenzyme A dehydrogenase; *MCAD*, medium-chain acyl-coenzyme A dehydrogenase; *SCAD*, short-chain acyl-coenzyme A dehydrogenase; *VLCAD*, very long-chain acyl-coenzyme A dehydrogenase; *SCHAD,* short-chain hydroxyacyl CoA dehydrogenase.

until analysis. Hemolyzed specimens can lead to false increases in long-chain acylcarnitines and should not be used for analysis (or, at a minimum, should be interpreted with caution). Results may be reported as either a qualitative interpretation or as quantitative results. Qualitative results require careful examination, because some diagnostic acylcarnitines are only minimally increased. In either case, interpretation should be included with recommendations for additional testing indicated for further evaluation of abnormal results. Analysis by MS/MS without chromatographic separation identifies compounds based on the molecular mass and fragmentation; therefore these methods sometimes cannot distinguish isobaric compounds with similar chemical structures. For example, elevation of the 5-carbon acylcarnitine can be indicative of either isovalerylcarnitine or 2-methylbutyrylcarnitine. Additional studies (such as urine organic acids) are necessary to distinguish between potentially life-threatening isovaleric academia and the more benign 2-methylbutyrylglycinuria.

Although plasma acylcarnitine analysis allows rapid diagnosis of many conditions previously diagnosed by urine organic acid analysis, acylcarnitine analysis does not identify all of the compounds identified in the broader screening of urine organic acids. In addition, plasma acylcarnitine concentrations vary with feeding and fasting, and the profile can be normal in some FAODs when the sample is collected postprandially. For this reason, the excretions of organic acids characteristic of an IEM are often a better indicator of recent metabolic control than are acylcarnitine concentrations. Specificity is increased when analyses of organic acids and acylcarnitines are combined.

Urine organic acid analysis

GC−MS is used primarily for detection of organic acids, derived from metabolism. Compounds are extracted from urine into an organic solvent, derivatized to volatile forms, and separated by volatility and solubility in the stationary phase of the gas chromatography column. Some laboratories pretreat urine samples with urease to remove urea, which can interfere with the detection of other compounds, prior to trimethylsilyl derivatization [4]. The derivatization process enhances the volatility of organic acids. The mass spectrometer produces a characteristic mass spectrum, which is then matched against a library of

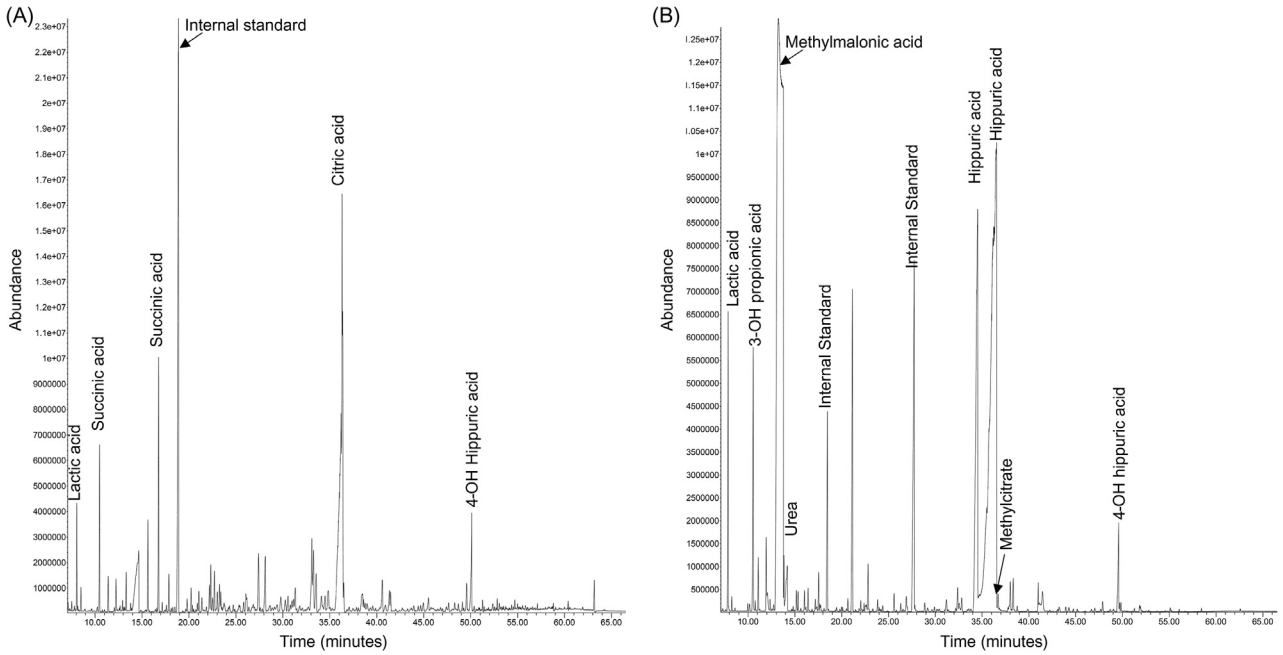

FIGURE 48.2 Urine organic acid profiles. Organic acids from urine after extraction with ethylacetate and trimethylsilyl derivatization. (A) Normal profile from a 2-week-old patient. (B) Urine from a patient with methylmalonic aciduria. Peaks are interpreted relative to the internal standard (2-phenylbutyric acid).

spectral data. Compounds are identified by both their *m/z* ratio as well as their retention time. Fig. 48.2 shows the urine organic acid profile of a healthy individual and a patient with MMA for comparison.

Urine is the preferred sample for screening organic acid analysis, because most abnormal metabolites are present in higher concentrations in urine than in plasma. Excretion of organic acids decreases with age as the renal tubules mature. Extraction of an amount of urine corresponding to a standard amount of creatinine makes it possible to visually compare profiles from one patient to the next, as well as several profiles obtained at various times for the same patient. Although quantitation is possible, it is usually done by comparing ion intensity for a particular compound to that of one or more internal standards. This provides only a semiquantitative estimate of the concentration because of the variations in extraction efficiency for different classes of compounds.

Once a particular IEM has been diagnosed, routine monitoring may include urine organic acid analysis or, in some conditions, measurement of the accumulated metabolites in plasma. Sensitivity of the analysis is increased by monitoring only a few ions characteristic of the compound in question [selected ion monitoring (SIM)] instead of the broad range of masses used in screening organic acid analysis. SIM/stable isotope dilution (SID) can also be used to quantitate selected organic acids when monitoring therapy in a patient previously identified with an IEM. Other methods that use tandem mass spectrometry and high-resolution mass spectrometry [hybrid quadrupole time-of-flight (TOF)] are used in some clinical laboratories. In some instances, the latter method offers both targeted quantitation and untargeted metabolite screening with increased sensitivity.

Extraction of urine organic acids for analysis can convert 2-ketoacids to their 2-hydroxy forms, thus impairing the detection of 2-ketoacids such as pyruvic acid and branched-chain 2-ketoacids found in maple syrup urine disease (MSUD), as well as, succinylacetone, the compound pathognomonic for tyrosinemia type 1. An oximation step with hydroxylamine hydrocline can be added to the procedure to help stabilize the keto-groups of these metabolites. Due to differences in methodology and instrumentation, a urine organic acids report from one laboratory may not exclude the same conditions excluded by another laboratory using different techniques. In addition, the organic acids characteristic of some conditions may not be present in urine when the patient is asymptomatic, and it may be necessary to repeat the analysis. In some disorders, the characteristic organic acids may be present in very low concentrations, and accurate quantitation is necessary.

The identification of compounds also depends on the quality of the reference library used for spectral data. It is recommended that laboratories periodically review or update these libraries to ensure that key diagnostic

metabolites are not missed in the screening procedure. The interpretation of organic acid profiles can be challenging due to the number of compounds that are detected in urine samples as well as the presence of interferences and artifacts produced from diet and medications. Ideally, the interpretation unites the results of urine organic acid analysis with the rest of the patient's clinical history.

Other metabolic testing

Enzyme activity or genetic testing can be used in the setting of equivocal biochemical findings for confirmation of a diagnosis. Specimens for enzyme activity testing may include skin fibroblasts or lymphocytes. In some cases, enzyme testing may involve invasive procedures to obtain the cell type with the enzyme defect and should be used as a last resort for diagnosis. DNA testing by either targeted mutation analysis or whole gene sequencing can be beneficial. Genotype−phenotype correlations can help in directing therapy and predicting disease course. As the genetic basis of many IEMs has been determined, genetic testing is being used increasingly to confirm diagnosis and perform carrier testing. One limitation of gene sequencing is that it may not identify all disease-causing mutations, and it can miss single-exon deletions and duplications. Additionally, in some cases, identification of variants of unknown significance can cause further ambiguity in cases where the clinical and biochemical diagnoses are uncertain. Of note, some newborn screening programs have now incorporated second-tier molecular testing to identify common disease-causing variants for faster diagnosis and confirmation of certain disorders such as galactosemia, medium-chain acyl-coenzyme A dehydrogenase (MCAD) deficiency, and very long-chain acyl-coenzyme A dehydrogenase (VLCAD) deficiency.

The disorders

Amino acid disorders

Disorders of amino acid metabolism are generally disorders of intoxication, due to dysfunctional catabolism of the carbon skeleton or dysfunctional transport across cellular bodies. The clinical presentation is highly variable and nonspecific, and the laboratory diagnosis is based on the accumulated metabolite. In most instances, plasma amino acid and urine organic acid analyses aid in the diagnosis of these disorders.

Phenylketonuria

PKU was the first disorder evaluated by newborn screening. Classical PKU is due to a complete deficiency in phenylalanine hydroxylase (PAH), which converts phenylalanine to tyrosine (Fig. 48.3). In PKU, increased phenylalanine and decreased tyrosine lead to neurotoxicity as well as impaired neurotransmitter production. Untreated PKU leads to severe mental retardation that can be prevented by adherence to a phenylalanine-restricted diet.

PKU is typically diagnosed by elevated plasma phenylalanine concentrations with a low or low-normal tyrosine. Additionally, excretion of phenyllactate, phenylpyruvate, and phenylacetate can be identified by urine organic acid analysis in patients with PKU; however, it is important to note that these metabolites may be commonly observed in newborns with immature livers. The majority of hyperphenylalaninemias are caused by mutations in the *PAH* gene, in which more than 400 variants have been identified. In the remainder (2% of cases), hyperphenylalaninemia is secondary to a deficiency in tetrahydrobiopterin (BH4), a cofactor required by PAH. Measurement of urinary pterins and blood dihydropteridine reductase activity is recommended to exclude defects in BH4 before

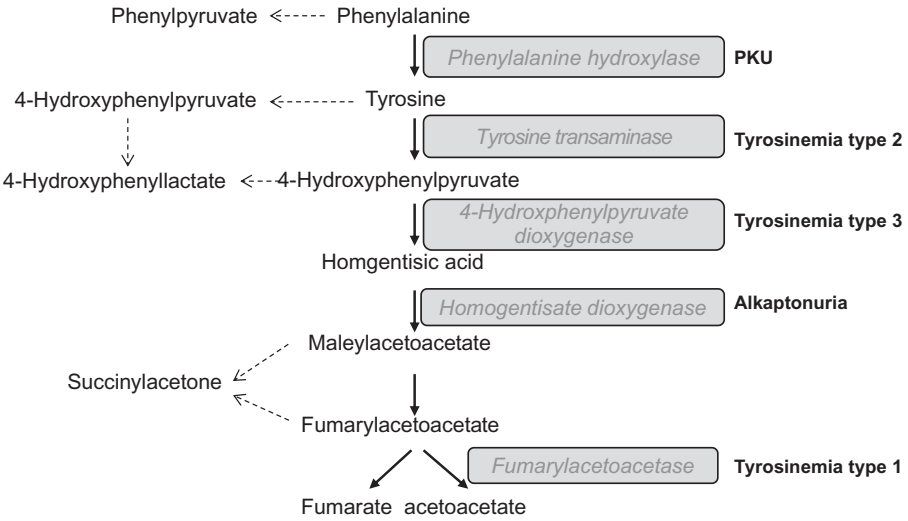

FIGURE 48.3 Disorders of phenylalanine and tyrosine metabolism. *Bold*: inborn errors of metabolism resulting from deficiencies in enzymes. *Dashed arrows*: abnormal production of metabolites. *PKU*, Phenylketonuria.

initiation of treatment as BH4 deficiency, as treatment course will vary depending on the type of hyperphenylalaninemia. Approximately 35% of all hyperphenylalaninemias are responsive to BH4 supplementation and allow for increased phenylalanine tolerance in the diet. Depending on the type of BH4 deficiency, patients may also require neurotransmitter replacement therapy. Treatment of PKU with a phenylalanine-restricted diet requires frequent monitoring with serial plasma amino acid analysis to ensure that the phenylalanine concentration is low enough to prevent brain damage, but not so low that phenylalanine deficiency results in growth retardation. Elevated maternal phenylalanine concentrations during pregnancy can result in serious complications, including intrauterine growth restriction, microcephaly, intellectual disability, and even fetal loss [5].

Hereditary tyrosinemias

Elevation of plasma tyrosine is most often due to liver disease, but it is also found in varying degrees in the inherited abnormalities of tyrosine metabolism (tyrosinemia types 1, 2, and 3, as well as alkaptonuria and hawkinsinuria). Furthermore, some newborns have transient tyrosinemia due to delayed maturation of 4-hydroxyphenylpyruvate dioxygenase. There are a number of steps in the metabolism of tyrosine. Deficiencies in the metabolic steps closest to tyrosine result in the highest elevation of plasma tyrosine. 4-Hydroxyphenyllactic acid and 4-hydroxyphenylpyruvic acid can be detected by urine organic acid analysis in all of the hereditary tyrosinemias, and it is not possible to distinguish among the hereditary tyrosinemias or between tyrosinemia due to liver disease or immaturity and hereditary tyrosinemia based on these compounds (Fig. 48.3). The presence of succinylacetone is pathognomonic for tyrosinemia type 1; however, its excretion may be so low that it cannot be identified except using SIM/SID. It is important to identify individuals with tyrosinemia type 1, because treatment with a tyrosine- and phenylalanine-restricted diet can reverse their liver disease, but most will develop hepatocellular carcinoma because of the carcinogenic activity of fumarylacetoacetate. Treatment with nitisinone (NTBC), an inhibitor of 4-hydroxyphenylpyruvate dioxygenase, prevents the accumulation of fumarylacetoacetate and dramatically reduces the risk of hepatocellular carcinoma.

Maple syrup urine disease

Deficiency of branched-chain ketoacid dehydrogenase (BCKDH) results in the accumulation of branched-chain 2-ketoacids and branched-chain amino acids (Fig. 48.4). MSUD is biochemically characterized by elevated blood concentrations of isoleucine, leucine, and valine, as well as increased urinary excretion of corresponding α-ketoacids: α-keto-3-methylvalerate, α-ketoisocaproate, and α-ketoisovalerate, which can be identified by urine organic acid analysis. Most importantly, the detection of alloisoleucine on plasma amino acid analysis is virtually pathognomonic for MSUD. Although newborn screening is available for MSUD, infants with classic MSUD are often already ill when the results of the newborn screening test become available. The marked elevation of leucine is responsible for the lethargy and coma that are the typical presentation of MSUD.

In classical MSUD, routine laboratory testing at presentation is often unremarkable, and urine dipsticks for ketones are usually negative in newborns. Urine does not usually have the characteristic maple syrup odor in newborns, but the odor may be present in cerumen. Amino acid analysis shows marked elevation of branched-chain amino acids; a typical profile is shown in Fig. 48.1. Although branched-chain amino acids can be markedly increased with prolonged fasting or episodes of vomiting, MSUD can be confirmed by the presence of alloisoleucine. It is important to note that medications with amines in their chemical structures, such as antiepileptics, can

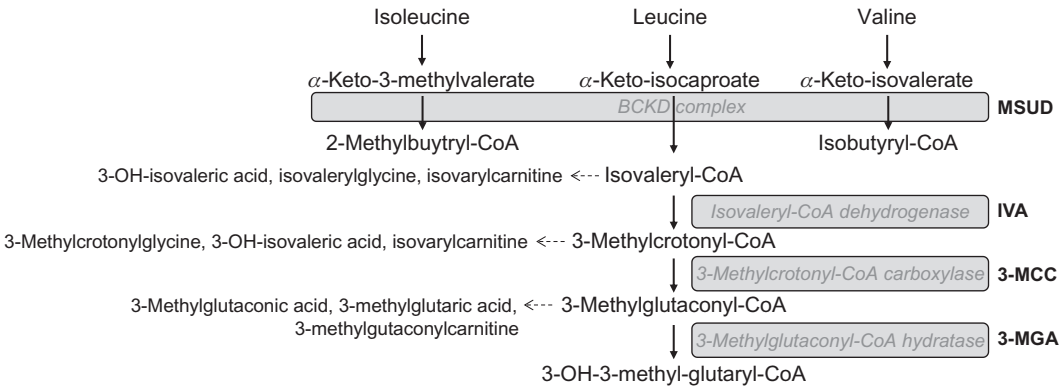

FIGURE 48.4 Disorders of branched-chain amino acid metabolism. *Bold*: inborn errors of metabolism resulting from deficiencies in enzymes. *Dashed arrows*: abnormal production of metabolites. *3-MCC*, 3-Methylcrotonyl-coenzyme A carboxylase; *IVA*, isovaleric aciduria; MGA: 3-methylglutaconic aciduria; *MSUD*, maple syrup urine disease.

coelute with alloisoleucine, resulting in falsely increased concentrations when an MS/MS-based detection method is not employed. Severe deficiency of BCKDH results in classical MSUD. Intermediate MSUD may not be diagnosed until later in life due to residual BCKDH activity, which can range from 3% to 40% in affected individuals. Some individuals with MSUD have enough residual activity of BCKDH that they have only intermittent symptoms with normal plasma amino acid concentrations between episodes. However, even individuals with intermediate or intermittent, MSUD can experience severe neurotoxicity if there is sufficient metabolic stress to overload the residual BCKDH activity.

Treatment of MSUD requires a diet restricted in the branched-chain amino acids: valine, isoleucine, and leucine. It is often necessary to supplement valine and isoleucine to maintain leucine at the desired concentration. As with other IEMs requiring a protein-restricted diet, regular monitoring is necessary to prevent amino acid deficiencies while maintaining branched-chain amino acids low enough to prevent toxicity.

Homocystinuria

The sulfur-containing amino acid cysteine is synthesized from methionine. This pathway proceeds via homocysteine, which can be remethylated to methionine. Homocystinuria can result from a number of enzyme deficiencies in this pathway, which requires folic acid, vitamin B_{12}, and pyridoxine (vitamin B_6). Even a small amount of homocysteine detected by plasma amino acid analysis is abnormal and indicative of disease. Various forms of homocystinuria can be distinguished by plasma methionine and the presence or absence of methylmalonic aciduria (MMA).

Classical homocystinuria is due to a deficiency in cystathionine-β-synthase (CBS) activity, and results in marked elevation of methionine in addition to homocystine; cysteine concentration may be decreased. Homocysteine is also increased in several disorders of folic acid and vitamin B_{12} metabolism, such as cobalamin C disease. In these conditions, methionine concentration is low. The combination of homocystinuria and MMA is found in two disorders of vitamin B_{12} metabolism.

Screening for the increased blood methionine seen in homocystinuria due to CBS deficiency is included in the newborn screening panel of many states. A number of other conditions can result in increased plasma methionine including liver disease, increased protein intake, and methionine adenosyltransferase deficiency. Newborn screening may not identify individuals with milder forms of CBS deficiency, because the blood methionine concentration is often not increased sufficiently in the first few days of life. Instead, these individuals often present with lens dislocation or thromboembolic event later in life. The increased risk of clotting episodes in homocystinuria led researchers to investigate milder elevations of homocysteine as a risk factor for strokes and myocardial infarction.

Diagnosis and management of all forms of homocystinuria require measurement of homocysteine in addition to plasma amino acids. The sulfhydryl groups of cysteine and homocysteine readily react with the free sulfhydryl groups of plasma proteins. Therefore most of the circulating homocysteine is found in homocysteine-cysteine or homocysteine dimers (10%−20%) or is protein bound (80%), and only 1%−2% is free or unbound homocystine. If amino acid analysis of a plasma sample is delayed, free cystine (cysteine dimers) and homocystine (homocysteine dimers) decrease, and the diagnosis may be missed. Instead, measurement of total plasma homocysteine provides a more reliable indication of homocystinuria. Immunoassays for total homocysteine are available on most automated chemistry/immunoassay systems. The general assay principle involves reducing the circulating forms of homocysteine to free homocysteine using reducing agents. Free homocysteine is then converted to S-adenosylhomocysteine (SAH), which serves as the analyte for a competitive immunoassay. These assays are more commonly used for assessment of cardiovascular risk, which is associated with mild hyperhomocystinemia. Please refer to Chapter 29, Pediatric laboratory medicine, for a discussion of laboratory testing related to cardiovascular disease. The analytical range of some automated tests for total homocysteine may not be adequate to allow accurate quantitation of the markedly increased total homocysteine found in individuals with CBS deficiency, and it may be necessary to dilute such samples.

Treatment of severe CBS deficiency centers around reduction of plasma homocysteine concentrations by a methionine-restricted diet, high-dose vitamin B_6, or betaine administration. Betaine lowers plasma homocysteine concentrations by donating a methyl group to homocysteine to generate methionine. Treatment decreases the risk of thrombosis as well as the mild developmental disabilities that can be seen in untreated, severe CBS deficiency. In contrast, homocystinuria due to disorders of folate and vitamin B_{12} is frequently associated with megaloblastic anemia, microcephaly, and more severe developmental disabilities, possibly due to inadequate supply of *S*-adenosylmethionine. In these conditions, treatment with betaine can decrease total homocysteine and increase plasma methionine.

Other amino acid disorders

A number of amino acid disorders can result in severe neonatal seizures. These include NKH, serine deficiency disorders, and pyridoxal-phosphate-dependent epilepsy.

CSF amino acid analysis is usually necessary to diagnose or exclude these conditions, because the results of plasma amino acid analysis may be normal or nonspecific. In NKH, plasma glycine is usually markedly increased, but this finding is not specific. Instead, diagnosis requires an elevation of CSF glycine and an increased CSF glycine/plasma glycine ratio (reference <0.08). Infants with serine deficiency disorders may have normal plasma serine, whereas CSF serine is uniformly decreased (6−8 μM; normal range 35−80 μM). Pyridoxal-phosphate-sensitive encephalopathy results in elevation of CSF threonine with mild elevation of glycine.

Sulfite oxidase deficiency is another cause of neonatal seizures. It can occur as an isolated deficiency or combined with xanthine oxidase deficiency due to molybdenum cofactor deficiency. Plasma taurine is increased, but this finding is common in formula-fed infants. Sulfocysteine can also be increased with decreased plasma cystine, but sulfocysteine is unstable and not included with amino acid standards and may be missed without careful inspection of the amino acid profile. Low plasma cystine is almost always due to delay in amino acid analysis and is not specific enough to be indicative of the need for additional testing. Diagnosis of sulfite oxidase deficiency is most often suggested by increased urine sulfite and extremely low plasma total homocysteine.

Organic acid disorders

Organic acidemias are a diverse group of IEMs, in which one or more nonamino acids accumulate in tissues and body fluids. In most organic acidemias, the characteristic organic acid(s) are present in urine; thus urine organic acid analysis by GC−MS is currently the gold standard for the identification of these disorders. Organic acids are derived from amino acid metabolism, ketone body and fatty acid metabolism, and Krebs cycle precursors and intermediates. In patients with metabolic defects in these pathways, both precursors and their side products or metabolites can be detected by urine organic acid analysis [6]. For instance, in patients with propionic academia, deficiency in the enzyme propionyl-CoA carboxylase results in the accumulation of propionyl-CoA, which further reacts with oxaloacetate to produce methylcitrate, a metabolite that is not present in the urine of healthy individuals.

The presence of a single organic acid at high concentrations is not necessarily diagnostic of an IEM. The excretion of these metabolites in the urine can vary based on protein intake and other factors. Ideally, the interpretation, essential for those other than metabolic specialists, unites the results of urine organic acid analysis with other laboratory findings as well as the patient's clinical history. If the sample is from a patient previously diagnosed with an IEM, it may be helpful to compare the profile of organic acids in the current sample with the results obtained in previous samples. With some organic acid disorders, specific plasma acylcarnitine patterns can aid in diagnosis as well as monitoring. Table 48.5 lists common organic acidurias as well as their associated urine metabolites and clinical features.

The most classic organic acid (OA) disorders result from defects in amino acid degradation. These disorders typically manifest in the newborn period, but can also present later in life. Vomiting, poor feeding, and lethargy are typical manifestations in the neonatal period. Milder forms of OA disorders are associated with repeat episodes of metabolic acidosis, hypoglycemia, and leukopenia. Some types of OA disorders have severe neurologic manifestations and present with acute encephalopathy, seizures, and ataxia. Below, we provide a few examples of commonly seen OA disorders.

3-Methylcrotonylglycinuria

3-Methylcrotonylglycinuria (3MCC) is the most frequent OA disorder detected by newborn screening in the United States, Europe, and Australia. It results from a deficiency in a biotin-dependent carboxylase, 3-α-methylcrotonyl-CoA carboxylase, involved in the degradation of leucine (Fig. 48.4). The presentation can range from severe neurological impairment to completely asymptomatic patients who only have a biochemical abnormality. The diagnosis is based on increased urinary excretion of 3-hydroxyisovaleric acid and 3-methylcrotonylglycine in the urine and increased plasma 3-hydroxyisovalerylcarnitine (C5-OH).

Isovaleric aciduria

Deficiency of isovaleryl-CoA dehydrogenase, an enzyme involved in the leucine degradation pathway, results in isovaleric aciduria (IVA; Fig. 48.4). A characteristic odor resembling "sweaty feet" caused by the accumulation of isovaleric acid has been described in patients. Typical manifestations include acidosis, ketosis, vomiting, lethargy, and coma. The diagnostic feature of IVA is elevated concentrations of isovalerylglycine and 3-hydroxyisovaleric acid in the urine; however, the latter is found only during metabolic decompensation. Elevations in plasma isovaleryl carnitine (C5) can also aid in the diagnosis and monitoring, and is used as the marker for newborn screening. Treatment involves a low protein, leucine-reduced diet with carnitine, and glycine supplementation.

Propionic acidemia and methylmalonic aciduria

Propionic acidemia (PA) and MMA are organic acid disorders due to defects in catabolism of isoleucine, valine,

TABLE 48.5 Urine metabolites and clinical presentation of selected organic acidurias.

Organic aciduria	Urine metabolites	Clinical presentation
Propionic acidemia	3-Hydroxypropionic acid Propionylglycine Methylcitrate Lactic acid	Poor feeding, vomiting, ketoacidosis, lethargy, coma, seizures, and cardiomyopathy
Methylmalonic aciduria	Methylmalonic acid 3-Hydroxypropionic acid Propionylglycine Methylcitrate Lactic acid	Poor feeding, vomiting, ketoacidosis, lethargy, coma, seizures, cardiomyopathy, and renal failure
Biotinidase deficiency	3-Hydroxypropionic acid Propionylglycine Methylcitrate Lactic acid 3-Methylcrotonylglycine 3-Hydroxoisovaleric acid	Seizures, ataxia, progressive psychomotor retardation, skin rash, and alopecia
Isovaleric acidemia	Isovalerylglycine 3-Hydroxyisovaleric acid	Poor feeding, vomiting, "sweaty feet" odor, lethargy, coma, cerebral edema, and ketoacidosis
3-Methylcrotonyl-CoA carboxylase deficiency	3-Methylcrotonylglycine 3-Hydroxyisovaleriac acid	Poor feeding, vomiting, ketoacidosis, lethargy, coma, and psychomotor retardation
Glutaric aciduria type I	Glutaric acid 3-Hydroxyglutaric acid Glutaconic acid	Macrocephaly, acute encephalopathy, hypotonia, and impaired neurodevelopment
3-Methylglutaconic aciduria type I	3-Methylglutaconic acid 3-Methylglutaric acid 3-Hydroxyisovaleric acid	Fasting hypoglycemia, delayed speech, and progressive psychomotor retardation

CoA, Coenzyme A.

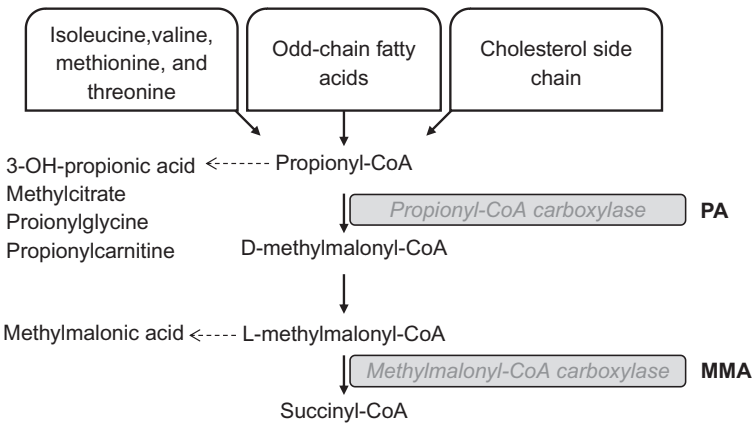

FIGURE 48.5 Metabolism of propionyl-coenzyme A and methylmalonyl-coenzyme A. Bold: inborn errors of metabolism resulting from deficiencies in enzymes. Dashed arrows: abnormal production of metabolites. *MMA*, Methylmalonic aciduria; *PA*: propionic acidura.

methionine and threonine, odd chain fatty acids, and cholesterol side chains (Fig. 48.5). Since this catabolic pathway provides succinyl-CoA to the Krebs cycle, PA and MMA are disorders of energy metabolism. Patients typically present with hypotonia, lethargy, and poor feeding. Decompensation can be rapid and severe. PA is caused by deficiency in propionyl-CoA carboxylase (whether primary or as part of multiple carboxylase deficiency). PA is diagnosed by presence of 3-hydroxypropionic acid, methylcitrate, proprionylglycine, and tiglylglycine in urine organic acid analysis. MMA refers to a group of disorders that result in the accumulation of methylmalonic and propionic acids caused by either methylmalonyl-CoA mutase deficiency, 5′-deoxyadenosylcobalamin metabolic defects, or vitamin B_{12} deficiency. Urine organic acid analysis of the MMA patient reveals elevations of methylmalonic acid, methylcitrate, and 3-hydroxypropionic acid. In both PA and MMA, elevation of C3 carnitine will be present in acylcarnitine analysis and is the marker used for newborn screening. PA and MMA are treated with protein-restricted diets fortified with amino acid supplements that are low in PA precursors, and carnitine supplementation.

Glutaric academia type I

Defects in glutaryl CoA dehydrogenase, an enzyme involved in the degradation of lysine, hydroxylysine, and tryptophan, results in GA1. Patients typically present with acute life-threatening encephalopathic crises usually within the first year of life. Diagnosis is based on detection of increased concentrations of glutaric acid, 3-hydroxyglutaric acid (characteristic of GA1), and glutaconic acids in the urine. Elevated glutarylcarnitine in plasma is also found and is used as the basis of newborn screening. Prompt recognition of this condition and restriction of lysine and tryptophan with carnitine supplementation can prevent neurological damage.

Urea cycle disorders

The urea cycle is important for the elimination of nitrogen from protein metabolism. Deficiency of each of the urea cycle enzymes has been described. In the urea cycle, ammonia is converted to urea through a series of reactions occurring in the mitochondria and cytosol (Fig. 48.6). Deficiencies of mitochondrial enzymes are collectively termed "proximal" UCDs, whereas the distal disorders involve cytosolic enzymes. Typically, affected individuals present with lethargy and coma within the first few days of life, but usually after the first 24 hours. Milder deficiencies may not present until much later in life. Males with X-linked ornithine transcarbamylase (OTC) deficiency may not become symptomatic until well into adult life, when their metabolic status is stressed by increased protein intake or increased protein turnover secondary to trauma, infection, or chemotherapy. Female carriers of OTC mutations that result in severe deficiency may also become symptomatic during times of increased metabolic stress. A common presentation is unexplained postpartum coma.

Hyperammonemia is a common presenting biochemical abnormality in individuals with UCDs. Individuals with UCDs often have very low blood urea nitrogen (as low as 0−1 mg/dL), but this finding is not specific for UCDs. Some UCDs can be diagnosed by amino acid analysis alone. Marked elevation of citrulline is indicative of argininosuccinate synthase deficiency. Milder elevation of citrulline is seen in argininosuccinate lyase deficiency where ASA also accumulates. Amino acid analyzers are often not programmed to identify ASA and its anhydrides, which may erroneously be identified by the instrument as other amino acids such as ethanolamine. Arginase deficiency is unique among the UCDs in that it is associated with only mild increases in plasma ammonia concentration. Affected patients often do not display symptoms of hyperammonemia and typically present outside the neonatal period with spastic diplegia, seizures, and cognitive deficits. Marked elevation of arginine is a hallmark of arginase deficiency, but it can also be seen in patients with other UCDs who are treated with IV arginine to replenish urea cycle intermediates during an episode of metabolic decompensation.

Increased plasma glutamine is a common finding in hyperammonemia, including postprandial hyperammonemia, and glutamine can be massively increased in UCDs. Elevation of plasma glutamine and alanine are common with deficiency of carbamyl phosphate synthase I (CPS I)

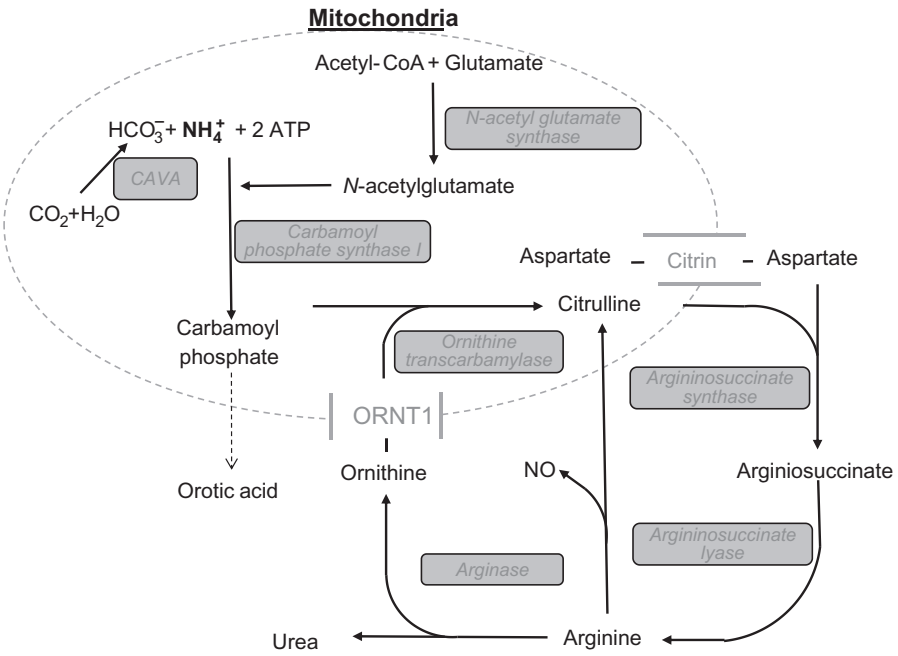

FIGURE 48.6 Urea cycle disorders. Urea cycle disorders involve the "proximal" reactions that occur in the mitochondria or "distal" reactions that occur in the cytoplasm as well as two transporters, citrin and mitochondrial 1 ornithine transporter. Carbonic anhydrase 5A produces the bicarbonate used by carbamoyl phosphate synthase I. In addition to its role in the urea cycle, arginine also serves as the source of nitric oxide.

and OTC. Plasma citrulline is often decreased, but ornithine and arginine are usually normal. Amino acid analysis cannot distinguish between CPS I and OTC deficiencies. Instead, organic acid analysis is needed to identify the increased orotic acid seen in OTC deficiency that results from accumulation of carbamyl phosphate in enzyme deficiencies after CPS I.

Massive elevation of ammonia may require dialysis initially. Once stabilized, ammonia-conjugating agents such as benzoic acid, phenylacetate, and phenylbutyrate allow additional diversion of ammonia from the urea cycle. Treatment of UCDs often includes protein restriction to decrease production of excess ammonia. Some dietary protein may be substituted by essential amino acid mixtures to allow higher total protein intake and improved growth. Supplementation with citrulline or arginine may also be necessary to replenish urea cycle intermediates. Despite optimal therapy, infants with neonatal hyperammonemia often have developmental delay when ammonia is markedly increased (>200 fmol/L) in the neonatal period. The enzyme deficiencies resulting in UCDs and their associated biochemical findings are listed in Table 48.6.

Fatty acid oxidation disorders

Beta-oxidation of most fatty acids occurs in the mitochondrion. Long-chain fatty acids are transported across the mitochondrial membranes by conjugation to carnitine. Once the acylcarnitines reach the mitochondrial matrix, the fatty acid is transferred back to CoA to form acyl-CoA thioesters. In FAODs, metabolism of acyl-CoAs is blocked, and acyl-CoAs accumulate with transfer of the fatty acid back to carnitine. The resulting accumulation of acylcarnitines can be analyzed by MS/MS. This testing can identify elevations of other CoA compounds, including acetyl-CoA that is increased with lipolysis and lactic acidosis and the short-chain acyl-CoAs that accumulate in organic acidemias. Fatty acid oxidation results in the production of acetyl-CoA that can be used to produce ketone bodies when glucose supply is inadequate. The enzymes involved in fatty acid oxidation are active on fatty acids of specific chain length. In FAODs, the chain length of the accumulating fatty acid intermediates influences the symptoms seen in these conditions.

Long-chain fatty acids are sequentially metabolized by VLCAD and long-chain hydroxyacyl-CoA dehydrogenase. Deficiencies of either of these enzymes may present with cardiomyopathy and myopathy due to energy deficiency in muscle, which preferentially uses fatty acids for fuel, or hepatic dysfunction due to accumulation of toxic acyl-CoA and acylcarnitine intermediates. Less severe deficiencies may present with hypoketotic hypoglycemia. Episodes of rhabdomyolysis are common after exercise or with metabolic stress and may be the presenting symptom in the mildest forms of these conditions. Long-chain FAODs are most often diagnosed by acylcarnitine analysis, because urine organic acid analysis may be normal and often shows only hypoketotic dicarboxylic aciduria when it is abnormal. This pattern, though suggestive of a FAOD, does not point to a specific diagnosis. Additionally, acylcarnitine analysis may be normal when

TABLE 48.6 Urea cycle disorders and associated biochemical findings.

	Disorder (defect)	Biochemical findings
Proximal UCD	*N*-acetyl glutamate synthase deficiency	Hyperammonemia, low citrulline, and arginine
	Carbamyl phosphate synthetase I deficiency	Hyperammonemia, low citrulline, and arginine
	Carbonic anhydrase 5A deficiency	Hyperammonemia, low citrulline, and arginine (lack of mitochondrial bicarbonate production also affects pyruvate carboxylase, propionyl-CoA carboxylase, and 3MCC-carboxylase)
	Ornithine transcarbamylase deficiency	Hyperammonemia, low citrulline and arginine elevated orotic acid, and uracil (urine)
Distal UCD	Argininosuccinate synthetase 1 deficiency or citrullinemia type I	Hyperammonemia, very high citrulline and low arginine, and elevated orotic acid (urine)
	Argininosuccinate lyase deficiency	Hyperammonemia, high citrulline and low arginine, ASA (plasma or urine), and elevated orotic acid (urine)
	Arginase deficiency	Mild hyperammonemia, elevated arginine, and elevated orotic acid (urine)
Transporter defects	ORNT1 deficiency or hyperornithinemia, hyperammonemia, and homocitrullinuria syndrome	Hyperammonemia, high ornithine, and high homocitrulline
	Citrin deficiency or citrullinemia type II	Mild-to-severe hyperammonemia and elevated citrulline

Notes: Because arginine supplementation is standard of care for many urea cycle disorders, arginine may be elevated due to therapeutic intervention.
ASA, Argininosuccinic acid; CoA, coenzyme A; *3MCC*, 3-methylcrotonylglycinuria; *ORNT1*, mitochondrial 1 ornithine transporter; *UCD*, urea cycle disorder.

the patient is asymptomatic, and acylcarnitine profile of cultured fibroblasts may be necessary for diagnosis.

Carnitine is required to transport long-chain fatty acids into the mitochondria. Fatty acids are transferred from CoA to carnitine by carnitine palmitoyl transferase I (CPTI) at the outer mitochondrial membrane. The acylcarnitines are transported across the mitochondrial intermembrane space by carnitine-acylcarnitine translocase (CACT), which counter transports free carnitine back to the outer mitochondrial membrane. Once the fatty acid enters the mitochondrial matrix, it is then transferred back to CoA by the action of carnitine palmitoyl transferase II (CPTII). Abnormalities in each of these enzymes as well as the active transport of carnitine have been described.

Because carnitine is required for metabolism of long-chain fatty acids, deficiencies of CPTI, CPTII, CACT, and the carnitine transporter typically have symptoms similar to those seen with long-chain fatty acid disorders. Severe deficiencies often present with cardiomyopathy or arrhythmia in the neonatal period, whereas individuals with milder deficiencies may have muscle weakness and episodic rhabdomyolysis. Plasma acylcarnitines may be diagnostic in more severe deficiencies of CPTI, CPTII, and CACT, but this testing may be unremarkable in mild deficiencies. An elevated free carnitine fraction, in the setting of low acylcarnitine and elevated (or high normal) total carnitine, may suggest a CPTI deficiency.

MCAD deficiency is the most common FAOD. It is often identified by abnormal newborn screening acylcarnitine profile, but it may present with hypoketotic hypoglycemia. Acylcarnitine analysis usually shows a characteristic profile (typically elevated C6, C8, C10:1), but it can be normal. Urine organic acid analysis can demonstrate the presence of hexanoylglycine (HG) and suberylglycine (SG), even when the patient is asymptomatic. These metabolites can also be quantitated by SID/SIM as part of acyl glycine analysis, and low excretion of HG and SG may require SID/SIM in some individuals with MCAD deficiency.

Short-chain acyl-coenzyme A dehydrogenase (SCAD) deficiency is difficult to diagnose, mostly because of continuing controversy about the clinical features of this condition. Some children have presented with neurologic problems and have shown elevations of ethylmalonic acid and methylsuccinic acid on organic acid analysis. However, most individuals with elevation of urinary ethylmalonic acid excretion do not have mutations in the SCAD gene. Some have a common polymorphism that results in mild reduction in SCAD activity. Research continues to determine the clinical significance of this polymorphism. In contrast to other FAODs, deficiency of short-chain 3-hydroxyacyl-CoA dehydrogenase results in hyperinsulinemic hypoglycemia.

Deficiency of multiple acyl-CoA dehydrogenase (MAD) enzymes (also known as Glutaric acidemia Type 2) is secondary to abnormalities of either electron transport flavoprotein (ETF) or ETF-coenzyme Q10 oxidoreductase (ETF-QO). ETF transfers electrons from the fatty acid dehydrogenases to the respiratory chain. ETF-QO is required to reoxidize ETF. Severe forms of MAD deficiency present in the neonatal period with dysmorphic facies and renal cysts and are often fatal in the neonatal period, but milder deficiency of MAD may be asymptomatic if fasting is avoided. Laboratory findings include fasting hypoketotic hypoglycemia, excretion of glutaric, ethylmalonic and dicarboxylic acids in the urine, and increased C4−C8 plasma carnitines.

Mitochondrial disorders

Mitochondria play an important role in production of ATP and found in large numbers in cells and tissues with high energy demand. Mutations in either mitochondrial DNA (mtDNA) or nuclear DNA can lead to mitochondrial dysfunction. Affected individuals with mutations in mtDNA can display mosaicism within a cell with a mixture of both wild-type and mutated mtDNA (heteroplasmy). The percentage of mutated mtDNA can vary among tissues and organs within the same individual as well as individuals within the same family. This variation may explain the varied phenotypes observed in patients with mtDNA disorders. Additionally, with more than 1000 nuclear genes encoding mitochondrial proteins, diagnosing these disorders can be challenging. Mitochondrial disorders associated with mutations in nuclear DNA can involve the respiratory chain, coenzyme Q10 biosynthesis, mitochondrial protein synthesis, or mtDNA maintenance. The common clinical phenotypes associated with mitochondrial disorders are poor growth, myopathy, exercise intolerance, developmental delay, neurological problems, visual and/or hearing problems, diabetes, and heart, liver, or kidney disease.

The overall prevalence of mitochondrial disorders is expected to be at 1:5000 affected individuals. A mitochondrial disorder evaluation is often warranted in children with neurologic dysfunction with multisystem involvement. The presence of distinctive phenotypes coupled with family history and genetic testing can make the diagnosis of a mitochondrial disorder straightforward. However, when a patient does not have a distinctive phenotype, measurement of plasma and CSF lactate, acylcarnitines, and urine organic acids can be helpful. Direct measurement of oxidative phosphorylation by high-resolution respirometry is another emerging technique that may be useful in confirming the presence of mitochondrial disease. Genomic testing can include sequencing of the exome, genome, or mtDNA. However, the main limitations of genetic approaches include false negatives due to poor sequence coverage (single gene/multiple

panel testing can be more accurate in these cases) and inability to detect deletions, duplications, triple repeat expansions, and epigenetic modifications.

Glycogen storage diseases

Glycogen provides a source of glucose when the glucose is not supplied continuously. Metabolism of glycogen is tightly regulated by kinases and phosphatases that activate and inactivate glucose-6-phosphatase and its kinase during periods of fasting in response to increased glucagon. Glycogen storage diseases (GSDs) comprise a large category of disorders caused by abnormalities in both the degradation and synthesis of glycogen. They present with either hypoglycemia or symptoms of organ dysfunction due to the accumulation of glycogen. Some GSDs have predominantly hepatic-associated issues with hepatomegaly, whereas others have predominant muscle presentations with associated muscle cramps and exercise intolerance. Forearm exercise testing can be used to identify the myopathic forms of GSDs, because lactic acid production during exercise is minimal in the absence of glucose release from glycogen. Similar results are obtained in glycolytic defects, because released glucose cannot be metabolized to pyruvic acid. Treatment is aimed at the prevention of hypoglycemia in those GSDs associated with short fast hypoglycemia.

Deficiency of acid maltase, also known as Pompe disease, is unique among the GSDs in that glycogen accumulates in the lysosome. Severe acid maltase deficiency results in hypotonia and hypertrophic cardiomyopathy in early infancy. Milder deficiency results in muscle weakness, typically associated with elevation of creatine kinase. Diagnosis of Pompe disease is usually based on enzymatic analysis of either liver or dried blood spots. Excretion of glucose tetrasaccharides in urine is increased in infants with Pompe disease, and quantitation of this metabolite can be used to monitor the effectiveness of enzyme replacement therapy.

Peroxisomal disorders

Peroxisomes are important in the metabolism of branched-chain, polyunsaturated, and very long-chain fatty acids. They also play a role in the synthesis of bile acids, isoprenoids, and ether phospholipids, such as plasmalogens. Peroxisomal disorders can arise due to either defects in peroxisome biogenesis or single peroxisomal enzyme deficiencies. Peroxisome biogenesis disorders (PBDs) are a group of conditions that result in deficiency of multiple peroxisomal functions due to inability to make peroxisomes or deficiency in the import of intraperoxisomal proteins. PBDs include the Zellweger spectrum disorders (Zellweger syndrome, neonatal adrenoleukodystrophy, and infantile Refsum disease) and rhizomelic chondrodysplasia punctata type 1. The most severe forms of these conditions present in the neonatal period with severe hypotonia, seizures, liver and renal disease, calcific stippling of long bone epiphyses, and dysmorphic facial features resembling Down syndrome.

Deficiencies of single peroxisomal enzymes have also been described. The most common of these are X-linked adrenoleukodystrophy (XALD) and Refsum disease. XALD is due to the deficiency of a peroxisomal membrane fatty acid transporter, which results in progressive neurologic deterioration and dementia starting in the early school years in the most severe form. XALD is a common cause of adrenal insufficiency in boys. A milder variant, adrenomyeloneuropathy, presents with increased spasticity in adulthood and may be misdiagnosed as hereditary spastic paraparesis. Some female carriers of XALD develop gait abnormalities in later adulthood. Although the diagnosis of XALD is possible based on measurement of very long-chain fatty acid (VLCFA), this test cannot predict the phenotype and is only abnormal in 80% of carrier females.

In Refsum disease, deficiency of phytanoyl-CoA hydroxylase results in accumulation of phytanic acid with resulting retinitis pigmentosa, sensory and motor neuropathies, and ataxia. Onset of symptoms most commonly occurs in late childhood or adolescence. Night blindness and retinitis pigmentosa are often the first signs of Refsum disease. Because phytanic acid is obtained via exogenous sources, a phytanic acid-restricted diet is effective in preventing progression of symptoms if the diet is started early enough. Of note, adult-onset Refsum disease is distinct from infantile Refsum disease, which is a PBD within the Zellweger spectrum.

Measurement of VLCFA, pipecolic acid, and phytanic acid in plasma and plasmalogens in red blood cells are commonly used to screen for peroxisomal disorders. Currently, XALD is the only peroxisomal disorder included on the RUSP. Screening for XALD typically involves the measurement of VLCFA, C26, by tandem mass spectrometry. A plasma fatty acid profile, performed by GC−MS, which includes measurement of VLCFAs (C22, C24, and C26), phytanic acid and pristanic acid can aid in evaluating peroxisomal disorders. In many cases, molecular analysis of peroxisomal genes allows for definitive diagnosis and identification of at-risk family members.

Lysosomal storage diseases

Lysosomes are responsible for degradation of a variety of cellular waste products. A number of IEMs have been described that result in accumulation of various materials in the lysosome. Features that suggest a lysosomal storage disease (LSD) include hepatosplenomegaly, coarsening

facial features, bony changes indicative of dysostosis multiplex, developmental regression, corneal clouding, and nonimmune hydrops fetalis. In addition, some LSDs may now be identified via newborn screening using multiplexed LC−MS/MS-based methods. LSDs are divided into mucopolysaccharidoses (MPSs), oligosaccharidoses, and sphingolipidoses.

MPSs occur when the degradation of the carbohydrate moiety of proteoglycans that are present at cell surfaces and in the extracellular matrix is incomplete due to deficiency of a lysosomal enzyme. The glycosaminoglycans (GAGs) that accumulate can be quantitated in urine. Separation of different classes of GAGs by thin-layer chromatography, electrophoresis, or HPLC allows identification of the accumulating GAGs and helps determine the most appropriate enzyme assay for definitive diagnosis. In some MPSs, the total excretion of GAGs is only mildly increased and separation of the GAGs is necessary to recognize the accumulation of a particular GAG. This is commonly seen with Sanfillippo syndrome types A−D and Morquio syndrome types A and B. In both cases, the disease subtypes are clinically and biochemically indistinguishable through GAG analysis alone; however, diagnosis can be made by either enzymatic or molecular testing. Development of recombinant enzyme replacement therapy has expanded the treatment of MPSs, but the infused enzyme does not cross the blood−brain barrier and the treatment is not effective against the neurodevelopmental effects of these conditions.

Individuals with oligosaccharidoses have abnormalities in the degradation of the oligosaccharide groups of glycoproteins. Their clinical features are similar to those seen in MPSs, but organomegaly is less common and measurement of GAGs is normal. Vacuolated lymphocytes may be noted in many of the oligosaccharidoses. Thin-layer chromatography or HPLC of oligosaccharides in urine reveals the accumulation of abnormal material that must be identified by comparison to the pattern observed in individuals with confirmed oligosaccharidoses. Newer methods for oligosaccharide analysis, which employ the use of matrix-assisted laser desorption/ionization-TOF mass spectrometry to analyze permethylated urine oligosaccharides, have been described and can be used for screening individuals with suspected oligosaccharidosis. No treatment is currently available for oligosaccharidoses.

Sphingolipids are complex lipids containing the amino alcohol sphingosine attached to a long-chain fatty acid with or without other polar groups or sugars. Many are required for myelin, and gangliosides (a sialic acid containing glycosphingolipid) are important in gray matter. Enzyme deficiencies have been described for each of the enzymes required to degrade sphingolipids. Some sphingolipidoses are associated predominantly with hepatosplenomegaly; these include Gaucher disease and Niemann−Pick disease types A and B. A more severe form of Gaucher disease results in neurodegenerative disease and may be due to more severe enzyme deficiency, because both forms are due to deficiency of glucocerebrosidase.

Fabry disease, an X-linked condition, results in storage of glycolipids in reticuloendothelial cells, which results in episodes of neuropathic pain and eventually in renal insufficiency. One form of Fabry disease results in hypertrophic cardiomyopathy. Metachromatic leukodystrophy and globoid (Krabbe) leukodystrophy are sphingolipidoses associated with prominent demyelination and peripheral neuropathy; white matter changes are prominent on MRI. The gangliosidosies, including Tay−Sachs disease, are characterized by neuronal storage that can be seen as a cherry red spot in the infantile presentation. In those sphingolipidoses that result in neurologic abnormalities, early onset disease typically presents with developmental regression, whereas psychiatric disturbances are more common with adult onset. Diagnosis of these conditions requires measurement of enzyme activity in leukocytes or fibroblasts, but the results must be interpreted with caution. In rare cases of gangliosidosis, enzyme activity is normal in vitro, but deficiency of the GM2-activator protein results in enzyme deficiency in vivo. In other cases, apparent enzyme deficiency in an asymptomatic adult is actually a pseudodeficiency due to deficient activity against the artificial substrate. Finally, in I-cell disease, which results from impaired targeting of lysosomal enzymes to their proper intracellular location, multiple enzymes may show increased activity in a plasma (but not cellular) sample due an increased concentration.

Congenital disorders of glycosylation

Congenital disorders of glycosylation are a continuously expanding group of disorders that affect glycoprotein biosynthesis. Protein glycosylation is an important post-translational modification that impacts protein folding, subcellular localization, as well as antigen−antibody and protein−receptor interactions. A variety of sugar chains are covalently attached to proteins by either O-glycosidic linkage to serine or threonine residues or by *N*-linkage to amino groups of asparagine residues. Measurement of carbohydrate-deficient transferrin is often used to screen for congenital disorders of glycosylations (CDGs) with deficient *N*-glycosylation. This testing was initially done by isoelectric focusing, but the use of this test as a screen for chronic alcohol abuse has resulted in the development of turbidimetric immunoassay, capillary zone electrophoresis, HPLC, and LC-MS methods that are more readily available. For some of these testing methods, interpretation of results is complicated by some benign variants

of the transferrin protein that alter the electrophoretic pattern.

Type 1 CDGs affect synthesis of the carbohydrate before transfer to the protein, whereas conditions affecting maturation of the carbohydrate group are classified as type 2. Within each type, disorders are lettered in order of report. The most common CDG is type PMM2-CDG (1a), which is due to deficiency of phosphomannomutase; this deficiency prevents conversion of mannose 6-phosphate to mannose 1-phosphate, which is required for transfer of mannose to GDP. This deficiency subsequently prevents the transfer of mannose to the carbohydrate backbone. Although many of these mannose residues are removed during later maturation of the glycoprotein, they are required for glycoprotein processing, and their absence prevents further modification of the carbohydrate group. Individuals with PMM2-CDG typically have unusual fat distribution with inverted nipples, coagulation abnormalities, cerebellar hypoplasia, developmental delay, and liver function abnormalities; many die in infancy, although adults have been reported. Most CDGs are associated with significant developmental disabilities, but gastrointestinal symptoms (diarrhea, liver fibrosis, and failure to thrive) predominate in types 1b and 1h; intellectual development is normal in these variants. Phosphomannose isomerase deficiency (CDG1b) is the only treatable CDG, and symptoms are decreased by treatment with mannose. In addition to genetic testing, CGDs with impaired *N*-glycosylation can be distinguished by measuring the relative abundance of specific *N*-glycans using LC−MS/MS.

Conclusion

IEMs are individually rare, yet collectively common. Since severe morbidity can be avoided in some diseases, it is important to make the correct diagnosis as soon as possible. The role of the clinical laboratorian in the diagnosis of IEM cannot be underestimated. Diagnosis of IEMs relies on specialized laboratory testing and its interpretation. It is important to rule out diseases that can be treated first, and to perform diagnostic testing before confirmatory or prognostic genetic testing.

Self-assessment questions

1. Most amino acid disorders are identified in which matrix?
   a. serum
   b. plasma
   c. urine
   d. CSF
2. Organic acid analysis most commonly uses which instrument?
   a. HPLC
   b. MS/MS
   c. LC−MSMS
   d. GC−MS
3. Acylcarnitine analysis is most commonly used to identify which class of disorders?
   a. urea cycle disorders
   b. glycogen storage disorders
   c. lysosomal storage disorders
   d. fatty acid oxidation disorders
4. Which amino acid is pathognomonic for MSUD?
   a. valine
   b. leucine
   c. isoleucine
   d. alloisoleucine
5. What is the most common fatty acid oxidation disorder?
   a. VLCAD
   b. LCAD
   c. MCAD
   d. SCAD

Introduction

Porphyrias are a group of rare metabolic disorders associated with defects in the heme biosynthetic pathway [1]. Partial deficiency or hyperactivity of one of the heme biosynthesis enzymes results in excess pathway intermediates that accumulate in body tissues and are excreted. These precursor compounds cause distinctive biochemical features and disease symptoms. Porphyria symptoms can mimic a variety of conditions, and thus porphyria can be difficult to diagnose.

Traditional classification of the porphyrias as hepatic or erythropoietic is based on the primary tissue in which overproduction of heme precursors occurs; however, porphyrias can be divided into two groups, acute (neurologic) and cutaneous (nonacute), according to their dominant clinical manifestations [2]. Characteristic patterns of accumulation of heme precursors due to abnormal enzyme activities are associated with each porphyria. These compounds can be detected readily in blood, urine, and feces, which permits biochemical assessment [3,4]. Appropriately chosen and interpreted, laboratory tests for porphyria are sensitive and specific, and play a crucial role in the diagnosis and management of these disorders.

Biochemistry: heme formation

Biosynthesis of heme occurs in all nucleated cells, primarily in developing erythrocytes of the bone marrow in which hemoglobin is generated, and to a lesser extent in hepatocytes, the site of formation of heme-containing enzymes [1]. The tetrapyrrolic heme structure is generated enzymatically in a sequential series of steps that takes place in two distinct cellular compartments; the first and the last three steps occur in the mitochondrion, and the intermediate steps take place in the cytosol (Fig. 49.1).

Eight enzymes catalyze the formation of protoporphyrin IX and the chelation of iron to produce heme. The initial and rate-limiting reaction in the pathway is the condensation of glycine and succinyl-coenzyme A to form δ-aminolevulinic acid (ALA), which is catalyzed by δ-aminolevulinic acid synthase (ALAS), Enzyme Commission (EC) number 2.3.1.37 [5]. Condensation of two molecules of ALA to generate the monopyrrole porphobilinogen (PBG) is mediated by PBG synthase (alternate name ALA dehydratase; EC 4.2.1.24). This step is followed by polymerization of four molecules of PBG to form the linear tetrapyrrole hydroxymethylbilane. The reaction is catalyzed by hydroxymethylbilane synthase (HMBS, alternate name PBG deaminase; EC 2.5.1.61); however, spontaneous polymerization can occur if PBG concentrations are high. Cyclization of the tetrapyrrole to form uroporphyrinogen III is catalyzed by uroporphyrinogen III synthase (EC 4.2.1.75) [6], although minor uncatalyzed cyclization occurs and the structural isomer uroporphyrinogen I is generated. Decarboxylation of uroporphyrinogen isomers is mediated stepwise through uroporphyrinogen decarboxylase (UROD; EC 4.1.1.37) to form the tetracarboxyl isomers coproporphyrinogen III and I. Only coproporphyrinogen III is oxidatively decarboxylated by coproporphyrinogen oxidase (CPOX; EC 1.3.3.3) to protoporphyrinogen IX [1]. Subsequent oxidation of the compound in a reaction catalyzed by protoporphyrinogen oxidase (PPOX; EC 1.3.3.4) produces protoporphyrin IX, and insertion of ferrous iron (Fe^{2+}) by ferrochelatase (FECH; EC 4.99.1.1) generates heme.

Heme biosynthesis is regulated in hepatic parenchymal cells by negative feedback inhibition. The intracellular concentration of free heme (heme pool) regulates synthesis of the ubiquitous ALAS isoform ALAS1 to control production of heme by inhibiting the first step of the

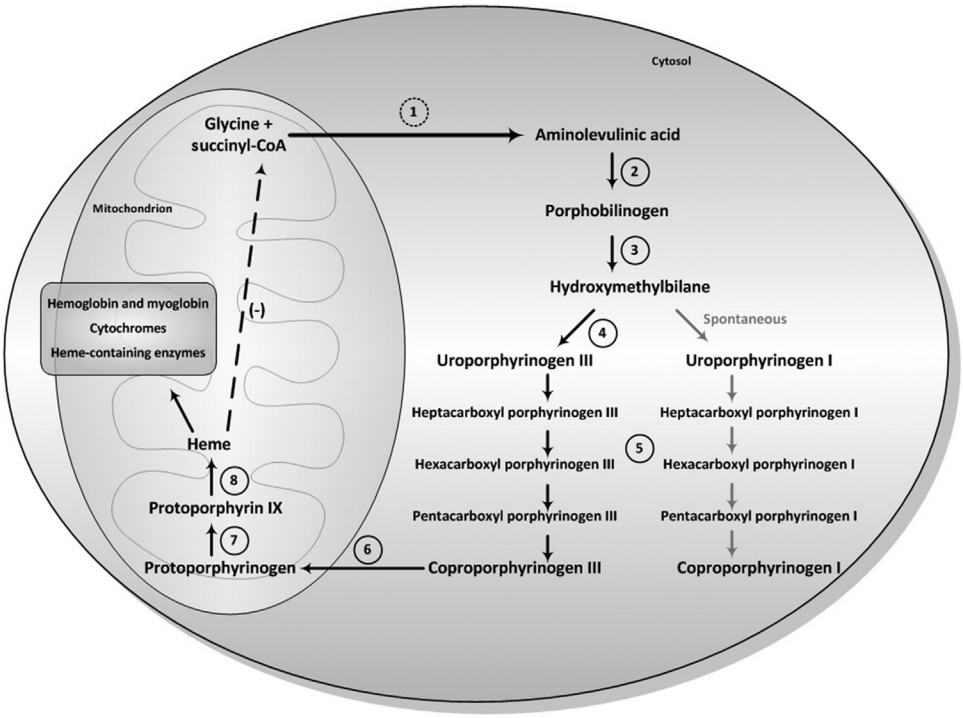

FIGURE 49.1 Heme biosynthetic pathway. Eight enzymes catalyze synthesis of heme from glycine and succinyl-coenzyme A. Heme production controls the hepatic pathway by regulating aminolevulinic acid synthase (1) activity. The other enzymes are: porphobilinogen synthase (2), hydroxymethylbilane synthase (3), uroporphyrinogen III synthase (4), uroporphyrinogen decarboxylase (5), coproporphyrinogen oxidase (6), protoporphyrinogen oxidase (7), and ferrochelatase (8). Production of heme regulates the activity of aminolevulinic acid synthase, the rate-limiting enzyme in the pathway, by negative feedback inhibition (−). Heme synthesis in erythroid cells is limited by iron (Fe^{2+}) availability. *Adapted with permission from M.L. Parnas, E.L. Frank, Porphyrias: a guide to laboratory assessment, Clin. Lab. News 36(4) (2010) 8−10 (Copyright AACC, used with permission).*

pathway. In erythropoietic cells, heme biosynthesis is controlled by the erythroid-specific enzyme ALAS2. Synthesis of ALAS2 is induced during active heme biosynthesis, and the rate of heme production is limited by the availability of iron (Fe^{2+}) [7].

Under usual conditions, the highly efficient biosynthetic pathway allows for most of the ALA produced to be converted to heme. Only minimal amounts of precursors and intermediates accumulate and are excreted, with the route of elimination directed largely by the intrinsic aqueous solubility of each compound. The water-soluble porphyrin precursors ALA and PBG are excreted in urine. The octacarboxylic intermediate uroporphyrinogen is water-soluble and excreted renally; the hydrophobic dicarboxylated protoporphyrin IX is excreted in feces via the biliary tract. The remaining porphyrin intermediates, including the tetracarboxylated coproporphyrinogens, are somewhat water-soluble and appear in both urine and feces. The porphyrinogens, cyclic tetrapyrrole intermediates that exist in the body in a reduced state, are oxidized rapidly on exposure to air to corresponding porphyrin compounds, the analytes measured in the clinical laboratory [2]. The precursors and porphyrins found in blood, plasma, urine, and feces are shown in Table 49.1.

Genetic disorders: porphyrias

Genetic abnormalities in any of the eight heme biosynthetic enzymes give rise to the porphyrias [1]. Inheritance for most of these diseases is autosomal dominant, and one functional gene is present. Enzyme deficiency is partial, and activity is sufficient to maintain heme homeostasis. In certain clinical circumstances, pathway metabolites that precede the enzymatic defect accumulate in the body, causing characteristic signs and symptoms of the various porphyrias. An X-linked dominant gain-of-function mutation in the erythroid-specific ALAS2 enzyme promotes enzyme activity and production of excess protoporphyrin to cause an X-linked dominant protoporphyria [8]. Although each type of porphyria originates from a different genetic abnormality, the clinical manifestations of these disorders are similar, allowing their classification into acute and cutaneous porphyrias [2].

Acute porphyrias

The disorders comprising this group of porphyrias are acute intermittent porphyria (AIP), variegate porphyria (VP), hereditary coproporphyria (HCP), and ALA dehydratase

TABLE 49.1 Accumulation and excretion patterns of heme precursors and porphyrin intermediates in body fluids during symptomatic episodes of porphyria. Diseases are grouped into acute and cutaneous porphyrias and listed in order of decreasing prevalence.

Porphyria	Enzyme	Erythrocyte porphyrins	Plasma fluorescence (nm)	Urine precursors	Urine porphyrins	Fecal porphyrins
Acute porphyrias						
Acute intermittent porphyria	HMBS	Not increased	618–622	PBG (ALA)	Uro (from PBG)	Not increased
Variegate porphyria	Protoporphyrinogen oxidase	Not increased	626–628	PBG (ALA)	Uro, copro III	Copro III, proto IX
Hereditary coproporphyria	Coproporphyrinogen oxidase	Not increased	618–622	PBG (ALA)	Copro III, uro	Copro III
ALA dehydratase deficiency porphyria	Porphobilinogen synthase	Zn-proto	N/A	ALA	Copro III	Not increased
Cutaneous porphyrias						
Porphyria cutanea tarda	Uroporphyrinogen decarboxylase	Not increased	618–622	Not increased	Uro, hepta, and isocopro	Isocopro
Erythropoietic protoporphyria	Protoporphyrin ferrochelatase	Proto IX	634–636	Not increased	Not increased	Proto IX
X-linked erythropoietic protoporphyria	ALA synthase (ALAS2)	Free proto IX; Zn-proto	634–636	Not increased	Not increased	Proto IX
Congenital erythropoietic porphyria	Uroporphyrinogen III synthase	Uro I Copro I	618–622	Not increased	Uro I, copro I	Copro I

deficiency porphyria (ADP). Each disorder is associated with a separate enzymatic defect (Table 49.1). AIP, VP, and HCP are inherited in an autosomal dominant manner; the extremely rare ADP is inherited as an autosomal recessive trait. AIP is the most common of the acute porphyrias, affecting approximately 1:75,000 Caucasian persons [4]. Acute porphyrias are characterized by acute, potentially life-threatening neurovisceral attacks with symptoms of diffuse abdominal pain, gastrointestinal ailments, peripheral neuropathies, and mental disturbances [2]. Hypertension and tachycardia are typical. Hyponatremia and seizures may occur during attacks [3]. Acute symptomatic episodes typically commence during early adulthood, occur more frequently in women than men, and may be accompanied by skin lesions in VP and HCP. Pediatric onset is unusual, but has been documented [9].

The genetic abnormalities present in the three autosomal dominant acute porphyrias lead to an enzymatic activity approximately 50% of that expected. Adequate heme concentration is maintained as a result of upregulation of ALA synthase. Consequently, the acute porphyrias have low clinical penetrance, with most individuals remaining asymptomatic for life and approximately 10% of persons with the genetic defect manifesting symptoms in the presence or absence of precipitating endogenous and exogenous factors [4]. These exacerbating agents include drugs, hormones, infection, or stress, and act by increasing hepatic demands for heme, which induces heme synthesis. The enzyme deficiency becomes rate-limiting, and precursors and intermediates accumulate. Incidence and severity of the attacks are variable and more frequent upon exposure to precipitating factors. An increase in urinary excretion of PBG and/or ALA is observed in all patients with acute symptoms and in some asymptomatic individuals [10]. In ADP, symptoms are precipitated by excess ALA, and only urinary ALA is elevated.

Insufficiency of PPOX (VP) or CPOX (HCP) produces porphyrins that inhibit HMBS, the third enzyme in the pathway, and consequently elevate PBG concentrations. For this reason, both VP and HCP are categorized as acute porphyrias; however, photosensitivity and skin lesions are the only clinical manifestation in approximately 60% of individuals with VP and some (~5%) of those with HCP [4].

Cutaneous porphyrias

The cutaneous porphyrias include porphyria cutanea tarda (PCT), erythropoietic protoporphyria (EPP), X-linked erythropoietic protoporphyria (XLP), and congenital erythropoietic porphyria (CEP) [11]. These disorders and the associated enzymes are listed in Table 49.1. The most prevalent nonacute porphyria, PCT, can be inherited as an autosomal dominant trait, but usually the disorder is sporadic in origin due to acquired inhibition of UROD activity in hepatocytes [12]. Approximately one person in 10−20,000 is affected. Excess alcohol consumption, use of tobacco or estrogens, hepatitis C or human immunodeficiency viral infection, halogenated aromatic hydrocarbon exposure, and hemochromatosis or iron overload contribute to inactivation of hepatic UROD and are risk factors for PCT [12]. The mode of inheritance of EPP is complex, and frequently, disease expression is associated with a combination of two molecular defects [4]. XLP is due to an X-linked dominant gain-of-function mutation that causes hyperactivity of the erythroid-specific ALAS2 enzyme and excessive production of protoporphyrin [13]. Approximately 90% of protoporphyria cases are due to loss-of-function mutations in the enzyme FECH; 5% of cases result from activating mutations in ALAS2. The remainder are of unknown genetic basis [14]. The very rare CEP is autosomal recessive.

Clinically, the cutaneous porphyrias are characterized by photosensitization of the skin resulting from accumulation of porphyrin intermediates in tissues. Manifestations of disease are attributable to the light-absorbing properties of the porphyrin ring [2]. Symptoms, particularly on the hands, forearms, neck, and face, arise with sun exposure of the skin. PCT and CEP are characterized by increased skin fragility and blistering skin lesions that heal slowly, leaving scars and hyperpigmentation or hypopigmentation. Hypertrichosis of the face, ears, and arms is common. Symptoms are more severe and appear earlier in CEP patients, who may experience disfiguring mutilation of light-exposed body parts, such as the nose, ears, and hands. Late onset CEP associated with myeloid malignancy has been reported in older adults [15]. In EPP and XLP, acute painful burning sensations, redness, and itching on sun-exposed areas occur as a result of accumulation of protoporphyrin in erythrocytes. Disease onset typically occurs in childhood.

In addition to these diseases, rare homozygous forms of porphyria, such as hepatoerythropoietic porphyria (HEP), and dual porphyrias attributed to the presence of two different heterozygous defects have been reported [1].

Diagnosis: laboratory evaluation

Although mutation analysis and enzyme assays are available, laboratory testing to diagnose porphyrin disorders usually commences with identification of characteristic patterns of excess porphyrin precursor and intermediate compounds in body fluids. The specimen selected for testing (blood, urine, or feces) depends on solubility of the metabolic intermediates. The porphyrin precursors ALA and PBG are water-soluble compounds that are excreted and detected in urine. Aqueous solubility of porphyrins varies with the number of carboxylic acid side chains attached to the tetrapyrrole ring. Uroporphyrin, with eight carboxylic acid groups, is soluble in aqueous solution and can be detected in plasma and urine. Hepta-, hexa-, and pentacarboxylated porphyrins, with seven, six, and five carboxyl groups, respectively, as well as the tetracarboxylated coproporphyrins, are measured in plasma, urine, and feces. Dicarboxylic porphyrins such as protoporphyrin are less water soluble, and are identified and measured in whole blood, plasma, and fecal specimens.

Porphyrin compounds are photoactive due to extensive conjugation of the tetrapyrrole ring, which allows absorption of light in the visible region [2]. Porphyrins absorb light of ~400-nm wavelength and emit a characteristic red fluorescence [16]. These photochemical properties produce some of the manifestations of porphyric disease and provide a means for detection of the compounds in body fluids tested in the clinical laboratory [17].

The goal of initial testing is to demonstrate abnormal amounts of porphyrin compounds. If excess porphyrins are observed, diagnosis is made by interpretation of the specific pattern of precursor and intermediate compounds in various body fluid specimens. Additional investigation can be performed to identify the enzymatic abnormality and guide treatment.

Initial testing for suspected porphyria

Testing for porphyria is guided by the clinical symptoms of the patient. For individuals who present with acute manifestations, including diffuse abdominal pain, peripheral neuropathy, and mental disturbances, and for whom there is high suspicion for an acute porphyria attack, measurement of PBG in a random urine specimen should be the first test ordered (Fig. 49.2).

FIGURE 49.2 Diagnostic algorithm. Parnas, E.L. Frank, Porphyrias: a guide to laboratory assessment, Clin. Lab. News 36(4) (2010) 8–10 (Copyright AACC, used with permission).*

A common method for measurement of PBG utilizes ion-exchange chromatography to isolate the compound and remove interferences, followed by reaction with 4-dimethylaminobenzaldehyde (Ehrlich's reagent) to produce a rose red compound that is detected spectrophotometrically to determine PBG concentration [18]. Elevated PBG concentration is considered a positive result and strongly suggests the presence of an acute porphyria. Additional biochemical testing is used to elucidate the specific type of acute porphyria. Frequently ALA is elevated, although to a lesser extent than PBG, and, with the exception of identification of the extremely rare ADP, measurement of excess PBG is sufficient to diagnose acute porphyria. A negative PBG result in a urine specimen collected from a symptomatic patient effectively excludes an acute porphyria attack due to AIP, VP, or HCP. Measurement of ALA in urine is performed to exclude ADP. In the absence of symptoms, PBG may not be increased, and a negative result does not completely rule out acute porphyria.

Prompt diagnosis of a suspected attack of acute porphyria is desirable, but testing for PBG is not routine and, in many areas, is performed only in specialized laboratories. A semiquantitative rapid test for urinary PBG offered commercially is no longer available [19], and urgent testing may not be performed at a local laboratory. Other simple, fast laboratory-developed methods have been proposed as screening tests [20]. Assays for PBG using mass spectrometry and nuclear magnetic resonance (^{1}H-NMR) have been designed [21–23]. An ideal method would provide rapid and sensitive near-patient testing to support early initiation of therapy and avoid administration of potentially harmful (hemin) or inappropriate (opioid analgesics) treatment.

Recommendations in some guidelines specify evaluation of cutaneous symptoms using fluorescence scanning to screen plasma and urine specimens for total porphyrins [24]. This screening may be accomplished using chromatographic assays that produce quantitative results. Urinary porphyrin isomers can be separated and measured within 10–12 min by high-performance liquid chromatography (HPLC). Urine specimens require minimal sample preparation, and HPLC assays are more automated than spectroscopic methods used for total porphyrin testing. Employing a single assay rather than a qualitative screen followed by additional testing efficiently identifies porphyria and is particularly useful if porphyria testing is performed at distant specialized laboratories, since sequential screening and confirmation could delay diagnosis and treatment.

For adults with clinical manifestations of cutaneous photosensitivity (blisters and skin fragility), an appropriate test is quantitative fractionation of urinary porphyrins in a 24-h specimen (Fig. 49.2). Typically, individual porphyrins are separated by HPLC and detected using fluorescence [25]. The compounds fluoresce between 600 and 660 nm when dissolved in acidic solution [1]. Excess urinary excretion of porphyrins, particularly uroporphyrin and heptacarboxyl porphyrin, with the appearance of isocoproporphyrin, a metabolite produced in an alternate biosynthetic pathway in conditions of deficient UROD activity, is diagnostic of PCT [1]. Chromatographic separation of the nonfunctional porphyrin I isomers from porphyrin III isomers identifies CEP. Massive amounts of uroporphyrin I and coproporphyrin I isomers are found in the urine of individuals affected with this rare disorder.

HPLC analysis of urine specimens from individuals with HCP and VP can be expected to show increased concentrations of coproporphyrin III if the specimen was collected when cutaneous symptoms were present. This finding is not definitive; however, the results can be used to exclude PCT and may prompt testing for PBG if the clinical situation is consistent with acute porphyria. Urinary porphyrins may not be increased if cutaneous symptoms are absent. Although AIP is not associated with cutaneous symptoms, a specimen collected from an affected individual during an acute attack may reveal significantly increased uroporphyrin due to spontaneous polymerization of PBG in the specimen. If PBG analysis was not ordered, the specimen should be tested for PBG to detect AIP. If urinary porphyrins are not increased, porphyria probably is not the cause of observed symptoms.

Individuals who experience acute phototoxic reaction to sun exposure (pain, redness, and itching of the face and hands or feet), particularly children, should be screened for elevated erythrocyte protoporphyrin in a whole blood specimen. Total measured porphyrins include both metal-free protoporphyrin and zinc protoporphyrin (ZPP), a metabolite formed by complexation of zinc ion with protoporphyrin [12]. Determination of ZPP as a fraction of total erythrocyte protoporphyrin distinguishes XLP from EPP [11,12]. Increased free erythrocyte protoporphyrin is consistent with EPP; in XLP, both free protoporphyrin and ZPP are elevated [4].

Additional biochemical testing

Following a positive screen for PBG and/or porphyrins, evaluation of plasma and fecal specimens provides additional diagnostic information. Quantitation of porphyrins in feces may be used to differentiate the acute porphyrias. Fecal porphyrin excretion is not increased appreciably in AIP. Significant fecal coproporphyrin excretion (10 or more times the upper reference limit) and an increased coproporphyrin III/I isomer ratio are characteristics of HCP, and VP is associated with increased fecal excretion of protoporphyrin and coproporphyrin [2]. Fecal isocoproporphyrin is a marker for PCT [26]. Testing plasma for porphyrin fluorescence confirms VP; a peak between 626 and 628 nm is pathognomonic [27]. Plasma fluorescence scanning can be used to monitor PCT and to support a diagnosis of protoporphyria.

HEP, a rare homozygous disorder of UROD deficiency, resembles CEP clinically, and can be differentiated by a predominance of protoporphyrin in blood and detection of isocoproporphyrin in feces [1].

Enzyme and molecular testing

Tests for enzymatic activity and molecular analysis, available from specialized laboratories [28], are best used to confirm a particular disorder in a previously diagnosed individual and to identify family members at risk for the disease [29]. Prediction of disease course or severity is not possible based on the results of molecular testing, but individuals carrying a mutation can be advised to prevent the development of symptoms by avoiding precipitating agents.

Secondary causes of increased porphyrin excretion

Abnormalities in metabolism and excretion of heme precursors and intermediates may occur in the absence of inherited porphyrias and can be caused by a variety of conditions (Table 49.2).

Isolated increases in concentrations of urinary coproporphyrin are encountered during porphyria testing and are typically associated with hepatic compromise similar to that associated with liver disease, drugs, or chronic consumption of alcohol [2]. In these conditions, coproporphyrin III is the predominant urinary isomer present. Impaired biliary excretion, such as that which occurs in obstructive jaundice, hepatitis, and cirrhosis, increases urinary coproporphyrin isomer I. Some inherited disorders of bilirubin metabolism (Dubin−Johnson and Rotor syndromes) alter biliary excretion of coproporphyrin isomers [30]. Urinary coproporphyrin may be increased, and more coproporphyrin I than coproporphyrin III is excreted renally. In unaffected individuals, the urinary coproporphyrin I/III isomer ratio is approximately 30%/70%. Inversion of the coproporphyrin isomer ratio to >80% coproporphyrin I is consistent with a diagnosis of Dubin−Johnson syndrome [31,32]. In Rotor syndrome, total urinary coproporphyrin and coproporphyrin I isomer concentrations are elevated; coproporphyrin I comprises approximately two-thirds of total coproporphyrin.

TABLE 49.2 Secondary causes of porphyrin metabolism abnormalities.

Condition	Abnormality
Hepatic dysfunction	
• Excess alcohol consumption and drugs	Urinary coproporphyrin III
Impaired biliary excretion	
• Cholestatic jaundice, hepatitis, and cirrhosis	Urinary coproporphyrin I
Disorders of bilirubin metabolism	
• Inherited jaundice	Urinary coproporphyrins I and III
Gastrointestinal system	
• Diet • Hemorrhage	Fecal porphyrins
Impaired renal function	
• Renal failure	Plasma porphyrins
Hematological disorders	
• Anemia	Zinc protoporphyrin
Heavy metal toxicity	
• Lead • Arsenic and mercury	ALA, coproporphyrin III, zinc protoporphyrin Urinary coproporphyrins
Hereditary tyrosinemia Type I	
• Enzyme inhibition by succinylacetone	ALA

ALA, Aminolevulinic acid.
Source: Modified from E.L. Frank, M.L. Parnas, The porphyrias: fundamentals and laboratory assessment, in: W. Clarke (Ed.), Contemporary Practice in Clinical Chemistry, third ed., AACC Press, Washington, DC, 2016, pp. 665–71 (Used with permission).

Lead intoxication increases porphyrins in body fluids and can cause attacks of acute abdominal pain and neurological disturbances that mimic acute porphyria attacks. Lead inhibits PBG synthase, the second enzyme in the heme biosynthesis pathway, and to a lesser extent CPOX [33]. As a result, lead toxicity is associated with significantly increased urinary ALA and coproporphyrin III excretion (Fig. 49.1). Lead reduces intracellular iron availability, and zinc replaces iron as a substrate for FECH; thus ZPP is formed in erythrocytes [34]. Tests for ALA, urinary porphyrins, and ZPP provide indirect evidence for lead toxicity. Definitive diagnosis is accomplished by demonstration of lead in blood and/or urine.

Specimen requirements

All specimens submitted for testing must be protected from light. Specimens should be stored and transported dark and cold. Porphyrins and precursor compounds are stable in unpreserved urine at 4°C for up to 48 h and can be frozen (−20°C) for several weeks [2]. Porphyrins in fecal specimens can be stored frozen (−20°C) for several months. Whole blood collected for protoporphyrin measurement should be anticoagulated with EDTA and stored in the dark at 4°C [35]. Urine specimens must be adequately concentrated to produce reliable results. Dilute urine specimens with creatinine concentrations of <25 mg/dL (~2 mmol/L) are not adequate for analysis. Creatinine concentration should be measured, and results for random urine collections should be reported as a ratio to creatinine concentration. Calculation using low creatinine concentrations measured in dilute urine will result in misleading analyte ratios.

Treatment and management of the porphyrias

Acute attacks of porphyria, which can be life-threatening, are treated by immediate withdrawal of suspected precipitating agents, treatment of coexisting illnesses and/or infections, and pain management with nonporphyrinogenic agents [4,36]. Treatment with intravenous heme preparations (hemin) is the preferred therapeutic approach. Hemin specifically inhibits hepatic ALAS activity, and effectively decreases urinary PBG and ALA

[3,4]. Medications that trigger porphyria attacks must be replaced with alternative medications [37]. Adequate nutrition and fluids must be sustained. Prevention of an acute attack is achieved through avoidance of precipitating factors, including specific drugs, alcohol, and tobacco; maintenance of adequate caloric intake, especially in the form of carbohydrates; and stress reduction [38]. Therapy can be monitored by measurement of urinary PBG excretion. Prophylactic hemin infusion may be considered, and liver transplant may be necessary for patients with severe, recurrent acute attacks. Potential new treatments include replacement enzyme therapy or gene therapy [39].

Treatment of nonacute porphyrias is primarily preventive. Cutaneous symptoms can be minimized by avoidance of ultraviolet (UV) and visible light exposure and use of protective clothing and topical opaque sunscreens [12,40]. For PCT, administration of low-dose chloroquine or hydroxychloroquine is used to stimulate hepatic secretion and urinary excretion of porphyrins. Therapeutic phlebotomy, recommended for patients with hemochromatosis, removes iron and decreases plasma ferritin concentration. Urinary or plasma porphyrin concentrations are measured to monitor disease. Precipitants such as excess alcohol consumption, use of hormones, iron supplements, and smoking should be avoided. Patients with EPP should avoid sun exposure through the use of protective clothing and topical sunscreens. Oral administration of β-carotene provides systemic photoprotection by quenching excited species formed by UV-activated porphyrins, thus preventing damage from oxidative radicals. A synthetic α-melanocyte-stimulating hormone analog, afamelanotide, may be used to promote melanin formation and enhance protective dermal pigmentation [41]. In CEP, strict avoidance of sunlight and protection of skin from trauma are essential. Blood transfusions help to decrease hemolysis and suppress overproduction of porphyrins [40]. Bone marrow transplantation is the only curative therapy for EPP and CEP.

Summary

The porphyrias are a group of rare diseases that result from genetic or acquired abnormalities in the enzymes required for heme biosynthesis. Porphyrias are characterized by accumulation of porphyrin precursor and intermediate metabolites that cause signs and symptoms of disease. Diagnosis of porphyrias is aided by laboratory testing to detect and quantify specific porphyrin precursors and intermediates in body fluids. Abnormalities in metabolism and excretion of heme precursors and intermediates may occur in the absence of porphyria. Conditions that alter porphyrin excretion include hepatobiliary malfunction, inherited disorders of bilirubin metabolism, and heavy metal intoxication.

Self-assessment questions

1. Initial laboratory testing to evaluate symptoms of porphyria is based on _____.
   - **a.** analysis of DNA for mutations using genetic techniques
   - **b.** biochemical testing for porphyrins and precursor compounds
   - **c.** functional and quantitative enzyme assays
   - **d.** liquid chromatography with fluorescent detection
2. Acute porphyria can be identified by laboratory testing for _____.
   - **a.** abnormal heme biosynthesis
   - **b.** decreased activity of porphyrin decarboxylation enzymes
   - **c.** increased porphobilinogen in a random urine specimen
   - **d.** spontaneous production of functional porphyrin isomers
3. Cutaneous porphyrias can be diagnosed by _____.
   - **a.** characteristic patterns of porphyrin excretion in a urine specimen
   - **b.** identification of zinc protoporphyrin in a whole blood specimen
   - **c.** scanning fluorescence of a urine specimen
   - **d.** spectrophotometric testing of a random urine specimen
4. The resident on-call in the ER contacts the pathology lab to ask about testing for a 10-year-old male child with a rash on his cheeks that appears following sun exposure. Which test should the resident order?
   - **a.** quantitative porphobilinogen in a random urine specimen
   - **b.** fractionated urine porphyrins measured in a 24-h collection
   - **c.** fractionated porphyrins in a fecal specimen
   - **d.** free erythrocyte porphyrin in whole blood
5. Evaluation of a 4-year-old child with a stomachache who is irritable and cranky should include _____.
   - **a.** analysis of porphyrins in a random urine specimen
   - **b.** fecal porphyrin analysis
   - **c.** spectrophotometric analysis of urine for porphobilinogen
   - **d.** testing for lead in whole blood

Learning objectives

After reviewing this chapter, the reader will be able to:

- List the important processes involved in pharmacokinetics.
- Discuss factors that significantly influence pharmacokinetics in various populations.
- Perform basic pharmacokinetic calculations using standard equations.
- Discuss pharmacokinetic variance in special populations such as neonates or obese patients.

Introduction

The relationship between drug administration and drug response is a complicated process, and is dependent on a number of factors. These include (1) route of drug administration; (2) dosing frequency; (3) biological factors including renal and hepatic function; (4) drug−drug, drug−food, and drug−hormone interactions; (5) therapeutic regimen compliance; and (6) genetic variation. The relative contributions of each of these variables lead to a drug response postadministration. These concepts are encompassed in the field of pharmacology, which focuses on drug action, uses, and effects. At a fundamental level, pharmacology may be stratified into two parts—pharmacokinetics (PK) and pharmacodynamics (PD). PK is often thought of as "what the body does to the drug," while PD refers to the action of the drug, or "what the drug does to the body." Further, both of these processes may be affected by genetic disposition; pharmacogenetics, or the influence of genetic variation on PK and PD, is discussed in further detail in Chapter 53, Pharmacogenomics. The principles of PK are useful for the interpretation of laboratory results, but are particularly necessary in the areas of therapeutic drug monitoring (TDM) (see Chapter 51: Therapeutic drug monitoring) and clinical toxicology (Chapter 52: Toxicology and the clinical laboratory). While the PD of particular drugs can have significant impacts on laboratory testing, this field is broad and beyond the scope of this chapter.

Pharmacokinetics and influencing factors

Several biological processes influence drug pharmacology. Typically, PK encompasses the contributions of absorption, distribution, metabolism, and excretion (ADME) on drug kinetics. ADME represent the process of a drug getting into the body, traveling to a site of action where either biologic activity will be exerted or the drug is inactivated, and then, ultimately the drug or metabolite is removed from circulation. Variability in each of these processes can contribute to overall drug efficacy.

Drug dosing and administration

While the amount of drug administered (the dose) is certainly an important factor in PK, the amount that reaches the systemic circulation will vary significantly based on the route of administration. Drugs can be administered either intravascularly or extravascularly, and the route of drug delivery will be a significant driver of downstream PK and PD processes. Intravascular drugs are those that are administered directly into the veins (intravenous) or arteries (intraarterial) of the patient. There is an absorption phase when drugs are delivered intravascularly; drug effects (therapeutic or adverse) are often more immediate, and drug effects may be more potent. Further, there are few options for recourse postadministration, making potential adverse reactions difficult to control or reverse. Extravascular drugs can be introduced through a number of pathways including oral administration (tablet, capsule, and liquid), intramuscular (IM) injection (solution or suspension), subcutaneous (SQ) injection (solution or suspension), transdermal administration (patch), sublingual or buccal administration (tablet or film), or inhalation (metered inhaler). During extravascular drug delivery, additional considerations may include (1) drug absorption

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00050-8

from the site of administration into the general systemic circulation; (2) the time to onset of pharmacologic effect is dependent on drug formulation and subsequent release from its delivery modality; and (3) potential reduction in drug delivery to systemic circulation due to first-pass metabolism.

Liberation of the drug from its dosage formulation is a specific component of dose administration. Oral formulations are typically enteral, and are frequently prepared as tablets or capsules. Such delivery systems may contain fillers or binders and may be manufactured to modulate drug release kinetics; dosages may be timed, fast-acting, or sustained release, based on specific formulation components. Oral administration can also occur using parenteral (liquid) formulations. Parenteral formulations primarily involve drug preparation in a liquid or lyophilized matrix and is the most common formulation used in injectable drug delivery (such as intravenous, SQ, and IM administration). Drug stability and solubility are important considerations for these formulations. Finally, drugs can be formulated for topical application, and manufacturing processes typically involve emulsification between hydrophobic (i.e., oil) and water-based solutions. Due to the heterogeneity in both drug delivery systems and formulations, drug liberation can significantly affect the pharmacokinetic analysis of a drug and must be taken into account in various clinical scenarios.

In laboratory medicine, the primary consideration of pharmacokinetic analysis is to either assess potential toxic exposure or optimize therapy. As such, compliance (or adherence) with a prescribed regimen is a critical consideration when assessing PK. If a patient is not taking the drug as prescribed (or directed) or is taking substances that can alter the pharmacokinetic profile of the drug in question, this can affect the interpretation of test results and the pharmacologic assessment. Frequently, patients do not follow the directions for over-the-counter medications nor report herbal or nutritional supplements that can affect drug disposition [1]. Research has demonstrated that even with potential life-threatening conditions such as HIV infection or cancer, patients sometimes do not take their medication as directed [2,3]. In fact, one indication for TDM that is becoming more common is to assess compliance or adherence with prescribed drug regimens (see Chapter 51: Therapeutic drug monitoring).

Absorption

Absorption is the process of drug transport from the site of administration to the body compartment where it is usually measured, which is typically blood. As mentioned previously, intravenous drug administration circumvents this process, as drug is directly delivered into systemic circulation. For oral drug formulations, including tablets, capsules, and oral solutions, drugs may be absorbed by the gastric mucosa after dissolution or mixing with intestinal fluid. Within the gastrointestinal (GI) tract, the primary site for formulation dissolution and drug absorption is the small intestine. There are many factors that can affect drug absorption, including pH, drug formulation, and drug transporter activity. For example, there can be drug loss in the GI tract due to P-glycoprotein transport, gastric acid hydrolysis, or intestinal enzyme metabolism.

Following oral administration of a drug, first-pass metabolism frequently occurs, further contributing to the decreasing gradient in concentrations from drug administration to drug delivery to the systemic compartment. Once a drug is absorbed via the GI tract, it enters into the portal circulatory system prior to delivery to the systemic blood system. Absorbed drug is transported, via the portal vein, to the liver, where initial biotransformation can occur prior to export into the systemic circulation. Biotransformation may result in the activation or deactivation of a drug, and can therefore influence its local pharmacologic efficacy. Bioavailability is a primary PD driver for orally administered drugs and is discussed further below.

Notably, absorption is also a critical process for alternative routes of drug delivery, including topical administration. When a drug is delivered topically (e.g., patch or ointment), absorption is driven by the ability of the drug to cross the skin barrier and enter into circulation via capillaries in the skin. Often, this approach is used as a delivery method for extended release, in which a drug depot builds up under the skin and slowly makes its way to the blood vessels. Alternatively, respiratory administration of drugs is another approach for systemic absorption, as there is only a thin layer of cells lining the alveoli and a high density of capillary blood vessels. Respiratory administration can occur via vapors, gases, or aerosols. Other routes of administration that require absorption include SQ or IM injection, but the barriers to absorption are much less because injections typically are delivered into well-perfused tissue.

Bioavailability is an important measure of how much drug reaches the systemic circulation after absorption, which is particularly significant for oral, topical, and inhalation routes of administration. Only the bioavailable drug can exert its pharmacologic activity. This parameter is typically expressed as a percentage of drug relative to the dose; as intravascular administration is directed into the system circulation, its bioavailability is 100% by definition. For inhalation or topical administration, the bioavailability will be limited by the ability of the drug to exit the tissue depot into the systemic circulation and will be driven by the lipophilicity of the drug. For oral

administration, the bioavailability will be dependent not only on the absorption of the drug in the GI tract, but also on the first-pass metabolism prior to the drug reaching the systemic circulation. Bioavailability is determined by comparing the area under the time−concentration curve (AUC) for a particular route of administration to the AUC for an intravenous administration of the drug.

Distribution

Distribution encompasses the reversible transfer of drug between the compartments and includes delivery of a drug to its physiologic site of action. Drug distribution can occur between different compartments; in clinical pharmacology, compartments where drugs can partition include blood plasma, interstitial fluids, fat tissue, intracellular fluids, and transcellular (e.g., pleural and peritoneal) fluids. Blood plasma is the primary compartment utilized in pharmacokinetic modeling and is the basis of a one-compartment pharmacokinetic model. Several factors influence drug distribution, and the overall process is dependent on both the physiochemical properties of the drug as well as the compartments to which a drug will be deposited. Drug lipophilicity and polarity are primary considerations in distribution into various physiologic compartments. Other considerations that influence the rate and amount of drug delivered to a target organ or tissue include vascular permeability, perfusion of blood into various compartments, binding of the drug to plasma proteins or tissue components, and the permeability of tissues and cell membranes to the drug molecule. For instance, drugs are more easily delivered to highly perfused organs, including the heart, kidney, and hepatic system, as opposed to less well-perfused peripheral tissues (e.g., muscle and fat deposits).

Of particular interest for certain drugs is the binding to plasma proteins, particularly albumin and α1-acid glycoprotein. It is well known that the "free drug" fraction, or fraction of the drug that is not protein-bound, is the biologically active form of the drug that interacts with the drug target, and is bioavailable to be distributed across cell membranes and into tissues. Typically, the compartmentalization of unbound drugs occurs between the blood plasma and the target compartments until an equilibrium is achieved. For highly protein-bound drugs ($>90\%$ bound), changes in protein binding due to drug−drug interactions, posttranslational modifications, or underlying pathophysiologic states such as portal vein obstruction or malnutrition can significantly affect a drug's pharmacokinetic profile and, ultimately, the patient's response to the drug. Discussion of free drug monitoring for therapeutic drug management can be found in Chapter 51, Therapeutic drug monitoring.

Metabolism

Metabolism is the process of converting one chemical species into another chemical species; this is primarily enzyme-driven. Drug metabolism reactions in PK can be classified as Phase I or Phase II reactions. The cytochrome P450 (CYP 450) enzyme superfamily is the set of enzymes primarily responsible for drug metabolism in the human body and is the main source of genetic variability in PK. Drug metabolism may result in the deactivation of a drug by converting it into a biologically inactive derivative of the parent molecule. However, some metabolites retain a fraction of parent drug biologic activity, and some are equally potent. In those cases, both drug and metabolite may be measured for therapeutic management.

Conversely, many drugs can be administered as prodrugs and are activated in vivo via enzyme catalytic activity. In such cases, the active metabolite may be more informative in understanding downstream pharmacologic effects. Therefore it should not be assumed that in vivo metabolism leads to decreased drug activity or potency; for example, therapeutic compounds such as azathioprine and tenofovir disoproxil fumarate, which are used for treatment of certain childhood leukemias and HIV, respectively, are administered as prodrugs, and are biologically activated via specific enzymatic cascades. Notably, neither drug is modulated by the CYP 450 family, and bioactivation occurs external to the hepatic system. Thus a key component of clinical pharmacology is to understand the mechanistic pathways of administered drugs. Common Phase I and Phase II reactions are shown in Table 50.1.

Phase I reactions include oxidation, reduction, and hydrolysis, and hydration—oxidation reactions are the most common. Mechanistically, Phase I oxidation enzymes can catalyze a monooxygenase reaction, which involves the incorporation of oxygen into an organic substrate, and

TABLE 50.1 Phase I and Phase II metabolic reactions.

Phase 1 reactions	Phase 2 reactions
Oxidation	Glucuronidation
Reduction	Glucosidation
Hydrolysis	Sulfation
Hydration	Acetylation
Dethioacetylation	Methylation
Isomerization	Glutathione conjugation
	Amino acid conjugation
	Fatty acid conjugation

the reduction of a second molecule of oxygen to water. The enzymatic reactions for Phase I metabolism occur primarily in the endoplasmic reticulum of hepatic microsomes. The majority of Phase I metabolism reactions (~80%–90%) in humans are catalyzed by the CYP 450 family of enzymes. In many cases, the Phase I metabolic reaction is a precursor to the Phase II reaction; in other words, the Phase I product is the substrate for a Phase II reaction.

CYP 450 enzymes are hemeproteins that include a ferriprotoporphyrin-9 core and are named for their characteristic absorbance at 450 nm due to the presence of this core. This family of enzymes is classified by their sequence homology; CYP enzymes with >40% homology belong to the same family and those with >55% homology are considered part of the same subfamily. When naming the enzymes, a number will be included at the end to denote isoforms from the same gene. The naming convention for isoforms of CYP enzymes is illustrated in Fig. 50.1.

Common drug metabolizing enzymes include CYP2D6, CYP2C9, CYP2C19, and CYP3A4. There is significant genetic variability in CYP 450 enzymes, and these polymorphisms are often responsible for interindividual variability in drug metabolism (for further discussion, see Chapter 53: Pharmacogenomics). In addition, CYP 450 enzymes are particularly susceptible to enzyme induction and inhibition (discussed below), meaning that drugs metabolized by these enzymes carry significant risk of drug–drug interactions when multiple drugs are ingested, as enzymatic activity can be modulated via positive or negative feedback mechanisms.

Phase II reactions are conjugation reactions, which couple the drug or metabolite with endogenous compounds to increase water solubility and polarity. These reactions primarily include glucuronidation, sulfation, methylation, and acetylation, as well as conjugation of amino acids, fatty acids, or glutathione. Phase II conjugation reactions can occur directly to the drug molecule or, as noted previously, to a molecule generated by a Phase I metabolic reaction. Phase II reactions deactivate the drug, either by decreasing receptor affinity or by enhancement of excretion from the body. Several phase II enzymes have been associated with genetic polymorphism, including uridine diphosphate glucuronosyltransferase (UGT), *N*-acetyltransferase (NAT) as well as other acetyltransferases, glutathione S-transferases, and methylases. To date, only polymorphisms in UGT and NAT enzymes have demonstrated clinical significance.

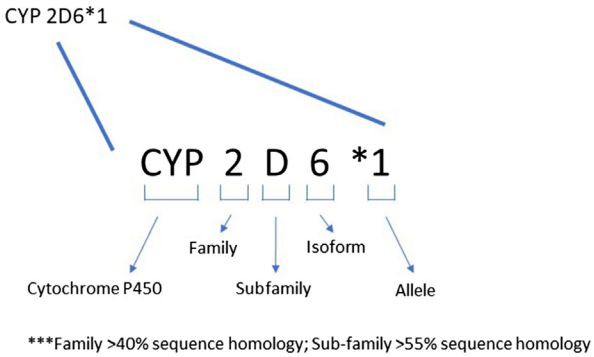

FIGURE 50.1 Cytochrome P450 enzyme naming convention. ***Family >40% sequence homology; subfamily >55% sequence homology.

Drug metabolism can be substantially influenced by enzyme induction or inhibition; many drug–drug interactions occur because of their inductive or inhibitory effects on drug metabolizing enzymes. In addition, food–drug interactions, herbal supplement interactions, and even lifestyle interactions (e.g., smoking and clozapine [4]) must be considered. Enzyme induction can occur through increased enzyme synthesis, protein stabilization, or activation of other components in the reaction—or some combination of these mechanisms. Enzyme inhibition can occur through competitive inhibition, conformational changes from binding to a nonactive site, accelerated protein degradation or destruction, or suppression of protein synthesis. There are several excellent resources where specific drug interactions are described in greater detail [5,6].

As previously mentioned, metabolism may also lead to the activation of a drug when the drug is administered in an inactive or prodrug form. This has been exploited as a drug delivery strategy and may be done to improve drug delivery or PK, to decrease toxicity, or to target the drugs to a specific type of tissue or cell in the body. Common examples include fosphenytoin, azathioprine, codeine, and primidone.

Excretion

Elimination and excretion are often used interchangeably; however, one is a subcategory of the other. Elimination refers to the irreversible removal of the drug from the compartment of measurement (primarily blood); this process can be achieved via metabolism (as previously discussed) and/or through excretion, which is the elimination of the drug or metabolite without chemical modification. The primary route of excretion is renal filtration; however, drugs or metabolites can also be eliminated through biliary excretion in the liver. In general, small, polar molecules (<200 Da) are excreted through the kidney, while larger or amphoteric substances are excreted via the liver. There can also be drug or metabolite excretion through the lungs, sweat, or mucosal secretion, but these are all minor pathways of clearing a drug from the body.

Drugs and metabolites are normally excreted by the kidney through a combination of three distinct processes: (1) glomerular filtration; (2) active tubular absorption/

secretion; and (3) passive, flow-dependent back diffusion. Glomerular filtration involves the unidirectional removal of a compound from blood and is predominantly dependent on renal perfusion and molecular size; only nonprotein bound drugs are filtered through the glomerulus. Renal secretion and absorption are energy-driven processes in the renal proximal tubules that rely on the activity of organic anion and cation transport receptors. Within the proximal tubules, small solutes, including small exogenous molecules, can be absorbed from the renal filtrate. Conversely, molecules like hydrogen ions and creatinine can be secreted into the proximal tubules, contributing to the renal filtrate. Passive back diffusion, or nonenergy-dependent reabsorption, also occurs in the renal tubules and is dependent on lipophilicity, filtrate pH, and urine flow rate. At low flow rates, there is a greater opportunity for diffusion of a drug from the renal filtrate back into circulation. The overall renal excretion of a drug (or metabolite) is the sum of filtration and secretion, minus reabsorption.

Given the importance of renal function in drug clearance; serum creatinine and creatinine clearance (see Chapter 35: Laboratory evaluation of kidney function) have been used as markers for drug clearance and safety. However, this was displaced by estimated creatinine clearance (eCrCl), originally calculated using the Cockcroft−Gault equation (C-G), which was developed in a small, homogenous population [7]. Currently, recommendations regarding drug dosing practices with respect to renal function are based on creatinine clearance determined by the C-G equation. This has led to challenges, as more accurate estimates of glomerular function have been determined and implemented as a standard of practice. Currently, most clinical laboratories provide estimated glomerular function using the modification of diet in renal disease [8] or chronic kidney disease-epidemiology collaboration (CKD-EPI) [9] equations; however, many dosing recommendations still refer back to the C-G estimations of renal function. Currently, the National Kidney Disease Education Program (NKDEP) has not endorsed any particular equation, as in many populations there is little difference in dosing based on the estimated glomerular filtration rate (eGFR) equation used. The NKDEP guidance recommends the use of either eGFR or eCrCl for drug dosing and to consider exogenous filtration markers, or a timed assessment of CrCl when dosing medications within narrow therapeutic indices or with high toxicity [9]. However, the National Kidney Foundation has supported the use of the CKD-EPI equation for clinical implementation due to its improved performance in estimating GFR.

In addition to protein synthetic and metabolic functions, the liver (see Chapter 31: Laboratory diagnosis of liver disease) also has an excretory function, where bile is produced and excreted. The physiologic functions of bile are as follows: (1) facilitate intestinal absorption of ingested lipids; (2) cholesterol elimination to maintain homeostasis; and (3) excretion of biotransformed waste products. In the context of drug excretion, some parent drugs and metabolites are excreted via bile into the intestinal tract. From there, they can be reabsorbed into the blood resulting via the enterohepatic recirculation cycle, or they can be excreted in stool. Enterohepatic recirculation can be significant for pharmacokinetic analysis, as it can result in a secondary peak for the drug if recirculation is significant.

As an extension of both distribution and clearance, drugs may be deposited in compartments that are ultimately excreted and transmitted to another individual. The chief example of this would be the partitioning of drugs into breast milk, resulting in neonate or infant exposure to a potentially active agent. The partitioning of a drug into breast milk is predicated on a number of factors, including drug distribution parameters such as drug lipophilicity and protein binding. From a matrix perspective, breast milk contains proteins, lipids, carbohydrates, and other nutrients; carbohydrate and lipid loads are higher in breast milk than blood. As such, drug delivery to breast milk will be dependent on penetration into a lipophilic compartment.

The distribution of drugs into breast milk can have significant consequences [10]. A case study in the mid-2000s described the neonatal toxicity and death due to the increased delivery of the codeine metabolite morphine into breast milk. In this case, the mother was prescribed acetaminophen-containing codeine for postpartum pain; she had a gene duplication for the CYP2D6 gene, which is associated with an ultrarapid metabolizer phenotype and increased metabolism of codeine to the potent morphine metabolite. The infant was exposed to lethal concentrations of morphine and expired shortly postbirth [11]. This case led to a black box warning on codeine, which directed limiting the use of codeine as an analgesic in postpartum mothers to the lowest dose for the shortest amount of time. In many settings, codeine is not prescribed to mothers for postpartum pain. In order to assist clinicians, within the NIH Toxicology Data Network, there is a lactation database that has important pharmacologic information on drug concentrations observed in breast milk and infant serum, as well as potential associated toxicities [12]. Understanding neonatal exposure to therapeutic (or illicit) substances is an important component of promoting infant health.

Pharmacokinetic calculations

For most calculations of pharmacokinetic parameters, the most straightforward model, a one-compartment model, is employed. While more complex models can be

constructed, this model is most commonly used for TDM and toxicology and treats the body as a single compartment, where the concentration of the drug in the blood tracks with a proportional change of concentration in all tissues of the body. Two-compartment models can also be used, where the first compartment is designated to be in rapid equilibrium with the blood, and a second compartment (e.g., adipose tissue) is present with a much slower equilibrium between it and the first compartment. A comparison of one- and two-compartment models is illustrated in Fig. 50.2. Similarly, while complex mathematical models can be employed, the kinetics are most often assumed to be zero-order or first-order kinetics. In zero-order kinetics, the rate of excretion or elimination is fixed, and independent of the amount of substance available. In first-order kinetics (also known as linear kinetics), there is a proportional relationship between the absorption and elimination rates and the amount of substance present; the rate constant that characterizes this proportionality represents a number of physiologic parameters. Most therapeutic substances of clinical interest demonstrate first-order kinetics, and common pharmacokinetic calculations describe these situations. It is important to note that for many drugs, mixed or capacity-limited kinetics are observed in the context of saturable systems, such as when the concentration of a drug or intermediate is present in higher concentrations than the enzymatic capacity for metabolism. In such cases, pharmacokinetic calculations are applied assuming that the system is in the linear range of its kinetics. Graphical examples of zero-, first-, and mixed-order kinetics are illustrated in Fig. 50.3.

Based on these simple physiologic and mathematical models, there are a few basic pharmacokinetic calculations that every clinical chemist should be able to perform:

Elimination constant

The elimination constant (k_{el}) is a simple calculation determined by measuring the concentration of drug in the blood at two time points during the terminal elimination phase:

$$k_{el} = \frac{\ln(C_1/C_2)}{t_2 - t_1}$$

where t_1 is the first time point, t_2 is the second time point, C_1 is the concentration measured at t_1, and C_2 is the concentration measured at t_2.

Elimination half-life

The elimination half-life is the amount of time required for 50% of the drug to be removed from the blood during the terminal elimination phase. This can be determined graphically from a linear plot of time versus log

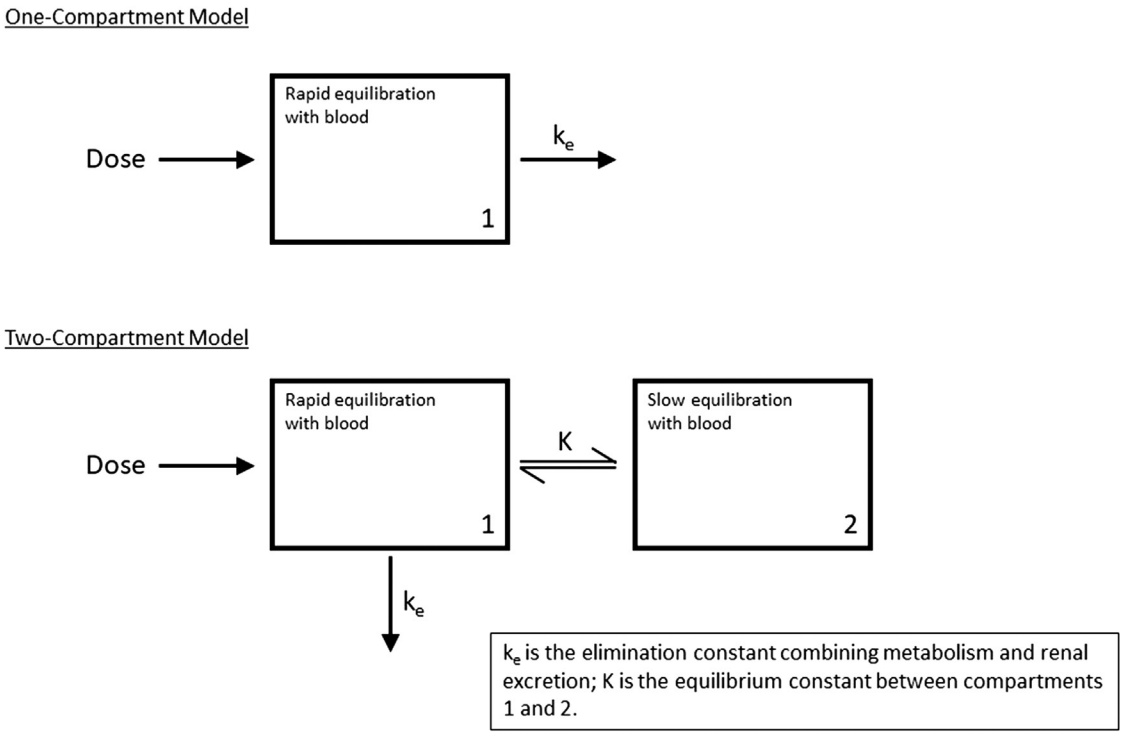

FIGURE 50.2 One- and two-compartment model schematic. k_e is the elimination constant combining metabolism and renal excretion and K is the equilibrium constant between compartment 1 and 2.

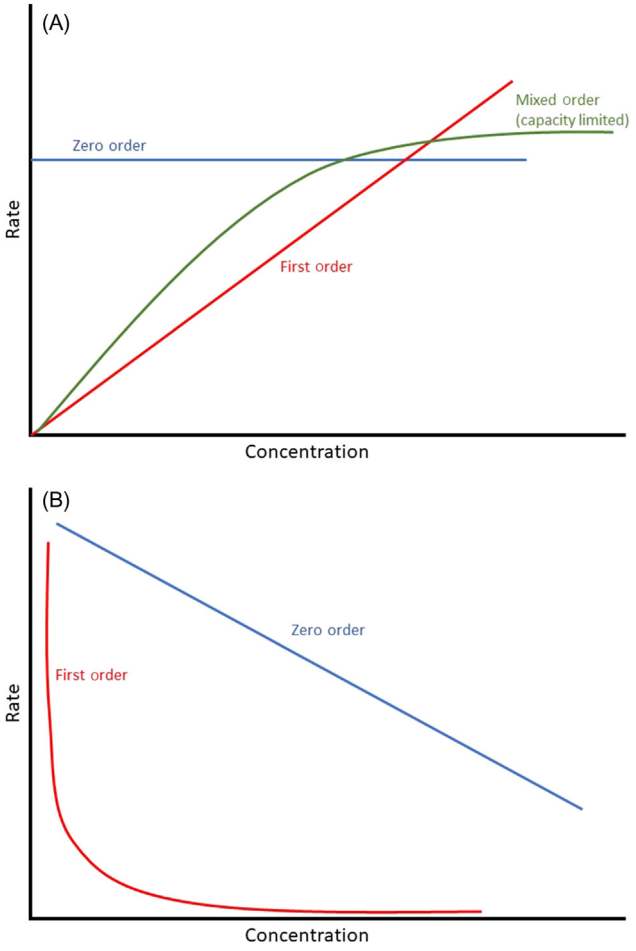

FIGURE 50.3 (a) Zero-, first-, and mixed-order absorption kinetics. (b) Zero- and first-order elimination kinetics.

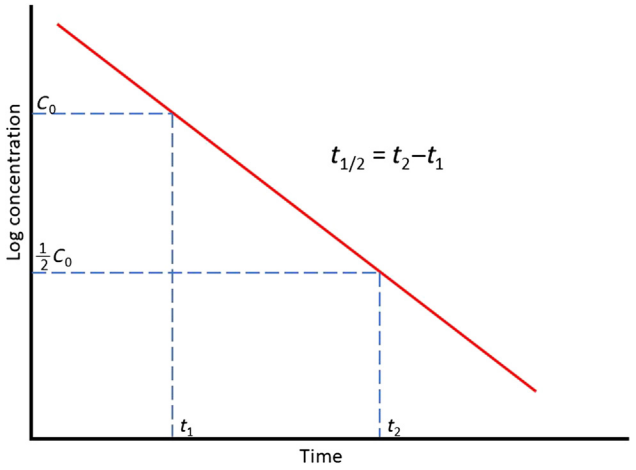

FIGURE 50.4 Graphical determination of half-life ($t_{1/2}$).

concentration (Fig. 50.4), or it can be calculated using the equation below:

$$t_{1/2} = \frac{0.693}{k_{el}}$$

In addition, based on the elimination half-life, the time needed for clearance of a drug can be estimated; approximately, 97% of the drug is eliminated by five half-lives, and just over 99% of the drug is eliminated when seven half-lives have passed.

Volume of distribution

The volume of distribution (V_d) is a descriptive parameter that relates the amount of drug distributed into tissue and intracellular fluid to the amount that remains in the blood compartment. V_d is expressed as the amount of fluid that would hypothetically be necessary to contain all of the drug administered. It is calculated using the equation below:

$$V_d = \frac{\text{Dose}}{C_{ss}}$$

The V_d can be compared with fluids in the body to get an idea of where a drug is distributed. The plasma volume is approximately 0.4 L/kg, and the total body water is approximately 0.6 L/kg; drugs that are primarily distributed in tissue will have V_d greater than these amounts.

The V_d for many drugs are published and available in the scientific literature, but it is important to note that these are population estimates only and have been typically established in healthy populations. Any deviation from the "normal" body composition due to population differences (e.g., neonates and pregnancy) or pathophysiology (e.g., burns, edema, pleural effusion, or ascites) will result in a V_d deviation from the published value. V_d can be used to estimate the starting dose necessary to achieve a target blood concentration by rearranging the equation above, and can also be used to estimate the replacement drug needed after dialysis.

Clearance

The clearance reflects excretion of the drug from the body by all routes and is linear (first-order) for most drugs. Clearance represents the amount of blood cleared of a drug per unit of time, and it is expressed in L/kg/h or mL/min. Clearance can be calculated in a number of ways, including:

$$\text{CL} = \frac{\text{Dose/dosing interval}}{C_{ss}};\ \text{or CL} = k_{el} x V_d;\ \text{or}$$
$$\text{CL} = \left(0.693/t_{1/2}\right) \times V_d$$

where C_{ss} is the steady-state concentration of the drug, k_{el} is the elimination constant, V_d is the volume of distribution, and $t_{1/2}$ is the elimination half-life.

Steady-state dose adjustment

For most drugs, the desired clinical response is not achieved with a single dose, so multiple doses are required. With multiple doses, the drug accumulates and increases in blood concentration until the amount of drug given is equal to the amount that is cleared; this is known as steady state. When the drug is administered in intervals that approximate the elimination half-life of the drug, steady state is typically achieved in seven doses (or seven half-lives); although for practical intents, five doses or half-lives are sufficient to assume steady state has been achieved.

Once steady state has been achieved, applied PK (or TDM, Chapter 51: Therapeutic drug monitoring) can be used to adjust the drug dosage to achieve a desired target concentration in the blood, provided the drug follows first-order kinetics. Calculation of the new dose can be performed using the equations below:

$$\text{Current dose}/\text{measured blood concentration} = \text{New dose}/\text{desired concentration}$$

so

$$\text{New dose} = \left(\text{Desired concentration}/\text{measured blood concentration}\right) \times \text{Current dose}$$

It is important to note that this approach cannot be used if the drug follows zero-order kinetics or if the patient has not achieved steady state. If the patient is not at steady state but the drug follows first-order kinetics, it is important to wait until the fifth dose is administered to utilize TDM and adjust the dose. When zero-order or nonlinear kinetics are present, the dose adjustment based on blood concentrations becomes an iterative, empiric process as the above proportionality equation does not apply. This does not invalidate the usefulness of dosing based on blood concentrations for nonlinear kinetics, as evidenced by common TDM applications such as phenytoin or methotrexate (see Chapter 51: Therapeutic drug monitoring).

Population pharmacokinetics and modeling

Although the aforementioned equations provide important information on pharmacokinetic parameters, more complex calculations and models are needed to characterize comprehensively drug PK, as there is significant variability in estimated pharmacokinetic parameters due to intra- and interindividual variabilities. This approach to PK has led to the specialized field of pharmacometrics, which is a multidisciplinary field that incorporates mathematical modeling, demographic information, drug concentrations, and patient health to estimate pharmacokinetic parameters on a population level, characterize pharmacokinetic-pharmacodynamic relationships, and generate mechanistic drug models. Population pharmacokinetics (PopPK) combines data (including laboratory, demographic, and pharmacy dosage information) from a large number of individuals into a single mathematical model. Physiologically based PK modeling (PBPK) utilizes complex models that account for specific anatomic and physiologic variables in addition to standard pharmacokinetic parameters. PBPK models employ extrinsic data (i.e., environmental factors, smoking, drug—-drug interactions, and patient demographics) to predict drug PK /ADME. Although this modeling approach is not used extensively in clinical laboratory medicine, PBPK models are common in pharmaceutical research and drug development. However, we can utilize the findings from these models to identify target concentrations for therapeutic compounds. Specialized software tools are typically required for the generation of popPK and PBPK models.

A type of model that has been used in the clinical laboratory setting is a Bayesian model. In Bayesian modeling, the pharmacometrician takes advantage of both the prior population-derived PK information as well as sparse data obtained from an individual patient or research subject. This is an iterative process where the initial therapeutic regimen is set using PopPK and then modified using new data from just a few patient blood samples.

Special populations

While most pharmacokinetic data are collected in healthy, early adult populations, it is important to note that these populations may not be the clinically relevant populations. While pharmacokinetic information can be applied to many patient populations, there are some special populations for which general pharmacokinetic models and assumptions for healthy adults do not apply. In addition to the populations described below, PK have been influenced by sex, ethnicity, and hormonal concentrations.

Neonate/pediatric

For pediatric patients and neonates in particular, there are significant differences in body composition and physiology that affect a drug's pharmacokinetic profile. In these patients, the drug dosage and dosing interval cannot be simply downadjusted by accounting for body mass (mg/kg). In general, pediatric patients have a lower amount of HCl in the stomach, slower gastric emptying, and lower production of bile acids, all of which significantly affect the absorption phase of PK relative to an adult population. In addition, pediatric patients typically have a higher percentage of body water and lower body fat, which affects

the distribution of drugs after absorption. The metabolic activity and adrenal function in neonates and children are significantly different from adults and can affect the metabolism phase of PK. For neonates with jaundice, the PK of highly protein-bound drugs (e.g., phenytoin) can be affected as bilirubin can compete with these drugs for binding sites on albumin—in these cases, free drug measurements are particularly important.

Geriatric

For older patient populations (>70 years of age), there are also significant differences relative to health. In patients with advanced age, there is decreased saliva and gastric HCl production, decreased gut motility, and variance in gastric emptying, all of which can significantly impact drug absorption. Older patients also tend to have increased body fat, decreased muscle mass, and decreased perfusion of tissues, all of which will alter drug distribution relative to healthy adults; older patients may also have a lower V_d than an adult population. With respect to drug metabolism, in geriatric patients, Phase I metabolism (e.g., CYP 450) is decreased, while Phase II metabolism (e.g., glucuronidation) is unchanged. Finally, renal function typically decreases with age, which affects the excretion of drugs and metabolites.

In addition to these physiologic factors, there are some important external factors to consider for this population. Polypharmacy is more common in geriatric patients, which can lead to increased risk of drug−drug interactions, and these patients are often taking nutritional supplements or complementary and alternative medicines that also can cause unintended drug interactions [1]. Older patients are also likely to be managed by multiple physicians and are more prone to self-medication or noncompliance with medications, all of which can complicate pharmacokinetic analysis. Given the prevalence of multiple pathologic conditions, the symptoms of drug toxicity can be similar to chronic disease symptoms or signs of aging, making the clinical assessment of drug response complex.

Obese

Obesity is defined as anyone with a body mass index greater than 30 kg/m^2, with serious obesity defined as greater than 40 kg/m^2. The prevalence of obesity and comorbidities associated with this condition is increasing globally and has significant implications for health care and include its impact on PK. While standard dosing of drugs is often achieved using body weight (mg/kg), it is generally recognized that at some point, there is a nonlinear relationship between the total body weight and the pharmacokinetic parameters. There are important changes in cardiac output, plasma protein concentration, and organ size and function that are associated with obesity, which will affect PK. A higher proportion of adipose tissue in this patient population leads to significant changes in drug distribution; the V_d for an obese patient may differ significantly from that of a nonobese person. Fatty liver disease can result in liver damage that could negatively impact metabolism. It should be noted that while total body weight does not have a linear relationship in obese patients, it has been demonstrated that lean body weight appears to maintain some degree of linearity with pharmacokinetic parameters and can be used in obese patients to optimize drug dosing [13]. The lean body weight can be calculated using the following equations [14]:

$$\text{LBW(male)} = \frac{9270 \times \text{TBW}}{6680 + (216 \times \text{BMI})}$$

or

$$\text{LBW(female)} = \frac{9270 \times \text{TBW}}{8780 + (244 \times \text{BMI})}$$

where LBW is Lean Body Weight, TBW is Total Body Weight, and BMI is Body Mass Index. The constants in this equation were derived empirically during development of the model.

Self-assessment questions

1. Which of the following types of drug formulation would be considered an intravascular route of administration?
   a. Extended-release capsule
   b. Transdermal patch
   c. PICC line
   d. Sublingual film
2. Phase 1 metabolic reactions include which of the following?
   a. Acetylation
   b. Hydrolysis
   c. Glucuronidation
   d. Methylation
3. A plasma concentration for an experimental drug is reported as 45 mg/L following a dose of 150 mg. The patient in this study is a 45-year-old male weighing 85 kg. Where is most of this drug found?
   a. Adipose tissue
   b. Plasma
   c. Urine
   d. Bile
4. Drug *X* is a highly protein-bound drug, primarily bound (>95%) to albumin. Which of the following will result in an increase in the free drug concentration?
   a. Hemolysis
   b. Hyperlipidemia
   c. Hypoglycemia
   d. Hyperbilirubinemia
5. Pediatric patients exhibit significant differences in PK compared with adults due to all of the following except:
   a. Cardiac output
   b. High proportion of body water
   c. Slower gastric emptying
   d. Metabolic differences
6. The primary route of elimination for most drugs is:
   a. Exhalation
   b. Biliary
   c. Renal
   d. Mucosal secretion
7. A patient has been administered a new drug, and the concentration in blood was measured at two time points during terminal elimination. At 4-hours postdose, the concentration was determined as 120 mg/L, and at 8-hours postdose, the concentration was determined as 55 mg/L. If the drug is discontinued, approximately how long will it take for 97% of the drug to be cleared?
   a. 17–20 hours
   b. 5–10 hours
   c. 2–4 hours
   d. 20–25 hours

Answers

1. c. PICC line. A PICC line is a peripherally inserted central catheter, that is, a venous catheter used for long-term IV drug or nutrition administration.
2. b. Hydrolysis. Phase I reactions include oxidation, reduction, and hydrolysis, while Phase II reactions are conjugation reactions such as the choices in A, C, and D.
3. b. Plasma. The calculated V_d = (dose/concentration)/patient weight. Dose = 150 mg; concentration = 45 mg/L, and patient weight = 85 kg. V_d = 0.039 L/kg, which is comparable with the average plasma volume (0.04 L/kg).
4. d. Bilirubin can compete with highly protein-bound drugs for albumin-binding sites.
5. a. Cardiac output. While cardiac output likely does vary between the kids and the adults, there can also be significant variability within the adult population, so cardiac output is not likely the reason for these population difference compared with the other three noted differences.
6. c. Renal. Most drugs are excreted renally either unchanged or metabolized followed by renal elimination of the metabolites.
7. a. 17–20 hours. First, the k_{el} is calculated from the two concentration measurements, and then, the half-life is calculated:

$$k_{el} = \left(\ln\left(C_1/C_2\right)\right)/(t_2 - t_1)$$
$$= \left(\ln\left(120/55\right)\right)/[8 - 4\text{hours}] = \ln(2.18)/4 = 0.19$$

$$t_{1/2} = 0.693/k_{el} = 0.693/0.19 = 3.65\text{hours}$$

97% of the drug is cleared in 5 half-lives, so it will take approximately 18 hours.

Chapter 51

Therapeutic drug monitoring

William Clarke

Department of Pathology, The Johns Hopkins University School of Medicine, Baltimore, MD, United States

Learning objectives

After reviewing this chapter, the reader should be able to:

- Define therapeutic drug monitoring (TDM).
- Describe the challenges of managing drugs with significant pharmacokinetic variability.
- List drugs that are commonly managed using TDM.
- Discuss the analytical methods available for TDM.

Management of therapeutic drugs

The vast majority of drugs are managed in a very standard way—the drugs are dosed on a unit per body mass (e.g., mg/kg) basis, and then, the dosage is adjusted based on the clinical response as empirically assessed by a physician. This is often described as "titration to clinical effect." However, for a small subset of drugs, the clinical effects (pharmacodynamics) can be assessed objectively through laboratory measurements—for instance, warfarin and assessment of coagulation via international normalized ratio measurement, or statin drugs and blood lipid levels. For an even smaller subset of drugs, the pharmacokinetic−pharmacodynamic relationship is not predictable from the dose, and the pharmacokinetics are highly variable between the individuals—for these drugs, management can be particularly challenging. It has been recognized that for drugs with high pharmacokinetic variability, measurement of serum concentrations to assess the patient's individual pharmacokinetics (see Chapter 49, The porphyrias: fundamentals and laboratory assessment) relative to a population-based pharmacokinetic profile is useful to avoid possible toxic side effects or to ensure that patients have achieved a stable therapeutic level. This use of applied pharmacokinetics is primarily referred to as therapeutic drug monitoring (TDM).

Principles of therapeutic drug monitoring

TDM in practice is performed by collection of a blood sample at a known time relative to administration of the last (or next) dose. The concentration of drug and/or metabolite is measured in the sample and compared with a target range or the predicted pharmacokinetics for the drug. In order for TDM to be effective and necessary, several criteria must be met: (1) the drugs must have a narrow therapeutic index (the difference between the minimum effective concentration and the toxic concentration, relative to the pharmacokinetic variability); (2) the relationship between the drug dose and the blood concentration must be highly variable and/or not predictable interindividual variability; (3) the relationship between blood concentration and clinical or toxic effect must be well defined; (4) there should be serious consequences for under- or overdosing; and (5) the result of TDM testing must be interpretable and actionable—there should be an effect on clinical outcomes. TDM results should answer a clinical question. In addition, TDM can be useful if the drug in question is administered with other compounds that potentially interact and affect the pharmacokinetics. A list of commonly monitored drugs can be found in Table 51.1.

There are some drugs that meet most of the criteria for TDM, but for which measurements of drug concentrations are not particularly useful. For instance, when the drug is administered as a prodrug—the biologically active form of the drug is a metabolite of the administered substance—measurement of the administered drug does not help with guidance of therapy and the active metabolite must be measured (e.g., irinotecan and SN-38). In other cases, the drug is converted into its active form intracellularly, so systemic blood measurements in serum or plasma are not necessarily reflective of the therapeutic activity (e.g., nucleotide/nucleoside reverse transcriptase inhibitors and peripheral blood mononuclear cells). In addition, drugs for which tolerance can be developed (e.g., narcotics and pain management) prevent the utility of TDM, as the effective blood concentration range is a moving target and not stable within an individual patient.

While the primary function of TDM is to allow for adjustment of the drug dose, there are other applications

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00051-X

TABLE 51.1 Therapeutic ranges for commonly monitored drugs.

Drug class	Drugs	Therapeutic range	Notes
Antiepileptics	Phenytoin	10–20 μg/mL	CNS toxicity >30 μg/mL
	Carbamazepine	4–12 μg/mL	
	Primidone	5–12 μg/mL	Phenobarbital is an active metabolite and should be monitored too
	Phenobarbital	15–40 μg/mL	Significant CNS depression >40 μg/mL
	Valproic acid	50–100 μg/mL	
	Lamotrigine	2.5–15 μg/mL	
	Levetiracetam	12–46 μg/mL	
	Gabapentin	2–20 μg/mL	
	Oxcarbazepine	3–35 μg/mL	Therapeutic range is for the active metabolite, MHD
	Topiramate	5–20 μg/mL	
Immunosuppressants	Tacrolimus	5–15 ng/mL	
	Cyclosporine A	100–400 ng/mL	
	Sirolimus	4–12 ng/mL	
	Everolimus	3–15 ng/mL	
	Mycophenolic acid	AUC = 30–60 mg/h.L	Trough = 1–4 μg/mL
Cardioactive drugs	Procainamide	4–8 μg/mL	NAPA = 10–20 μg/mL; 5–30 μg/mL combined
	Lidocaine	1.5–5 μg/mL	
	Quinidine	2–5 μg/mL	
	Digoxin	0.8–2 ng/mL	
Psychoactive drugs	Amitriptyline + metabolite	80–200 ng/mL	Active metabolite = nortriptyline
	Nortriyptline	70–170 ng/mL	
	Imipramine + metabolite	175–300 ng/mL	Active metabolite = desipramine
	Desipramine	100–300 ng/mL	
	Lithium	0.4–1.2 mmol/L	
Antimicrobial drugs	Gentamicin	<2 μg/mL, trough	5–10 μg/mL, peak
	Tobramycin	<2 μg/mL, trough	5–10 μg/mL, peak
	Amikacin	<5 μg/mL, trough	20–25 μg/mL, peak
	Vancomycin	10–20 μg/mL	
	Voriconazole	1–5.5 μg/mL	
Chemotherapy drugs	Methotrexate	5–10 μM, 24-h postdose	0.5–1 μM, 48-h postdose; 0.05–0.1 μM, 72-h postdose
	Busulfan	900–1500 μmol.min	
Bronchodilators	Theophylline	10–20 μg/mL	
	Caffeine	8–20 μg/mL	

CNS, Central nervous system; *MHD*, monohydroxycarbamazepine; *NAPA*, N-acetylprocainamide.

of TDM results (e.g., questions to be answered). For example, TDM in antiretroviral management in patients with HIV is not really necessary for optimization of dose; however, it is vitally important to confirm adherence to the prescribed drug regimen in the context of increasing viral loads and apparent therapeutic failure. The TDM results can be used to assist in the determination of whether the patient has developed viral resistance to the prescribed drugs or whether they have just stopped taking their drugs. Another question that can be answered is whether drug is being absorbed at all. For instance, gastrointestinal inflammation could prevent drugs administered orally from entering the circulation. It is important to remember that while TDM is a tool for assessing the clinical presentation of the patient, it is not intended to be interpreted in a vacuum. Most therapeutic target intervals were not derived from large clinical studies, but are based on the observations and data from a single site. The absence of a therapeutic interval does not mean that TDM lacks utility, provided that there are specific criteria for the interpretation of the result and it will aid in clinical decision-making.

Analytical and clinical laboratory considerations for therapeutic drug monitoring

Much of the early work in TDM was performed using high-performance liquid chromatography or gas chromatograpy techniques (Chapter 8, Chromatography and electrophoresis); however, TDM became much more accessible as commercial immunoassays (Chapter 12, Immunoassays) were developed by a number of vendors. Unfortunately, development of commercial assays for TDM has stagnated, whether due to the relative small size of potential markets or perception that the role of pharmacokinetics in personalized medicine will decrease based on advances in genomics. Based on this, increased research effort in the area of assay development using noncommercial platforms is rapidly growing, especially in the area of liquid chromatography–tandem mass spectrometry (LC-MS/MS). While immunoassays provide rapid results and can be automated using instrumentation readily available in the clinical laboratory, chromatography-based methods (especially LC-MS/MS) often provide greater sensitivity and specificity, as well as the ability for rapid development of assays in response to clinical needs—although often at the cost of throughput and ease of use. A modern clinical laboratory performing TDM uses a combination of these technologies to provide services, with reference laboratories becoming more and more important for applications that are infrequently utilized in a single hospital or medical care setting.

Typically, TDM is performed using serum or plasma samples collected once the patient has reached steady state (see Chapter 50, Pharmacokinetics). An example of a therapeutic range relative to steady-state concentrations can be seen in Fig. 51.1. Steady state is achieved after seven half-lives of the drug has been administered to the patient; however, in practice, five half-lives is an acceptable surrogate (97% of steady state is achieved) to estimate a steady-state concentration. In some special cases, drugs are distributed primarily in the cellular component of blood (e.g., immunosuppressive drugs into red blood cells), and in those cases, anticoagulated whole blood is the preferred specimen. For TDM measurements, serum or plasma separator tubes are typically avoided, as the gel in these tubes may nonspecifically bind drugs in the sample and alter the concentration. The laboratory should also ensure they are aware of potential interferences from tube additives (e.g., citrate and phenytoin) and that appropriate containers are used during specimen collection. Once the patient has reached steady state, the

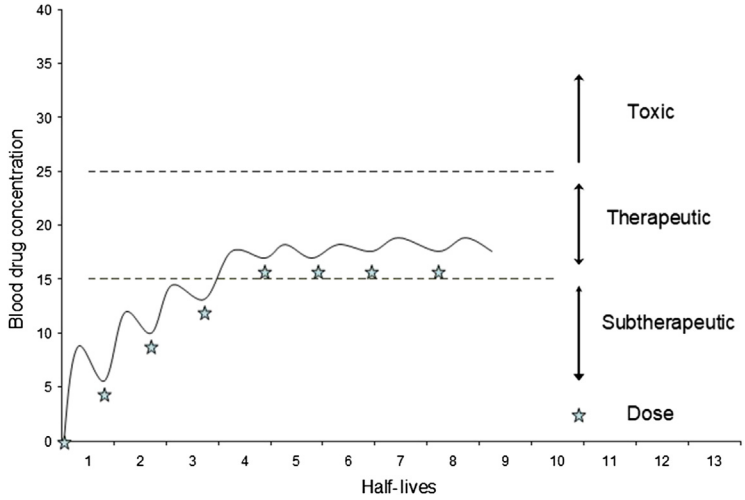

FIGURE 51.1 Illustration of steady-state drug concentrations as a function of drug half-life.

blood sample for TDM is typically drawn for a predose assessment (often referred to as a "trough" concentration). This type of sample is preferred, because measurements of peak concentrations are problematic and highly variable due to variability of other steps in the process—primarily variability in dose administration and specimen collection, with inconsistent documentation. The predose specimens are generally collected 30−60 minutes prior to the next scheduled dose, where the pharmacokinetics are the least variable. In some cases, peak or postdose specimens are analyzed, but this is less common and specific examples will be discussed later in the chapter.

For interpretation of the TDM results, it is vital that the time of the last dose and the time of specimen collection are captured as accurately as possible, regardless of whether a peak or predose measurement is used. While generally applicable therapeutic ranges (or target ranges) are provided with the result, it is important to note that this is a population-specific guidance and not a patient-specific guidance; the therapeutic target for a specific patient can vary based on their disease, body composition, formulation of the drug given to the patient, and many other factors (see Table 51.2). The optimal concentration for the patient is ultimately determined by the person providing care for that patient. In some instances, for highly protein-bound drugs, the free drug concentration is measured rather than the total drug concentration, as that is the biologically active form of the drug. In these cases, the sample is typically prepared using ultrafiltration to remove proteins (including protein-bound drug) from the sample, and free drug is subsequently measured in the ultrafiltrate. In addition, for some drugs, it is more appropriate to measure the active metabolite rather the parent drug—whether that parent drug is active or whether the parent drug is a prodrug as part of the drug formulation and delivery strategy. When both the parent drug and metabolite have biologic activity, both should be measured and a therapeutic range incorporating both should be established.

TABLE 51.2 Factors that influence TDM results.

Drug	Formulation
	Route of administration
	Dose regimen
	Pharmacokinetics: Vd, half-life, metabolites, etc.
Patient	Age
	Body composition
	Renal function
	Hepatic function
	Compliance
	Pregnancy
	Protein status
	Inherited variability in drug handling processes (pharmacogenetics)
	Disease
Specimen	Collection tube material, preservatives, and separator gels
	Time collected relative to dosing
	Sampling methods
	Storage
	Handling
Analytical method	Preanalytical processing (e.g., filtration and extraction)
	Densitivity
	Specificity
	Matrix effects
Other	Concomitant medications
	Supplements
	Diet
	Clerical errors

Clinical areas where therapeutic drug monitoring is routine practice

Epilepsy

There are many different drugs available for treatment of seizures—these drugs typically work by acting on neurotransmission pathways in the brain. In the treatment of epilepsy, TDM has a significant value, because the drugs act upon the central nervous system (CNS) to treat seizures, but they also can cause toxic CNS effects. In some cases, the drugs can cause seizures, making it difficult to differentiate subtherapeutic effects from toxic effects. TDM is useful to determine quickly whether drug concentrations are too low or too high upon initiation of therapy. In addition, once a baseline concentration has been established for patients on chronic therapy, blood levels can be used to investigate loss of seizure control or unexpected toxicity in a stable patient.

Phenytoin and *fosphenytoin* (prodrug for phenytoin) are widely used for treating epilepsy in a broad range of populations. Phenytoin has been in use for epilepsy since 1936; fosphenytoin was developed in 1996. Phenytoin is used primarily for tonic−clonic seizures and is not effective for absence seizures. The drug has a high bioavailability, but the rate of absorption is highly dependent on formulation—in some cases, absorption can occur up to

48 hours after administration. There is significant pharmacokinetic variability as phenytoin is metabolized by CYP2C19 and 2C9, is susceptible to drug−drug interactions, and is highly (approximately 90%) protein-bound. The typical target interval for this drug is 10−20 μg/mL, with CNS toxicity typically observed with concentrations >30 μg/mL [1]. Phenytoin is highly protein-bound, and if the clinical presentation does not match the total drug concentration, the free drug concentration is often measured in addition to the total. The target concentration for free (unbound) phenytoin is generally listed as 1−2.5 μg/mL.

Carbamazepine is a drug that was introduced for treatment of epilepsy in 1962. It is used in the treatment of generalized seizures, as well as partial and partial-complex seizures. This drug is CYP3A4-metabolized and affected both by inhibitor and inducers of this enzyme family—interestingly, its inductive capabilities lead to a drug−drug interaction with itself for patients on chronic therapy, giving increased blood concentrations. The therapeutic interval is defined as 4−12 μg/mL [2], and blood concentrations greater than 12 μg/mL are associated with adverse CNS effects, including respiratory depression, convulsions, and coma.

Primidone is a barbiturate drug used primarily for treatment of epilepsy in children; it is also used in the treatment of essential tremor. Primidone is primarily metabolized in the liver to phenobarbital via CYP2C19, and given that both parent drug and primary metabolite are biologically active, both must be monitored when primidone is used for antiepileptic therapy. The therapeutic target for primidone is 5−12 μg/mL and adverse effects are seen at concentrations greater than 15 μg/mL [3]. Clinical toxicity is primarily due to accumulation of phenobarbital and is manifested as reduced respiratory function and CNS depression. Primidone is CYP450-metabolized, and it is susceptible to drug−drug interactions.

Phenobarbital is another barbiturate drug used for treatment of epilepsy; as noted above, it is also the primary biologically active metabolite of primidone. Phenobarbital can be used alone as a therapeutic compound or in conjunction with other antiseizure medications. It is a broad-spectrum antiepileptic drug used to manage all seizure types with the exception of absence seizures. Phenobarbital is not extensively protein-bound (40%−60% bound to albumin); therefore measurement of free drug concentrations is not required to assess therapeutic efficacy. The therapeutic interval for phenobarbital is 15−40 μg/mL, with blood concentrations of greater than 40 μg/mL, leading to significant CNS depression [4]. Phenobarbital has a significantly longer half-life than many drugs that are monitored and is thus not as sensitive to timing of collection as other drugs.

Valproic Acid is a drug that has long been used for treatment of epilepsy (since 1962; FDA cleared in 1978), but is also used for the treatment of bipolar disorder, migraines, and neuropathic pain. In epilepsy, it us used primarily for treatment of absence seizures, but has also been used for the treatment of generalized tonic−clonic and complex partial seizures. As with phenytoin, valproic acid is highly protein-bound and measurement of the free (or unbound) drug can be used for patient management. The therapeutic interval is defined as 50−100 μg/mL, with concentrations greater than 100 μg/mL associated with significant toxic effects including hepatic, gastrointestinal, and CNS toxicity [5].

Lamotrigine is one of the newer generations of antiepileptic drugs; it was introduced for treatment of epilepsy in the early 1990s. The mechanism of action for lamotrigine is inhibition of glutamate and aspartate release. Currently, it is not only used for its antiseizure effects, but it is also used as a mood stabilizer in treatment of bipolar disorder and clinical depression. It is a broad-spectrum antiepileptic drug used for all types of seizures. The therapeutic interval is generally reported as 2.5−15.0 μg/mL (C_0 concentration) [6]. Lamotrigine also demonstrates enzyme autoinduction effects, with up to 20% reduction of blood concentrations occurring after 2 weeks of therapy. Adverse effects from elevated lamotrigine concentrations include vision abnormalities and GI toxicity.

Levetiracetam is another newer generation antiepileptic drug used for treatment of partial myoclonic, tonic−-clinic, and partial seizures. It is also used for the treatment of manic states in bipolar disorder and for migraine headaches. Levetiracetam has a relatively short half-life (∼6−7 hours) and is cleared renally, so any renal dysfunction or acute kidney injury may warrant TDM and/or dose adjustment. The generally reported therapeutic interval for C_0 samples is 12−46 μg/mL; no toxic threshold has been established [7]. The minimum concentration associated with seizure control is 3 μg/mL. Clinical toxicities associated with increased levetiracetam concentrations include general anemia, neutropenia, and significant drowsiness (somnolence). These toxicities can sometimes occur even when the drug concentration is within the therapeutic interval.

Gabapentin is another of the newer antiepileptic drugs introduced in the early 1990s for treatment of seizures. Since its introduction, it has also found use for treatment of neuropathic pain, restless leg syndrome, anxiety, bipolar disorder, and insomnia. In epilepsy, it is often used for the treatment of drug-resistant partial seizures. Gabapentin does not undergo any hepatic metabolism and is cleared almost completely by renal excretion—the elimination half-life is approximately 5−7 hours in patients with normal renal function. The generally reported therapeutic interval for C_0 concentrations is 2−20 μg/mL [8]. Toxic effects of high gabapentin

concentration include extreme fatigue, drowsiness, dizziness, and ataxia (loss of full control of body movements).

Oxcarbazepine is a prodrug that is metabolized to a biologically active metabolite, 10-hydroxy-10,11-dihydrocarbamazepine, known more commonly as monohydroxycarbamazepine (MHD). MHD is responsible for the antiseizure activity of the drug, and it is the component that is measured in the blood for TDM. The half-life for MHD is longer than that of oxcarbazepine (8−10 hours vs. 1−2.5 hours). The therapeutic interval for MHD is reported generally as 3−35 μg/mL [9]. Toxicity associated with MHD includes dizziness, drowsiness, GI toxicity, tremor, ataxia, and abnormal gait. These toxicities can sometimes occur even when the drug concentration is within the therapeutic interval.

Topiramate is a newer broad-spectrum antiepileptic drug that has also been used for treatment of seizures including those from Lennox−Gastaut syndrome in children and also bipolar disorder, cluster headaches, and trigeminal neuralgia. It exerts antiseizure activity through multiple mechanisms and is notable in that it blocks seizure activity without also increasing the potential for inducing seizures with increasing concentration. The serum half-life for topiramate is 20−30 hours, and the therapeutic interval is generally listed as 5−20 μg/mL. However, there is significant overlap in blood concentrations between the responders and the nonresponders. Toxicity associated with topiramate includes poor cognition and physical side effects such as fatigue, somnolence, joint pain, and GI toxicity.

Transplantation

Transplantation is an extremely complex medical procedure, and immunosuppression is central to controlling the body's response to the transplanted organ to ensure a successful xenograft. Management of these powerful drugs requires the balance of ensuring enough drug exposure to prevent rejection while keeping the concentration of the drug low enough to avoid toxic effects. The use of immunosuppression has evolved significantly over the years from the mid-20th century until now. With current protocols, TDM is an essential tool in the process, allowing rapid titration of blood concentrations of the drug to maximize immunosuppression and avoid acute rejection while minimizing adverse events from exposure to the drug.

Tacrolimus is a calcineurin inhibitor and the most widely used immunosuppressive drug used in transplantation. It can be administered either intravenously or orally, and exhibits significant interindividual variability. This drug exerts its immunosuppressive effects by blocking the synthesis of cytokines and inflammatory mediators. Tacrolimus is monitored in whole blood rather than serum or plasma, and a general therapeutic interval is reported as 5−15 ng/mL for C_0 concentrations [10], although, in practice, target concentration ranges are more narrow and dependent on the type of organ transplanted as well as the time from transplantation. Adverse effects of elevated concentrations of tacrolimus in blood include nephrotoxicity, neurotoxicity, hypertension, and nausea.

Cyclosporine A (CsA) is a calcineurin inhibitor that has been available for longer than tacrolimus, but is not as widely used. It exerts its immunosuppressive effects by blocking the activation of T lymphocytes. CsA is available both in intravenous and oral forms, with variable absorption and distribution; it is also highly protein bound. CsA is found in both plasma and red blood cells, but measurement of the drug primarily occurs in whole blood samples, as the drug distributes into red cells in vitro after collection as the temperature falls. The general target interval for C_0 concentrations is 100−400 ng/mL [11], although the target in clinical practice is dependent on multiple factors including type of transplant, time from transplantation, method of analysis, and coadministered drugs. There is some evidence that C_2 (peak concentration 2 hours after administration) is more closely correlated with clinical outcomes [12]. CsA is metabolized in the liver by CYP3A4, and the drug demonstrates significant interindividual pharmacokinetic variability and is susceptible to drug−drug interactions. Adverse effects of high CsA concentrations include renal toxicity, as well as liver or CNS effects.

Sirolimus is an IL-2 inhibiting drug that targets the mammalian target of rapamycin (mTOR) receptor, which interrupts the cell cycle. Sirolimus is primarily metabolized by CYP3A4/5, so it exhibits significant pharmacokinetic variability and is susceptible to drug−drug interactions. The half-life of sirolimus is relatively long (48−72 hours) compared with other immunosuppressants, so it takes longer to achieve steady-state concentrations after initiation of therapy or with a dosage change. There is also a prodrug available called temisirolimus, which is metabolized to sirolimus via CYP3A4. Sirolimus inhibits T-cell activation and proliferation by inhibiting mTOR, which leads to cell cycle interruption. Generally, the therapeutic interval for sirolimus is 4−12 ng/mL, but as with the other drugs, target concentrations are dependent on transplant type and comedications, as well as other physiological parameters [13]. Sirolimus is measured in whole blood samples rather than serum or plasma due to its significant distribution into red blood cells. The benefit of this drug is that it does not have renal toxicity, making it appealing for use in kidney transplantation. However, significant toxic effects are still possible including leukopenia, thrombocytopenia, and hypercholesterolemia.

Everolimus is a structural analog of sirolimus, and as such, they share the same target and mechanism of action (mTOR inhibition). The primary difference between

everolimus and sirolimus is that everolimus has a shorter half-life (18−36 hours) and its toxic effects are less significant. Everolimus is metabolized via CYP3A4, and is subject to drug−drug interactions, including inhibition by coadministration of cyclosporine. Therefore it is still important to manage this drug using TDM for optimal therapeutic effect while minimizing toxicities. Everolimus is measured in whole blood samples for TDM. The target therapeutic interval is 3−15 ng/mL, with modifications based on coadministered medications, transplant type, and time from transplantation [14].

Mycophenolic acid (MPA) is an inhibitor of inosine monophosphate dehydrogenase (IMPDH), which inhibits cell group by inhibition of purine synthesis. Purine synthesis catalyzed by IMPDH is the rate-limiting step in proliferating lymphocytes, so inhibition by MPA significantly decreases the response of the activated T cells. MPA is the active compound; however, the drug is actually administered as a prodrug such as mycophenolate mofetil (CellCept) or mycophenolate sodium (Myfortic), both of which are extended release formulations. The drug is used in conjunction with either calcineurin or mTOR inhibitors as adjuvant therapy for immunosuppression. MPA has a relatively short half-life (9−18 hours) and is not distributed into red blood cells like the other commonly used immunosuppressant drugs. Important differences for MPA include (1) the measurement of the drug is in plasma rather than whole blood; and (2) a peak or C_0 measurement is not sufficiently correlated with area under the curve (AUC), so a single measurement is not sufficient. It is recommended that AUC with limited sampling be used for TDM of this compound [15]. The standard AUC target for transplantation is 30−60 mg/h.L. When a single measurement is used, a predose range of 1−4 ug/mL is considered therapeutic, with modification depending on the coadministered drug. The primary toxicity for MPA is gastrointestinal toxicity—there is some debate of whether TDM is really needed for MPA or whether the dose can just be reduced when GI toxicity is observed.

Cardioactive drugs

Historically, in cardiology, certain therapeutic agents have been used to control arrhythmia in patients with abnormal heart physiology. However, these historic therapeutic agents displayed two important tendencies. First, each of the agents demonstrated significant pharmacokinetic variability. Second, while these drugs can control arrhythmia when the dose is optimized, they can also cause arrhythmia when concentrations in blood are too high. Based on these characteristics, it was recognized that TDM is a pivotal tool in optimal management of these agents, as toxic effects can even appear at concentrations just slightly higher than the target range.

Procainamide is an antiarrhythmic drug used for control of both atrial and ventricular arrhythmias, and *N-acetylprocainamide* (NAPA) is the primary metabolite that also elicits antiarrhythmic activity (via a different mechanism). The primary mechanism of action for procainamide is through Na^+ channel blockade. The half-life of procainamide is approximately 3−4 hours and the half-life for NAPA is closer to 6 hours, and both compounds exhibit significant interindividual variability. The therapeutic target for procainamide is 4−8 μg/mL, and for NAPA, it is 10−20 μg/mL; when considered together, the therapeutic target interval for procainamide and NAPA combined is 5−30 μg/mL [16]. Adverse effects associated with high concentrations of procainamide and NAPA include hypotension, induced arrhythmia, and widening of QRS intervals (associated with chronically high exposure).

Lidocaine is a drug commonly used for emergent treatment of acute or life-threatening arrhythmias. Lidocaine is also a Na^+ channel blocker, but it is more weakly bound than the procainamide. It is highly protein-bound (to α-1-acid glycoprotein) and is metabolized in the liver. Since lidocaine is used in acutely ill patients and α-1-acid glycoprotein is an acute phase reactant, it is common for the free/unbound fraction of the drug to change rapidly along with the patient condition, thus changing the effective concentration of the drug. However, despite this, the free fraction of lidocaine is not commonly monitored. In addition, the hepatic metabolism of the drug means that the pharmacokinetics can be significantly impacted by changes in liver perfusion or liver injury, which is particularly pertinent in an acutely ill population. The therapeutic interval for lidocaine is reported as 1.5−5 μg/mL [17]. Toxic effects from high lidocaine concentrations include bradycardia, hypotension, and CNS dysfunction.

Quinidine is used for both atrial and ventricular arrhythmias, but it is less commonly administered due to the GI side effects present even when blood concentrations are within the therapeutic range. It is a stronger Na^+ channel blocker than lidocaine. Blood concentrations are best measured as C_0 levels, and the therapeutic interval is reported as 2−5 μg/mL [18]. Concentrations greater than 5 μg/mL are associated with hypotension, ventricular tachycardia, or fibrillation, and cinchonism and QT interval elongation on an electrocardiogram. Interestingly, the QT interval elongation is a desired effect for patients with Brugada Syndrome, making it a preferred treatment in that population [19]. Several metabolites of quinidine have been shown to have biologic activity, but they are not routinely monitored.

Digoxin is a cardiac glycoside used in treatment of cardiac arrhythmia and also congestive heart failure.

Digoxin demonstrates multiple mechanisms of action, including regulation of cation flux in myocardial cells as well as sympathetic nervous and endocrine systems that impact cardiac function. One of the primary toxic effects of the drug at higher than therapeutic concentrations is cardiac arrhythmia that is difficult to differentiate from the clinical indication for the drug in the first place. The therapeutic interval for digoxin is reported as 0.8−2.0 ng/mL [20]. Toxic symptoms in addition to arrhythmia include GI toxicity and neurologic symptoms. Digoxin assays can encounter significant interference from digoxin-like immunoreactive factors or Digibind (Fab fragments specific for digoxin used for treatment of overdose).

Psychoactive drugs

In the treatment of psychiatric disorders such as depression or schizophrenia, pharmacotherapy is commonly managed by titration to clinical effect. This approach is taken because of the lack of robust relationship between the dose administered (or blood concentration) and the clinical response to therapy—the evaluation of response to therapy is often subjective in nature. It can vary based on the variability of how the patients communicate their experience and also the way the clinicians perceive their interaction with the patient. However, for some drugs, the adverse effects of the drug can be objectively measured and correlated with blood concentration of the drug. In these cases, TDM is a useful tool for psychoactive drug management.

Tricyclic antidepressants include amitriptyline, nortriptyline, imipramine, desipramine, and clomipramine, and are used for treatment of major depression. While a robust relationship between blood concentration and therapeutic clinical effect is difficult to define, there is a well-described relationship between the blood concentrations of the tricyclic antidepressant drugs and the toxic effects (life-threatening cardiac arrhythmia). It is because of this significant toxicity and potential for suicide using the prescribed therapeutic drug that tricyclic antidepressants are not widely used at present. However, in certain patient populations, these drugs are still preferred, and when used, TDM is necessary to ensure patient safety. Blood concentrations greater than 500 ng/mL are generally reported as toxic and are associated with increased risk of cardiac arrhythmia [21]. For other antidepressant drugs such as selective serotonin reuptake inhibitors and selective norepinephrine reuptake inhibitors, the toxic side effects of the drugs are not so severe, and without a well-defined therapeutic interval, TDM of these drugs is not commonly performed.

Lithium is a drug that is widely used for treatment of bipolar disorder; specifically, it is used for control of the manic phase in the disorder. The blood concentration of lithium can be affected by changes in other physiologically relevant electrolytes. For instance, increased intake of sodium can enhance lithium excretion, while decreased physiologic sodium concentration can lead to reduced lithium excretion. Lithium is cleared from circulation only by the kidneys, so decreased renal function can lead to toxic accumulation of the drug. The therapeutic interval for lithium is generally reported as 0.4−1.2 mmol/L, with toxic effects seen at concentrations greater than 1.5 mmol/L [22]. Clinically significant side effects of high lithium concentrations include renal failure and excessive water and electrolyte loss. Chronic lithium administration can also affect thyroid function (up to 35% of patients treated with lithium develop hypothyroidism), so thyroid function should be monitored regularly for patients on lithium therapy [23].

More recently, TDM of antipsychotic drugs has emerged as an area of interest for TDM in psychiatry—particularly for monitoring adherence to therapy. While the same challenges exist for these drugs as in antidepressants in terms of drug exposure predicting clinical success in treatment, there is growing interest in using drug monitoring to assess adherence to therapeutic regimens. Common drugs subjected to TDM for this purpose include clozapine, olanzapine, risperidone, quetiapine, and aripiprazole. Of course, to assess whether a patient is taking the drug does not require a blood sample or TDM—one recent study has demonstrated the potential of using urine metabolites for assessment of adherence in patients treated with aripiprazole [24]. However, TDM is still not a standard of practice for most psychiatric patients.

Infectious disease

In the treatment of infectious diseases, the biologic activity of the drug is directed against the microorganism responsible for the infection and not toward the person taking the drug. Given this mechanism of action, the therapeutic index is quite wide and the while many of the drugs have significant pharmacokinetic variability and it is important to have the drug concentration (exposure) higher than the minimal effective concentration against the microorganism, the lack of toxic effects against the host/patient allows for a high enough dose to ensure sufficient blood concentrations for efficacious treatment for patients regardless of pharmacokinetic variability. However, some antimicrobial drugs do have both significant pharmacokinetic variability and significant clinical toxicity for the patient. In these cases, TDM is a valuable tool for optimal management of patients on antimicrobial therapy.

Aminoglycoside antibiotics include gentamicin and tobramycin (effective against both Gram-positive and Gram-negative bacteria), as well as amikacin (effective primarily against Gram-negative bacteria). Aminoglycosides

are characterized by their short half-lives (1−2 hours) and lack of oral bioavailability—they are all administered intravenously. The aminoglycoside antibiotics are renally cleared and exhibit significant interindividual pharmacokinetic variability. Traditional dosing of these drugs includes dosing every 6−8 hours, with peak monitoring target concentrations of 5−10 μg/mL for gentamicin and tobramycin and 20−25 μg/mL for amikacin [25]. However, due to the antibiotic residual effect [26], where the antibiotic effects of the drug are related to the peak exposure concentration versus toxic effects that are related to the duration of exposure, daily dosing (or pulse dosing) is more commonly applied in current regimens. For this therapeutic paradigm, all of the doses for a day are combined into a single administered dose for the entire day. When this approach is taken, the peak therapeutic target intervals established in the literature are no longer applicable, and TDM is performed using C_0 monitoring primarily to ensure that the drug is being cleared. In this approach, C_0 levels should be less than 2 μg/mL. Significant toxic effects are commonly observed when these drugs are used, including irreversible ototoxicity and renal toxicity in the form of renal tubular damage.

Vancomycin is a glycopeptide antibiotic used for treatment of many Gram-positive bacterial infections and also demonstrates treatment efficacy for some Gram-negative bacteria as well. It works particularly well for methicillin-resistant staph aureus infection. Similar to the aminoglycosides, vancomycin does not have oral bioavailability and it is administered as an intravenous infusion. The half-life of vancomycin is 4−6 hours, and it is typically given twice per day. It is cleared via the kidneys with significant interindividual variability—TDM is performed using trough levels with a target concentration interval of 10−20 μg/mL [27]. Toxic effects of vancomycin include ototoxicity and nephrotoxicity, although these toxic effects are more commonly seen when the drug is coadministered with drugs that share a similar toxicity profile such as the aminoglycoside antibiotics.

Voriconazole is a triazole antifungal drug that is used to treat invasive fungal infections (such as candidiasis or aspergillosis) and also for prophylaxis in severely immunocompromised patients, such as advanced HIV patients or those with leukemia or in preparation for bone marrow transplantation. Voriconazole is administered both orally and intravenously, with an oral bioavailability of 96%. It is metabolized in the liver, and demonstrates significant interindividual pharmacokinetic variability and also is susceptible to a number of drug−drug interactions. The reported therapeutic target interval for voriconazole is 1.0−5.5 μg/mL, and adverse side effects include GI toxicity, headache, peripheral edema, and visual disturbances. The primary toxicity associated with blood concentrations greater than 6.0 μg/mL is liver toxicity [28].

While the antimicrobial drugs previously discussed are those most commonly managed using TDM, there are some emerging applications in the area of infectious disease. As the drug posaconazole is more frequently used to treat antifungal infections, there are those that suggest it should be monitored similarly to voriconazole and for the same reasons [29]. In addition, there has been an increase recently regarding the application of TDM for antituberculosis drugs. Beta-lactam drugs exhibit significant pharmacokinetic variability, and there are a number of studies that suggest TDM may be of benefit in patients administered those drugs as well.

Oncology

In the treatment of cancer, most drugs are dosed based on body surface area normalization (e.g., mg/m^2), and then, the patients are monitored for significant toxicity or tumor response—this is similar to the "titrate to clinical effect" scheme described earlier. However, in cancer treatment, there is an additional consideration of maximum tolerated dose (MTD). Since the drugs are known to be toxic, part of the clinical trials during drug development involves assessment of dose limiting toxicity relative to the administered dose in a small number of patients, in order to determine the maximum amount of drug that should be given. When patients are receiving the MTD and not exhibiting symptoms of toxicity, treatment is continued without dose adjustment until it is determined whether the treatment is affecting the cancer. However, it is important to note that many chemotherapy drugs have significant pharmacokinetic variability, so that when MTD is given to the patient and no toxic effects are observed, it is not certain that the patient is getting just the right dose, it may be that the patient is actually getting less drug than needed (or that they can tolerate). Based on this, some have advocated for the concept of maximum tolerated exposure [30], which would require blood concentration measurements. TDM is not routine in the management of chemotherapy for the most part.

Methotrexate is a folic acid antagonist drug that initially was used as an immunosuppressant drug in transplantation, but has found more widespread use in the treatment of malignancy or autoimmune disease. It exerts its activity by inhibiting the enzyme dihydrofolate reductase, which decreases concentrations of tetrahydrofolate and ultimately leads to the cell death. The adverse effects can be reversed with leucovorin (a folic acid derivative), which restores tetrahydrofolate-dependent synthesis of pyrimidines and leads to cell rescue. As with many other drugs that require TDM, methotrexate exhibits significant interindividual variability and is susceptible to drug−drug interactions. In the treatment of autoimmune disorders, low-dose methotrexate is used, and typically, TDM is not

needed for management of these patients. However, in treatment of malignancy, the risk of adverse effects on normal cells is much greater and the drug is commonly used with leucovorin to prevent damage to noncancer cells. The amount of leucovorin needed is dependent on the rate of methotrexate clearance, so methotrexate concentrations are measured over multiple days. The target concentration intervals are 5−10 μM at 24 hours postdose, 0.5−1.0 μM at 48 hours postdose, and 0.05−0.1 μM at 72 hours postdose [31]. When methotrexate concentrations are greater than those time-dependent target intervals, addition leucovorin is needed. The adverse effects of high methotrexate levels include hepatotoxicity, leukopenia, and ulcerative stomatitis.

Busulfan is an alkyl sulfonate drug that functions as a nonspecific alkylating neoplastic agent. It inhibits the growth of cancerous cells by alkylating DNA. Busulfan was initially approved as a treatment for chronic myeloid leukemia (CML); however, it is currently primarily used as a conditioning agent along with cyclophosphamide, fludarabine, or total body irradiation prior to bone marrow transplantation. Busulfan can be given as either an oral or intravenous formulation; the kinetics are more predictable when given intravenously. TDM-based dosing of busulfan is not based on a single measurement, but is instead based on 6-hour AUC. The general target AUC is between 900 and 1500 μmol.min. When the AUC is less than 900, the risk of incomplete bone marrow ablation is increased, along with the chances of graft rejection or graft-versus-host disease—in these cases, the dose should be increased. AUCs greater than 1500 are associated with liver toxicity known as sinusoidal obstructive syndrome, also known as venoocclusive disease, which can result in significant organ damage and poor clinical outcomes [32]. In some newer treatment protocols, once-daily dosing of busulfan is used rather than four times per day dosing, with higher AUC targets [33].

While TDM has been sparsely utilized in oncology with the exception of methotrexate and busulfan, there is an emerging body of evidence suggesting that it can be a useful tool for managing other chemotherapy drugs. There is a growing body of scientific literature suggesting that phenotpying for the thiopurine drug mercaptopurine by measuring the drug metabolites (TDM) is useful for managing the drug; however, it is just as common or more so to obtain the genotype prior to dosing or determine the enzymatic activity directly through the bioassay of the red blood cells for a patient [34,35]. There are a large number of studies supporting TDM in the scientific literature for optimization of 5-fluorouracil (5-FU) management, including one of the few randomized control trials published in 2008 [36]. However, despite the large number of studies suggesting the utility of 5-FU monitoring, it has not become a standard of practice. More recently, clinical studies have demonstrated the potential for TDM to reduce toxicity in patients receiving taxanes (docetaxel and paclitaxel) for treatment of cancer [37]. Finally, several studies have suggested that TDM for management of imatinib in the settings of CML [38] and gastrointestinal stromal tumors [39] has potential to affect patient outcomes positively. However, despite the emerging amount of evidence, TDM remains far from routine implementation in oncology settings.

Self-assessment questions

1. Criteria for effective TDM include:
   - **a.** list of concomitant medications for the patient
   - **b.** the relationship between the drugs dose and the blood concentration must be highly variable and/or not predictable
   - **c.** the relationship between blood concentration and clinical effect must be well defined
   - **d.** a and b
   - **e.** b and c
2. In addition to adjustment of drug dosage for optimizing therapy, TDM can also be useful for:
   - **a.** ensuring a complete medical record
   - **b.** assessment of medication adherence
   - **c.** risk management
   - **d.** nothing; it is only effective for dose optimization
3. Timing of sample collection is most important for drugs with which of the following?
   - **a.** Very short half-lives
   - **b.** Variable bioavailability
   - **c.** Active metabolites
   - **d.** No recognized circadian rhythm effects
   - **e.** Very long half-lives
4. Which one of the following classes of drugs is commonly monitored at the peak and the trough?
   - **a.** Antiepileptics
   - **b.** Aminoglycosides
   - **c.** Cardioactive drugs
   - **d.** Immunosuppressants
   - **e.** Tricyclic antidepressants
5. Which of the following immunosuppressive drugs requires multiple time points for effective TDM?
   - **a.** Cyclosporine A
   - **b.** Tacrolimus
   - **c.** MPA
   - **d.** Sirolimus
   - **e.** Everolimus
6. Which of the following drugs is commonly monitored in oncology?
   - **a.** 5-FU
   - **b.** Docetaxel
   - **c.** Doxorubicin
   - **d.** Methotrexate

Learning objectives

After reviewing this chapter, the reader will be able to:

- Define the different toxidromes and describe some of the key signs and symptoms and agents that can cause each one.
- For each of the following cellular hypoxia causative agents, describe the agent, the toxic effects, the treatment, and the method(s) of analysis, including specimen requirements: carbon monoxide, cyanide, and methemoglobin-forming agents.
- For each of the following alcohols, describe the pharmacological action, the metabolites, the antidote, other biomarkers of exposure, and the method(s) of analysis, including specimen requirements: ethanol, isopropanol, methanol, and ethylene glycol.
- For each of the following analgesics, describe the toxic effects of overdose, the dose and time of symptom onset, the metabolizing enzyme and metabolite, the antidote, and the method(s) of analysis, including specimen requirements: acetaminophen and salicylate.
- For the following drugs, describe the pharmacological response, significant metabolic pathways, clinical uses if any, the antidote, and the screening and confirmatory tests: amphetamines/methamphetamines, barbiturates, benzodiazepines, cannabinoid, cocaine (COC), marijuana, opioids, phencyclidine, synthetic opioids, and tricyclic antidepressants.
- For the following metals be able to recognize common physical signs/symptoms of toxicity, identify appropriate laboratory tests, specimen types, the mechanism of toxicity, and the treatment or management of toxicity: lead, arsenic, mercury, cadmium, and chromium.

Background

Toxicology is an extensive, multidisciplinary science with an overarching goal to determine the effects of chemicals on living systems. Numerous potential toxins can cause harm, including over-the-counter or prescription drugs, herbal medications, common household products, environmental agents, occupational substances, drugs of abuse, and chemical terrorism threats. Unfortunately, there is no specific antidote or treatment for most toxins; therefore supportive care is the most appropriate intervention [1]. In clinical practice, it is also not required or realistic to test for all of the potential toxins that a person may have been exposed to. In fact, approximately 25 substances account for 80% or more of the cases treated in emergency departments [2]. Therefore the scope of clinical toxicology testing depends on the local pattern of drug abuse, the resources of the laboratory, and the clinical need of the institution to provide care for its patients.

In the end, all compounds have the potential to be toxic, and the amount a person is exposed to or consumes determines if the compound is poisonous or not. Poisonings most commonly involve products or chemicals readily available to the victim. One way to evaluate the toxicity of a substance is to look at the median lethal dose or lethal dose 50% (LD_{50}). The LD_{50} is the amount of a substance that is required to cause death in half of the exposed population; the LD_{50} is typically determined in animal studies. In the end, the basic pharmacokinetic principles discussed previously in Chapter 49, The porphyrias: fundamentals and laboratory assessment, affect the extent of the toxicity. In addition, preexisting organ dysfunction, genetic factors, health status, or preexposure to compounds that can alter the biotransformation of the compound can all influence the toxic effects. Furthermore, the duration and frequency of the exposure can also affect the onset and severity of toxicity.

Laboratory methods

A variety of different analytical approaches are commonly utilized in toxicology laboratories including rapid spot tests, immunoassays, chromatographic methods [e.g., high-performance liquid chromatography (HPLC) or gas chromatography (GC)], chromatographic methods combined with mass spectrometry (MS; e.g., GC−MS, GC−MS/MS, LC−MS, or LC−MS/MS), and high-resolution mass spectrometry (e.g., HRMS, TOF, and Orbitrap) [3]. One key

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00052-1

issue in selecting an appropriate methodology to use in the clinical laboratory is the speed of analysis, or turnaround time (TAT) required. A drug test that requires several hours to complete the analysis or a test that is not available 24 hours a day/7 days a week is less useful to physicians treating a poisoned patient in the Emergency Department.

As a result, when a patient presents with a potential toxicology-related health problem, the diagnosis is often determined by (1) reviewing the case history; (2) physical exam findings; (3) ancillary tests (e.g., electrocardiogram); and (4) applying a rational and evidence-based approach to laboratory testing. Screening procedures are designed for a relatively rapid and generally qualitative detection of a particular drug or drug class. In general, screening tests have adequate clinical sensitivity but may not be highly specific. Therefore a negative result from a screening procedure may rule out, with reasonable certainty, the presence of a clinically significant concentration of a particular analyte. However, a positive result should be considered only "presumptive positive," and it should be confirmed by an alternate procedure with greater specificity.

Toxidromes

Toxic syndromes (toxidromes) are a group of signs and symptoms that occur together and characterize a particular abnormality or class of poisons. The most common toxidromes include (1) anticholinergic; (2) cholinergic; (3) opioid; (4) sedative-hypnotic; and (5) sympathomimetic (Table 52.1). However, many poisonings involve more than one agent, and some toxidromes have overlapping features. For example, anticholinergic findings are very similar to sympathomimetic findings, with an exception being the effects on sweat glands: anticholinergic agents produce warm, flushed dry skin, but sympathomimetic agents produce diaphoresis. Toxidrome findings may also be affected by individual variability, comorbidity, and coingestants. When accurately identified, the toxidrome may provide valuable information for a quicker diagnosis and subsequent treatment, although the many limitations impeding acute toxidrome diagnosis must be carefully considered.

Cholinergic toxidrome

Acetylcholine is a neurotransmitter found throughout the central nervous system (CNS), including (1) the sympathetic and parasympathetic autonomic ganglia; (2) the postganglionic parasympathetic nervous system; and (3) the skeletal muscle motor end plate. The symptoms associated with cholinergic poisoning are due to the inhibition of acetylcholinesterase (AChE), which results in the buildup of excessive levels of acetylcholine at the synapses or neuromuscular junctions and varies depending on the balance of nicotinic and muscarinic stimulation. Activating muscarinic receptors stimulates or inhibits cellular function at visceral smooth muscle, cardiac muscle, and secretory glands. Two mnemonics have been developed to help remember cholinergic clinical effects: DUMB BELLS (diarrhea, urination, miosis, bradycardia, and bronchorrhea-bronchoconstriction, emesis, lacrimation, lethargy, and sweating-salivation) [4] and SLUDGE [salivation, lacrimation, urination, defecation, gastrointestinal (GI) distress, and emesis-eye findings] [5]. The respiratory effects of cholinergic poisoning tend to be dramatic and are considered to be the major factor, leading to the death of its victims.

Agents that cause these cholinergic clinical effects inhibit AChE, and include organophosphate and carbamate insecticides (cholinesterase inhibitors), certain species of mushrooms that contain muscarinic and nicotinic receptor agonists such as nicotine.

Anticholinergic toxidrome

Characteristics of the anticholinergic syndrome are essentially the opposite of the cholinergic syndromes, and have long been taught using the old medical adage, "dry as a bone, blind as a bat, red as a beet, hot as a hare, and mad as a hatter," which corresponds with a symptomatic person's anhidrosis, mydriasis, flushing, fever, and delirium, respectively. Depending on the dose and time following exposure, various CNS effects may manifest from an anticholinergic agent. Restlessness, apprehension, abnormal speech, confusion, agitation, tremor, picking movements, ataxia, stupor, and coma all have been described following exposure to various anticholinergics. Compounds exhibiting anticholinergic actions competitively block the action of acetylcholine at its receptors, both centrally and peripherally. Numerous substances can cause the anticholinergic syndrome. Some of the more common agents include antihistamines, atropine, cyclic antidepressant drugs, phenothiazines, anti-Parkinson's drugs, cyclobenzaprine, scopolamine, and several plants such as *Datura stramonium* (Jimson weed).

Opioid toxidrome

Opioids can induce coma, respiratory depression, bradycardia, hypotension, hypothermia, miosis, pulmonary edema, decreased bowel sounds, and decreased reflexes. Common causes of this syndrome, in which CNS depression and miosis are two key signs, include morphine, codeine, diacetylmorphine (heroin), oxycodone, hydrocodone, hydromorphone, and methadone. Meperidine and propoxyphene toxicity has been associated with mydriasis (pupil dilation), but not with miosis (pupil constriction).

TABLE 52.1 Summary of the toxidromes.

Toxidrome	Signs and symptoms	Common toxins
Anticholinergic	Agitation	Antihistamines, anti-Parkinson's drugs, antipsychotic drugs, and tricyclic antidepressants
	Blurred vision	
	Decreased bowel sounds	
	Dry skin	
	Fever	
	Flushing	
	Hallucinations	
	Ileus	
	Lethargy/coma	
	Mydriasis	
	Myoclonus	
	Psychosis	
	Seizures	
	Tachycardia	
	Urinary retention	
Cholinergic	Diarrhea	Organophosphate and carbamate insecticides, and some mushrooms
	Urination	
	Miosis	
	Bradycardia	
	Bronchorrhea	
	Emesis	
	Lacrimation	
	Salivation	
Opioid	Bradycardia	Opiates (e.g., morphine and codeine), propoxyphene, and alpha-2 agonists (e.g., clonidine and oxymetazoline).
	Decreased bowel sounds	
	Hypotension	
	Hypothermia	
	Lethargy/coma	
	Miosis	
	Shallow respirations	
	Slow respiratory rate	

(*Continued*)

TABLE 52.1 (Continued)

Toxidrome	Signs and symptoms	Common toxins
Sedative-hypnotic	Ataxia	Benzodiazepines, barbiturates, ethanol, and meprobamate
	Blurred vision	
	Confusion	
	Diplopia	
	Dysesthesia	
	Hypotension	
	Lethargy/coma	
	Nystagmus	
	Respiratory depression	
	Sedation	
	Slurred speech	
Sympathomimetic	Agitation	Amphetamines, caffeine, cocaine, ephedrine, and phencyclidine
	Diaphoresis	
	Excessive motor activity	
	Excessive speech	
	Hallucinations	
	Hypertension	
	Hyperthermia	
	Insomnia	
	Restlessness	
	Tachycardia	
	Tremor	

Numerous drugs can also mimic the opioid syndrome by inducing coma, respiratory depression, and miosis, including alpha-2 agonists (e.g., clonidine and oxymetazoline) and antipsychotics.

Sedative hypnotic toxidrome

Sedative-hypnotics are a broad class of drugs (e.g., benzodiazepines, barbiturates, meprobamate, ethchlorvynol, and zolpidem) that can induce sedation, respiratory depression, hypotension, hyporeflexia, nystagmus, dysarthria, staggering gait, apnea, and coma. Numerous sedative-hypnotics have been utilized to commit drug-facilitated crimes (see below), such as the solution of chloral hydrate in ethanol. There are few diagnostic clinical features that distinguish the drugs in this class from one another.

Sympathomimetic toxidrome

Their physiological and toxic effects associated with the sympathomimetic toxidrome reflect increased sympathetic activity due to increased release of catecholamines, inhibition of neurotransmitter reuptake, and/or direct stimulation of alpha- and beta-adrenergic receptors. Physiologic responses to activation of the adrenergic system are complex and depend on the type of receptor activated; some are excitatory and others have opposing inhibitory responses. Stimulation of the sympathetic nervous system produces CNS excitation (agitation, anxiety, tremors, delusions, and paranoia), tachycardia, hypertension, mydriasis, hyperpyrexia, and diaphoresis. In severe cases, seizures, cardiac arrhythmias, and coma may occur. Examples of drugs that produce a sympathomimetic

response include amphetamines, COC, phencyclidine (PCP), ephedrine, methcathinone, and pseudoephedrine.

Key laboratory formulas

Anion gap

Obtaining a basic metabolic panel in all poisoned patients is recommended and is an important initial screening test. When low serum bicarbonate is discovered on a metabolic panel, the clinician should determine if an anion gap (AG) exists. The formula most commonly used for the AG calculation is as follows:

$$\mathrm{AG} = \left[\mathrm{Na}^{+}\right] - \left[\mathrm{Cl}^{-} + \mathrm{HCO}_3^{-}\right].$$

The primary cation (sodium) and anions (chloride and bicarbonate) are represented in the equation. Other serum cations are not commonly included in this calculation, because their concentrations are relatively low (e.g., potassium) or assigning a number to represent their respective contribution is difficult (e.g., magnesium and calcium). Similarly, a multitude of other serum anions (e.g., sulfate, phosphate, and organic anions) are not commonly measured and therefore are excluded when determining the AG. These "unmeasured" ions represent the gap calculated using the previous equation. The normal range for an AG is typically to be 8−16 mmol/L, but it has been suggested that, because of changes in the technique used to measure chloride, some have suggested a reference interval of 6−14 mmol/L [6]. Practically speaking, useful mnemonics for causes of high AG metabolic acidoses are the classic MUDPILES (representing methanol, uremia, diabetes, paraldehyde, iron (and isoniazid), lactate, ethylene glycol, and salicylate) and the more recently proposed GOLD MARK (glycols (ethylene and propylene), oxoproline, L-lactate, D-lactate, methanol, aspirin, renal failure, and ketoacidosis; see [7]).

Osmolal gap

The main osmotically active constituents of serum are Na^{+}, Cl^{-}, HCO_3^{-}, glucose, and urea. Several formulas based on measurement of these substances have been used to estimate serum osmolality [7]. In practice, one has not shown itself to be superior to the others, yet each equation demonstrates significant differences in the osmolal gap (OSMg) reference interval [8]. Therefore reference intervals must be validated on appropriate patient populations. Two commonly used formulas (in conventional and SI units) are presented here:

$$\mathrm{OSMc}\left(\mathrm{mOsm/kg}\right) = 2\,\mathrm{Na}\left(\mathrm{mmol/L}\right) + \mathrm{glucose}\left(\mathrm{mg/dL}\right)/18 + \mathrm{urea}\left(\mathrm{mg/dL}\right)/2.8$$

$$\mathrm{OSMc}\left(\mathrm{mOsm/kg}\right) = 2\,\mathrm{Na}\left(\mathrm{mmol/L}\right) + \mathrm{glucose}\left(\mathrm{mmol/L}\right) + \mathrm{urea}\left(\mathrm{mmol/L}\right)$$

or

$$\mathrm{OSMc}\left(\mathrm{mOsm/kg}\right) = 1.86\,\mathrm{Na}\left(\mathrm{mmol/L}\right) + \mathrm{glucose}\left(\mathrm{mg/dL}\right)/18 + \mathrm{urea}\left(\mathrm{mg/dL}\right)/2.8 + 9$$

$$\mathrm{OSMc}\left(\mathrm{mOsm/kg}\right) = 1.86\,\mathrm{Na}\left(\mathrm{mmol/L}\right) + \mathrm{glucose}\left(\mathrm{mmol/L}\right) + \mathrm{urea}\left(\mathrm{mmol/}L\right) + 9.$$

The difference between the measured osmolality (OSMm), measured by freezing-point depression, and the calculated osmolality (OSMc) is referred to as delta-osmolality, or the OSMg

$$\mathrm{OSMg} = \mathrm{OSMm} - \mathrm{OSMc}.$$

Traditionally, a normal OSMg has been defined as 10 mOsm/kg or less. Researchers have found the OSMg to vary depending on the population studied. Elevated OSMg implies the presence of unmeasured osmotically active substances. Volatile alcohols (ethanol, methanol, isopropanol, acetone, and ethylene glycol), when present at significant concentrations, may cause an increased serum osmolality and a subsequent increase in the OSMg. However, it is important to remember that volatile alcohols are not detected when osmolality is measured with a vapor pressure osmometer. Therefore, for the purpose of determining the OSMg, only osmolality measurements based on freezing-point depression are acceptable.

A significant residual OSMg (>10 mOsm/kg) would suggest the possible presence of isopropanol, methanol, acetone, or ethylene glycol. This information, in conjunction with the presence or absence of metabolic acidosis or serum acetone, is helpful to the clinician when specific measurements of alcohols other than ethanol and of ethylene glycol are not available on an emergency basis (Table 52.2). It must be realized that ketones and substances administered to patients, such as polyethylene glycol (burn cream), mannitol (osmotic diuretic), and propylene glycol (solvent for medications including diazepam and phenytoin), may also increase serum osmolality.

Pharmacology and analysis of specific drugs and toxic agents

The toxic, pharmacologic, biochemical, and analytical characteristics of several individual drugs and toxins are discussed in this section.

Agents that cause cellular hypoxia

CO and methemoglobin-forming agents interfere with oxygen transport, resulting in cellular hypoxia. Cyanide

TABLE 52.2 Laboratory findings characteristic of ingestion of alcohols.

Alcohol	Serum osmolal gap	Metabolic acidosis with anion gap	Serum acetone	Urine oxalate
Ethanol	+	−	−	−
Methanol	+	+	−	−
Isopropanol	+	−	+	−
Ethylene glycol	+	+	−	+

+, Present; −, absent.

interferes with oxygen use and therefore causes an apparent cellular hypoxia.

Carbon monoxide

CO is a colorless, odorless, and tasteless gas that is a product of incomplete combustion of carbonaceous material. Common exogenous sources of carbon monoxide (CO) include cigarette smoke, gasoline engines, and improperly ventilated home heating units. Small amounts of CO are produced endogenously in the metabolic conversion of heme to biliverdin.

CO complexes tightly with the heme Fe^{2+} of hemoglobin to form carboxyhemoglobin. The binding affinity of hemoglobin for CO is ∼250 times greater than that for oxygen. Thus high concentrations of carboxyhemoglobin limit the oxygen content of blood. Moreover, the binding of CO to a hemoglobin subunit increases the oxygen affinity for the remaining subunits in the hemoglobin tetramer. At a given tissue PO_2 value, less oxygen dissociates from hemoglobin when CO is also bound, thereby shifting the hemoglobin−oxygen dissociation curve to the left. Consequently, CO not only decreases the oxygen content of blood, but also decreases oxygen availability to tissue, thereby producing a greater degree of tissue hypoxia than would result from an equivalent reduction in oxyhemoglobin due to hypoxia alone [9].

The toxic effects of CO are a result of tissue hypoxia. Organs with high oxygen demand, such as the heart and brain, are more sensitive to hypoxia and thus account for the major clinical sequelae of CO poisoning. It must be emphasized that the carboxyhemoglobin concentration, although helpful in diagnosing CO exposure, does not always correlate with the clinical findings or prognosis [7]. Other factors that contribute to toxicity include length of exposure, metabolic activity, and underlying disease, especially cardiac or cerebrovascular disease. Treatment for CO poisoning involves removal of the individual from the contaminated area and administration of oxygen. The half-life ($t_{1/2}$) of carboxyhemoglobin in the body is variable; in room air, the approximate $t_{1/2}$ is ∼4−5 hours; during hyperbaric oxygen therapy, it is as short as 12−20 minutes [10].

CO may be released from hemoglobin and then measured by GC, or it may be determined as carboxyhemoglobin by spectrophotometry. GC methods are extremely accurate and precise for very low concentrations of CO. However, spectrophotometric methods are more widely used, since they are rapid, convenient, accurate, and precise, except at very low concentrations of carboxyhemoglobin (<2%−3%).

Methemoglobin

An acquired methemoglobinemia may be caused by various drugs and chemicals, as well as by oxides of nitrogen and other oxidant combustion products; consequently, prolonged smoke inhalation may be a potential cause of methemoglobinemia [7]. The heme iron in hemoglobin is normally present in the ferrous state (Fe^{2+}). When oxidized to the ferric state (Fe^{3+}), methemoglobin is formed, and this form of hemoglobin cannot bind oxygen. The normal percentage of methemoglobin is <1.5% of total hemoglobin. The severity of symptoms usually correlates with measured methemoglobin levels; methemoglobin percentages up to 20% may cause slate-gray cutaneous discoloration, cyanosis, and chocolate-brown blood. Percentages between 20% and 50% may cause dyspnea, exercise intolerance, fatigue, weakness, and syncope. More severe symptoms of dysrhythmias, seizures, metabolic acidosis, and coma are associated with methemoglobin percentages of 50%−70%, and >70% may be lethal [11].

All of these symptoms are a consequence of hypoxia that is associated with the diminished O_2 content in the blood, and with decreased O_2 dissociation from hemoglobin species in which some, but not all, subunits contain heme iron in the ferric state. The PO_2 is normal in these patients, and therefore is the calculated hemoglobin oxygen saturation. Thus a normal PO_2 in a cyanotic patient is a significant indication for the possible presence of methemoglobinemia.

Specific therapy for toxic methemoglobinemia involves the administration of methylene blue, which acts as an electron transfer agent in the NADPH−methemoglobin reductase reaction. Ascorbic acid can also reverse methemoglobin by an alternate metabolic pathway, but is of minimal use acutely because of its slow action [12].

Direct measurement of methemoglobin may be performed by the spectrophotometric method of Evelyn and Malloy [13] or by automated multiwavelength measurements with a cooximeter.

Cyanide

Cyanide salts are used in numerous industries, such as metallurgy, photographic developing, plastic manufacturing, fumigation, and mining. Other sources include organic compounds acetonitrile, plants, and drugs such, as nitroprusside, which contains five cyanide molecules. Cyanide readily crosses all biological membranes, avidly binds to heme iron (Fe^{3+}) in the cytochrome $a-a_3$ complex within mitochondria, and causes decoupling of oxidative phosphorylation [14]. Patients exposed to toxic concentrations of cyanide may exhibit rapid onset of symptoms typical of cellular hypoxia, including the following: flushing; headache; nausea and vomiting; anxiety, confusion, and collapse; initial hypertension and tachycardia progressing to hypotension; cyanosis bradycardia; apnea; coma; seizures; complete heart block; and death if the dose is sufficiently large [15]. If cyanide toxicity is suspected, a cyanide antidote may be administered without waiting for laboratory confirmation. Available antidotes are hydroxocobalamin (Cyanokit) and sodium thiosulfate and sodium nitrite (Nithiodote).

Cyanide measurements can be performed using several methodologies, including spectrometry following microdiffusion separation, GC with electron capture, nitrogen selective or MS detection methods, or LC followed by fluorescence and MS detection methods [16].

Alcohols

Several alcohols are toxic and medically important; they include ethanol, methanol, isopropanol, acetone (also a metabolite of isopropanol), and ethylene glycol.

Ethanol

Ethanol is the most widely used and often abused chemical substance. Consequently, measurement of ethanol is one of the most frequently performed tests in the toxicology laboratory. Ethanol is considered a CNS depressant. Symptoms vary from euphoria and decreased inhibitions, to increased disorientation and incoordination, and then to coma and death (Table 52.3). When consumed with other CNS depressant drugs, ethanol exerts a potentiation or synergistic depressant effect. This can occur at relatively low alcohol concentrations, and numerous deaths have resulted from combined ethanol and drug ingestion [17]. Ethanol is metabolized principally by liver alcohol dehydrogenase to acetaldehyde, which is subsequently oxidized to acetic acid by aldehyde dehydrogenase. The rate of elimination of ethanol from blood approximates a zero-order process. This rate varies among individuals, averaging ~15 mg/dL/h for males and 18 mg/dL/h for females [18].

TABLE 52.3 Blood alcohol concentrations and clinical effects.

Blood alcohol concentrations (mg/dL)	Clinical effects
50−100	Sedation and increased reaction times
100−200	Impaired motor function, slurred speech, and ataxia
200−300	Emesis and stupor
300−400	Coma
>500	Respiratory depression and death

Ethanol is also a teratogen, and alcohol consumption during pregnancy can result in a baby with fetal alcohol spectrum disorder. These effects may include physical, mental, behavioral, and/or learning disabilities with possible lifelong implications and are 100% preventable when a woman completely abstains from alcohol during her pregnancy.

Methanol

Methanol is used as a solvent in several commercial products, including windshield wiper fluid, copy machine fluids, fuel additives, paint remover or thinner, antifreeze, canned heating sources, deicing fluid, shellacs, and varnishes. It may be consumed intentionally by individuals as an ethanol substitute, for suicide, or accidentally when present as a contaminant in illegal whiskey, or inadvertently by children.

The CNS effects of methanol are substantially less severe than those of ethanol. Methanol is oxidized by liver alcohol dehydrogenase (at about one-tenth the rate of ethanol) to formaldehyde. Formaldehyde, in turn, is rapidly oxidized by aldehyde dehydrogenase to formic acid, which may cause serious acidosis, optic neuropathy, potentially resulting in blindness, CNS bleeding, or death [7]. The mainstay of therapy for methanol toxicity includes the administration of fomepizole or ethanol as a

competitive alcohol dehydrogenase inhibitor, and hemodialysis can be performed when required. Methanol poisoning can be lethal if not recognized early. Unfortunately, in some instances, a latent period can be as long as 12–24 hours before toxicity is recognized, making laboratory identification of this poisoning critical [19].

Isopropanol and acetone

Isopropanol is readily available as a 70% aqueous solution for use as rubbing alcohol, but can also be found in cleaners, disinfectants, antifreezes, cosmetics, solvents, inks, and pharmaceuticals. It has about twice the CNS depressant effect as ethanol [16]. Isopropanol is a secondary alcohol (the hydroxyl group is attached to a central, rather than a terminal carbon), and it is metabolized by alcohol dehydrogenase to a ketone, not an acid; Therefore ingestions do not cause significant metabolic acidosis [20]. Isopropanol has a short $t_{1/2}$ of 2.5–3.0 hours, as it is rapidly metabolized to acetone, which is eliminated much more slowly ($t_{1/2}$, 3–6 hours) [16]. Therefore concentrations of acetone in serum often exceed those of isopropanol during the elimination phase following isopropanol ingestion. Acetone has CNS depressant activity similar to that of ethanol, and, because of its longer $t_{1/2}$, it may prolong the apparent CNS effects of isopropanol [16]. Supportive care is the mainstay of treatment, with rare reports of dialysis in cases of severe intoxication.

Ethylene glycol

Ethylene glycol is present in antifreeze products, deicing products, detergents, paints, and cosmetics. It may be ingested accidentally or for the purpose of inebriation or suicide. Because it tastes sweet, some animals are attracted to it. Veterinarians are often familiar with ethylene glycol toxicity because of cases involving dogs or cats that drank radiator fluid.

Ethylene glycol itself has initial CNS effects resembling those of ethanol [21]. However, metabolism of ethylene glycol by alcohol dehydrogenase to glycolaldehyde is then metabolized to glycolic, glyoxylic, and oxalic acids [16]. Oxalate readily precipitates with calcium to form insoluble calcium oxalate crystals. There is a lack of correlation between ethylene glycol concentration and severity of toxicity. It is thus impossible to define a serum ethylene glycol concentration associated with a high probability of death largely due to the timing of the blood collection in relation to the ingestion and the amount that had already been metabolized to more toxic metabolites. However, the serum glycolic acid concentration correlates more closely with clinical symptoms and mortality than does the concentration of ethylene glycol. Because of the rapid elimination of ethylene glycol ($t_{1/2}$, 2–5 hours), its serum concentration may be low or undetectable at a time when glycolic acid remains elevated [16]. Thus the determination of ethylene glycol and glycolic acid provides useful clinical and confirmatory analytical information in cases of ethylene glycol ingestion. The mainstay of therapy for ethylene glycol toxicity includes administration of ethanol or fomepizole as a competitive alcohol dehydrogenase inhibitor and dialysis.

Analysis of ethanol

Serum/plasma and blood ethanol

Serum, plasma, and whole blood are suitable specimens for the determination of ethanol. Alcohol distributes into the aqueous compartments of blood; because the water content of serum is greater than that of whole blood, higher alcohol concentrations are obtained with serum as compared with whole blood. Experimentally, the serum-to-whole blood ethanol ratio is 1.18 (1.10–1.35) [22] and varies slightly with hematocrit [23]. Therefore laboratories that perform alcohol determinations should make the specimen of choice clear. For legal purposes, whole blood is what the court system uses to determine if someone is driving under the influence. Therefore, if a serum or plasma alcohol was obtained, it must be converted into its whole blood equivalent when used at trial.

To measure ethanol in serum/plasma, enzymatic analysis is the method of choice for many laboratories. In this method, ethanol is measured by oxidation to acetaldehyde with NAD, a reaction catalyzed by ADH. With this reaction, the formation of NADH, measured at 340 nm, is proportional to the amount of ethanol in the specimen [24]:

$$\text{Ethanol} + \text{NAD} \xrightarrow{\text{ADH}} \text{Acetaldehyde} + \text{NADH}.$$

Under most assay conditions, ADH is reasonably specific for ethanol, with interferences by isopropanol, acetone, methanol, and ethylene glycol of typically $<1\%$. As a precaution, the venipuncture site is recommended to be cleansed with an alcohol-free disinfectant, such as aqueous benzalkonium chloride. Since NADH is responsible for the measurable complex leading to alcohol findings with the enzymatic test for ethanol, it is known that, for some assays when patients have significantly elevated lactate and lactate dehydrogenase, it can result in a spurious positive finding, and it is suspected that other dehydrogenases and substrates may cause similar interference [25].

Analysis of volatile alcohols (methanol, isopropanol, and acetone)

Development of GC methods for volatiles plays a significant step in the recognition and treatment of volatile alcohols. Flame ionization GC remains the most common

method for the detection and quantitation of volatile alcohols in biological samples [16]. Not only does it distinguish between ethanol, methanol, isopropanol, and acetone, but also it has the capability to measure concentrations as low as 10 mg/dL (0.01%). Headspace injection GC is an excellent method for the measurement of methanol, isopropanol, acetone, and ethanol. In addition, an adaptation of this technique may be used to measure formate, the toxic metabolite of methanol, after esterification to methyl formate. Conversely, direct injection GC is the method of choice for ethylene glycol, because it has a higher boiling point and is not as amenable to headspace analysis.

Ethanol biomarkers

Ethyl glucuronide (EtG), ethyl sulfate (EtS), and phosphatidylethanols (PEths) are biomarkers of ethanol consumption. EtG and EtS are phase II metabolites of ethanol. EtG is formed through the UDP-glucuronosyltransferase catalyzed conjugation of ethanol with glucuronic acid [26], and EtS is also formed directly by the conjugation of ethanol with sulfate group [27]. PEths are formed by phospholipase D in the presence of ethanol [28]. Due to the long urinary elimination time ($\leq$80 hours), its specificity for ethanol exposure, and its low detection limits, EtG is utilized as a marker of recent ethanol intake in a variety of clinical settings, including medical monitoring for relapse, emergency department patient evaluation, and transportation accident investigation.

Monitoring both EtG and EtS in urine improves sensitivity and specificity. EtG, but not EtS, can be either produced or decreased postspecimen collection [29]. Upper respiratory infections, as well as beta-glucuronidase hydrolysis, may lower levels of EtG but do not impact EtS [30]. However, there are challenges associated with the implementation of EtG and EtS to assess prior ethanol consumption. These include the absence of cutoff concentrations to distinguish between drinking and incidental exposure, such as nonbeverage sources of ethanol exposure (i.e., hand sanitizers and mouthwash) [31,32], nonstandardization of laboratory reporting limits, potential sample stability limitations, and microbial activity in collected samples. All of these factors may complicate interpretation of results [33]. However, some interpretive guidance recommendations have been proposed; EtG of $>$1000 ng/mL may indicate: heavy drinking in the previous 48 hours, or light drinking the same day. An EtG from 500 to 1000 ng/mL may indicate: heavy drinking in the previous 3 days, light drinking in the past 24 hours, or intense "extraneous exposure" within 24 hours. Values of $<$500 ng/mL may indicate: heavy drinking in the previous 3 days, light drinking in the past 36 hours, or recent "extraneous" exposure [30].

PEths are a group of phospholipids with a common phosphoethanol head group with two fatty acid chains that differ in chain length and degree of unsaturation [28]. PEth is a promising marker because of its persistence in blood for as long as 3 weeks after only a few days of moderately heavy drinking (about four drinks per day) [30].

Analgesics (nonprescription)

Analgesics are substances that relieve pain without causing loss of consciousness. When used in excess, analgesics such as acetaminophen and salicylate can result in a toxic response.

Acetaminophen

Acetaminophen (*N*-acetyl-*p*-aminophenol, paracetamol) has analgesic and antipyretic actions. In common with the group of drugs referred to as nonsteroidal antiinflammatory drugs (e.g., aspirin, ibuprofen, and indomethacin), the pharmacologic actions of acetaminophen are related to its competitive inhibition of cyclooxygenase enzymes. This results in decreased production of prostaglandins, which are important mediators of inflammation, pain, and fever [34]. In normal doses, acetaminophen is safe and effective, but may cause severe hepatotoxicity or death when consumed in overdose quantities.

Acetaminophen is normally metabolized in the liver to glucuronide (50%−60%) and sulfate ($\approx$30%) conjugates (Fig. 52.1). A smaller amount ($\approx$10%) is metabolized by a cytochrome P450 mixed-function oxidase pathway that is thought to form the highly reactive intermediate, *N*-acetyl-*p*-benzoquinone imine. This intermediate normally undergoes electrophilic conjugation with glutathione and then subsequent transformation to cysteine and mercapturic acid conjugates of acetaminophen. With acetaminophen overdose, the sulfation pathway becomes saturated; consequently, a greater portion is metabolized by the

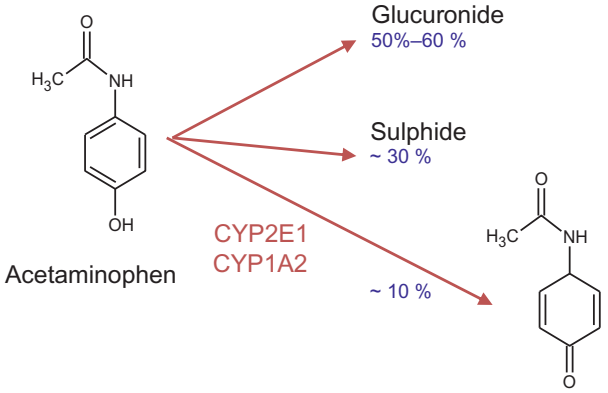

FIGURE 52.1 Metabolic pathway of acetaminophen.

P450 mixed-function oxidase pathway. When the tissue stores of glutathione become depleted, arylation of cellular molecules by the benzoquinoneimine intermediate leads to hepatic necrosis [35].

The initial clinical findings in acetaminophen toxicity may be absent of relatively mild and nonspecific (nausea, vomiting, and abdominal discomfort); hepatic necrosis typically begins 24−36 hours after toxic ingestion and becomes most severe by 72−96 hours [36]. Although uncommon with severe overdose, coma and metabolic acidosis may occur before development of hepatic necrosis [37]. Specific therapy for acetaminophen overdose is the administration of *N*-acetylcysteine (NAC), which acts as a glutathione substitute and provides substrate to replenish hepatic glutathione or to enhance sulfate conjugation, or both. The time of administration of NAC is critical. Maximum efficacy is observed when NAC is administered within 8 hours, and efficacy declines with time; therefore it is most effective when administered before hepatic injury occurs, as signified by elevations of AST and ALT [7].

The measurement of serum acetaminophen concentrations becomes important for proper assessment of the severity of overdose and for appropriate decision making for antidotal therapy. If serum acetaminophen results are not available locally, treatment with NAC should begin until levels are available. The Rumack−Matthew nomogram relates serum acetaminophen concentration and time following acute ingestion to the probability of hepatic necrosis [38]. However, the Rumack−Matthew nomogram suffers from many limitations including it begins at 4-hour postingestion, it was developed in adult patients only after a single acute ingestion, and the time of ingestion must be known. Foreknowledge of all of these parameters are not frequently known in many instances of acetaminophen overdose.

Many spectrophotometric methods are available for the determination of acetaminophen. In general, these methods are relatively easy to perform but are subject to significant interferences, such as bilirubin or bilirubin byproducts, absorbing at similar wavelengths, and thus may produce especially misleading results [7]. Methods specific for parent acetaminophen should be used to prevent interferences with nontoxic metabolites. Immunoassays are widely used for this purpose, as they are rapid, easily performed, and accurate. Most chromatographic methods are very accurate and are considered reference procedures. A qualitative, one-step lateral flow immunoassay (cutoff of 25 μg/mL) may be used for point-of-care testing, but it has a low positive predictive value [39].

Salicylate

Acetylsalicylic acid (aspirin) has analgesic, antipyretic, and antiinflammatory properties. These therapeutic benefits derive from its ability to inhibit biosynthesis of prostaglandins by inhibition of cyclooxygenase enzymes (COX-1 and COX-2 isoenzymes) [34]. Aspirin also interferes with platelet cyclooxygenase, reducing the formation of thromboxane A_2, a potent mediator of platelet aggregation.

Salicylate is eliminated mainly by conjugation with glycine and to a lesser extent with glucuronic acid [34]. These metabolic pathways may become saturated even at high therapeutic doses. Consequently, serum salicylate concentrations may increase disproportionately with dosage, and there is a relationship between dose and salicylate clearance. Salicylate elimination $t_{1/2}$ is prolonged at higher doses (15−30 hours) as compared with lower doses (2−3 hours). Following acute salicylate overdose, patients may initially be asymptomatic, especially if the product is enteric-coated, which delays its dissolution in the gastric environment. Salicylate toxic patients may develop nausea, vomiting, abdominal pain, tinnitus, tachypnea, oliguria, and altered mental status, ranging from agitation to lethargy to coma. Salicylates directly stimulate the central respiratory center and thereby cause hyperventilation and respiratory alkalosis. In addition, salicylates cause uncoupling of oxidative phosphorylation. As a result, heat production (hyperthermia), oxygen consumption, and metabolic rate may be increased. Salicylates also enhance anaerobic glycolysis but inhibit the Krebs cycle and transaminase enzymes, which leads to accumulation of organic acids and thus to metabolic acidosis. The primary acid-base disturbance observed with salicylate overdosage depends on age and severity of intoxication [7].

Toxic doses of aspirin may lead to the formation of concretions or bezoars in GI tract and pylorospasm, which can lead to delays in drug absorption. Serum salicylate in such instances may not reach maximum concentrations for 6 hours or longer. Concentrations alone are of poor prognostic value; however, certain clinical findings are predictors of a poor prognosis, including pulmonary edema, fever, coma, and acidosis. Initial serial concentrations should be performed every 2 hours while the patient is monitored clinically. Interpretation of salicylate concentrations as a guide for clinical management decisions can be difficult. Perhaps, the most well-known attempt at utilizing salicylate concentrations to predict the severity of salicylate toxicity was the nomogram developed by Done [40]. However, the Done nomogram was primarily based on healthy pediatric patients with a single acute ingestion of nonenteric-coated salicylate. As a result, it is often regarded as having limited clinical utility by providers. Treatment for salicylate intoxication is directed toward: (1) decreasing further absorption; (2) increasing elimination; and (3) correcting acid-base and electrolyte disturbances. Activated charcoal binds aspirin and

prevents its absorption. Elimination of salicylate may be enhanced by alkaline diuresis and in severe cases by hemodialysis. Sodium bicarbonate may be given to alleviate metabolic acidosis [7].

Classic methods for the measurement of salicylate in serum are based on the Trinder method [41]. These procedures rely on the reaction between salicylate and Fe^{3+} to form a colored complex that is measured at 540 nm. Other methods for salicylate quantitation include fluorescent polarization immunoassay and a salicylate hydroxylase-mediated photometric technique [7]. These procedures are subject to some of the same interferences as the Trinder method, but the salicylate hydroxylase method is considered more specific and has been adapted to automated analyzers. GC and LC methods are the most specific methods for salicylate [16], but their general availability, especially for emergency use, is limited.

Drugs of abuse

Drug use and abuse are widespread in society, and public awareness has been heightened as to their impact on public safety and on lost productivity in the workplace. To resolve these issues, governmental, industrial, educational, and sport agencies are increasingly requiring drug testing of prospective and existing employees, students, and participants in professional and amateur athletics. Moreover, drug abuse during pregnancy is a matter of concern, both medically and socially [42]. Testing for drugs of abuse may be a medical requirement for (1) organ transplantation candidates; (2) pain management clinics; (3) drug abuse treatment programs; and (4) psychiatric programs. Drug testing for these purposes represents a significant activity for toxicology laboratories. Although there are many drugs and drug classes that are abused, and there is geographic variation in their identity and prevalence, not all can be discussed in this chapter; therefore only the ones that are the most commonly encountered will be discussed.

Testing for drugs of abuse usually involves testing a single urine specimen for a variety of drugs. It should be noted, however, that testing of a single random urine drug specimen detects only recent drug use (Table 52.4), and it does not differentiate casual use from chronic drug abuse. Urine drug testing (UDT) also cannot determine the degree of impairment, the dose of drug taken, or the exact time of use.

Amphetamine-type stimulants

Several stimulants and hallucinogens chemically related to phenylethylamine are referred to collectively as amphetamine-type stimulants (ATSs). They are considered to be sympathomimetic drugs, meaning that they mimic endogenous transmitters in the sympathetic nervous system [43].

Amphetamine and methamphetamine

Amphetamine and methamphetamine are CNS stimulant drugs that have some legitimate pharmacologic use [44], including narcolepsy, obesity, and attention-deficit hyperactivity disorders (ADHDs). They produce an initial euphoria and have a high abuse potential. These drugs have a stimulating effect on both the central and peripheral nervous systems. In the brain, a primary action is to elevate the concentrations of extracellular monoamine neurotransmitters (dopamine, serotonin, and norepinephrine) by promoting presynaptic release from the nerve endings [45]. Amphetamine and methamphetamine are

TABLE 52.4 Common classes of medications and detection window in urine.

Drug/drug class	Average detection window (urine)
Amphetamine/methamphetamine	~3 days
Barbiturates	Short-acting: 4–6 days
	Long-acting: 2–3 weeks
Benzodiazepines	~1–10 days
Cocaine and metabolite (benzoylecgonine)	~3 days
THC	3–90 days depending on usage
Lysergic acid diethylamide	~10 days
Opioids/opiates	~3 days
Phencyclidine	~8 days

THC, Tetrahydrocannabinol.

substrates for the dopamine, serotonin, and norepinephrine transporters.

Amphetamine and methamphetamine: (1) increase blood pressure, heart rate, body temperature, and motor activity; (2) relax bronchial muscle; and (3) depress the appetite. Abuse of these drugs may lead to strong psychological dependence, marked tolerance, mild physical dependence, and a severe form of chronic intoxication psychosis similar to schizophrenia. Tolerance and psychological dependence develop with repeated use of amphetamines [44].

Amphetamine is extensively metabolized to a variety of metabolites, including norephedrine and *p*-hydroxyamphetamine, both of which are pharmacologically active, and may be glucuronidated prior to excretion [43]. Methamphetamine is metabolized in liver primarily by hydroxylation and, to a lesser extent, by *N*-demethylation to amphetamine. Renal elimination is dependent on urine pH, and, although typically ~30% of a dose is excreted unchanged, this may vary from as much as 74% in acidic urine to as little as 1% in alkaline urine [16]. Therefore elimination $t_{1/2}$ (renal excretion and hepatic metabolism) varies from 7 to 34 hours depending on urine pH [46]. Similarly, methamphetamine is eliminated in urine in a pH-dependent manner, similar to amphetamine.

Designer stimulants

The terms "designer drugs" and "club drugs" were originated in the 1980s [47]. These drugs include phenylethylamine, benzylpiperazine, phenylpiperazine, pyrrolidinophenone, and cathinone and derivatives, and have gained popularity and notoriety among people who participate in all-night dance parties (raves) and those who visit nightclubs. Most designer drugs produce feelings of euphoria and energy and a desire to socialize; they also promote social and physical interactions. They are used at these events to enhance energy for prolonged partying and/or dancing, and to distort or enhance visual and auditory sensations. Due to the large variety of designer amphetamines, only a few will be discussed here.

3,4-Methylenedioxymethamphetamine and 3,4-methylenedioxyamphetamine

Methylenedioxymethamphetamine (MDMA, also known as "ecstasy" and "molly") is categorized as a stimulant as a result of its sympathomimetic effects, but is also categorized as an empathogen–entactogen [47]. Similar to amphetamine and methamphetamine, MDMA causes release of biogenic amines by reversing the action of their respective transporters. It has a preferential affinity for the serotonin transporter and therefore most strongly increases the extracellular concentration of serotonin [45]. MDMA undergoes hepatic metabolism including *N*-demethylation to the active drug methylenedioxyamphetamine (MDA) [48], paramethoxyamphetamine (PMA), and paramethoxymethamphetamine (PMMA): PMA and PMMA are methoxylated phenylethylamine derivatives with effects similar to but more potent than those of MDMA [49]. PMA is a metabolite of PMMA [50], but it is also an especially toxic designer amphetamine that has resulted in several deaths from its unsuspected ingestion as an ecstasy substitute. PMA is 10 times more active than MDMA in elevating brain serotonin concentrations and inhibiting serotonin uptake, but it has only a few effects on the dopamine system [51]. Multiple deaths have been associated with its use; symptoms usually mimic serotonin syndrome and include hyperthermia, tachycardia, seizures, cardiac dysrhythmias, and coma.

Cathinone and derivatives

Cathinones are β-ketoamphetamines with structural similarity to dopamine and amphetamine. Cathinone is a naturally occurring stimulant found in the leaves of the Khat plant (*Catha edulis*). Synthetic derivatives of cathinone emerged as drugs of abuse in approximately 2003 and were sold as "Bath Salts" and labeled as "not for human consumption." As new designer cathinone derivatives are produced by clandestine laboratories, the US government attempts to schedule as many of these drugs as possible (Synthetic Drug Abuse Prevention Act of 2012 and Synthetic Cathinones Control Act of 2013). The race continues to schedule synthetic drugs with high abuse potential and no known medicinal value.

Cathinone derivatives are abused because of their psychostimulant and hallucinatory effects, but have also been involved with human toxicity and fatality. Cathinones block dopamine and serotonin neurotransmitter reuptake, thereby prolonging the effects at peripheral and central neural junctions [52]. Common clinical presentations in patients are agitation, paranoia, auditory and tactile hallucinations, psychosis, myoclonus, and headaches. These symptoms can be severe and last for several days. Peripheral effects may include hyperthermia, hypertension, tachycardia, hyponatremia, nausea, vomiting, and chest pain as seen during sympathomimetic toxidrome.

Methylphenidate (Ritalin)

Methylphenidate (MPH) is a phenethylamine derivative with psychostimulant properties similar to amphetamine but is chemically distinct. It is commonly used to treat ADHD and narcolepsy [45]. Its pharmacologic properties are essentially the same as those of the amphetamines. MPH is rapidly metabolized to ritalinic acid and has a $t_{1/2}$ of ~4 hours. Diversion and abuse of MPH have been increasing among children and adults because of its stimulant and purported aphrodisiac properties. In overdose,

the clinical effects of MPH are similar to those of amphetamine and produce signs of generalized CNS stimulation that may lead to convulsions [45].

Analytical methods for amphetamine-type stimulants

Most "amphetamine" immunoassays have been designed to detect amphetamine/methamphetamine; some have been designed to detect MDMA and MDA and others to more broadly capture the ATS group—all with varying cross-reactivities [53]. Not all amphetamine immunoassays were suitable for detection of the amphetamine-derived designer drugs and especially not for the cathinone- and piperazine-derived substances [7]. Alternatively, other chemically related compounds, such as pseudoephedrine and phentermine, have been shown to produce positive results. Immunoassays from different manufacturers can also have very different "interference" profiles. On the other hand, detection of methylphenidate by immunoassays is problematic, since it does not cross-react with most commercial amphetamine immunoassays. The detection of MPH is also made difficult by its generally low concentration, while its metabolite, ritalinic acid, is present in much higher concentrations; it is also unstable upon storage, even when frozen [16].

In the end, any positive immunoassay for amphetamine or methamphetamine should be confirmed. In addition, if other designer stimulants are suspected, a negative immunoassay screen cannot rule out the presence of these drugs. Fortunately, numerous GC- and LC-based methods for identification and quantitation of these drugs in biological samples have been put forth.

Barbiturates

The success of barbital in 1903 and phenobarbital in 1912 [54] spawned the synthesis and testing of numerous derivatives, of which approximately 50 were distributed commercially. Because of their low therapeutic index and high potential for abuse, they have been largely replaced by the much safer benzodiazepines.

Barbiturates continue to be, although much less frequently than in the past, subject to abuse. Due to their rapid onset and short duration of action, the short- to intermediate-acting barbiturates that are used as sedative-hypnotics (amobarbital, butabarbital, butalbital, pentobarbital, and secobarbital) are most commonly abused. The longer-acting barbiturates (mephobarbital and phenobarbital), used primarily for their anticonvulsant properties, are rarely abused. The detection period in urine following ingestion of barbiturates varies with different assays and depends on the pharmacologic properties of the drugs. Short- to intermediate-acting barbiturates generally may be detected for 1−4 days following use; long-acting barbiturates, such as phenobarbital, may be detected for several weeks after long-term use. Anesthetic doses of barbiturates, such as pentobarbital, are used to reduce intracranial pressure from cerebral edema associated with head trauma, surgery, or cerebral ischemia [7]. Therefore appropriate analytical methods are necessary to monitor serum pentobarbital concentrations in these circumstances. The barbiturates produce varying degrees of CNS depression, ranging from mild sedation to general anesthesia. With long-term administration of gradually increasing doses, tolerance to effects on mood, sedation, and hypnosis occurs more readily, and is greater than tolerance to anticonvulsant and lethal effects; thus, as tolerance increases, the therapeutic index decreases [54].

Numerous commercial immunoassays for barbiturates are available. Most use antibodies directed toward secobarbital, and, although the degree of cross-reactivity of other barbiturates varies with each assay, most have sufficient cross-reactivity to detect the major therapeutically used barbiturates [16,55]. Several confirmation methods for barbiturates have been described. These include both GC and HPLC and MS [16].

Benzodiazepines

Benzodiazepines are any of a group of compounds having a common molecular structure and acting similarly as CNS depressants. The term *benzodiazepine* refers to the portion of the structure composed of a benzene ring fused to a seven-membered diazepine ring and a phenyl ring attached to the 5-position of the diazepine ring [55]. As a class of drugs, benzodiazepines are among the most commonly prescribed drugs in the Western hemisphere because of their (1) efficacy; (2) safety; (3) low addiction potential; (4) minimal side effects; and (5) high public demand for sedative and anxiolytic agents. Long-term benzodiazepine use poses a risk for the development of dependence and abuse, particularly for those agents with the shortest $t_{1/2}$, the highest potency (alprazolam and triazolam), and the greatest lipophilicity (diazepam). Regular use will produce tolerance to most of the adverse effects of benzodiazepines [56]. Tolerance may take weeks or months to develop, although this will depend on the dose of drugs used, the frequency of administration, and the pharmacokinetic $t_{1/2}$ of the drug.

The benzodiazepines given by themselves or in combination with other drugs, particularly narcotic analgesics (opioids), are among the most widely abused drugs. Their ability to suppress or dampen withdrawal symptoms and to boost the effects of heroin and other opioids has made them a favored drug type among the drug-using population [56]. They are also widely used by the COC-using population, especially clonazepam because of its ability to

increase the seizure threshold [56]. They are also used in drug-facilitated crimes [56].

Benzodiazepines may be divided into four categories based on their elimination $t_{1/2}$: (1) ultrashort-acting agents; (2) short-acting agents, with $t_{1/2}$ of <6 hours; (3) intermediate-acting agents, with $t_{1/2}$ of 6–24 hours; and (4) long-acting agents, with $t_{1/2}$ of >24 hours [54] These pharmacokinetic properties, in part, determine the primary clinical applications for some benzodiazepines. For instance, midazolam ($t_{1/2}$, 1–4 hours) is used for preanesthetic sedation or for sedation for endoscopic procedures because of its rapid onset and short duration of action. Benzodiazepines useful in treating anxiety generally have intermediate to long elimination $t_{1/2}$ (alprazolam and diazepam), and those primarily used as anticonvulsants (clonazepam) have the longest. Elimination $t_{1/2}$ is not the sole determinant of duration of action of benzodiazepines, and, in some cases, the rate of drug redistribution from the CNS may be a more important factor [7]. Benzodiazepines undergo hepatic oxidation (phase I) and conjugation (phase II), often forming metabolites with pharmacologic activity (Table 52.5). Following these reactions, conjugation with glucuronic acid occurs; these glucuronidated metabolites constitute the major urinary products of benzodiazepines (Fig. 52.2) [16].

Virtually, all results of the pharmacologic effects of benzodiazepines are caused by their actions on the CNS. The most prominent of these effects are (1) sedation; (2) hypnosis; (3) decreased anxiety; (4) muscle relaxation; (5) anterograde amnesia; and (6) anticonvulsant activity. Only two effects of these drugs result from peripheral actions: (1) coronary vasodilation, which is observed after

TABLE 52.5 Half-life and primary metabolite of select benzodiazepines.

Drug	Half-life (h)	Significant phase I metabolites
Short-acting		
Midazolam	1–4	α-Hydroxy-midazolam
Estazolam	10–24	3-Hydroxy-estazolam
Flurazepam	1–3 47–100 (*N*-desalkyl-flurazepam)	Hydroxy-ethyl-flurazepam *N*-desalkyl-flurazepam[a]
Temazepam	3–13	Oxazepam
Triazolam	1.8–3.9	α-Hydroxy-triazolam
Intermediate-acting		
Flunitrazepam[b]	9–25	7-Amino-flunitrazepam
Long-acting		
Diazepam	21–37	Nordiazepam[a] Oxazepam[a] Temazepam[a]
Quazepam	39–53	3-Hydroxy-quazepam *N*-desalkyl-2-oxo-quazepam 2-Oxo-3-hydroxy-quazepam
Alprazolam	6–27	α-Hydroxy-alprazolam
Chlordiazepoxide	6–27	Nordiazepam[a] Oxazepam[a]
Clonazepam	19–60	7-Amino-clonazepam
Clorazepate[c]	2 31–97 (nordiazepam)	Nordiazepam[a] Oxazepam[a]
Lorazepam	9–16	
Oxazepam	4–11

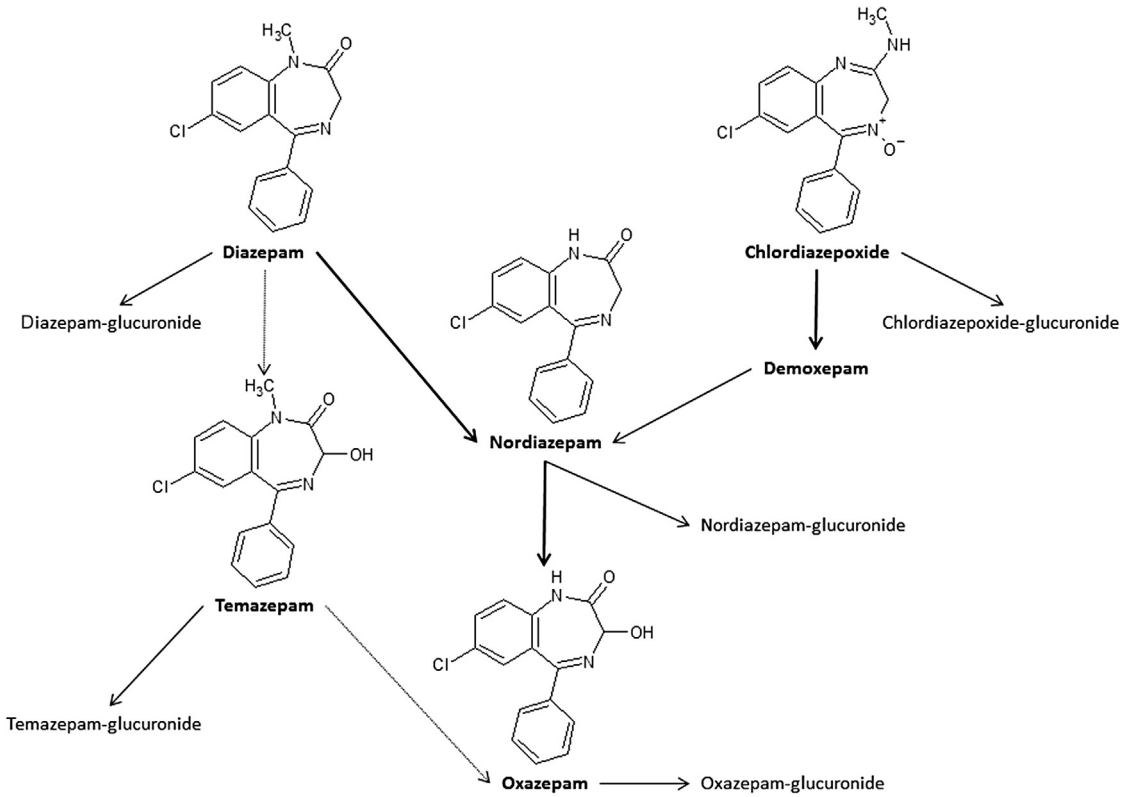

FIGURE 52.2 Metabolic pathway of select benzodiazepines.

intravenous administration of therapeutic doses of certain benzodiazepines; and (2) neuromuscular blockade, observed only after the administration of very high doses. Ethanol increases both the rate of absorption of benzodiazepines and associated CNS depression. Except for additive effects with other sedative or hypnotic drugs, reports of clinically important pharmacodynamic interactions between benzodiazepines and other drugs have been infrequent.

Long-acting benzodiazepines (diazepam, chlordiazepoxide, and clorazepate) are given in relatively large doses and may be detected for several days to weeks or even months following long-term use. Short-acting benzodiazepines (alprazolam and triazolam) are used in lower doses and might be detected only for a few days. The treatment of benzodiazepine toxicity is primarily supportive. Flumazenil may be used in select cases and is a competitive inhibitor of the benzodiazepine site on the GABA complex. It finds its greatest utility in the reversal of benzodiazepine-induced sedation from minor surgical procedures. However, flumazenil should not be administered as a nonspecific coma-reversal drug and should be used with extreme caution after intentional benzodiazepine overdose, because it has the potential to precipitate withdrawal in benzodiazepine-dependent individuals and/or to induce seizures in those at risk.

Benzodiazepines are measured using a variety of techniques. However, their structural diversity and wide variations in potency provide a challenge for laboratories to detect all relevant members in one analytical scheme. Currently, there are several commercial immunoassay systems available for the detection of benzodiazepines and metabolites, but they differ somewhat in their ability to detect each of the respective benzodiazepines, their metabolites, and glucuronide conjugates. Cross-reactivity in screening immunoassays of the various benzodiazepines and their metabolites varies considerably from manufacturer to manufacturer, and screening assays are not able to distinguish between the individual benzodiazepines. Most assays are calibrated to the common metabolites oxazepam, temazepam, or nordiazepam [57]. However, the large number of different functional groups that may be present on the benzodiazepine nucleus makes it difficult to detect all drugs in this class, and some compounds such as lorazepam, clonazepam, midazolam, and flunitrazepam may not be detected by many assays.

GC–MS with derivatization confirmation method is still common [56]; however, LC–MS and LC–MS/MS are becoming increasingly useful and popular because of the ability to detect benzodiazepines and metabolites without derivatization [16]. Typically, benzodiazepines and their metabolites have been extracted from biological

specimens by liquid−liquid extraction or solid-phase extraction. When urine specimens are analyzed, a hydrolysis step to cleave the glucuronide conjugates is frequently used [55]. Enzymatic hydrolysis is preferred over acid hydrolysis, because some benzodiazepines are unstable and rearrange to form benzophenones [55].

Cannabinoids

Cannabinoids are the most commonly used illicit substance in the world and come from the *Cannabis sativa* and *Cannabis indica* plants. Cannabinoids have been used as a medicinal and an illicit psychotropic agent for centuries. Recently, within the United States, several states have independently decriminalized or legalized the use and sale of medical and/or recreational cannabinoids. Delta-9-tetrahydrocannabinol (THC), the primary psychoactive component, is typically consumed by smoking the plant leaves, flower buds, and sometimes stems. THC has also been extracted from the glandular hairs of cannabis flowers and produced as a resin (hashish). Hashish is often a more potent form, and has been mixed into foods, brewed as tea then ingested, or smoked. Hemp oil has also been extracted from cannabis seeds for use in soaps, body care products, and dietary supplements, and is used because of its high essential fatty acid content, but negligible THC content.

The main psychotropic effects of THC are (1) euphoria; (2) distorted perceptions; (3) relaxation; and (4) a feeling of well-being. Additional effects may include feelings of euphoria and relaxation, altered time perception, lack of concentration, impaired learning and memory, and mood changes such as paranoia, psychosis, and panic attacks [58]. Although marijuana is the most frequently used illicit drug, it does have some limited legitimate medicinal use to treat anorexia and nausea in patients with acquired immunodeficiency syndrome and those with nausea and vomiting associated with chemotherapy, or asthma and glaucoma [59]. Recently, the Food and Drug Administration (FDA) has approved cannabidiol (CBD; Epidiolex) to treat seizures associated with Lennox−Gastaut syndrome or Dravet syndrome in patients 2 years of age and older (https://www.fda.gov/newsevents/newsroom/pressannouncements/ucm611046.htm, accessed November 15, 2018).

The main psychotropic effects after inhalation of marijuana occur within minutes and persist for several hours. The peak plasma concentration of THC is dependent on the dose and numerous factors contribute to the variability in dose, such as (1) method of consumption; (2) depth of inhalation; (3) exposure frequency; and (4) cannabis potency [58]. Onset of clinical symptoms and peak plasma concentrations after oral ingestion of THC is slower than after inhalation, primarily as the result of first-pass hepatic clearance, and two THC peaks are frequently observed because of enterohepatic circulation [58]. THC is metabolized by CYP450 liver enzymes to >100 metabolites. The main active metabolite, 11-hydroxy-delta-9-THC, is further oxidized to the most abundant inactive 11-nor-9-carboxy-THC (THC-COOH) [58] Some researchers have used the concentration and ratio of THC and its metabolites to predict acute versus chronic exposure to marijuana [60]. Epidiolex is administered and an oral solution of 100 mg/mL of CBD [61]. It has a T_{max} of 2.5−5 hours, is highly protein bound, and has an elimination $t_{1/2}$ of 56−61 hours [61]. CBD is metabolized primarily in the liver by CYP2C19 and CYP3A4 enzymes, into an active metabolite 7-OH-CBD, which is further oxidized to an inactive metabolite 7-COOH-CBD molecule [61].

In light of recent and ongoing legislation regarding medical and recreational cannabis, interest in monitoring cannabis use and abuse has increased. An immunoassay method is typically used to screen for potential cannabinoid use. Immunoassay screens have been designed to detect cannabis use in urine samples using antibody reagents developed against the inactive THC-COOH metabolite; these reagents cross-react with numerous other THC metabolites. A presumptive positive sample should be confirmed by quantitative GC−MS or LC−MS/MS. Concerns have been raised with regards to the potential for false-positive results from dietary sources and "passive inhalation" of sufficient side-stream marijuana smoke from nearby users. Numerous studies have been conducted to investigate exposure to THC from second-hand smoke, concluding that the SAMHSA cutoff (THC-COOH 50 ng/mL cutoff, immunoassay) is thought to be sufficient to separate moderate passive exposure from first-hand inhalation exposure to THC [62,63]. Therefore it is improbable that a passive inhaler would be able to sustain exposure to significant THC concentrations long enough to produce a positive drug screen.

A positive result from a urine cannabinoid screen or confirmation does not indicate intoxication or degree of exposure. The window of detection for the urine concentration of THC-COOH varies among casual (2−7 days) and chronic abusers (up to 73 days) of marijuana and is dose dependent [7]. Variables affecting the duration of detection include (1) dose; (2) frequency of exposure; (3) route of exposure; (4) body composition; (5) fluid excretion; and (6) method of detection. Therefore monitoring of abstinence is particularly challenging. Dilution of urine due to normal biological fluctuations (hydration) or ingested adulterants can cause a negative result one day and a positive on the next. To correct for hydration fluctuations, urine concentrations of THC-COOH per milligram creatinine are normalized for monitoring individuals who are resuming cannabis use. Some people

suggest that, using these normalized THC-COOH:creatinine concentrations, a ratio is calculated by comparing any normalized urine specimen (U2) with a previously collected normalized urine specimen (U1). "New use" is defined as a U2/U1 ratio of $\geq 0.5-1.5$ collected from urine specimens taken more than 24 hours apart and containing THC-COOH concentrations of >15 ng/mL [64–66]. Using the 1.5 cutoff rate results in decreased false-positives, but increased false-negative decisions [64]. Another model has been proposed to distinguish new versus residual use in chronic daily users [67].

Monitoring minor cannabinoids present in cannabis and their metabolites has also been proposed as a mechanism to distinguish recent use from prolonged elimination. Several minor cannabinoids, such as CBD, cannabinol, cannabigerol, tetrahydrocannabivarin (THCV), and its metabolite, 11-nor-9-carboxy-THCV, have been proposed as possible markers of recent cannabis intake in different biological matrices [68–73]. Finally, because of the use of CBD in epilepsy, numerous studies are evaluating the potential for a more traditional therapeutic drug management style approach to monitoring of CBD concentration in blood or serum of patients taking this drug to control seizures.

Synthetic cannabinoids

Synthetic cannabinoids are not naturally occurring compounds, but synthetic compounds originally developed as potential therapeutic compounds used to characterize cannabinoid receptors (CB-1 and CB-2). Numerous compounds have been described in the scientific literature, and clandestine labs continue to substitute functional moieties and synthesize new compounds. Synthetic cannabinoids are commonly sprayed on dried plant material and smoked. The clinical effects of these agents have not been well defined, with most clinical reports based on patient history of what was taken versus what was truly present in the product abused. Clinical effects of synthetic cannabinoids may be similar to THC. Yet some reported effects, such as anxiety, agitation, psychosis, and suicidality, may be more prominent.

While there are commercial enzyme-linked immunoassays available, no single immunoassay kit can detect all known synthetic cannabinoid compounds. GC–MS, LC–MS/MS, LC–HRMS, or TOF may be utilized to screen and/or confirm the growing release of new synthetic cannabinoids entering the market, but labs have to consistently update the targets, as new compounds appear quickly in an attempt to outpace detection and legislation. Furthermore, the metabolism of synthetic cannabinoids is complex, such that many of the compounds have common metabolites, and confirmatory testing should not only be able to detect the large number of metabolites, but also be adaptable to accommodate the rapidly changing landscape of drugs being introduced.

Cocaine

COC is an alkaloid found in *Erythroxylon coca*, which grows principally in the northern South American Andes and to a lesser extent in India, Africa, and Java [74]. In clinical medicine, it has been used mainly for local anesthesia and vasoconstriction in nasal surgery, and to dilate pupils in ophthalmology. COC is still one of the most common illicit drugs of abuse, and, according to the National Survey on Drug Use and Health, the 2017 rate of use for COC (powder and crack combined) among individuals aged 12 and older has remained relatively stable since 2002 (https://www.samhsa.gov/data/nsduh/reports-detailed-tables-2017-NSDUH, accessed June 28, 2019).

COC is sold on the street in two forms: a hydrochloride salt (powder) and a free-base product known as "crack." The hydrochloride salt form of COC is administered by nasal insufflation ("snorting") or intravenously. "Crack" is a free-base form that has not been neutralized by an acid to make the hydrochloride salt. It comes as a rock crystal that is heated and its vapors smoked. The term refers to the crackling sound heard when it is heated [74].

The metabolism of COC is complex and occurs via both nonenzymatic hydrolysis and enzymatic transformation in the plasma and liver, where it is rapidly metabolized to benzoylecgonine (BE) and ecogonine methyl ester, both of which are inactive [74]. COC contains two ester moieties; the alkyl ester is hydrolyzed to its major metabolite BE via spontaneous hydrolysis at physiologic and alkaline pH [75]. It has been shown that COC is also hydrolyzed to BE by liver carboxylesterases [76]. BE is considered to be a pharmacologically inactive metabolite, but because its $t_{1/2}$ is longer than that of COC, it is the most commonly monitored analyte in urine for determination of COC use. BE is further metabolized to minor metabolites such as *m*-hydroxybenzoylecgonine (m-HOBE) and *p*-hydroxybenzoylecgonine [74]. Of these, m-HOBE has been shown to be an important metabolite in the meconium of COC-exposed babies [77,78]. Norcocaine (NC) is an *N*-demethylated metabolite of COC produced by liver cytochrome P450; it is of clinical interest because of its conversion into hepatotoxic metabolites [74]. Anhydroecgonine methyl ester (AEME; methyl ecgonidine) has been identified as a unique COC metabolite after smoked COC ("crack") administration. Anhydroecgonine ethyl ester (AEEE; ethyl ecgonidine) has been identified in COC smokers who also use ethyl alcohol [79].

COC has cardiovascular effects and is a potent CNS stimulant that elicits a state of increased alertness and euphoria with pharmacological actions similar to those of amphetamine but of shorter duration. These CNS effects

are thought to be largely associated with the ability of COC to block dopamine reuptake at nerve synapses, thereby prolonging the action of dopamine in the CNS [74]. COC also blocks the reuptake of norepinephrine at presynaptic nerve terminals; this produces a sympathomimetic response that may result in (1) mydriasis; (2) diaphoresis; (3) hyperactive bowel sounds; (4) tachycardia; (5) hypertension; (6) hyperthermia; (7) hyperactivity; (8) agitation; (9) seizures; or (10) coma. Sudden death due to cardiotoxicity may occur following COC use. Death may also occur following the sequential development of hyperthermia, and respiratory arrest. Excited delirium and extreme physical activity may lead to rhabdomyolysis, acute renal failure, and disseminated intravascular coagulopathy [74].

COC is effective as a local anesthetic and vasoconstrictor of mucous membranes and, therefore, is used clinically for nasal surgery, rhinoplasty, and emergency nasotracheal intubation. COC is also frequently used with other drugs recreationally, most commonly ethanol. In simultaneous COC and ethanol use, liver methylesterase catalyzes the conversion of COC to BE and the transesterification of COC to cocaethylene (CE) [74].

The elimination $t_{1/2}$ for COC ranges from 0.5 to 1.5 hours, and for BE from 4 to 7 hours [7]. Only small amounts of COC are excreted in urine. The elimination $t_{1/2}$ for CE is 2.5−6 hours [7], which is considerably longer than that for COC. BE excretion is detectable for 1−3 days following COC use. However, for chronic heavy COC users, the detection time may extend to 10−22 days following the last dose [16], apparently because of tissue storage of COC.

Due to the above mentioned longer elimination $t_{1/2}$ of BE, it is the analyte of choice in screening for COC use [74]. The initial screening test for BE is typically immunoassay, and screening immunoassays frequently have a 300-ng/mL or 150-ng/mL cutoff for it. Most confirmation assays offer quantification of both the parent drug and metabolite. Numerous methods have been described for the measurement of COC and its metabolites. GC techniques for analysis of COC and its metabolites require derivatization, and GC−MS methods are still frequently the method of choice [16]. LC−MS/MS methods have also been described, including COC, BE, and m-HOBE, along with other relevant secondary metabolites, such as CE, NC, AEME, and AEEE [80].

Lysergic acid diethylamide

Lysergic acid diethylamide (LSD) is synthesized from D-lysergic acid, a naturally occurring ergot alkaloid found in the fungus *Claviceps purpurea*, which grows on wheat and other grains. LSD shares structural features with serotonin (5-hydroxytryptamine; a major CNS neurotransmitter and neuromodulator) [81]. LSD binds to serotonin receptors in the CNS and acts as a serotonin agonist. The principal psychological effects of LSD are perceptual distortions of color, sound, distance, and shape (synesthesia); depersonalization and loss of body image; and rapidly changing emotions from ecstasy to depression or paranoia. The physiologic effects of LSD are related to its sympathomimetic actions and include mydriasis (most frequent and consistent), tachycardia, increased body temperature, diaphoresis, and hypertension; at higher doses, parasympathomimetic actions may be observed [e.g., salivation, lacrimation, nausea, and vomiting (muscarinic actions)]. Neuromuscular effects may include paresthesia, muscle twitches, and incoordination (nicotinic actions) [81].

LSD is used illicitly because of its hallucinogenic effects. The most common adverse effects of LSD are panic attacks. In addition, unpredictable recurrence of hallucinations (flashbacks) may occur weeks or months after last drug use, and LSD may elicit psychotic reactions. No evidence suggests that repeated LSD use results in dependence or withdrawal symptoms [81].

Popular dosage forms include powder, gelatin capsule, tablet, and LSD-impregnated sugar cubes, filter paper, or postage stamps. The drug is rapidly absorbed from the GI tract; the effects begin within 40−60 minutes, peaking at ∼2−4 hours, and subside by 6−8 hours. The elimination $t_{1/2}$ is ∼3 hours. The metabolism of LSD in humans is incompletely understood, but 2-oxo-3-hydroxy-LSD is present in urine at concentrations of 10- to 43-fold greater than LSD [82]. *N*-demethyl-LSD is also present in urine specimens, but at concentrations approximately equivalent to those of LSD [83].

The typical dose is low (20−80 μg) and is rapidly metabolized, and only ∼1%−2% of the drug is excreted unchanged in urine. Thus detection of LSD presents an especially difficult analytical challenge. Even with sensitive assays, the detection window for LSD is generally only 12−24 hours [84]. Immunoassays are targeted to detect LSD, and confirmation assays may be performed by GC−MS, GC−MS/MS, LC−MS/MS, or LC−MS [16].

Opioids

The term *opioid* describes a wide range of compounds encompassing the natural and semisynthetic opiates—essentially variations on the structure of morphine—and fully synthetic opioids with minimal structural homology to the natural alkaloids [85]. The defining characteristic of this class of drugs is their interaction with opioid receptors [86].

For pain management, opioids are used frequently in treating acute needs, such as postsurgical analgesia, and in relieving moderate-to-severe chronic pain (see later section). However, most opioids are highly addictive and

have potentially life-threatening side effects; thus the benefits of their use must be carefully weighed against the chance of serious consequences. In addition, the development of tolerance and the risk of prescription diversion complicate even further the process of monitoring long-term opioid therapy for compliance and efficacy.

The hallmark of opioids is their ability to interact with the family of opioid receptors that are variably distributed throughout the body. These include mu-opioid receptor, delta-opioid receptor, and kappa-opioid receptor (MOR, DOR, and KOR, or μ, δ, and κ, respectively). Opioid receptor agonists typically produce analgesia, and antagonists block this response [86]. The metabolism of opioids is varied, but numerous biotransformations are common to these drugs (Table 52.6). Several of the most commonly used opiates are formed in vivo by metabolism of other compounds, as is seen with codeine demethylation, resulting in conversion to morphine [86]. This interconversion is a frequent source of confusion and must be considered when the results of opiate screens are interpreted (Fig. 52.3).

Natural opium alkaloids

Morphine

The archetypical opiate, morphine, is used as the basis of comparison for relative characterizations of the opioid class. Morphine interacts primarily with MOR to mediate its effects, but it also shows some affinity for KOR [86]. Its major metabolites are glucuronide conjugates, including inactive morphine-3-glucuronide ($\sim$60% of metabolite), active morphine-6-glucuronide (M6G; $\sim$10% of metabolite), and a small amount of morphine-3,6-diglucuronide [86].

With long-term administration and when morphine concentrations are high, a minor fraction is converted to hydromorphone (up to 2.5% of the urine morphine concentration) [16]. M6G has greater MOR agonist activity than morphine and appears to contribute less to unwanted side effects [86]. The elimination $t_{1/2}$ for glucuronides is longer than for morphine. Therefore glucuronides accumulate in serum to greater concentrations than morphine, and, in patients with renal insufficiency, morphine glucuronides are thought to significantly contribute to opioid toxicity [86].

Codeine

Codeine shows poor affinity for MOR and has only about one-tenth the analgesic potency of morphine [16]. Analgesia is attributed to the small fraction ($<$10%) of codeine converted to morphine by CYP2D6 via *O*-demethylation; therefore it is generally considered a prodrug. Both codeine and morphine may be detected in urine following codeine ingestion; however, after 30 hours, only morphine may be detectable [16]. Long-term, high-dose administration leads to metabolism to hydrocodone (up to 11% of the urine codeine concentration) [87].

Genetic variation may play a significant role in the metabolism of codeine and several other opioids. More than 130 alleles have been described for CYP2D6, with resultant enzymatic activity ranging from essentially zero, in the case of null alleles, to many times higher than normal, in the case of amplified alleles (https://www.pharmvar.org/gene/CYP2D6, accessed June 28, 2019). Thus, at the same codeine dose, patients with minimal CYP2D6 activity (poor metabolizers) would likely receive inadequate analgesia because of lack of conversion to morphine; however, patients with very high CYP2D6 activity

TABLE 52.6 Half-life and primary metabolite of select opioids.

Drug	Half-life [16]	Significant phase I metabolites
Natural opium alkaloids		
Morphine	1.3–6.7 h	
Codeine	1.2–3.9 h	Morphine
Semisynthetic opiates		
Heroin	2–6 min	6-Monoacetymorphine morphine
Hydrocodone	3.4–8.8 h	Hydromorphone
Hydromorphone	3–9 h

Oxymorphone	4–12 h	

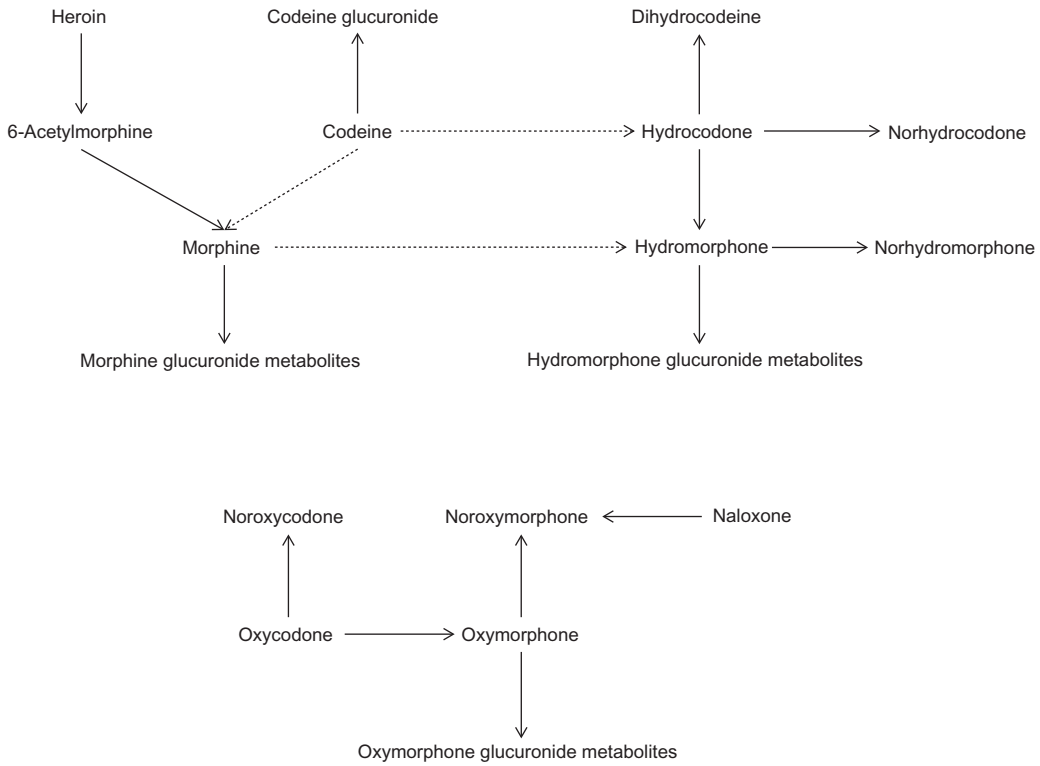

FIGURE 52.3 Metabolic pathway of opiates.

(ultrarapid metabolizers) would be at risk for adverse responses to excessive morphine [86].

Semisynthetic opiates

Heroin

Heroin is a synthetic opiate that is made from morphine and is also called *diacetylmorphine*; it has an analgesic potency two-to-three times that of morphine, possibly because of increased penetration across the blood−brain barrier. Heroin itself is rarely found in body fluids because of its extremely short $t_{1/2}$ (2−6 minutes); the metabolite, 6-acetylmorphine, is hydrolyzed to morphine; although it has a longer $t_{1/2}$ (6−25 minutes), it is detectable in urine only for ∼8 hours after administration [16]. 6-Monoacetylmorphine (6-MAM) is also four-to-six times more potent than morphine. Other than the presence of heroin's unique metabolite 6-MAM, the metabolic profile of heroin resembles that of morphine. Given that acetylcodeine is a common contaminant of heroin, both morphine and low concentrations of codeine are frequently detected in urine following heroin use.

Hydrocodone and hydromorphone

Hydrocodone has approximately six times the potency and greater oral bioavailability than codeine [16]. Hydrocodone is *O*-demethylated to hydromorphone, and *N*-demethylated to form norhydrocodone. Similar to codeine, hydrocodone is metabolized by CYP2D6 to an active metabolite (hydromorphone) and therefore may be subject to pharmacogenetic variability in patients with abnormal CYP2D6 activity [88]. The clinical impact of this is unclear. It has been suggested that most of the pharmacologic effects of hydrocodone actually result from the hydromorphone formed during metabolism. However, studies are somewhat contradictory [16]. On the other hand, hydromorphone is five-to-seven times more potent than morphine and can be used as an analgesic by itself. Similar to morphine, hydromorphone is metabolized in large part to a 3-glucuronide [16].

Oxycodone and oxymorphone

Oxycodone is a potent analgesic with high oral bioavailability [86] that is frequently formulated in combination with acetaminophen. Therefore the detection of acetaminophen along with oxycodone in the urine of patients who display an opiate toxidrome should lead to measurement of serum acetaminophen to assess toxicity. Although its own strong analgesic activity precludes oxycodone from being considered a prodrug, it is converted to a highly active metabolite, oxymorphone, through CYP2D6 activity [16]. This conversion appears to be less of a concern for CYP2D6 poor metabolizers, in whom oxycodone itself still provides analgesia, than for ultrarapid metabolizers,

who could be at increased risk for adverse effects [89]. Oxymorphone also provides potent analgesia. The majority of oxymorphone is metabolized to the 3-glucuronide; a minor metabolite, 6-hydroxyoxymorphone, is also active [16].

Fully synthetic opioids

Fentanyl

Fentanyl has a rapid onset and short duration of effect. Fentanyl provides the structural backbone for a number of related, ultrashort-acting opioids, including remifentanil and sufentanil. Norfentanyl, the primary metabolite, is inactive [90]; the high potency of fentanyl and the clinical insignificance of its metabolites make it a preferred analgesic for patients with major organ failure [91]. Transdermal fentanyl patches are used for long-term administration and are gaining popularity among drug abusers, even though nonstandard application of the patch (e.g., chewing and extraction) carries substantial risk for overdose [92].

Meperidine

Meperidine has analgesic potency comparable with or somewhat lower than that of morphine [93]. One major metabolite, normeperidine, also has analgesic activity; normeperidine is thought to be responsible for the serotonergic toxicity of meperidine, particularly in patients receiving concomitant monoamine oxidase inhibitors [86]. Meperidine use has declined in recent years in favor of alternatives.

Methadone

A relatively long-acting opiate, methadone, is used both for analgesia and in the treatment of opioid addiction [86]. It is thought to provide: (1) milder withdrawal; (2) somewhat lower potential for abuse; and (3) reduced exposure to the risks of illicit intravenous drug use. Methadone has affinity for both MOR and DOR [94], the latter of which may explain its apparent utility in patients whose pain no longer responds to other opioids [86]. Substantial interindividual and intraindividual variability in metabolism and elimination has been noted; both urine pH and seemingly self-inducible metabolism substantially influence the pharmacokinetics of this compound, as do commonly administered drugs such as benzodiazepines and antiretrovirals [86]. Although a large fraction of methadone is excreted unchanged, measurement of a metabolite, such as 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine (EDDP), in the setting of addiction treatment provides evidence for patient compliance rather than an exogenously spiked sample. EDDP excretion is less pH-dependent than is clearance of the parent drug [16,86]. Use of the methadone/EDDP ratio to assess compliance has been suggested but is complicated by the pharmacokinetic variability already described.

Tramadol

Unlike the majority of opioid agonists, tramadol has low abuse potential and therefore is unscheduled. It has low affinity for opioid receptors and mediates analgesia through opioid-independent regulation of neurotransmitter uptake; however, its main active metabolite (*O*-desmethyltramadol) is a potent opioid receptor agonist [87]. These mechanisms are thought to work synergistically to provide greater total pain relief than the sum of each individual component. Metabolism to *O*-desmethyltramadol occurs via CYP2D6; thus opioid-like effects are subject to genetic variability [95]. However, because of its effects on neurotransmission, tramadol has the potential to cause serotonergic toxicity even in patients lacking CYP2D6 [87].

Opioid antagonists and mixed agonist/antagonists

These clinically useful compounds produce very different physiologic responses, depending on the situation. For example, in opioid-naive patients, mixed agonist/antagonists (MAAs) provide MOR-mediated analgesia with less risk of an adverse reaction, but the same dose in an opioid-tolerant patient may precipitate immediate withdrawal. In medical usage, coadministration of low-dose antagonists or MAAs alleviates minor opioid-induced side effects and appears useful in preventing opioid tolerance. In opioid addiction treatment, the addition of a low-dose antagonist to maintenance therapy seems to minimize subjective "feel-good" effects without substantially worsening withdrawal symptoms.

Buprenorphine

Buprenorphine is an MOR partial agonist and a KOR antagonist. Low doses provide analgesia through MOR activation, but, unlike full agonists, pain relief has a maximal threshold or "ceiling effect" [96]. Buprenorphine is available as sublingual tablets (with or without naloxone) for the treatment of opioid dependence and as a transdermal patch [97]. Buprenorphine is metabolized via *N*-dealkylation by CYP3A4 to the active compound, norbuprenorphine, both of which can be further conjugated to inactive metabolites [98,99].

Naloxone

The prototypical opioid antagonist, naloxone, binds nonspecifically to all three receptor types, with the greatest

effect at MOR and the least effect at DOR [86]. Naloxone is commonly used in comatose patients as a therapeutic and diagnostic agent. When given in appropriate amounts in patients who are comatosed because of opiate intoxication, the clinician will see restoration of respiratory function, and improved level of consciousness. Its clinical efficacy lasts for as little as 45 minutes. Therefore patients are at risk for recurrence of narcotic effect. This is particularly true for patients exposed to opioids with long elimination $t_{1/2}$, such as methadone and sustained-release opioid products. Its efficacy is much greater by intravenous administration as compared with oral and sublingual routes [97]. This characteristic is advantageous in deterring misuse of prescribed opioids: oral or sublingual opioid/naloxone formulations provide the desired benefit when taken properly, but when diverted for intravenous use cause opioid antagonism and may precipitate withdrawal [97].

Opioid analysis

Given their relatively rapid TAT and ability to identify several opiates, immunoassays are commonly used to screen for opiates. For clinical application, a cutoff of 300 ng/mL morphine (or morphine equivalents) is commonly used to distinguish negative from positive urine specimens, whereas a cutoff of 2000 ng/mL is common for workplace drug screening. Antibodies in opiate screens commonly target morphine, because commercial immunoassay development has largely been driven by detection of illicit heroin use. Wide variability in cross-reactivity to other opiates has been noted; thus some opiates or opioids with high abuse potential, such as oxycodone, are often poorly detected [16]. To address this problem, several immunoassays are commercially available for individual opioids, such as fentanyl, methadone, and buprenorphine, which do not cross-react with the opiate immunoassay at all.

Phencyclidine and ketamine

On the street, PCP and ketamine are sold under a variety of names. They are available as a colorless, odorless liquid, or as a white powder. PCP is listed as a Schedule II drug in the US Federal Controlled Substance Act and is not approved for human use. Ketamine is a Schedule III drug, used as an anesthetic for short surgical procedures. Both drugs have been used illicitly in human cases of drug abuse, as well as in cases of drug-facilitated crimes. Ketamine and PCP share similar structural features and pharmacologic actions [83]. They are classified as dissociative anesthetics, because they produce rapid-acting dissociation of perception, consciousness, movement, and memory [83,100]. The effects are dose dependent and vary between individuals. Some individuals experience effects similar to the psychosis observed in schizophrenia. An anesthetic dose produces profound analgesia, where the individual is awake yet incapacitated, with limited voluntary limb movement. Both PCP and ketamine have also been associated with psychological disturbances.

PCP [1-(1-**p**henyl**c**yclohexyl)-**p**iperidine] is used recreationally for its mind-altering "out of body" experience. Recreational use of PCP declined in the 1980s but has reemerged in recent years. Presentation of adverse effects, such as dysphoria, ataxia, nystagmus, agitation, anxiety, paranoia, amnesia, seizures, muscle rigidity, hostility, delirium, delusions, and hallucinations, is unpredictable. Evidence of flashbacks has been documented with PCP use [100]. With repeated use of PCP, psychological dependence may develop, but tolerance or withdrawal syndrome is not profound. A sense of superhuman strength coupled with lack of pain perception may lead to excessive physical exertion and accidental or intentionally induced trauma. Thus PCP-related deaths most often are secondary to these adverse behavioral drug effects. Treatment of PCP toxicity is supportive [100].

Ketamine was discovered during subsequent studies characterizing PCP analogs. The liquid or powder form can be easily disguised in a victim's beverage; this has resulted in its use in drug-facilitated crimes. Ketamine powder can even be sprinkled onto marijuana or tobacco and smoked. It produces effects similar to those of PCP. Ketamine has a $t_{1/2}$ of $\sim 2-3$ hours [16] and is metabolized to norketamine, which has about one-third the activity of ketamine, and to dehydronorketamine, which may also be active [83]. Duration of anesthetic effects is dose dependent (usually <1 hours), and effects on the senses, judgment, and coordination can have a longer duration ($\approx 6-24$ hours). At higher doses, ketamine causes delirium, amnesia, dissociative anesthesia, hallucinations, delirium, hypersalivation, nystagmus, impaired motor function, hypertension, and potentially fatal respiratory problems. Effects on blood pressure and respiratory depression are significantly enhanced when coingested with alcohol.

Initial screening is typically done by immunoassay. Whether or not PCP and ketamine are included in a general urine drug screen depends on applicable regulations and on the prevalence of use in the local community. In some locations, the prevalence of PCP or ketamine use may be too low to warrant routine screening. Immunoassays are generally reliable; however, for PCP, false-positives have been reported because of high concentrations of dextromethorphan, diphenhydramine, and thioridazine [16]. Immunoassay-positive specimens should be confirmed, most commonly using GC−MS or LC−MS/MS analyses [16].

Specimen validity testing

Specimen validity testing is primarily performed to ensure a valid urine specimen was collected for drug testing. Several techniques can be used by people attempting to mask or adulterate drug use to avoid detection. These tactics may include the exchange of urine from a drug-free individual; or dilution of the urine specimen by excessive consumption of water, use of a diuretic or simple addition of water to the specimen to reduce drug concentrations to below cutoff limits. Also, readily available substances, such as detergent, bleach, salt, alkali, ammonia, tetrahydrozoline, or acid, may be added to the specimen after collection in an attempt to interfere with immunoassay screening procedures. Other more sophisticated adulterants specifically marketed to avoid drug detection include glutaraldehyde (Urine Aid; Clear Choice), nitrite (Klear; Whizzies), chromate (Urine Luck; Sweet Pee's Spoiler), and a combination of peroxide and peroxidase (Stealth). These adulterants also interfere with immunoassays to variable degrees, and the oxidizing agents (nitrite, chromate, and peroxide/peroxidase) may result in destruction of morphine, codeine, and the principal metabolite resulting from marijuana use, thus interfering with GC−MS confirmation and immunoassays [101].

Direct observation of urine collection is the most stringent means to guard against specimen exchange or adulteration. However, an individual's right to privacy and dignity must be weighed against the need for the highest degree of certainty of specimen integrity. Alternative measures to prevent specimen adulteration include (1) limitations on clothing or other personal belongings allowed in the specimen collection area; (2) addition of coloring agent to toilet water; and (3) inactivation of the hot water tap. In addition, several validity checks for specimen integrity may be made at the collection site and at the testing site. Validity testing criteria have been established by the Department of Health and Human Service for the drug testing program mandated for US federal employees (https://www.transportation.gov/odapc/part40, accessed July 2, 2019).

Pain management

UDT is an essential tool and recommended by numerous clinical practice guidelines for pain management. In the United States, in the late 1990s, awareness grew about the personal and economic costs of poorly controlled pain. Billions of dollars were being spent each year to treat between 30- and 80-million Americans with debilitating, chronic pain [102]. Congress reacted by passing into law the "Decade of Pain Control and Research." Overnight, pain became the fifth vital sign and the successful treatment of pain synonymous with quality of care.

In short order, the negative consequences of widespread opioid use surfaced. Since 1999, the number of opioid-related deaths in the United States has more than doubled and now exceeds the number of deaths related to heroin and COC abuse combined [103−105]. In 2012, drug overdose was the leading cause of injury death, surpassing that from motor vehicle crashes between the ages 25 and 64 [106]. For every one death from opioid abuse, there are 35 emergency department visits, 161 cases of abuse, and 461 cases of misuse, contributing to more than $55 billion dollars in society and work-related costs [107].

UDT in clinical pain management practice is fundamentally different than forensic drug testing. Forensic testing follows chain of custody, and the expectation is that the results for illicit and controlled substances will be negative. In virtually, all clinic pain medicine practices, no chain of custody collection procedures are used, and the controlled medication that patients are prescribed should be present if patients are compliant. The absence of prescribed medications is as much of a professional and ethical conundrum as the presence of illicit or unexpected controlled substances. In addition, the pain physician must be keenly aware that a urine sample yielding consistent results ensures only that the expected parent compound and metabolites are present; not that the patient is using the medication as prescribed. This point cannot be overlooked, as medication nonadherence in the chronic pain population is between 30% and 50% [108].

UDT includes screening tools, such as point of care (POC) and laboratory-based immunoassay testing, as well as confirmatory testing. POC testing is advantageous, because results can be obtained during the clinic visit and could be used for high-risk patients who have to travel far. POC testing could be used at the initial visit where inconsistent results or finding other illicit substances could influence the decision to initiate opioid therapy, or not [109]. However, changes in Medicare reimbursement for POC testing has made it less attractive in the private setting, and its use will likely decrease [110]. Instead, more comprehensive, laboratory-based definitive tests will be recommended for routine compliance monitoring for pain management patients.

Overall, laboratory-based and POC-based immunoassays have moderate sensitivity and low specificity [111]. They provide information about the general drug classes present in the urine but cannot distinguish between drugs within the same class. Immunoassays may completely miss semisynthetic or synthetic opioids, and therefore should be carefully interpreted based on the known limitations of the specific immunoassay used. Therefore confirmatory testing with GC/LC should be considered when screening results are inconsistent with prescribed medications and incorporated as a random part of routine monitoring. The higher cutoff values inherent to most

immunoassays also result in high false-negative rates and may cause the physician to miss aberrant use of prescriptions medication or falsely accusing a patient of diversion. However, in some settings, confirmatory testing can cost in excess of $100 per drug class; therefore restraint should be used.

Recently, numerous algorithmic approaches to UDT in pain medicine have been suggested. While finer details differ, there are a few clear messages [105,107,109,111]:

1. UDT should be used to monitor all patients on chronic opioid therapy.
2. The patient should be informed of and willing to participate in random UDT as documented at the initiation of therapy, in the opioid prescribing contract.
3. Random UDT testing is preferred to scheduled testing, as patients can and will modify usage if told in advance.
4. UDT prior to the initial consultation or POC testing during the initial visit might aid in the decision to initiate opioid therapy.
5. It is important to stratify patient risk into low and high or low, medium, and high categories based on initial screening, comorbid conditions, previous drug/alcohol abuse, and family history.
6. At a minimum, UDT should be performed once per year.
7. More frequent UDT is recommended for patients who are medium-to-high risk.
8. All unexplained results based on urine drug screening should undergo confirmatory testing.
9. Confirmatory testing should be performed at least once per year.
10. Urine temperature, pH, creatinine content, and specific gravity should also be tested to help identify adulterated samples.
11. *Inconsistent* or unexplained results should be discussed with the performing lab and then with the patient in an open, truthful manner.
12. In the event that misuse, abuse, or diversion is suspected, the physician must choose to continue the current treatment plan, take corrective action in an attempt to retain the patient, or dismiss the patient from practice.
13. Corrective actions include counseling, decreasing the time interval between appointments, limiting the number of pills, and referring to an addiction specialist.
14. Dismissing a patient from practice should be based on a prewritten policy that is reviewed with the patient.

In January 2018, the executive summary of the American Association of Clinical Chemistry Laboratory Medicine Practice Guideline (LMPG)—Using Clinical Laboratory Tests to Monitor Drug Therapy in Pain Management Patients was published [112]. The purpose of this LMPG was to provide clinical and laboratory practice recommendations developed using evidence-based approaches to address specific questions regarding the appropriate use of diagnostic tests to monitor adherence or compliance to controlled substances in the pain management population. Ultimately, this guideline produced 26 evidence-based and seven consensus-based recommendations on the use of laboratory and POC tests to monitor the use of controlled substances in pain management patients. One of key evidence-based recommendations is that first-line definitive testing (either qualitative or quantitative) is recommended for detecting the use of relevant over-the-counter medications, prescribed and nonprescribed drugs, and illicit substances in pain management patients. In addition, specimen validity testing (e.g., pH) is recommended, since it is an effective tool to ensure that laboratory test results are correctly interpreted in pain management patients. Specimen validity testing determines the suitability of the urine specimen collected/received, which directly affects the ability to correctly identify relevant over-the-counter medications, prescribed and nonprescribed drugs, and illicit substances used by pain management patients

In the end, UDT is an important tool in clinical pain medicine. The current epidemic of prescription medication abuse underscores the need for a consistent approach to monitoring that utilizes both subjective and objective measures. While some advocate that routine UDT should include all testable substances with abusive potential, such practices are costly and likely unnecessary in many cases. High-risk patients, classified by using validated clinical screening tools, require more careful and more frequent monitoring. POC and other EIA screening methods cannot differentiate between medications within the same drug class and may completely miss semisynthetic and synthetic opioids. For this reason, confirmatory testing with GC/LC should be performed at least annually and on all inconsistent samples. If misuse, abuse, or diversion is suspected, the physician must act in a way that promotes patient health and safety, while abiding by state and federal law. Such actions should be openly discussed and explicitly written in the opioid prescribing contract, signed at the initiation of every opioid treatment plan.

Drugs of abuse testing using other types of specimens

The collection of biological samples for the purpose of determining exposure to various agents is dominated by blood and urine. Blood is considered invasive, and the collection of urine may require some invasion of privacy and loss of dignity; urine specimens are also subject to

adulteration or manipulation to evade detection. For these reasons, alternate biological specimens have been investigated.

Meconium

Illicit drug use during pregnancy is a major social and medical issue. Drug abuse during pregnancy is associated with significant perinatal complications, including a high incidence of (1) stillbirth; (2) meconium-stained fluid; (3) premature rupture of the membranes; (4) maternal hemorrhage (abruptio placentae or placenta previa); and (5) fetal distress [113]. In the neonate, the mortality rate and morbidity (e.g., asphyxia, prematurity, low birth weight, hyaline membrane disease, infection, aspiration pneumonia, cerebral infarction, abnormal heart rate and breathing patterns, and drug withdrawal) are increased [113].

Unfortunately, identification of the drug-exposed mother or her neonate is not easy. Maternal admission of the use of drugs is often inaccurate, principally because of denial about addiction or fear of the consequences stemming from such admission. Likewise, many infants who have been exposed to drugs in utero may appear normal at birth and show no overt manifestations of drug effects. Drug testing is an objective means of determining drug exposure in both mother and infant. Urine testing of the mother or newborn can detect only recent drug use (within a few days before birth), and urine collection from newborns may be problematic.

The first intestinal discharge from newborns is meconium, which is a viscous, dark green substance composed of intestinal secretions, desquamated squamous cells, lanugo hair, bile pigments, and blood. Meconium also contains pancreatic enzymes, free fatty acids, porphyrins, interleukin-8, and phospholipase A_2 primary bile acids with a small quantity of secondary bile acids. Meconium begins to form during the second trimester and continues to accumulate until birth; drugs taken by the mother can be detected in the meconium of the newborn [114].

The disposition of drug in meconium is not well understood. The proposed mechanism is that the fetus excretes drug into bile and amniotic fluid. Drug accumulates in meconium by direct deposition from bile or through swallowing of amniotic fluid [114,115]. The first evidence of meconium in the fetal intestine appears at approximately the 10th−12th week of gestation; meconium slowly moves into the colon by the 16th week of gestation [116]. Therefore the presence of drugs in meconium has been proposed to be indicative of in utero drug exposure up to ~5 months before birth—a longer historical measure than is possible by urinalysis [114].

The collection of meconium is noninvasive, making sample collection easy; however, meconium testing does have some limitations. Meconium is usually passed by full-term newborns within 24−48 hours, after which transition to stool. Infants with low birth weight (<1000 g) have been shown to pass their first meconium at a median age of 3 days. Thus meconium collection is missed because of delayed passage, and meconium may not be available soon after birth for early detection of intrauterine drug exposure.

In the clinical laboratory, meconium is an unfamiliar matrix; it is a sticky material that is more difficult to work with than urine. Meconium drug screening has been adapted to various analytical techniques, including radioimmunoassay, enzyme immunoassay, and fluorescence polarization immunoassay. Urine drugs-of-abuse screening assays frequently use meconium extracts and therefore must be investigated for possible effects of matrix on accuracy, precision, and assay linearity. However, some other immunoassay screening methods have been used. As with any immunoassay-based drug screen, confirmation by MS is critical. Confirmation assays for meconium are more difficult than those for urine. Recovery of drugs from meconium is sometimes low (30%−50%). A variety of GC−MS, LC−MS, and LC−MS/MS methods and their advantages and disadvantages have been described elsewhere [77,117,118].

Umbilical cord tissue

Alternatively, umbilical cord testing has been proposed as an alternative sample type to detect intrauterine drug exposure. It has some potential advantages over meconium in that sample quantity is not an issue, it is easier to collect in a single collection, and you do not have the potential of missing it, since meconium can be passed in utero. However, many questions also still remain to be answered about the disposition of drugs in this matrix. In a study comparing the detection of drugs in umbilical cord tissue and meconium for the confirmation of in utero drug exposures, the authors showed that cord tissue was less sensitive for the detection of five of the six drug classes [119]. Other studies [120] showed that drugs detected in paired meconium and umbilical cord tissue samples are often discordant; therefore the tests are not equivalent. However, one test is not always superior. Therefore it is a valid alternative sample type being utilized.

Oral fluid

Analysis of saliva for drugs was first used almost 30 years ago for the purpose of therapeutic drug monitoring [121]. It has since been evaluated for use in toxicology, with recognition of its advantages over other biological matrices. Most studies on saliva in humans use whole saliva. The term “oral fluid” is preferred for the specimen collected from the mouth. Oral fluid is a complex fluid consisting not only of secretions from the three major pairs

of salivary glands (parotid, submandibular, and sublingual), but also of secretions from the minor glands (labial, buccal, and palatal), bacteria, sloughed epithelial cells, gingival fluid, food debris, and other particulate matter [122]. The concentration of drug from each secretion and the relative contributions of the various glands to the final fluid may vary [123].

Several advantages are associated with monitoring oral fluid as contrasted with monitoring plasma or serum concentrations [124]. Collection of oral fluid is considered to be a noninvasive procedure, and some of the risks associated with the drawing of blood are avoided. Furthermore, for the patient, fear, anxiety, and discomfort that may accompany the drawing of blood are diminished. A disadvantage is the small volume of sample collected, and the window of detection for drugs is shorter than for urine. The problem of small sample size can be overcome by using methods that simultaneously detect multiple drug groups [125,126].

In recent years, great interest has been expressed in the use of oral fluid testing for monitoring the compliance of individuals on drug maintenance programs, and for workplace drug testing. Low concentrations of drugs and metabolites necessitate sensitive screening methods, which typically are immunoassays [126]. Again, the low concentrations of drugs have necessitated that confirmatory methods be equally as sensitive. Many confirmatory methods have been developed for oral fluid testing of abused drugs, including GC−MS, LC−MS, and LC−MS/MS.

Hair

For more than 30 years, hair has been analyzed for toxic metals, including lead, arsenic, and mercury. At first, the examination of hair for organic substances, specifically drugs, was not possible, because the analytical methods were not sensitive enough [127]. Baumgartner et al. [128] published the first report on the detection of morphine in the hair of heroin abusers using RIA. Since that time, interest in analysis of hair for the purpose of detecting drug use has increased.

It is generally accepted that drugs enter hair by at least three mechanisms: (1) from blood that supplies the growing hair follicle; (2) through sweat and sebum; and (3) via the external environment [127]. The exact mechanism by which chemicals are incorporated into hair is not known. Factors that may affect how efficiently drugs are incorporated into hair are not well established but may include rate of hair growth, anatomic location of hair, hair color (melanin content), and hair texture (thick or fine, and porous or not); these are determined by genetic factors and by the effects of various hair treatments [127]. For example, in-vitro substantially higher binding was found with hair from black men than with hair from blond white men, suggesting that melanin pigment plays an important role in drug binding. Studies have demonstrated that, after the same dosage is given, dark hair incorporates much more of the drug than is incorporated by blond hair [129]. This may lead to bias in hair testing for drugs of abuse and discussions about possible genetic variability of drug deposition in hair and is still under evaluation.

Hair is advantageous as a biological specimen, because it is easily obtained, with less embarrassment; it is not easily altered or manipulated to avoid drug detection. Once deposited in hair, drugs are very stable, and analysis can be performed even after centuries [130]. Hair also differs from other human materials used for toxicological analysis, such as blood or urine, because of its substantially longer detection window (months to years). Hair grows at a relatively constant rate. The average rate of hair growth is usually stated to be 0.44 mm/day.

Drugs, when deposited in hair, are generally present in relatively low concentrations (pg/ng/μg/mg); thus sensitive analytical techniques are required for detection. Immunoassay procedures have been modified for use with hair [127]. Although GC−MS is generally the method of choice, various GC−MS/MS or LC−MS/MS methods may be used for targeted analysis. As mentioned, external exposure to drugs causes them to be detected in hair. Externally deposited substances easily contaminate the hair because of its high surface-to-volume ratio. Substances deposited in hair from the environment are loosely bound to the surface of the hair, and thus are removed by appropriate decontamination procedures. These usually involve a washing step [127,131]. It is fundamental to be able to distinguish between passive exposure (environmental contamination) and actual use.

Metals

Elemental toxicity is still a concern today despite having a better awareness and understanding of the dangers. On a daily basis, people are exposed to various elements through the environment, their occupation, and/or the consumption of food or water. While some elements are absolutely essential for life (e.g., sodium, potassium, and magnesium), others may be essential but only required in very low concentrations (e.g., chromium), and still others have absolutely no biological role at all (e.g., lead). Toxic heavy metals (e.g., lead, mercury, and arsenic) are individual metals or metal compounds that can negatively affect people's health. In very small amounts, many of the elements may not cause any toxicity, but, when they are present in larger amounts, they can become toxic.

Diagnosing metal toxicity

Laboratory tests play a key role in confirming the diagnosis of elemental toxicity. Demonstration of all of the

following is necessary to make a definitive diagnosis including (1) an identifiable source for the elemental exposure; (2) the patient has clinical signs and symptoms of toxicity consistent with the identified element; and (3) an abnormal concentration of the element is found in the appropriate test matrix (e.g., blood, serum, or urine). Since elements are ubiquitous in the environment and the laboratory result plays a key role in the diagnosis, it is critical that the preanalytical variables are controlled to minimize sample contamination that can lead to an incorrect diagnosis. For example, most of the common blood collection tubes used have rubber stoppers made of aluminum silicate, which could lead to falsely elevated (abnormal) aluminum results if a sample is collected in these tubes. As a result, special metal-free collection tubes, collection techniques, and processing/handling of serum samples are required to prevent misinterpretation or misdiagnosis of element toxicity.

Lead

Lead is a naturally occurring blue–white metal, which is ubiquitous in the environment and has no known biological function in humans. Lead is used in the production of batteries, ammunition, and pipes. Common sources of exposure include older household paints (prior to 1972), ceramic products, leaded gasoline (prior to 1978), soil (especially near freeways), and water transported through lead pipes or lead soldered pipes. Due to the serious adverse effects of low levels of lead in children, the CDC and American Academy of Pediatrics recommend lead screening in all children who are Medicaid-eligible or enrolled and in those children with identified higher risks (e.g., live in older housing and have a sibling with elevated levels). The CDC reference blood lead level for adults and children is <5 μg/dL. Since children are lower to the ground where lead-contaminated dust accumulates and they engage in hand-to-mouth activities, they ingest and inhale more lead-contaminated dust. While ingested lead is poorly absorbed ($<10\%$) in adults, up to 50% may be absorbed in children especially those who are iron- or calcium-deficient [117]. Once absorbed, more lead also crosses the blood–brain barrier in children and has effects on their developing nervous system.

Clinical signs and symptoms of lead toxicity can include severe abdominal pain, vomiting, headaches, poor concentration, weight loss, ataxia, seizures, and death. One of the mechanisms of toxicity for lead is that it inhibits several enzymes that are necessary for the synthesis of heme from porphyrin including amino levulinic acid dehydratase. Inhibition of this enzyme leads to an accumulation of protoporphyrin in erythrocytes and anemia. To detect or confirm exposure to lead, a venous collected whole blood sample is the preferred specimen type for lead testing. The Occupational Safety Health Administration (OSHA) also requires monitoring of zinc protoporphyrin along with the whole blood lead level to monitor occupational exposure. The type of treatment depends on the patient's blood lead level, but asymptomatic patients usually only requiring separation from the source of exposure where chelation therapy using oral dimercaprol or D-penicillamine can be used for the more severe lead poisonings/toxicity.

Arsenic

Arsenic has a long history as a poison used to eliminate undesirable acquaintances. It is listed as the No. 1 toxicant on the 2015 Agency for Toxic Substances and Disease Registry Substance Priority List of Hazardous Substances based on a combination of frequency, toxicity, and potential for human exposure (http://www.atsdr.cdc.gov/SPL/index.html, accessed November 15, 2018). Arsenic exists in numerous toxic (inorganic) and nontoxic (organic) forms. Nontoxic forms of arsenic (arsenobetaine and arsenocholine) are present in many foods especially shellfish and predator fish (e.g., cod and haddock). The toxic forms include arsenite (As_{3+}), the more toxic arsenate (As_{5+}), and the less toxic metabolites; monomethylarsonic acid; and dimethylarsinic acid. The largest source of exposure is from pesticides, but arsenic is also used in pharmaceuticals, the glass and ceramic industry, and metallurgy.

Acute arsenic toxicity can present quickly with abdominal pain, vomiting, diarrhea, muscle cramps, hypertension, and tachycardia. Several weeks after the exposure, transverse white bands (mee's lines) on the fingernails may be seen. Chronic arsenic toxicity typically presents with dermatological (hyperpigmentation), neurological (decreased muscle strength in lower extremities), hematological (anemia and leukopenia), and GI symptoms. Since blood concentrations of arsenic are only elevated for only a short time after administration, urine measurements are the preferred matrix to screen for arsenic poisoning. However, if the total arsenic concentration is elevated, a speciation or fractionation test must be performed to determine if the toxic (inorganic) forms or nontoxic (organic) forms of arsenic are present. Therefore it is recommended that patients abstain from eating seafood several days before collecting a urine sample for arsenic testing. Treatment consists of removal from the source of exposure, supportive measures, and chelation therapy (e.g., British antilewisite).

Cadmium

Cadmium is ubiquitous and found in all rocks and soil. It is used in batteries, electroplating, as pigments in paints,

and as a stabilizer in plastic production. Exposure to cadmium can occur through eating food, drinking water, smoking tobacco, or various occupational exposures. Symptoms of cadmium poisoning include nausea, vomiting, abdominal pain, and diarrhea. In a similar fashion to arsenic, mercury, and lead, cadmium also damages the kidneys leading to glucosuria and proteinuria, which slowly over time can lead to renal and hepatic failure. Typically, blood cadmium concentrations can be used to monitor acute toxicity, while urine levels can be used to assess body burden. For occupational monitoring, the OSHA recommends a panel that includes cadmium in blood and urine, as well as beta-2-microglobulin in urine. Collection of urine samples using a rubber catheter or use of colored plastic urine collection containers should be avoided, since it can falsely elevate the test results due to the cadmium in the rubber and pigments in the plastic. Therapy includes removal of the patient from the source and supportive care. Chelation therapy is contraindicated, since it exposes the kidney to large quantities of the nephrotoxic cadmium.

Chromium

Chromium is a naturally occurring element found in rocks, animals, plants, and soil. Chromium is present in several different forms [e.g., chromium(0), chromium(III), and chromium(VI)]. It is used extensively in the manufacturing of stainless steel, chrome plating, leather tanning, dyes for printing, and as a cleaning solution. It is an essential element, and a deficiency of chromium is associated with impaired glucose tolerance and diabetes. Symptoms associated with chromium toxicity vary based upon route of exposure and dose, and may include dermatitis, impairment of pulmonary function, gastroenteritis, hepatic necrosis, bleeding, and acute tubular necrosis. More recently, chromium toxicity due to the release of chromium ions during the normal and abnormal wear of metal-on-metal (MOM) prosthetic implants has gotten attention. Orthopedic implants are created from various metal alloys with the most common being cobalt and chromium. As a result, the FDA recommended monitoring MOM wear using whole blood measurement of chromium to minimize preanalytical variables and contamination in symptomatic patients (http://www.fda.gov/MedicalDevices/ProductsandMedicalProcedures/ImplantsandProsthetics/MetalonMetalHipImplants/ucm331971.htm, accessed November 15, 2018). Urine chromium levels can also be used to monitor other short-term exposure.

Gadolinium

Gadolinium (Gd) is an element that is commonly found in image contrast agents used during magnetic resonance imaging (MRI) studies. These gadolinium-based contrast agents (GBCAs) increase the clinical utility and sensitivity of these exams, providing enhanced medical care by improving the effectiveness of the imaging studies [132]. An estimated 30-million Gd-enhanced MRIs are conducted around the world each year [133]. Recently these agents have come under scrutiny, and, in 2017 the FDA released several safety announcements through its MedWatch system regarding the use of GBCAs. The new warning concerns the fact that Gd can be retained in patients bodies (e.g., the brain and other tissues) for months to years after receiving these drugs. The December 2017 FDA announcement also noted that there are differences in the two types of GBCAs (e.g., linear and macrocyclic) used. Of the two, linear agents result in more retention of Gd in patients, and retention for a longer period of time than macrocyclic GBCAs. Regardless of the new warnings, the FDA concluded that the benefit of the approved GBCAs continues to outweigh any potential risk—the European Medicines Agency reached a similar conclusion. Although ongoing studies continue to examine if there are any potential adverse effects of the long-term retention of Gd, the only known adverse health effect to date related to Gd retention is a rare condition called nephrogenic systemic fibrosis (NSF) [134]. NSF is a relatively uncommon condition where fibrous plaques develop in the dermis and, often, in deeper connective tissues, and is characterized by thickening of the skin [134]. Reported cases of NSF have occurred almost exclusively in patients with severe renal disease, and almost all have been associated with prior use of GBCAs.

Measurement of Gd is not routinely conducted nor formally recommended by the FDA, or any professional practice guidelines. However, laboratories using inductively coupled plasma−mass spectrometry (ICP−MS) in the assessment of other elements should check for Gd in patients recently administered GBCAs, since it can suppress the measurement of other elements due to space-charge effects, resulting in a loss of accuracy/recovery for the element of interest [134]. Serum and urine Gd testing is available, but only confirms past exposure to Gd. Currently, there is no definitive or diagnostic test for Gd toxicity.

Mercury

Hg is widely found in the environment and occurs both naturally and as the result of industrial processes, with the single largest source of Hg being its natural out-gassing from granite rock. Metallic mercury is a silvery, slightly volatile liquid at room temperature. Mercury can also combine with other elements, such as chlorine, sulfur, or oxygen, to form inorganic mercury compounds or "salts." It can also combine with carbon to make organic mercury compounds. The most common one, methylmercury, is

produced mainly by microscopic organisms in the water and soil. Previously, mercury was used in thermometers and barometers, but those are being phased out due to concerns about its toxicity. Mercury has also been used in dental amalgams, lighting as mercury vapor lamps, in the pulp and paper industry as a whitener, as a catalyst in the synthesis of plastics, and as a potent fungicide in antifouling and latex paints.

Symptoms of mercury toxicity depend on the type of exposure (inhalation, ingestion, or dermal) and on the chemical form of mercury. Symptoms of acute mercury poisoning include dermatologic (blue−black pigmentation), neurologic (headaches, confusion, and ataxia), GI (metallic taste, nausea, and vomiting), and hematologic (anemia and thrombocytopenia). Laboratory assessment of mercury exposure can be done using whole blood, urine, or hair. Urine can specifically be used to follow the effectiveness of chelation therapy and is thought to indicate better the mercury burden of the kidneys. Treatment includes removal from the source of exposure, supportive care, decontamination, and chelation therapy.

Analytical techniques used to measure metals in biological fluid include atomic absorption spectrometry, ICP−MS, and LC−ICP−MS. These techniques are specific, sensitive, and provide the clinical laboratory with the capability to measure a broad array of metals at clinically significant concentrations.

Tricyclic antidepressants

Tricyclic antidepressants (TCAs) are frequently prescribed for the treatment of depression and neuropathic pain. The TCAs have been largely supplanted by the newer, less toxic selective serotonin reuptake inhibitors and other atypical agents for depression, which now are accepted broadly as drugs of first choice, particularly for medically ill or potentially suicidal patients and for the elderly and the young.

Cardiovascular effects, the most serious manifestation of TCA overdose, account for the majority of fatalities. Several mechanisms may contribute to cardiovascular toxicity [135]:

1. Anticholinergic effects and inhibition of neuronal reuptake of catecholamines result in tachycardia and potential for early hypertension.
2. Peripheral alpha-adrenergic blockade causes vasodilation and contributes to hypotension.
3. Cardiac fast sodium channel blockade and potassium efflux blockade, resulting in QRS and QT prolongation, respectively, and risk for decreased cardiac output and ventricular dysrhythmias.
4. Metabolic and/or respiratory acidosis that may further contribute to inhibiting the cardiac fast sodium channel.

TCAs are measured by chromatographic or immunoassay methods. Immunoassays are rapid and relatively easy to perform, but may be subject to interference by other drugs, such as chlorpromazine, thioridazine, cyclobenzaprine, and diphenhydramine [136−138], and are not able to necessarily identify which TCA is being quantitated. In cases of overdose, qualitative identification (serum or urine) is sufficient, because the severity of intoxication is more reliably indicated by an increase in the QRS interval than by the serum concentration.

Agents related to cholinergic syndrome

Agents inducing cholinergic syndrome are diverse, but the commonality is their ability to produce uncontrolled acetylcholine transmission through inactivation of cholinesterase enzymes or direct stimulation of acetylcholine receptors. The duration of acetylcholine action is controlled by AChE and butyrylcholinesterase (pseudocholinesterase). AChE is found in red blood cells, nervous tissue, and skeletal muscle. Butyrylcholinesterase is found in plasma, liver, heart, pancreas, and brain.

Pesticides (organophosphate and carbamate compounds)

Organophosphate (e.g., malathion, parathion, diazinon, and Dursban) and carbamate (e.g., Sevin and Furadan) insecticides, as well as military nerve agents [e.g., sarin (GB), soman (GD), tabun (GA), and VX], exert their toxicity by inhibiting the action of AChE, thereby causing a pronounced cholinergic response [5]. Excess synaptic acetylcholine stimulates muscarinic receptors (peripheral and CNS) and stimulates but then depresses or paralyzes nicotinic receptors. Activation of peripheral muscarinic receptors causes signs and symptoms described by the mnemonics SLUDGE or DUMB BELLS (see “Toxidromes” section). Whereas, CNS neurotoxic effects include (1) restlessness; (2) agitation; (3) lethargy; (4) confusion; (5) slurred speech; (6) seizures; (7) coma; (8) cardiorespiratory depression; and (9) death. Stimulation or paralysis of nicotinic receptors at the neuromuscular junction causes muscle fasciculation, cramping, weakness, and respiratory muscle paralysis; stimulation of nicotinic receptors at sympathetic ganglia results in a sympathomimetic syndrome that includes hypertension, tachycardia, pallor, and mydriasis. The actual signs and symptoms observed with these toxins depend on the balance of muscarinic and nicotinic receptor activation.

Specific therapy for organophosphate and carbamate insecticide poisoning includes administration of atropine to block the muscarinic (but not nicotinic) actions of acetylcholine. In addition, pralidoxime is given to reactivate cholinesterase. Pralidoxime binds to the cholinesterase catalytic site and, via nucleophilic attack by its oxime

group, dephosphorylates or decarbamylates the serine group. Administration of pralidoxime may not be necessary in cases of carbamate insecticide poisoning, because carbamylated cholinesterase spontaneously reactivates within a few hours.

Diagnosis of organophosphate and carbamate toxicity depends mainly on exposure history, physical presentation, clinical suspicion, and laboratory support. Cholinesterase activity is measured to assess exposure and to monitor reactivation during treatment. AChE and butyrylcholinesterase enzyme activity are typically monitored using Ellman colorimetric or Michel electrometric analyses using whole blood, plasma, serum, and dried blood spots [139,140].

Self-assessment questions

1. A previously healthy 4-year-old child was brought to the local hospital because of nausea, vomiting, and increased breathing difficulty. An empty container of roach poison was found near the child. The child had tearing bilaterally, rhinorrhea, gurgling sonorous respirations when supine, and was incontinent (urine/stool). Based on her clinical presentation, the most likely explanation for the toxicity and treatment or antidote would be:
   a. carbamate poisoning; fresh frozen plasma
   b. arsenic poisoning; ascorbic acid
   c. organophosphate poisoning; atropine/pralidoxime
   d. chromium poisoning; EDTA chelation therapy
   e. iron poisoning; deferoxamine
2. A 78-year-old man was found unresponsive in his bed after the first cold day of winter. There is a kerosene heater still on from the previous night. On attempts to arouse him, officers note the cherry hue of his lips, cheek, and mucous membranes. The most likely mechanism of his death was:
   a. accidental ingestion of ethylene glycol
   b. hepatic necrosis with fatty changes
   c. inhibition of fatty acid synthesis
   d. binding of carbon monoxide to hemoglobin
   e. inhibition of iron incorporation into hemoglobin
3. Which of the following compounds may be responsible for a combined anion and osmol gap?
   a. aspirin
   b. cyanide
   c. iron
   d. isoniazid
   e. ethylene glycol
4. A patient is brought into the ED with the following symptoms: coma, respiratory depression, and pinpoint pupils. He is given naloxone and responds. The expected result on the urine toxicology screen is that it will be positive for:
   a. PCP
   b. cocaine
   c. amphetamine
   d. opiates
   e. marijuana
5. A 6-year-old male is brought to the Emergency Room by his mother. The child has been nauseous and vomiting for 2 days and complains his stomach hurts. His physical exam showed the following: $T = 98.6°F$, blood pressure = 110/70 mm Hg, heart rate = 103 bpm, and respiratory rate = 22 breaths/min. He was jaundiced and diaphoretic. Laboratory testing showed the following:

		Reference range
• Sodium	130 mmol/L	(135–145)
• Potassium	4.0 mmol/L	(3.4–4.7)
• Chloride	101 mmol/L	(98–109)
• Glucose	88 mg/dL	(75–99)
• ALT	1200	(<45)
• AST	1050	(10–45)
• PT-INR	3.1	(0.8–1.2)
• Urine drug of abuse panel	Negative	(Negative)
• Salicylate	Negative	(Negative)
• Acetaminophen	35 mg/L	(10–30)

The most likely diagnosis/treatment for the child is:

a. salicylate overdose/activated charcoal
b. acetaminophen overdose/*N*-acetylcysteine (Mucomyst)
c. alcohol overdose/dialysis
d. digoxin overdose/Digibind
e. warfarin overdose/vitamin K

Answers

1. c

Chapter 53

Pharmacogenomics

Gwendolyn A. McMillin

Department of Pathology at the University of Utah School of Medicine, ARUP Laboratories; Salt Lake City, UT, United States

Learning objectives

After reviewing this chapter, the reader will be able to:

- Explain how pharmacogenetics can help guide drug and dose selection decisions.
- Describe examples of gene–drug pairs used to qualify a patient for drug therapy.
- Describe examples of gene–drug pairs used to optimize drug dose.
- Discuss limitations of pharmacogenetic testing.

Introduction

Pharmacology is the study of how drugs exert both desirable (e.g., therapeutic) and undesirable (e.g., toxic) effects. The two major disciplines that explain the processes associated with drug response are pharmacokinetics, describing what the body does to a drug, and pharmacodynamics, describing what the drug does to the body. Proteins commonly involved in pharmacokinetics include drug metabolizing enzymes and drug transporters. Proteins commonly involved in pharmacodynamics include signaling pathways (e.g., enzymes, receptors, and ion channels) and immune mediators. Regardless of the downstream effect, each protein is derived from genes that may exhibit variation, and that variation tends to cluster in certain populations. Common variations include nucleotide base changes, insertions or deletions of nucleotides, and copy number variations (CNVs). Such a genetic variation may influence protein expression and/or function. The association of specific gene variants with discrete aspects of pharmacokinetics and/or pharmacodynamics is known as pharmacogenetics. The genes involved in the pharmacogenetic associations are called pharmacogenes. Many drug–gene pairs are now described that can be used to guide drug and dose selection to maximize therapeutic response and minimize risk of toxicity for an individual patient. The recognition that many genes within a genome can be involved in the response to a drug has contributed to the vision of pharmacogenomics, wherein several pharmacologically relevant variants are detected and characterized for many genes, and eventually the whole genome. As variation in drug response is rarely explained by only one gene, and as many individuals take more than one drug, pharmacogenomics has great potential to improve patient therapy decisions over what a single drug–gene pair can accomplish. That said, the terms pharmacogenetics and pharmacogenomics are often used interchangeably.

Drug response

A person's unique response to a drug is the phenotype that results from the coordination of pharmacokinetic and pharmacodynamic processes for that drug or combination of drugs, in that person. Possible drug response phenotypes include the following: (1) efficacy without toxicity; (2) efficacy with toxicity; (3) toxicity without efficacy; or (4) neither efficacy nor toxicity. Responses may be dose-dependent or may occur independent of dose. Recognition of drug response phenotypes that cluster within families has led to characterization of many pharmacogenetic associations. Based on these associations, genetic tests have been developed to predict whether a person is likely to respond to a drug, whether a person is at increased risk for an adverse event, and/or whether a person might respond best to a nonstandard dose of a particular drug, before the drug is ever administered. However, drug response phenotypes are not typically explained by genetics alone.

The drug response phenotype is also influenced by nongenetic factors, such as age, sex, clinical health (e.g., kidney function and liver function), comedications, diet, and lifestyle factors (e.g., use of alcohol and/or nicotine). Specific drug formulation and route of administration may also influence response to drugs. Thus pharmacogenetics is but one tool that is used to inform and guide drug

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00053-3

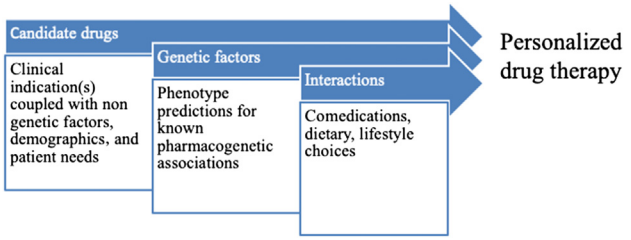

FIGURE 53.1 Many factors are used to select a drug and dose of drug for an individual patient. This schematic illustrates that candidate drugs for a clinical indication/diagnosis are narrowed based on genetic and nongenetic factors, including the potential for drug–drug and food–drug interactions.

and dosing decisions. As illustrated in Fig. 53.1, there may be several candidate drugs available to treat a patient for a particular clinical indication based on diagnosis and nongenetic factors. By incorporating genetic predictions of drug response along with clinical factors, patient demographics and the potential for drug–drug and drug–food interactions, therapy can be personalized, making both drug and dosing decisions more accurate.

Pharmacogenetic testing

Clinical pharmacogenetic testing is currently focused on detection of discrete genetic variants that are associated with well-defined aspects of pharmacokinetics and pharmacodynamics for a specific drug or class of drugs. As illustrated in Fig. 53.2, a laboratory test is designed to detect specific genetic variants (e.g., single nucleotide variants, insertions/deletions, and CNVs), referred to as genotypes. This information is used to assign alleles, often making assumptions about haplotypes/diplotypes (i.e., whether multiple variants occur on just one chromosome or whether such variants are divided between two chromosomes). The reason that haplotypes are often inferred is that most analytical methods can detect a gene variant but the method cannot determine the phase (chromosome position) of each variant. As such, specialized testing that can discriminate phase and frequency statistics is often used to predict the specific chromosome on which the pattern of genetic variants is likely to reside. The alleles are then assembled as a diplotype; this information is then used to predict the phenotype. Translation tables for both alleles and phenotypes are available through many resources, such as the Pharmacogenomics Knowledgebase (PharmGKB) [1]. Standardization of terms to define the predicted phenotype has also been proposed [2].

Some pharmacogenes are relatively simple to detect. For example, the association of many human leukocyte antigen (HLA) gene variants with potentially life-threatening drug hypersensitivity reactions requires a test that can identify the presence of at least one variant allele. The mode of inheritance is autosomal dominant for the well-known association between *HLA-B*57:01* and risk of hypersensitivity to abacavir; so, it does not matter whether one or two affected alleles are detected. The potentially life-threatening immune-mediated reaction that can precipitate when a carrier of the *HLA-B*57:01* allele is challenged with abacavir occurs regardless of dose or variation in pharmacokinetics, making implementation a rather straightforward process. Thus a carrier that is naïve to abacavir is disqualified from initiating that therapy. Alternative drugs are offered instead [3].

The *SLCO1B1* gene is also relatively simple from an analytical perspective, in that a test designed to detect only one variant is sufficient to predict increased risk of myopathy from simvastatin therapy, a commonly prescribed drug used for cholesterol reduction. The organic anion transporter polypeptide 1B1, encoded by *SLCO1B1*, transports active simvastatin acid from the blood stream into the liver. Detection of the variant (rs4149056, c.521 T > C) is associated with reduced transporter function, resulting in an accumulation of the drug and subsequent muscle toxicity. One copy of the variant allele predicts decreased transporter function; two copies of the variant allele predict poor transporter function. This is in contrast to the *HLA-B*57:01* example above, because the mode of inheritance of *SLCO1B1* and most other pharmacogenes are autosomal codominant, leading to a range of phenotype predictions [2]. A carrier of a variant *SLCO1B1* allele could minimize risk of the toxicity by using a lower dose or an alternate drug. Monitoring creatine kinase concentrations may also be useful for detecting and managing muscle toxicity associated with statin therapy [4].

Common nomenclature systems in pharmacogenetics classify combinations of sequence variants as star (*) alleles, where *1 usually reflects the reference allele (commonly referred to as "normal"), and numbered star alleles are assigned sequentially as new variants are identified [5]. Variants are defined, and nomenclature is archived by repositories, such as the Pharmacogene Variation (PharmVar) Consortium. Few clinical laboratories offer complete gene sequencing, phase, and CNV determinations for pharmacogenes. Instead, most testing is targeted, designed to detect only select variants of known clinical significance. Pragmatically, the *1 allele is assigned by default when none of the targeted variants are detected. Therefore the true accuracy of a *1 allele designation is unlikely and depends on whether the assay detects all possible variants that an individual may carry. The star (*) approach to nomenclature has been adopted for many pharmacogenes. A summary of recommendations for nomenclature reporting pharmacogene data is shown in Table 53.1 [6].

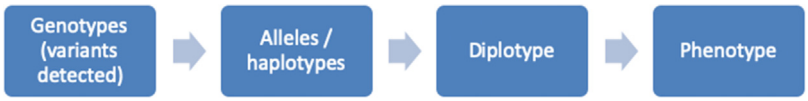

FIGURE 53.2 Translation of pharmacogenetic results relies on comparison of results with consensus nomenclature to define alleles, haplotypes, diplotypes, and, ultimately, the predicted phenotype. The phenotype may also be influenced by nongenetic factors, such as drug−drug interactions.

TABLE 53.1 General recommendations for pharmacogenetics nomenclature standardization and reporting [6].

Category	Recommendation
Naming the pharmacogenetic variants	Use HUGO Gene Nomenclature Committee nomenclature to specify the gene
	Report variants using Human Genome Variation Society nomenclature
	Use a Locus Reference Genomic reference sequence gene and/or a specific Human Genome Reference Assembly as a reference sequence. Both the reference sequence number and version number of the sequence (if applicable) should be indicated
	Report reference sequence numbers from the National Center for Biotechnology Information dbSNP database, the PharmVar database, or other reliable source
	Use haplotype translation tables to convert star (*) alleles or other legacy nomenclature to fully specified Human Genome Variation Society nomenclature for each variant in the haplotype. Note that nomenclature can be subject to change based on new findings and consensus
Test reporting	Report each variant and/or haplotype observed
	List variants and haplotypes that can be detected by the test (specific sites for genotyping tests or regions for sequencing-based tests)
	Describe the test, including limitations such as types of variants that cannot be detected
	The test description should be made publicly available on the laboratories' website, and/or by registration of the test in the NIH Genetic Testing Registry

Genes that code for drug metabolizing enzymes are among the best characterized and most commonly cited pharmacogenes. An example of nomenclature used to classify cytochrome P450 (CYP) drug metabolizing enzymes and the associated genes is shown in Fig. 53.3. *CYP2D6*, is one of the most clinically relevant pharmacogenes, but is also one of the most complicated. For example, the *CYP2D6*4* allele is defined primarily by the c.1847 G > A (rs3892097) variant, and subtypes are determined by combinations of additional variants [7]. The *4A subtype (PharmVar *CYP2D6**4.001) is defined by a combination of seven variants. There are over 100 unique star (*) alleles and many more subtypes defined for *CYP2D6*, making this an extremely difficult gene to interrogate with accuracy and specificity. That said, CYP subtypes do not usually affect the phenotype prediction and are most important for characterizing inheritance patterns in families, or for supporting research studies.

Classification of alleles and associated haplotypes/diplotypes is used for predicting the phenotype. When considering genes that code for drug metabolizing enzymes, each allele is classified based on predicted

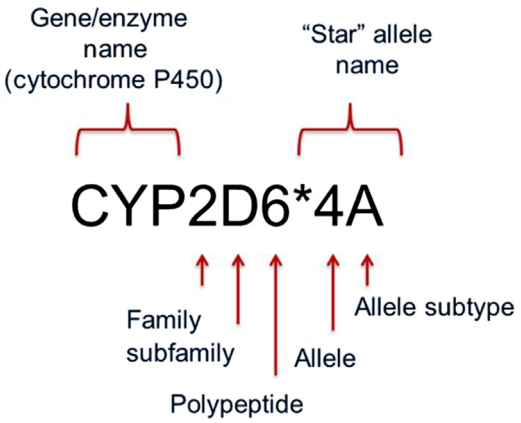

FIGURE 53.3 Description of how the cytochrome P450 drug metabolizing enzymes and associated genes are named using the isozyme subtype 4A of *CYP2D6* as an example.

enzyme function, such as normal, decreased function, no function, or increased function. A diplotype, which may be presumed based on whether phase analysis to delineate haplotypes is performed, is further translated into predicted drug metabolizer status (i.e., phenotype), which

TABLE 53.2 Examples of standardized terms for pharmacogenetic phenotype predictions from diplotypes published by the Clinical Pharmacogenetics Implementation Consortium [2].

Category	Phenotype term for diplotype	Functional definition	Genetic definition	Example gene diplotype
Drug metabolizing enzymes	Ultrarapid metabolizer	Enzyme activity higher than rapid metabolizers	More than two functional alleles or two increased function alleles	*CYP2C19*17/*17*
	Rapid metabolizer	Increased enzyme activity	Combinations of normal and increased function alleles	*CYP2C19*1/*17*
	Normal metabolizer	Fully functional enzyme activity	Two functional alleles or combinations of functional and decreased function alleles	*CYP2C19*1/*1*
	Intermediate metabolizer	Reduced enzyme activity	Combinations of normal function, decreased function, and/or no function alleles	*CYP2C19*1/*2*
	Poor metabolizer	Little-to-no enzyme activity	Combinations of no function alleles and/or decreased function alleles	*CYP2C19*2/*2*
Transporters	Increased function	Increased transporter function	One or more increased function alleles	*SLCO1B1*1/*14*
	Normal function	Fully functional transporter	Two functional alleles or combinations of functional and decreased function alleles	*SLCO1B1*1/*1*
	Decreased function	Reduced transporter function	Combinations of normal function, decreased function, and/or no function alleles	*SLCO1B1*1/*5*
	Poor function	Little-to-no transporter function	Combinations of no function alleles and/or decreased function alleles	*SLCO1B1*5/*5*

could be normal, intermediate, poor, rapid, or ultrarapid. For example, a poor metabolizer is predicted when two copies of nonfunctional alleles are inherited (e.g., *CYP2D6*4/*4*). Terms for phenotype predictions are now standardized for some pharmacogenes, as shown in Table 53.2 [2].

The *4 is the most common no-function *CYP2D6* allele. However, one of the variants used to define all, but one currently recognized *4 allele subtype (c.100 C > T, rs1065852), is also used to define dozens of other *CYP2D6* alleles, and some of which exhibit different phenotypic characteristics than the *4 allele (e.g., *CYP2D6*10*). This is an example wherein a genotype may be misclassified as the wrong allele and subsequent diplotype, such as assigning *4/*10 instead of *1/*4. Misclassification of alleles may occur with targeted testing and when consensus nomenclature is not consulted. Such misclassification has potential clinical significance if it affects the phenotype prediction. In this case, a *4/*10 would be classified as an intermediate metabolizer, whereas a *1/*4 would be classified as a normal metabolizer. Another analytical challenge is that many newly recognized *CYP2D6* alleles are gene hybrids that incorporate pieces of pseudogenes, such as *CYP2D7*, into a portion of the *CYP2D6* gene (e.g., *CYP2D6*36*). The *CYP2D6*36* is relatively common in Asian populations, but many gene hybrids are rare and are still being recognized, defined, and characterized.

Many important variants reside in noncoding regions or occur as a consequence of CNVs [1]. Few traditional or massively parallel sequencing methods are optimized to detect all clinically relevant pharmacogenetic information. As a consequence of these analytical challenges, there is an overall lack of standardization in the specific alleles detected among laboratories for *CYP2D6*, and for some other complicated pharmacogenes. Complementary testing that provides more comprehensive detection of genetic variants (e.g., full gene sequencing versus targeting only common variants) or testing that characterizes the phenotype directly (e.g., therapeutic drug monitoring, metabolic ratios, and enzyme activity testing) can refine the clinical value of pharmacogenetic testing, particularly for complicated pharmacogenes, such as *CYP2D6*.

TABLE 53.3 Tiers of testing proposed for *CYP2C19* by the Association for Molecular Pathology [8].

Tier	Star allele	Allele function	Defining variant	Common HGVS nomenclature (NM_00769.2)
1	*2	No function	rs4244285	c.681 G > A
	*3	No function	rs4986893	c.636 G > A
	*17	Increased function	rs12248560	c. − 806 C > T
2	*4A	No function	rs28399504	c.1 A > G
	*4B	No function	rs12248560, rs28399504	c. − 806 C > T, c.1 A > G
	*5	No function	rs56337013	c.1297 C > T
	*6	No function	rs72552267	c.395 G > A
	*7	No function	rs72558186	c.819 + 2 T > A
	*8	No function	rs41291556	c.358 T > C
	*9	Decreased function	rs17884712	c.431 G > A
	*10	Decreased function	rs6413438	c.680 C > T
	*35	No function	rs12769205	c.332−23 A > G

HGVS; Human Genome Variation Society.

Efforts to harmonize pharmacogenetic testing are underway, such as the Association for Molecular Pathology's recommendations for clinical *CYP2C19* testing. Well-characterized alleles were considered based on availability of accurate testing, reference materials, multiethnic allele frequencies, and clinical guidance documents for interpretation and implementation. As shown in Table 53.3, there are three alleles that were recommended for "Tier 1" testing. Tier 1 testing defined the minimum content that a clinical laboratory should offer, and could offer, based on meeting the criteria described above. "Tier 2" testing expands on that list to include variant alleles of clinical importance to a smaller group of individuals, or for which analytical characteristics are not yet mature [8]. Consistent with the recommendations in Table 53.1, the variant alleles listed in Table 53.3 are defined based on primary causative variant [reference sequence (rs) number and common designation, with rf], along with the predicted function of each allele. Clinical laboratories that offer pharmacogenetic testing can be found through the voluntary National Institutes of Health Genetic Testing Registry [9].

In addition to concerns about accuracy of haplotype and diplotype assignments used to predict phenotype that were raised above, the actual drug response phenotype is affected by other genetic factors not detected by the test (e.g., other pharmacogenes involved in drug response), as well as demographic factors (e.g., age and sex), clinical factors (e.g., body size and kidney function), and nongenetic factors, such as drug−drug and food−drug interactions. For example, a person who inherits no *CYP2D6* variants would be anticipated to exhibit normal metabolism and achieve therapeutic concentrations of CYP2D6 drug substrates, but a drug may not be effective if the physiology to support the drug's mechanism of action is impaired or absent (e.g., opioid receptors that cannot respond to a opioid substrate that requires metabolic activation via CYP2D6). Also, a person who inherits no *CYP2D6* variants could exhibit a poor metabolizer phenotype if comedicated with an inhibitor of CYP2D6, such as fluoxetine. The US Food and Drug Administration (FDA) classifies drugs as strong, moderate, or weak inhibitors [10]. These coadministered drugs can elicit a poor metabolizer phenotype by inhibiting CYP2D6. A genetically predicted intermediate metabolizer is particularly vulnerable to drug−drug interactions. In addition, some supplements and food can inhibit CYP enzymes. For example, grapefruit juice is recognized to inhibit CYP3A4 activity, leading to reduced metabolism of associated drug substrates. As such, assignment of drug metabolizing enzyme pharmacogenetics to phenotype predictions and associated clinical implementation is multifactorial.

Pharmacogenetics implementation

The Clinical Pharmacogenetics Implementation Consortium (CPIC) and other organizations, such as the Dutch Pharmacogenomics Working Group (DPWG), publish guidelines for translation of the pharmacogenetic

TABLE 53.4 Examples of pharmacogenetic associations for which dosing guidelines were published by the Clinical Pharmacogenetics Implementation Consortium [1].

Drug	Gene	Utility		FDA label classification
		Qualify	Dose selection	
Carbamazepine	*HLA-B*15:02*	X		*Requirement* for genetic testing
Ivacaftor	*CFTR*	X		*Requirement* for genetic testing
Rasburicase	*G6PD*	X		*Requirement* for genetic testing
Abacavir	*HLA-B*57:01*	X		*Recommendation* for genetic testing
Clopidogrel	*CYP2C19*	X		*Recommendation* for genetic testing
Thiopurines	*TPMT*	X	X	*Recommendation* for genetic testing; includes azathioprine, mercaptopurine, and thioguanine
Fluoropyrimidines	*DPYD*	X	X	*Actionable*; includes 5-fluorouracil, capecitabine, and tegafur
Tricyclic antidepressants	*CYP2D6* and *CYP2C19*		X	*Actionable*; includes amitriptyline, doxepin, desipramine, imipramine, nortriptyline, and trimipramine; value of *CYP2D6* and/or *CYP2C19* is drug specific
Selective serotonin reuptake inhibitors	*CYP2D6* and *CYP2C19*		X	*Actionable*; includes citalopram, escitalopram, fluvoxamine, and paroxetine; value of *CYP2D6* and/or *CYP2C19* is drug specific
Opioids	*CYP2D6*	X	X	*Actionable;* includes codeine and tramadol
Phenytoin	*HLA-B*15:02* and *CYP2C9*	X	X	*Actionable*
Simvastatin	*SLCO1B1*	X	X	*Informative*
Tacrolimus	*CYP3A5*		X	Not currently addressed
Warfarin	*CYP2C9*		X	*Actionable*; includes dosing information
	VKORC1			
	CYP4F2			

TPMT, Thiopurine s-methyltransferase.

information to phenotype predictions and, subsequently, recommendations for specific drug, dosing, and management decisions unique to an individual patient. These guidelines do not make recommendations about when or whether testing should occur, but rather focus on evidence-based considerations that may better inform medication decisions when pharmacogenetic information is available. Examples of gene–drug pairs for which dosing guidelines are published by the CPIC are shown in Table 53.4, along with comments regarding the classification of the association by the FDA. The FDA has adopted language in drug labeling, indicating that testing is "required," "recommended," "actionable," or "informative."

Gene-based dosing guidelines typically represent gene–drug pairs that are associated with the highest level of evidence for clinical use. The CPIC levels of evidence (A–D) are assigned based on endorsement for a specific gene–drug association by professional medical associations and/or the PharmGKB assignments of evidence at Level 1 or 2. The PharmGKB grades gene–drug associations on a scale from 1 (highest level of evidence) to 4 (lowest level of evidence). Level-1 associations are replicated in multiple clinical cohorts with statistically significant differences in outcomes when the pharmacogene is used to inform medication decisions. The CPIC assigns gene–drug associations as Level "A" when the evidence supports a prescribing action, including alternate therapy or changes in dosing. A CPIC grade of "B" indicates the evidence is "moderate," but that prescribing actions may be appropriate. The CPIC also grades gene–drug associations as Level C or D when the PharmGKB classifies a

TABLE 53.5 Examples of pharmacogenetic-guided dosing recommendations published by the Clinical Pharmacogenetics Implementation Consortium [1].

Example result	Phenotype prediction	Implications for outcome	Dosing recommendations
HLA-B*57:01			
Negative	Not a carrier	"Normal" risk of abacavir hypersensitivity	Use label-recommended dosage and administration
Positive	Carrier	Increased risk of abacavir hypersensitivity	Select alternate drug; avoid use of abacavir
TPMT			
*1/*1	Normal metabolizer	"Normal" (low) concentrations of thioguanine nucleotide metabolites	Use label-recommended dosage and administration. Adjust based on degree of myelosuppression and disease-specific guidelines. Allow 2–4 weeks to reach steady state after each dose adjustment
		Note that thioguanine nucleotide metabolite concentrations with thioguanine are 5–10× higher than with mercaptopurine or azathioprine	
*1/*2, *1/*3A, *1/*3B, *1/*3C, and *1/*4	Intermediate metabolizer	Moderate-to-high concentrations of thioguanine nucleotide metabolites	Reduce dose by 30%–50% and adjust based on degree of myelosuppression and disease-specific guidelines. Allow 2–4 weeks to reach steady state after each dose adjustment
*3A/*3A, *2/*3A, *3C/*3A, *3C/*4, *3C/*2, and *3A/*4	Poor metabolizer	Extremely high concentrations of thioguanine nucleotide metabolites	Reduce daily dose by 10-fold and dose thrice weekly instead of daily
		Fatal toxicity possible without dose decrease	Adjust based on degree of myelosuppression and disease-specific guidelines. Allow 4–6 weeks to reach steady state after each dose adjustment. For nonmalignant conditions, consider nonthiopurine alternative

TPMT, Thiopurine s-methyltransferase.

gene as Level 1 or 2 but no prescribing actions are recommended based on genetics, and/or when alternative medications are unclear. The discriminating factors between Levels C and D relate to whether testing is common (C) or rare (D) and whether the pharmacogene is associated with CPIC Level A or B for other drugs: yes for C, no for D. The PharmGKB Level-3 gene–drug associations are supported by a single statistically significant study (not replicated yet), and Level-4 gene–drug associations are supported by only case reports, nonsignificant studies, or in vitro evidence only. These evidence levels and associated dosing guidelines are updated as new data become available.

Examples of specific CPIC dosing recommendations are shown in Table 53.5. The CPIC, DPWG, FDA drug labeling, and other sources of pharmacogenetic information are summarized and updated by the PharmGKB [1]. The FDA has included pharmacogenetic information in labels for more than 300 drugs. The European Medicines Agency, Health Canada (Santé Canada), and the Pharmaceuticals and Medical Devices Agency of Japan have also included pharmacogenetic information in labeling for hundreds of drugs. The PharmGKB and other public resources offer many educational resources regarding clinical associations with pharmacogenetic variants, tools for allele and phenotype assignments, allele frequency tables, pathways, and tools for implementation of pharmacogenetics in a clinical setting. Performing pharmacogenetic testing for well-characterized gene–drug pairs, such as those in Table 53.4, can improve accuracy of many pharmacotherapy decisions before a drug is ever administered. However, dose optimization will still rely largely on trial and error, results of related laboratory and clinical monitoring, supplementary laboratory biomarkers, patient compliance, and patient feedback.

Guidance for clinical implementation of pharmacogenetic associations today falls into two major categories: qualification for therapy or dose optimization. The

primary utility is indicated in Table 53.4 for select gene−drug pairs, to serve as examples of how pharmacogenetic information may be used. First, a pharmacogenetic test may qualify a person for drug therapy by either predicting risk of adverse drug reactions or response/nonresponse. As discussed above, detection of at least one *HLA-B*57:01* allele would disqualify a patient for abacavir therapy due to increased risk of a potentially life-threatening hypersensitivity reaction. See Table 53.5 for examples of guidance comments from the CPIC for *HLA-B*57:01* test results. Similarly, detection of an *HLA-B*15:02* allele would disqualify a patient for therapy with carbamazepine or phenytoin (see Table 53.4). These hypersensitivity reactions are not dose-dependent, so cannot be avoided by adjusting dose for a vulnerable patient. *CYP2C19* testing is another example of a gene wherein the presence of a loss of function variant may disqualify a patient from treatment with drugs, such as clopidogrel, which requires metabolic activation, mediated primarily by CYP2C19, to be effective. As a result, patients who are CYP2C19 poor metabolizers are unlikely to respond desirably to clopidogrel [11]. In contrast, testing *CFTR* is used to qualify patients for ivacaftor, because this drug is the first FDA-approved therapeutic developed to target a specific *CFTR* defect. Ivacaftor works by improving the transport of sodium through the CFTR ion channel, which is only effective in patients that have impaired CFTR conductance. The specific variants and combinations of variants associated with response are included in the CPIC guideline [12].

Pharmacogenetic testing results can also be used to adjust the initial dose. Most examples of dose optimization are based on drug metabolism. For extremes of metabolic phenotypes, such as ultrarapid and poor metabolizers, dosing recommendations frequently suggest avoiding drugs that require the affected enzyme. A drug that is inactivated by metabolism may accumulate to potentially toxic blood concentrations in a poor metabolizer. An ultrarapid metabolizer may inactivate the drug to an extent that blood concentrations never become therapeutic. An example of this scenario is provided by CYP2D6 and nortriptyline, wherein drug avoidance is recommended for both poor and ultrarapid metabolizers [13]. In contrast, a drug that is activated by metabolism may produce far more active drug than intended in an ultrarapid metabolizer. For example, codeine is converted to the much more potent drug morphine, primarily based on a reaction mediated by CYP2D6. As such, an ultrarapid metabolizer is at risk of an unintentional overdose after receiving a standard dose of codeine. For a poor metabolizer, codeine may never be activated sufficiently for any response. The CPIC guidelines for codeine suggest alternative drugs for both ultrarapid and poor CYP2D6 metabolizers [14]. For intermediate metabolizer phenotypes, a dose adjustment may compensate for the anticipated change in metabolic activation or inactivation, but the impact of the impaired metabolism is drug-dependent. For nortriptyline, the CPIC recommends a 25% dose reduction for CYP2D6 intermediate metabolizers. The dose can then be optimized with therapeutic drug monitoring. However, no specific dose adjustment is recommended for codeine in CYP2D6 intermediate metabolizers.

Another classic example that falls into this second category of clinical implementation is the thiopurine s-methyltransferase (TPMT) enzyme, coded by a gene of the same name, and thiopurine toxicity. With normal TPMT activity, approximately 90% of thiopurine drugs (e.g., azathioprine, mercaptopurine, and thioguanine) are inactivated. As such, a TPMT poor metabolizer does not inactivate thiopurine drugs and requires a reduction in dose of approximately 90%. The recommendation for TPMT intermediate metabolizer is to reduce the standard dose by 30%−50%. See Table 53.5 for examples of guidance comments from the CPIC for *TPMT* testing to adjust the dose of thiopurine drugs. In this case, both phenotype (e.g., enzyme activity and metabolic ratios of the drugs) and genotype testing can help to inform and optimize dosing. The most recent revision of the CPIC guideline for thiopurine drugs also includes *NUDT15*, which is a gene that codes for nudix (nucleoside diphosphate-linked moiety X)-type motif 15 [15]. Like *TPMT*, nudix is involved in detoxification of active thiopurine metabolites, and loss-of-function variants in *NUDT15* are also associated with an increased risk of dose-related toxicity. The *TPMT* and *NUDT15* variants increase the risk of dose-related toxicity independently, and will exert additive effects. As such, variant alleles of either one or both genes are associated with recommendations for dose reduction. Optimization of dose may require a combination of clinical monitoring and therapeutic drug monitoring.

Limitations

Limitations of pharmacogenetics and pharmacogenomics testing reflect the evolution of this field. The analytical and/or translational concerns addressed throughout this chapter should guide evaluation of testing and interpretive tools in the clinical marketplace. Resources such as CPIC guidelines and FDA-approved labeling recommendations have been incorporated into clinical decision support tools, including alert messages in the electronic medical record and dose calculators. In addition, many laboratories have adopted proprietary algorithms that may provide recommendations based on single genes or combinations of genes. The latter approach is termed “combinatorial” and is currently most prevalent for informing psychotropic medication decisions. Some of the combinatorial

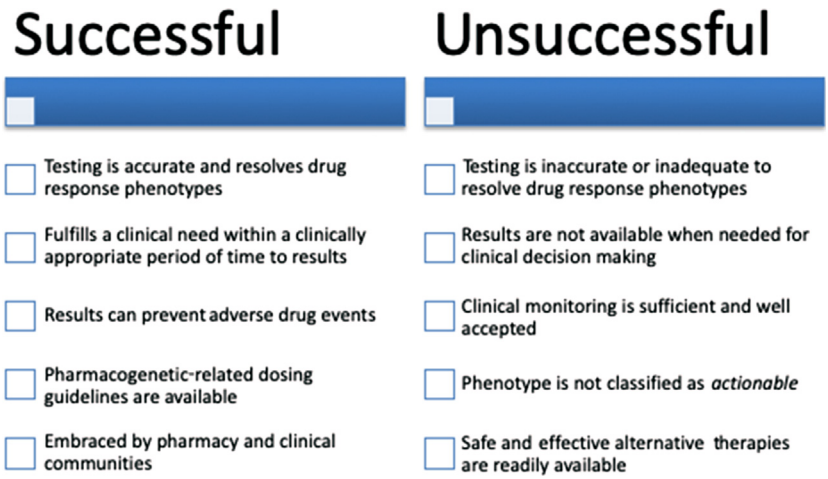

FIGURE 53.4 Examples of factors affecting the successes and limitations of pharmacogenetic applications.

algorithms have been evaluated in randomized clinical trials but most have not. Some algorithms also incorporate clinical, lifestyle, pharmacy admissions, and demographic information to predict risk of adverse drug events or therapeutic failure, particularly for patients receiving polypharmacy. Traditional laboratory testing, including pharmacogenetics testing, requires involvement of the provider to order and interpret a test.

Recently, direct to consumer testing (DTC) has become available for pharmacogenetics. Direct patient access to pharmacogenetic information improves portability of results and may facilitate engagement of multiple medical specialties. DTC testing also helps empower the consumer with information that could impact medication decisions, including selection of nonprescribed medications and supplements. This empowerment could be beneficial to the consumer, but could also introduce risk to the consumer if he or she chooses to change medication and/or dosing decisions independent of clinical providers. Regardless of how results are delivered, pharmacogenetic testing results need to improve patient care beyond what can be achieved with existing standards of care to be successful, and need to engage a multidisciplinary team, representing all stakeholders for a specific application. Examples of these and other factors that influence success of pharmacogenetic testing applications are summarized in Fig. 53.4.

Clinical pharmacogenetic laboratories often provide an interpreted phenotype based on the genotype results. Laboratories that are accredited by the College of American Pathologists (CAPs) are required to include a summary of methods and the variants that can be detected on the report, but, overall, the lack of consensus for pharmacogenetic nomenclature (e.g., *alleles, rs#, Human Genome Variation Society, diplotype versus haplotype, etc.), and variable assay designs add to the complexity of analyzing and reporting results from pharmacogenetic assays. Proficiency testing offered through the CAPs has demonstrated both successes and failures in performance among laboratories performing pharmacogenetic testing [16]. The recommendations indicated in Table 53.1 should be considered when developing a laboratory report for pharmacogenetic testing results.

Self-assessment questions (True/False)

1. Pharmacogenetic testing can always determine the specific drug that will benefit a patient most.
2. Pharmacogenetic testing prevents the need for therapeutic drug monitoring.
3. *HLA-B* alleles can predict an increased risk of hypersensitivity reactions to certain drugs.
4. Guidelines for implementation of pharmacogenetic testing describe the specific gene variants that should be targeted by a laboratory test.
5. Copy number variations in *CYP2D6* could influence the drug response phenotype.
6. A drug that is activated by metabolism may be contraindicated in a person that has inherited no function genetic variants for the primary enzyme involved in metabolism of that drug.
7. A person that inherits a loss of function variant in *TPMT* should not receive thiopurine drugs.
8. Star (*) alleles are commonly used to describe alleles for pharmacogenes.
9. Pharmacogenetic variants are rare in most populations.
10. Application of pharmacogenetic variants to clinical care requires consideration of drug interactions.

Chapter 54

Infectious diseases

Esther Babady

Clinical Microbiology Service, Department of Laboratory Medicine, Memorial Sloan Kettering Cancer Center, New York, NY, United States

Learning objectives

After reviewing this chapter, the reader will be able to:

- Describe clinical syndromes caused by herpesviruses, and advantages and limitations of each laboratory testing method.
- Describe clinical syndromes caused by hepatitis viruses, and advantages and limitations of each laboratory testing method.
- Describe clinical syndromes caused by HIV, and advantages and limitations of each laboratory testing method.

Herpesviruses

Herpesviruses are double-stranded, linear DNA viruses classified in the *Herpesviridae* family. Eight herpesviruses, subdivided into three subfamilies, cause infections in humans (Table 54.1). The *Alphaherpesvirinae* subfamily includes three viruses: herpes simplex virus 1 (HSV-1), herpes simplex virus 2 (HSV-2), and varicella-zoster virus (VZV). Three viruses make up the *Betaherpesvirinae* subfamily: cytomegalovirus (CMV), human herpesvirus 6, and human herpesvirus 7. The third subfamily, the *Gammaherpesvirinae*, includes Epstein–Barr virus (EBV) and human herpesvirus 8. Herpesviruses are responsible for a wide range of clinical syndromes ranging from asymptomatic infections to severe disease with devastating sequelae, particularly in the very young and in immunocompromised hosts.

Herpes simplex viruses

Herpes simplex viruses (HSVs), also known as human herpesviruses, include two antigenically different strains: HSV-1 and HSV-2. Entry of HSV-1 and HSV-2 into the host cells is facilitated through the interactions of viral surface glycoproteins to specific cell receptors. HSV viral particles are transported from the entry site to the sensory neurons by retrograde transport along the peripheral nerves, where they invade sensory neurons. Following primary infections, HSV-1 and HSV-2 establish latency in the dorsal root ganglia, with reactivation occurring due to immunosuppression or other stressors [1,2].

HSV-1 is transmitted primarily through contact with oral secretions and lesions. HSV-1 may infect any mucocutaneous surface, resulting in either an asymptomatic, subclinical infection or primarily in orolabial herpes, commonly known as "cold sores." HSV-1 keratitis is the

TABLE 54.1 Herpesviruses classification.

Viruses	Subfamily	Site of latency	Example of syndromes
Herpes simplex virus 1	*Alphaherpesvirinae*	Sensory neurons	Gingivostomatitis
Herpes simplex virus 2	*Alphaherpesvirinae*	Sensory neurons	Neonatal herpes
Varicella-zoster virus	*Alphaherpesvirinae*	Sensory neurons	Varicella (chickenpox)
Epstein–Barr virus	*Gammaherpesvirinae*	Lymphocytes	Infectious mononucleosis
Cytomegalovirus	*Betaherpesvirinae*	Tissues Endothelia cells Leukocytes	Pneumonitis
Human herpes virus 6	*Betaherpesvirinae*	Lymphocytes	Roseola
Human herpes virus 7	*Betaherpesvirinae*	Lymphocytes	Roseola
Human herpes virus 8	*Gammaherpesvirinae*	Lymphocytes	Kaposi sarcoma

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00054-5

most common cause of infectious corneal blindness in the United States. Other clinical syndromes associated with HSV-1 infections include esophagitis, pneumonitis, hepatitis, encephalitis, and myelitis. Although infections caused by HSV-1 were traditionally thought to occur only above the waistline, current data show that HSV-1 is responsible for ~25% of genital herpes ulcers [1].

HSV-2 infections result from direct contact with genital secretions of individuals shedding the virus, including sexual contact or through perinatal transmission during vaginal delivery. HSV-2 is the most common cause of genital ulcers worldwide with >500 million people infected. A recent report from the World Health Organization (WHO) estimates that neonatal herpes occurs in 10 per 100,000 live births, equivalent to an overall burden of 14,000 cases per year [3]. Neonatal herpes can result in serious long-term neurologic sequelae if not diagnosed and treated quickly. Risk factors for transmission of HSV-2 from pregnant women to neonates include primary infection during pregnancy, seropositivity status of the mother, and delivery methods. HSV-2 causes clinical syndromes similar to those described for HSV-1, as well as aseptic meningitis, which is a complication of genital herpes that presents in a small percentage of patients [2]. Current antiviral options for HSV infections include intravenous acyclovir for neonatal herpes and meningitis and oral acyclovir, famciclovir, or valacyclovir for genital herpes [4–6].

Laboratory testing

Although the viruses share structural similarities, HSV-1 and HSV-2 differ by up to 50% in their genome sequences, allowing for easy discrimination by molecular methods. Differentiation of the two serotypes using commercial immunoassays is more challenging, as both viruses have several antigens that share similar epitopes. Commercial, type-specific antibody assays that differentiate between HSV-1 and HSV-2 anti-IgG are available. Serological testing may be useful in providing a diagnosis in subclinical or asymptomatic infections, where the virus or viral DNA may be undetectable, and for rapid evaluation of patients presenting with clinical manifestations of sexually transmitted diseases [2]. The importance of distinguishing between HSV-1 and HSV-2 infections using type-specific serological assays includes the following: (1) determination of the serostatus of pregnant women to evaluate risk of acquiring HSV infections from a serodiscordant partner; and (2) the identification of asymptomatic herpes (i.e., in the absence of lesions) to distinguish between genital and oral herpes [7,8].

Serological HSV assays have several limitations. First, they have limited utility in diagnosing acute infections in neonates (i.e., inability to differentiate from mother IgG) or other patient populations, including immunocompromised patients [9,10]. Second, while genital herpes is primarily due to HSV-2 and oral herpes is associated with HSV-1, serological assays cannot identify the site of infection. Third, the levels of IgM may not be detectable early in the course of the infection. Finally, false-positives due to cross-reactivity between the two viruses may occur, most commonly in low prevalence populations [2].

Both direct fluorescent antibody (DFA) and indirect fluorescent antibody (IFA) assays are commercially available for detection of HSV antigens in clinical specimens. Type-specific monoclonal antibodies are used to differentiate between HSV-1 and HSV-2. In addition, DFA/IFA may be used to confirm a cytopathic effect, which is characteristic of HSV detected in viral cell culture. The test principles are based on the visual detection of virally infected cells, fixed on a glass slide, using fluorescein-labeled monoclonal antibodies against HSV-1/2 antigens [11]. These assays are manual and include several steps (centrifugation, incubation, and reading); however, they are associated with relatively rapid turnaround times (TATs) of ~2 hours. However, DFA/IFA testing performed directly on clinical samples is not recommended for routine diagnosis of acute HSV infections due in part to their lower sensitivity when compared with viral culture and molecular tests [2,11]. When performed, many laboratories will reflex negative DFA/IFA tests to either viral cultures or molecular tests.

Nucleic acid amplification test (NAT) or molecular tests are the most sensitive method for the diagnosis of active HSV infections. Several commercial assays are FDA-cleared or approved for the qualitative detection of HSV-1 and HSV-2 in cutaneous and mucocutaneous lesions (Table 54.2). In addition to detecting viral nucleic acids, these molecular tests can differentiate between HSV-1 and HSV-2. The sensitivity and specificity of molecular tests range between 95% and 100% when compared with viral culture, and assays have laboratory TATs ranging from 20 minutes to <4 hours. This is markedly improved when compared against the laboratory TAT of viral cultures, which are on the order of days. Detection of HSV DNA alone, however, should be interpreted with caution, since asymptomatic shedding has been reported and its significance in transmission of HSV infection is not well understood [2].

Aside from the detection of HSV in lesions, molecular testing is the method of choice for the diagnosis of aseptic meningitis/encephalitis (M/E) caused by herpesviruses, via the detection of HSV-1/2 in cerebrospinal fluid (CSF) [12]. However, to date, only one real-time PCR assay, the Simplexa HSV 1 and 2 direct test (Focus Diagnostics, Inc.), is commercially available for detection of HSV in CSF. This test is a qualitative, real-time PCR assay that amplifies, detects, and differentiates between HSV-1 and

CMV, Cytomegalovirus; *CSF*, cerebrospinal fluid; *EA*, early antigen; *EBNA*, Epstein–Barr virus nuclear antigen.; *EBV*, Epstein–Barr virus; *HSV-1*, herpes simplex virus; *HSV-2*, herpes simplex virus 2; *IA*, immunoassay; *IVD*, in vitro diagnostics; *NAT*, nucleic acid amplification test; *VCA*, viral capsid antigen.

HSV-2 in CSF samples without nucleic acid extraction prior to amplification. The sensitivity and specificity of this approach, when compared against a laboratory-developed test (LDT) based on Roche analyte-specific reagents (ASRs), were 96.2% and 97.9%, respectively [13]. An FDA-cleared multiplexed molecular panel, The BioFire M/E panel, is commercially available for the rapid detection of common pathogens associated with infectious M/E, including HSV-1 and HSV-2. In one study, the percent agreement between the M/E panels for the detection of HSV-1 and HSV-2 compared against singleplex HSV-1 and HSV-2 were 82.6% and 96.0%, respectively [14].

Human cytomegalovirus

Human CMV, also known as human herpesvirus 5, is one of the most common infections worldwide, with an estimated age-adjusted seroprevalence of 50.4% in the United States. Infections caused by CMV range from subclinical or asymptomatic infections to severe diseases that may occur in neonates and immunosuppressed hosts, including solid-organ transplant (SOT) and hematopoietic stem cell transplant (HSCT) recipients.

Transmission of CMV occurs following exposure to body fluids from infected individuals. Upon primary infection, CMV viral particles enter host cells by binding to cell surface receptors via viral glycoproteins. Internalization of viral particles occurs either through fusion or endocytosis. Viral replication occurs in the host nucleus followed by virion assembly inside the Golgi apparatus prior to extracellular release and propagation. CMV has wide cell tropism, as such infections result in a variety of syndromes. Lifelong latency, where the virus does not replicate, is established primarily in myeloid cells (i.e., monocytes), and reactivation can occur at any time, particularly postimmune trauma (i.e., inflammation and immunosuppression).

The following modes of CMV transmission have been described: vertical transmission from mother to child (intrauterine or perinatally), horizontal transmission following close contact, such as in daycare centers or sexual contacts, and via blood transfusions or organ transplantations. Primary infection in healthy hosts is often asymptomatic, although, in some cases, patients may develop either a mononucleosis syndrome similar in presentation (fatigue and fever) to infections caused by the EBV. In rare instances, more serious complications, such as arthralgia, myalgia, and aseptic meningitis, have been observed [15].

CMV remains the most common congenital infection in the Western world. Current approaches to prevention of congenital CMV infections include passive immunization of seronegative mothers through administration of CMV hyperimmune globulin, thereby reducing potential exposure to infected individuals. Although most congenital infections are asymptomatic, approximately 10%–15% of neonates develop symptomatic congenital CMV as a result of primary infection in utero. Of these, 90% will develop sequelae, including cognitive deficits, as well as hearing and visual loss. The degree of severity of congenital CMV sequelae is highest if transmission occurs during the first trimester and less severe if acquired perinatally [15,16].

CMV disease, defined as the presence of detectable CMV DNA or antigen and clinical symptoms, is a significant cause of morbidity and mortality in both SOT and HSCT recipients [17]. Risk factors associated with the development of CMV disease in SOT include the CMV serostatus of both the donor (D) and the recipient (R), with the highest risk seen for the donor positive/recipient negative (D+/R−) pair, the type of organ transplanted and the type and degree of immunosuppression posttransplantation. Current management strategies for transplant patients include antiviral prophylaxis and preemptive therapy, both of which have resulted in decreased incidence of early (i.e., first 4 months posttransplant) CMV disease. However, late CMV infections still occur, with gastrointestinal disease being the most common presentation in most transplant groups [18].

Protection against CMV infection is mediated through T-cell immunity, particularly involving both CD8 and CD4 T-lymphocytes. Highly immunosuppressed, CMV seropositive HSCT recipients, including those receiving T-cell depleted or unrelated donor grafts, are particularly at high risk of developing CMV disease. In addition, both autologous and allogeneic HSCT treated with high-dose corticosteroids are at increased risk for CMV infection. The most serious CMV disease manifestation in HSCT recipients is CMV pneumonia, which has a significantly high mortality rate, even with current antiviral management approaches [19,20].

Laboratory testing

Several serologic assays are available for the diagnosis of CMV infections (Table 54.2). These assays provide indirect evidence of recent or past infections and are used primarily to establish serostatus. Diagnosis of acute CMV infection by serology requires the collection of paired serum samples with the first sample collected soon after symptoms appear, and a second sample collected 2–4 weeks following the primary infection. A fourfold increase in CMV IgG titers between the samples collected at these time points strongly suggests a recent or acute infection [21]. Alternatively, performance of single CMV IgM or CMV IgG plus IgG avidity testing can be used to diagnose an acute infection. In general, the utility of serological testing for acute infections is relatively low, especially in cases where a follow-up, convalescent serum sample (following resolution of symptoms) cannot be collected, or in posttransplant patients who may have delayed immune recovery. CMV serology has a high prognostic value and is useful in determining CMV status of expectant mothers and during pretransplant evaluations of donors and recipients to determine risk of transmitting virus to a child or acquiring posttransplant infections, respectively.

More direct methods to the diagnosis of acute CMV infection are based on the detection of CMV antigens or nucleic acids. Detection of CMV antigens in blood (antigenemia) is used for both diagnosis and monitoring of patients with CMV infections. The most common antigen measured is pp65, a 65-kDa phosphoprotein found in infected leukocytes and endothelial cells [22]. Detection of antigenemia requires collection of 5–10 mL of whole blood followed by isolation of leukocytes and fixation on glass slides. Monoclonal CMV antibodies are then added to form a complex with the pp65 antigens present in fixed leukocytes. A second antibody, conjugated to fluorescein isothiocyanate, binds to the antibody–antigen complex. Positive cells fluoresce green and can be observed and counted under a fluorescent microscope. Although the assay time is relatively short (~2 hours), and the assay does not require specialized laboratory equipment, except for a fluorescent microscope, antigenemia has several limitations: (1) leukocytes have to be isolated soon after collection for maximum sensitivity; (2) the assay is labor-intensive with several steps (including centrifugation and multiple wash steps) and long hands-on time; and (3) a minimum number of cells (e.g., 150,000–200,000 cells) have to be obtained for the test to be valid, which limits the utility of the assay in neutropenic patients. Furthermore, interpretation of the test is subjective, and there is no standardization across assays and laboratories. Various thresholds (e.g., number of pp65-positive cells/50,000 leukocytes) have been established by individual

centers to distinguish asymptomatic shedding from active infection, to initiate or discontinue antiviral therapy, and to predict the risk for acquiring CMV diseases [22]. However, thresholds are not standardized across transplant centers, and this method has been phased out in most clinical laboratories.

In most centers, CMV infections and CMV diseases are often diagnosed using molecular assays due to their rapid TATs, increased sensitivities, and objective interpretation of results. Because CMV infections do not always predict development of CMV disease, the increased sensitivity of molecular assays may also present a challenge when determining the significance of a positive result. The most common amplification method used for CMV detection is real-time PCR, including qualitative and quantitative molecular methods. Qualitative real-time PCR assays are primarily used for the detection of CMV DNA in various body fluids (e.g., CSF and bronchial washings) and tissues. All current assays are LDTs based on either commercially available ASRs or user-developed primers and probes [23]. The lower limit of detection (LOD) among molecular assays can vary as much as 10-fold, and such information should be considered carefully during assay selection and implementation. High sensitivity may be required for diagnosis of central nervous system infections, in which any positive result would be considered diagnostic of CMV M/E and requires immediate treatment, while a higher limit of detection may be acceptable for a respiratory specimen, where asymptomatic shedding is more common and additional clinical information would be required to diagnose CMV pneumonia.

Quantitative real-time PCR assays are an integral part of the clinical management of transplant patients. Early detection of CMV by quantitative real-time PCR often results in more frequent monitoring of viral loads. Once a preestablished viral threshold is reached (depending on patient population), appropriate antiviral therapy may be implemented to prevent development and progression of CMV disease. This approach, referred to as preemptive therapy, has been shown to result in less drug toxicity compared with a prophylaxis approach, where antiviral drugs are administered prior to detection of CMV reactivation.

Until recently, most quantitative real-time PCR assays used were LDTs, which showed a high degree of variability across centers and made standardization challenging. This variability is explained in part by differences in genes targeted for amplification, sample types used, nucleic acid extraction and amplification methodologies, and units used to express results. Recently, two developments occurred that resulted in improved standardization of CMV results: (1) the release of the first WHO CMV international standards; and (2) the approval by the FDA of several CMV quantitative molecular assays. All FDA-cleared assays have traceability to the first WHO International Standard for Human Cytomegalovirus. In one multicenter, international study, the Roche quantitative assay was shown to perform consistently well across laboratories when testing was performed on a standardized CMV panel. However, variability between each individual LDT and the Roche assay was observed when using a set of plasma samples from immunosuppressed patients [24]. Several studies have reported data on head-to-head comparisons of FDA-cleared molecular tests for CMV viral loads. In general, the assays correlate well (r value > 0.8), although differences were observed at the lower end of the linear range for assays with LOD (e.g., Abbott real-time CMV vs the Roche CAP/CTM assay) [25,26].

Epstein–Barr virus

EBV, also known as human herpesvirus 4, is transmitted through contact with contaminated oral secretions, blood products, or transplanted cells and/or organs. Similar to CMV, initial exposure to EBV occurs between early childhood and adolescence [27]. Lytic replication of EBV occurs in both B-lymphocytes and epithelial cells, followed by establishment of a latent viral state in B-lymphocytes. Two of the most recognized syndromes caused by EBV are infectious mononucleosis (IM) and posttransplant lymphoproliferative disorders (PTLDs). In immunocompetent hosts, primary infection with EBV either may be asymptomatic or result in IM. The illness is mild and characterized by nonspecific symptoms, such as fever, headache, sore throat, and fatigue; the most commonly characteristic clinical triad includes pharyngitis, fever, and cervical lymphadenopathy [27]. PTLDs result from either reactivation or primary infection with EBV in immunosuppressed hosts (e.g., SOT and HSCT recipients) following loss of T-cell functions [28]. Manifestations of PTLDs vary from benign to severe diseases related to the oncogenic properties of EBV, with EBV-associated lymphomas (e.g., Burkitt's lymphoma) and carcinomas (e.g., nasopharyngeal carcinoma) representing the severe end of the spectrum [28,29].

Laboratory testing

Heterophile antibodies.

Diagnosis of EBV infections by serology can be complex and is based on the detection of several immunoglobulins including both EBV nonspecific antibodies and EBV-specific antibodies [30]. Heterophile antibodies are produced in response to antigens produced during EBV IM (EBV heterophile antigens or Paul–Bunnell antigens) or as a result of serum sickness (type III hypersensitivity reaction caused by proteins present in certain medications)

or rheumatoid factors (non-EBV heterophile antigens or Forssman antigens). These molecules are nonspecific for EBV-derived antigens. Traditionally, detection of heterophile antibodies relied on their ability to bind and agglutinate erythrocytes of various animal species (sheep, goat, and horse). To increase assay specificity for EBV heterophile antibodies, serum samples were first incubated with guinea pig kidney cells to adsorb and remove any Forssman heterophilic antibodies present in the sample. Today, most agglutination tests (e.g., monospot test) use polystyrene latex beads coated with Paul–Bunnell antigens instead of animal erythrocytes. Precipitation of latex beads with a patient serum sample within 10 minutes suggests the presence of EBV heterophile antibodies. In rare instances, false-positive results may occur in patients with lymphoma or autoimmune diseases, and false-negative results may occur in pediatric patients.

Anti-EBV antibodies.

Detection of an antibody response to the following EBV viral antigens is used to diagnose various stages of EBV infections: the viral capsid antigen (VCA), early antigen (EA), and Epstein–Barr virus nuclear antigens (EBNAs) (Table 54.3). Antibodies (IgM and IgG) to the VCA appear first, often within 1–4 weeks of the primary infection. While VCA IgG remains detectable for life, VCA IgM levels decrease and disappear within the first 8 weeks; the loss of VCA IgM is followed by the appearance of VCA IgA. In about 5% of cases, VCA IgM may persist, resulting in aberrant serological profiles that require testing of additional markers for proper result interpretation (Table 54.3). Anti-EA IgG also appears early during the infection life cycle and may persist for several months. EBNA-1 IgG appears last and persists for several months to years. Acute EBV infections are characterized by the detection of VCA IgM with or without IgG, while past infection shows VCA IgG and EBNA-1 IgG only. However, EBV serology profile interpretation may be challenging and requires supplemental testing, including IgG avidity testing, which is used to evaluate the maturity of IgG, with recent infections characterized by low avidity (weak binding and immature IgG) and past infections characterized by high affinity (strong binding and mature IgG). Other useful supplemental testing includes heterophile antibodies and NAT [30].

NAT approaches are useful for the detection of EBV DNA in a wide range of specimen types and for monitoring of EBV reactivation in blood samples (whole blood, serum, plasma, or peripheral blood monocyte) of high-risk patients (including SOT and HSCT recipients) to prevent PTLD [31] (Table 54.2). Because EBV may reactivate without causing symptoms, quantitative NAT assays are most useful in distinguishing significant viral loads from background levels, although no standard threshold has yet been established. High viral loads are often detected in patients with PTLD, and changes in viral loads of >0.5 log copies/mL between consecutive samples are traditionally considered significant. However, to date, there are no FDA-cleared molecular EBV NAT assays. All molecular EBV assays are LDTs, which may result in increased variability across laboratories and do not allow for results to be easily compared across centers. Sources of variability in the use of LDTs include viral target (e.g., single copy vs multicopies target), sample types (whole blood vs plasma), nucleic acid extraction methods (manual vs automated), amplification platforms, calibrators and standards used, and reporting units (e.g., copies/mL vs copies/mg) [32]. To standardize the wide range of NAT methods available, the first WHO International Standards for EBV were developed in 2011 and became available for calibration of secondary reference materials to international unit (IU). In a recent study, the use of the EBV WHO standards to convert viral loads from copies/mL to IU/mL resulted in lower EBV values and reduced variability in viral load measurements [33]. These data are encouraging as laboratories continue to aim for standardization of EBV viral loads and establishment of universally clinically significant EBV viral load thresholds.

Hepatitis viruses

Hepatitis viruses are a diverse group of viruses that include both DNA and RNA viruses and are responsible for causing viral inflammation of the liver. These viruses

Hepatitis E	*Herpesviridae*	*Herpesvirus*	Linear, ssRNA	Fecal–oral	Yes

differ in their genome composition, structure, mode of transmission and associated syndromes, and their propensity for causing chronic infections. All hepatitis viruses can cause jaundice and elevations in serum alanine aminotransferase (ALT) or aspartate aminotransferase (AST) activity measurements. In general, acute hepatitis is clinically defined as an acute illness with discrete onset of symptoms (e.g., fever, headache, malaise, anorexia, nausea, vomiting, diarrhea, and abdominal pain) and jaundice, typically in the presence of elevated liver enzyme (AST and ALT) measurements. Laboratory testing is required to confirm viral hepatitis and correctly identify the responsible virus.

In addition to the five major hepatitis viruses (Table 54.4) discussed in this section, two other hepatitis viruses, hepatitis G virus and GB virus type C, have been described. Transmission of these two viruses may occur through blood transfusion or intravenous drug use. However, their prevalence and clinical significance are not well understood [34].

Hepatitis A

Hepatitis A virus (HAV) is a single-stranded RNA virus belonging to the *Picornaviridae* family along with other gastrointestinal viruses, such as enteroviruses. As a nonenveloped virus, HAV can survive in the environment for several months, requiring high temperatures ($>185°F$) and chlorine for inactivation. HAV is transmitted through ingestion of contaminated food or water and causes gastroenteritis symptoms, such as nausea and diarrhea. The incubation period of HAV is ~ 28 days, and symptoms resolve rapidly, usually within several weeks. Unlike other hepatitis viruses, there have not been any reports of HAV causing chronic infections [35]. Vaccination for HAV was introduced in the United States in 1996 and is recommended by the Advisory Committee on Immunization Practice as part of the routine childhood vaccination schedule, with most children receiving vaccination before the age of 2 years. In a 2007 report, the rate of HAV infections in the United States was reported at 1.0 case per 100,000 persons, a 92% decrease compared with the 1995 rate of 12.0 case per 100,000 population [36].

Laboratory testing

Symptoms caused by HAV are indistinguishable from infections caused by other hepatitis viruses. In addition to clinical symptoms described above, acute HAV infection requires laboratory testing derived primarily from the serologic detection of antibodies (IgM and IgG) to HAV capsid proteins. HAV IgM antibodies appear 5–10 days prior to the onset of symptoms, and become undetectable within 6 months of exposure. IgG antibodies appear 4–8 weeks after infection and remain present for the lifetime of the patient. Commercially available serologic assays are designed to detect total anti-HAV (IgG and IgM), and, if positive, a reflex test for anti-HAV IgM alone can be performed to diagnose acute infections. Although enzyme immunoassays (EIAs) for anti-HAV IgM are sensitive, false-positive results have been reported in various situations, including in patients with autoimmune diseases, in the presence of high titers of rheumatoid factor, and in patients with resolved HAV infections. These situations underscore the importance of testing for HAV in the appropriate clinical context [37].

Hepatitis B

Hepatitis B virus (HBV) is a small, circular, partially double-stranded DNA virus from the *Hepadnaviridae* family. The HBV virions exist as both infectious and noninfectious particles. The noninfectious particles are spherical or tubular-enveloped virions with embedded hepatitis B surface antigen (HBsAg), but no other viral

components. The infectious viral particles, known as Dane particles, are complete virions with HBsAg in the envelope, a viral genome, and both the HBV core antigen and the hepatitis e antigen contained within the virion [38]. Up to 10 HBV genotypes (genotypes A−J) and >30 subtypes have been described to date. HBV genotypes differ by >8% in their genome sequences, while subtypes differ by 4%−8%. HBV has a worldwide distribution with genotypes showing variability across geographic regions. In the United States, genotypes A, B, and C are the most prevalent with reported rates of 35%, 22%, and 31%, respectively [39].

HBV is the leading cause of viral hepatitis, with over 2 billion infected people worldwide and >350 million with chronic infections. In 2017, an estimated 22,100 cases of acute HBV occurred in the United States, a rate that has remained stable over the last several years due in part to successful immunization efforts and better surveillance. This is despite a slight increase in incidence, which has been associated with the recent opioid crisis [40,41]. Transmission of HBV occurs through direct contact with infected body fluids. In high prevalence regions (i.e., >8%), transmission of HBV most often occurs perinatally, from infected mothers to neonates during delivery. In low endemicity regions, transmission occurs primarily through percutaneous and sexual routes, or from close contact.

Symptoms of HBV infections are similar to those caused by other viral hepatitis agents, with malaise, fever, nausea, and possible jaundice being reported. While acute HBV infection is self-limited in most individuals, progression to chronic HBV does occur in a subset of infected patients. Risk factors for developing chronic HBV infections include host immune function and age when exposure occurs; up to 50% of children develop chronic HBV infection when exposed between the ages of 1 and 5. This number drops to ~10% if older children and adults become virally infected [42]. Chronic HBV infection proceeds in three distinct phases: an immune-tolerant phase, an immune-active phase, and an inactive carrier phase. The immune-tolerant phase occurs in infants who acquired the virus perinatally and is characterized by active HBV replication, but no disease or symptoms. The immune-active phase occurs when the HBV is acquired from person to person and is characterized by active disease with positive HBV serologies and liver inflammation. Patients may progress from the immune-tolerant phase to the immune-active phase over several decades. The inactive carrier phase is a resolution phase, where patients have recovered from acute infection and have no or little active disease (i.e., no liver abnormalities). Patients in the inactive carrier phase may reactivate the virus in cases of stress or immunosuppression. Complications of chronic HBV infections include liver cirrhosis and hepatocellular carcinomas (HCCs), which carry high morbidity and mortality rates [43].

Laboratory testing

Diagnosis of acute and chronic HBV infections is based on the detection of various serological markers as summarized in Table 54.5 [44]. The incubation period following exposure to HBV ranges from 6 weeks to 6 months. Several commercial assays are FDA-cleared and available for the detection of HBV antigens and antibodies. Most methods used are based on EIA and CLIA (Table 54.6). Laboratory testing via immunoassays is used for screening, diagnosis, and confirmation of HBV immunity.

Hepatitis B surface antigen and antibodies

Acute HBV infection is characterized by high titers of HBsAg, which appear within 3−4 weeks postexposure, peaks at ~12 weeks, and becomes undetectable after 4−6 months. Detection of HBsAg often requires confirmation, especially when the signal-to-cutoff threshold is low, to prevent the reporting of false-positive results.

Algorithms for samples requiring reflex to confirmatory testing is usually established by manufacturers and performed per package insert instructions. Confirmation is done via a neutralization assay, in which the positive patient serum sample is pretreated with or without high titers of anti-HBsAg. The resulting antigen−antibody

complex effectively neutralizes the HBsAg, if present. A decrease of at least 50% in the intensity of the signal between the neutralized and nonneutralized samples is considered confirmation of HBsAg presence. False-negative HBsAg results may occur due to genetic variants that result in structural changes in the "a" determinant, the major antigenic determinant of HBV, which is recognized by most of the commercial monoclonal antibodies. These HBsAg variants are designated "escape mutants" and may cause occult HBV infection, in which HBV DNA is detected in the liver with or without detectable HBV DNA in the serum in an HBsAg negative patient.

Detection of hepatitis B surface antibodies (anti-HBs) reflects recovery from acute HBV infection and provides immunity against reinfection. In cases of natural infection and recovery, both the anti-HBs and total hepatitis B core antibody (anti-HBc) are detectable. Detection of anti-HBs alone indicates immunity acquired through hepatitis B vaccination or through passive immunization with hepatitis B immune globulin, a prophylaxis treatment to prevent HBV infection in certain patient populations (e.g., infants exposed perinatally or immunosuppressed patients).

Hepatitis B e antigen and antibodies

Active replication of HBV virus is measured through detection of either the hepatitis B e antigen (HBeAg) or HBV DNA. HBeAg, a soluble protein contained in the core of HBV virions, becomes detectable within 4 weeks of exposure and disappears around 12 weeks postinfection. The presence of HBeAg in serum indicates a high degree of infectivity. Similar to HBsAg detection, serum samples positive for HBeAg must be confirmed through a neutralization assay. Mutations in the core and precore regions of the HBV genome can result in virus that does not produce HBeAg. HBeAg-negative patients with chronic HBV have a higher risk of clinical complications. HBeAg can also be used to monitor treatment response. Detection of the anti-HBeAg reflects a decrease in infectivity and recovery from acute infection.

Hepatitis B core antigen and antibodies

The core antigen of HBV is an intracellular antigen, present in hepatocytes but not detectable in serum. Shortly, after the appearance of HBsAg, anti-HBc IgM appears and remains detectable for up to 8 months; this is followed by the appearance of anti-HBsAg. In chronic HBV infections, both the HBsAg and the total anti-HBc molecule remain detectable over the course of months to years. Antibodies to the core antigens are measured as either IgM only or total anti-HBc. A negative total anti-HBc suggests no exposure to HBV, while a positive total anti-HBc may reflect acute, chronic, or resolved infections, depending on the presence of other markers of HBV infection.

Hepatitis B DNA

Molecular assays for HBV DNA are used for diagnosis, as well as to establish pretreatment viral load baseline, monitor treatment response, and viral genotyping [45]. FDA-approved molecular assays are available for the detection of HBV DNA virus (Table 54.7). Detection of HBV DNA is especially useful to diagnose acute HBV infection in cases of occult HBV infections and in cases of negative HBeAg due to precore or core mutants. Quantitative HBV DNA NAT assays have sensitivities ranging from 10 to 29 IU/mL, with upper limits of quantitation of $>10^7$ IU/mL. Patients with viral loads of at least 2000 IU/mL (if HBeAg is negative) or 20,000 IU/ml (if HBeAg is positive) and elevated liver enzymes qualify for antiviral treatment.

Treatment of chronic HBV infections requires long-term therapy, ranging from 6 months to 36 months. Current treatment options include the use of nucleoside (e.g., lamivudine and entecavir) and nucleotide (e.g., tenofovir) analogs with immune-modulating drugs (pegylated interferon) [46]. Given the extended duration of treatment, HBV strains can develop mutations associated with resistance and treatment failure. Although not routinely performed, genotyping assays are useful in predicting response to therapy (genotype B often responds better) and in predicting risk of progression to liver diseases. Direct sequencing of HBV may be used to detect the presence of mutations known to confer resistance to antiviral agents used for treatment of chronic HBV. There are currently no FDA-cleared methods for genotyping, although two assays targeting the polymerase gene of HBV genome are commercially available for use.

Hepatitis C

Hepatitis C virus (HCV) is a single-stranded, linear RNA virus belonging to the *Flaviviridae* family in the *Hepacivirus* genus. Other members of this family include arthropod viruses, such as West Nile virus and Dengue virus. HCV was discovered in 1989 and originally termed non-A, non-B hepatitis, as reagents against the known hepatitis viruses at the time were not reactive with this new entity. The HCV genome is ~9.6 kb and encodes 10 proteins, including six nonstructural (NS; e.g., NS2 and NS3) and four structural (a core protein, transmembrane protein, and two glycoproteins) proteins. Six HCV genotypes and >50 subtypes have been described to date. The genotypes have <60% sequence identity in the overall genome, while subtypes have >75%–85% identity in their core/E1 and NS5B sequences. The most common

genotype worldwide and in Western countries is HCV genotype 1. Genotype 2 is found in Mediterranean countries and the Far East, genotype 3 in Europe, genotype 4 in the Middle East, genotype 5 in South Africa, and genotype 6 in Asia. HCV genotype information is an essential part of treatment strategies, especially with the newly available antiviral drugs [47].

HCV is a blood-borne pathogen, transmitted primarily by contact with infected blood, tissues, organs, and needles. Infection may also be transmitted through sexual intercourse and perinatally during child delivery. Acute HCV hepatitis may be asymptomatic or may produce nonspecific symptoms, such as malaise, nausea, dark urine, and jaundice. The incubation period varies between 0 and 6 months, and infection may resolve without any treatment. Chronic HCV infection develops in 50%−85% of acute hepatitis cases, and, without management, can lead to hepatic fibrosis, cirrhosis, end-stage liver diseases, and HCC. An estimated 170 million individuals are chronically infected with HCV worldwide with 3.2 million living with the disease in the United States. HCV is the most common reason for liver transplantation and the most common cause of death from liver disease [48].

Laboratory testing

Laboratory methods for the diagnosis of HCV infections include serology to detect total HCV antibodies and

molecular methods to detect HCV RNA [49]. Detection of HCV antibodies is useful for both screening and diagnosis, but serology does not distinguish between acute, chronic, or resolved infections. Current immunoassays represent the third generation for anti-HCV antibodies detection, and many are based on the detection of three-to-four recombinant HCV NS proteins, which increases the specificity of the assay over previous generations that used viral lysates to capture antibodies. One lateral flow immunoassay (OraQuick HCV, OraSure Technologies, Inc.) is available for point-of-care testing and is CLIA waived for testing on finger stick or venipuncture whole blood with a rapid TAT. The sensitivity and specificity of this rapid test are comparable to those of EIA assays. Screening immunoassays have high sensitivity and specificity. However, in low prevalence populations, specificity may only be moderate and, as such, confirmation of positive results is required (Fig. 54.1). Confirmation is done using an HCV RNA NAT assay (Table 54.7).

In addition to their utility for confirmation, NAT assays are used for monitoring treatment response (quantitative HCV NAT) and as prognostic assays to predict response to treatment (genotyping assays). Quantitative HCV NAT platforms target the NS regions of HCV and have linear ranges between 12 and 10^9 IU/mL. The lower limit of quantification is an important feature of these NATs, as definition of cure or sustained virologic response relies on a laboratory report of "undetectable" HCV RNA at the end of treatment and 6 months after the end of treatment. Current recommendation is that an appropriate HCV quantitative assay should have an LLOQ of at least 25 IU/mL with an LOD of 15 IU/mL [50]. Genotyping assays, which target the 5′ UTR of the HCV genome, are important to predict response to treatment as well as in therapy tailoring and for the determination of testing intervals. In addition to genotyping assays, HCV drug-resistance tests based on sequencing of the NS proteins NS3 and NS4A are important to optimize HCV therapy. Mutations or polymorphisms that confer resistance to direct-acting antivirals (DAAs) may be identified in treatment-naïve patients, in which case these mutations are referred to as baseline resistance-associated substitutions (RASs), or in patients treated with DAAs, which are referred to as treatment-emergent (or treatment-selected) RASs [51]. A combination of HCV genotype information and the presence or absence of specific RASs and other host factors (e.g., treatment-naïve patients or patients with cirrhosis) dictates the regimen of DAAs that will be used for each patient. For example, the treatment regimen for a treatment naïve genotype 1a patient without cirrhosis includes four recommended options (varying in length from 8 to 12 weeks) with four alternative DAA combinations (varying in duration from 12 to 16 weeks) [51]. The complexity of HCV treatment regimens underscores the importance of molecular tests in the management of HCV infections.

Previous CDC HCV screening recommendations to prevent HCV transmission were focused on screening of blood/organs donors and high-risk populations (i.e., injection drug users). In 2012 and 2013, the CDC released HCV screening guidelines that recommended a one-time testing, regardless of risk, for persons born between 1945 and 1965 presenting at a healthcare facility. This recommendation stemmed from surveillance data showing high

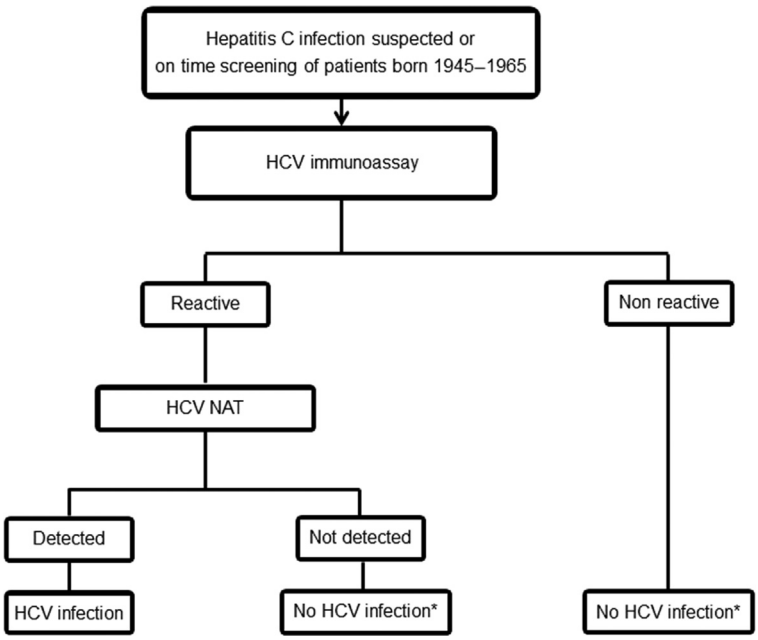

FIGURE 54.1 CDC recommended hepatitis C testing algorithm. *Additional testing should be done as appropriate.

prevalence of HCV in that age group, five times that of other adults' age groups. Increased testing should result in earlier identification of infected individuals at increased risk for complications of chronic HCV infections [48].

Hepatitis D

Hepatitis D virus (HDV) is an incomplete, single-stranded, circular RNA virus that requires the presence of HBV virus to replicate [52]. It is the only member of the *Delatviridae* family. Transmission of HDV occurs percutaneously or from contact with infected mucosal surfaces. The virus may be transmitted concomitantly with HBV virus (coinfection) or in patients with chronic HBV infection (superinfection). HDV may cause acute infections, which can be either asymptomatic or present with classic symptoms of hepatitis. Acute HDV infection is diagnosed based on symptoms and detection of HDV RNA (by reverse transcriptase PCR) or HDV antigen or anti-HDV IgM (by EIA/ELISA). In chronic HDV, total anti-HDV may be detected for several years along with HDV RNA or HDV antigen. Testing for HDV is not routinely performed in clinical laboratories and is often referred to specialized laboratories.

Hepatitis E

Hepatitis E virus (HEV) is a single-stranded RNA virus belonging to the *Herpesviridae* family. Four genotypes (HEV 1−4) have been identified, with HEV-1 and 2 prevalent in developing countries and HEV-3 and 4 more commonly found in developed countries. Like HAV, HEV is a nonenveloped virus, and, although it can survive in the environment for several months, it is more susceptible to heat and disinfectants than HAV. HEV is transmitted through the fecal−oral route, and the clinical presentation ranges from subclinical, asymptomatic infection to severe, fulminant hepatitis. Unlike HAV, HEV chronic infections have been reported, mostly in immunocompromised patients, such as SOT recipients. HEV has worldwide distribution, but it is highly endemic (i.e., >25% seroprevalence) in several countries in Africa, the Middle East, South-East Asia, and Central America [53].

Laboratory testing

In regions of low endemicity, like the United States, HEV should be considered only if travel history to a region of high endemicity is recorded or no other viral causes of hepatitis have been identified. The incubation period for HEV ranges from 3 to 8 weeks with anti-HEV IgM detectable within the first 4 weeks and falling to undetectable levels between 6 and 12 months. Anti-HEV IgG starts appearing a few days after the anti-HEV IgM, and, unlike anti-HAV IgG, they may become undetectable between 1 and 5 years following primary exposure.

There are no FDA-approved assays for the detection of HEV antibodies or HEV RNA. Acute HEV infection is diagnosed based on detection of anti-HEV IgM only or the detection of HEV RNA in serum and stool samples, which are detectable early after exposure and becomes undetectable approximately 3 and 5 weeks, respectively, after onset of symptoms. Detection of anti-HEV IgG alone reflects past infection. Commercial assays are available to detect HEV antibodies in serum samples (EIA/ELISA, rapid immunochromatographic, and point-of-care tests) and HEV RNA in serum and stool samples (reverse-transcriptase PCR). Although most of these assays target open reading frames 2 and 3 of the HEV, the use of different antigen preparations (recombinant vs synthetic antigens) has resulted in increased variability in the performance characteristics of serological HEV assays. In one recent study comparing five commercial assays, sensitivity of anti-HEV IgM and IgG ranged from 24% to 72% and 42% to 96%, respectively, with specificity of >96% for both IgM and IgG. HEV RNA was detected in several patients who were negative by serology, which prompted the authors of the study to recommend the use of HEV RNA assay to supplement diagnosis of acute HEV hepatitis [54].

Human immunodeficiency virus

Human immunodeficiency virus (HIV) is an enveloped, positive-sense, single-stranded RNA virus from the *Retroviridae* family, in the *Lentivirus* genus. The HIV genome is segmented, 9.7-kb long, with 9−10 genes coding several proteins including structural proteins: capsid protein (p24) encoded by the *gag* core gene; viral enzymes: protease (p12), reverse transcriptase (p66/p51), and integrase encoded by the *pol* gene; envelope proteins (gp 120 and gp 41) encoded by the *env* gene; and several regulatory proteins. Two species of HIV have been identified. HIV-1 is the most common virus worldwide and is divided into four groups (M, N, O, and P), several subtypes (A−K), and multiple circulating recombinant forms (CRFs). HIV-1 subtype B is the most common species found in North America and Europe. HIV-2 is found primarily in West Africa and is divided into two major groups (A and B) and a few subtypes and CRFs [55].

Transmission of HIV occurs through sexual contact, percutaneously, through blood transfusions with pathogen-containing blood, organ transplantation, or perinatally during vaginal delivery. Transmission through transfusion or organ transplantation occurs less frequently due to stringent screening of donors. Similarly, transmission from mother to newborn infant is less common in developed countries where women have better access to prenatal care and better

management of infants born to seropositive mothers, including prophylaxis or empiric HIV therapy (e.g., zidovudine, lamivudine, or nevirapine for high-risk transmission or zidovudine for low-risk transmission) [56]. Following infection, HIV binds primarily to CD4 T-lymphocytes present on the mucosal surface. Binding occurs between HIV viral envelope glycoproteins (e.g., gp 120) and the CXCR4 receptors or CCR5 chemokine receptors found on CD4 T-lymphocytes or macrophages, respectively. As is characteristic for retroviruses, the RNA genome is first converted by the viral reverse-transcriptase enzyme to a complementary DNA copy, which becomes integrated in the host cell genome, forming the HIV provirus. Furthermore, viral replication occurs using both host and viral replication enzymes, forming new virions that are propagated to other cells [57].

There are three clinical stages of HIV infection (Fig. 54.2). The first stage, acute or primary HIV, is characterized by flu-like symptoms of malaise and fever. This stage is highly infectious and lasts several weeks following viral acquisition. Recovery from acute HIV is followed by establishment of the infection, which is associated with mild or no symptoms. This stage can last for several years and, if not treated, can proceed to the third and last stage, acquired immunodeficiency syndrome (AIDS), where the CD4 T-cell count is low (<200 cells/mm^3) and opportunistic infections (e.g., pneumocystis) are common. Globally, the number of people living with HIV was reported at 36.9 million in 2017 with 1.8 million new infections and 940,000 AIDS-related deaths; many HIV-positive individuals are coinfected with HBV, HCV, or tuberculosis [58]. In the United States, approximately 40,000 cases of new HIV infections occurred in 2016, a decline of 5% from 2011 to 2015 [59]. Cases of AIDS have decreased steadily since the AIDS epidemic of the late 1980s, due in part to a combination of increased access to care, improved diagnostic tests, and efficacious combinatorial antiretroviral treatment (ART) regimens.

Laboratory testing

Diagnostically, the period of time immediately following infection is termed the eclipse period, since no diagnostic markers (antigens, RNA, or antibodies) can be detected during that time [60]. In weeks 1–4 after infection, HIV RNA concentrations increase drastically with levels reaching several millions copies per milliliter of plasma, a concentration that remains high for several months, and decreases to steady level for the duration of the asymptomatic phase of infection. Retrospective studies have shown that, in untreated hosts, the asymptomatic, chronic phase of HIV infection can last approximately 10 years, with some hosts (elite controllers) remaining asymptomatic for >20 years. This state is due in part to factors

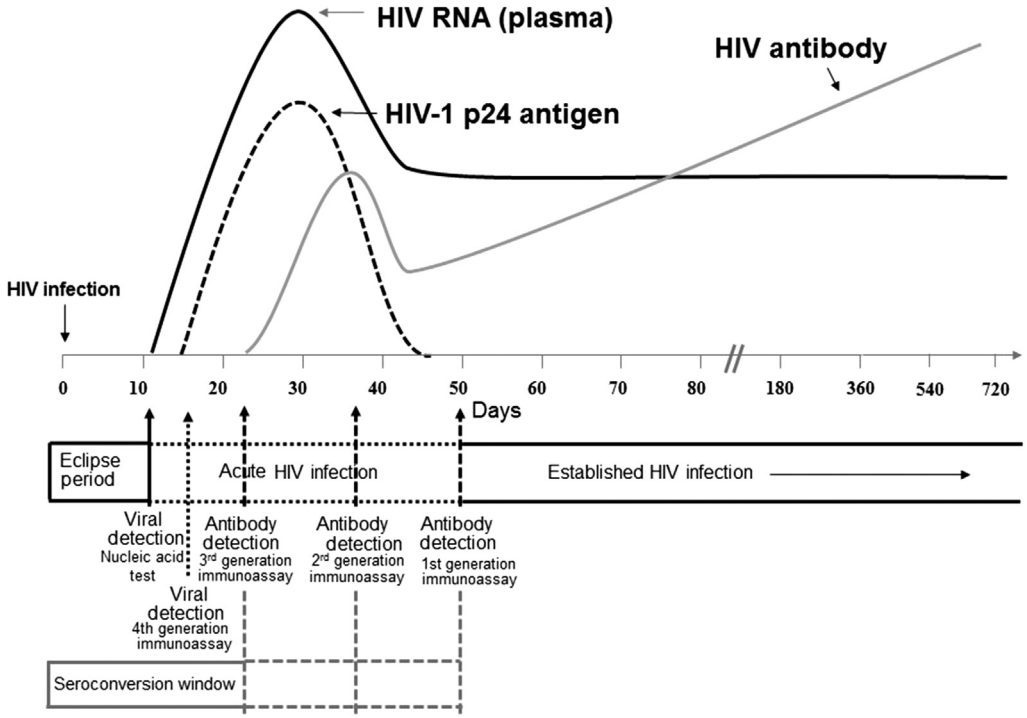

FIGURE 54.2 Stages of human immunodeficiency virus infections and corresponding markers. *Reproduced from the Centers for Disease Control and Prevention and Association of Public Health Laboratories, Laboratory testing for the diagnosis of HIV infection: updated recommendations. <http://stacks.cdc.gov/view/cdc/23447> (Published June 27, 2014; accessed 21.10.19).*

related to the virus itself (e.g., mutations) but is primarily a result of a balance between the host immune functions (e.g., T-cell diversity and mucosal tissues) and viral replication [61]. The p24 antigen will peak after 4 weeks and become undetectable by the end of the acute stage postviral acquisition. HIV antibodies start rising approximately a month after primary infection and steadily increase during the acute and asymptomatic phases, reaching peak levels during AIDS (Fig. 54.2).

Diagnosis of HIV infections and AIDS has improved significantly from the original tests, with improved sensitivity for both serological and NAT assays. Immunoassays are used for screening and diagnosis of HIV infections and can provide information of acute versus established infection. Traditionally, HIV immunoassays have been described in terms of assay generation, but current efforts aim at changing the nomenclature to focus on the target analytes being tested (e.g., IgG sensitive tests and p24 sensitive tests) [62]. The first-generation HIV immunoassays were designed using viral culture cell lysates and could only detect HIV-1 IgG antibodies (IgG sensitive tests). Those assays were eventually replaced with the second-generation assays that detected antibodies to both HIV-1 and HIV-2, but still, only IgG antibodies. The third-generation assays, which are still in use, provided the added advantage of detecting both IgM and IgG antibodies (IgM/IgG sensitive tests) to HIV-1 and HIV-2. These assays have improved specificity compared with the second-generation assays based on their use of synthetic or recombinant antigens. The fourth-generation immunoassays (p24/IgM/IgG sensitive assays) are designed to detect both the p24 antigen and the HIV-1/2 IgM and IgG antibodies. These assays utilize a combination of synthetic or recombinant antigens and monoclonal antibodies and allow for diagnosis of acute HIV to be shortened by up to 5 days (via p24 antigen detection), resulting in detection as early as 3 weeks postinfection (Fig. 54.2). Given that HIV viral loads are highest during the acute HIV phase, rapid and sensitive methods that identify infected individuals are key to limit transmission of the virus. An FDA-cleared fifth-generation HIV immunoassay is also available and differs from the fourth-generation assays in that it can detect and differentiate between the p24 antigen, the HIV-1 antibodies, and the HIV-2 antibodies in patient samples. A summary of the most common HIV immunoassays and their methodologies (EIA or CLIA) is listed in Table 54.6.

A few rapid HIV tests, including one fourth-generation test, are available as FDA-waived point-of-care tests. These rapid tests are based on lateral flow immunoassays or immunochromatographic methods. One test, the Geenius HIV Ag/Ab test (Bio-Rad), has replaced the HIV Western blot (WB), a first-generation test, as the recommended supplemental test following a reactive screen to differentiate between nonacute HIV-1 and HIV-2 infections (Fig. 54.3). Several studies have shown that rapid HIV tests have significantly higher accuracy and sensitivity than WB and detect seroconversion 7–15 days

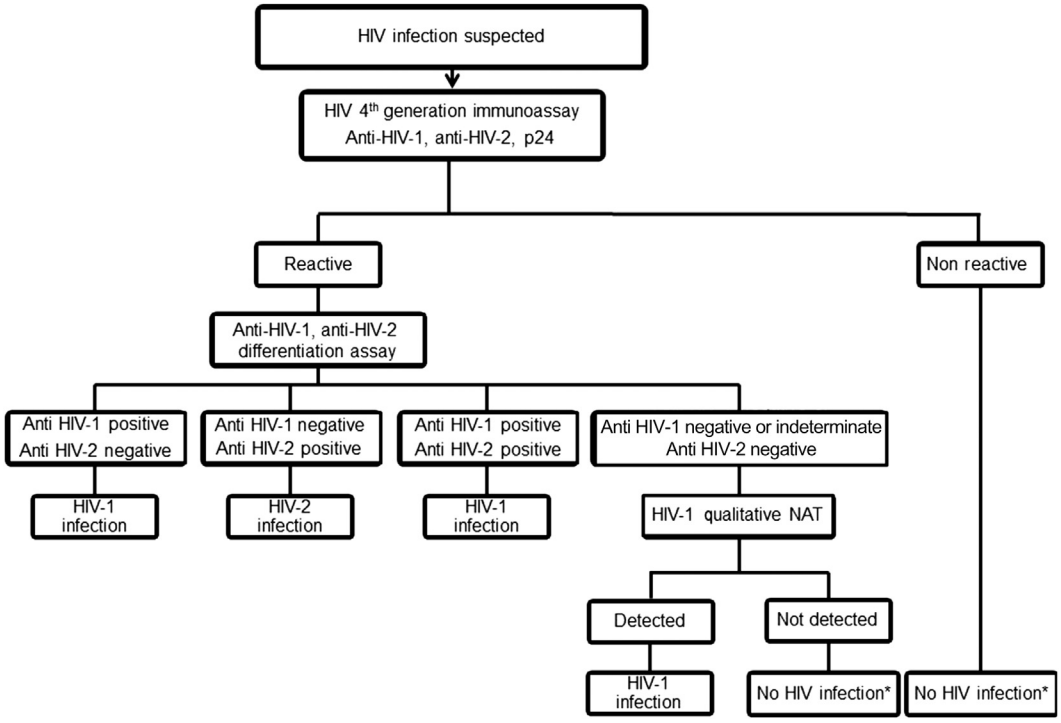

FIGURE 54.3 CDC and Association of Public Health Laboratories recommended testing algorithm for HIV infection. *Additional testing should be done as appropriate. *Available at <http://stacks.cdc.gov/view/cdc/50872> (Updated January 2018; accessed 21.10.2019).*

earlier than WB. However, current recommendations for the use of rapid, fourth-generation HIV tests vary depending on where testing is performed. While instrumented, the fourth-generation HIV tests are the preferred screening tests; if performed in a clinical laboratory, the point-of-care-based rapid fourth-generation HIV test may be used as the first step of the algorithm. However, if the rapid test is performed in a CLIA-waived setting and the result is positive, confirmation should be performed in a laboratory, starting with screening using an instrumented, fourth-generation HIV test [60,63,64].

HIV NAT assays serve multiple roles, including the following: (1) diagnosis of acute HIV infections (qualitative NAT); (2) monitoring of antiviral treatment response (quantitative NAT); and (3) detection of antiviral resistance (genotyping assays) [65]. Only one qualitative NAT assay, the Aptima HIV-1 RNA, is FDA-cleared for use in HIV diagnosis and as a supplemental assay to confirm a reactive fourth-generation antigen/antibody screen result. HIV-1 RNA has improved sensitivity when compared with WB for confirming HIV-1 acute infections, and decreases the eclipse period. HIV viral monitoring is used to establish a baseline HIV viral load and monitor successful response to ART. Several FDA-cleared quantitative HIV NAT assays are commercially available and all target HIV-1 viral loads. Such assays are generally optimized for group M subtypes (Table 54.7). Virologic blip (isolated detectable HIV RNA level that is followed by a return to virologic suppression) and low-level viremia (detectable HIV RNA of $<$200 copies/mL) may be early indicators of virologic failure (the inability to achieve or maintain suppression of viral replication to an HIV RNA level of $<$200 copies/mL) [66]. The LOD and the lower limit of quantification of these assays have continued to decrease, and most are as sensitive as the qualitative HIV-1 RNA tests, with values ranging from 20 to 175 copies/mL (Table 54.7). NAT assays are also useful for diagnosis of neonates and infants born to HIV-1 positive mothers. Molecular testing, either for proviral HIV DNA or for HIV RNA, is the recommended diagnostic approach for infants born of seropositive mothers, and current guidelines recommend testing at birth (for high-risk cases) or at 14–21 days, 1–2 months, and 4–6 months to confirm infection.

HIV-1 drug resistance testing is conducted more commonly using genotyping assays, although phenotypic assays are still available. Molecular tests have a faster TAT (days instead of weeks) and are technically easier to perform than phenotypic assays, which require growth of the virus in cell culture. Genotyping assays analyze protease and RT gene sequences to identify mutations known to confer resistance to the main classes of antiretroviral drugs (protease inhibitors, nucleoside reverse-transcriptase inhibitors, and nonnucleoside reverse transcriptase inhibitors). The assays generally include three steps: nucleic acid extraction, reverse-transcription PCR, and cycle sequencing of amplicons generated by PCR. Due to the heterogeneity of the HIV genome, most genotyping assays include several sets of sequencing primers for complete coverage of the protease and RT genomic sequences. Analysis of sequenced viruses is usually performed automatically by instrument software, and a report is generated that includes a list of mutations identified and corresponding drug resistance patterns. Genotyping assays are performed at baseline, prior to initiation of ART, and to guide alternative ART selection in cases of therapeutic failure. These assays are often performed in reference laboratories and often require a minimum viral load (e.g., 500 copies/mL) for analysis. Newer methodologies, including whole-genome sequencing, have increased sensitivity for detection of small populations of HIV-1 variants and may eventually circumvent the need for a minimum viral load [67].

HIV testing guidelines have changed drastically since the first CDC recommendations were published in 1989. The most current guidelines from the CDC and the Association of Public Health Laboratories recommend that initial testing for HIV diagnosis be performed using a laboratory-based fourth-generation immunoassay. A reactive screen should be followed by testing with a manual second-generation antibody test (Bio-Rad Geenius) to differentiate between HIV-1 and HIV-2. If the antibody test is negative for both HIV-1 and HIV-2, additional testing using an HIV-1 NAT should be performed (Fig. 54.3).

In addition to tests that target the HIV virus or antibody response, measurement of CD4T lymphocytes levels is an integral part of diagnosis and monitoring of HIV-infected patients. CD4 counts reflect the patient's immune recovery and should be measured in all patients at entry into care and at various intervals (every 3–6 months) during care depending on response to ART. In general, more frequent testing is recommended if CD4 counts are $<$200 cells/mL, and testing is optional if CD4 counts are $>$500 cells/mL and the patients is virologically suppressed (i.e., viral load is undetectable).

Conclusion

Herpesviruses and blood-borne viruses, including hepatitis and HIV viruses, have a significant impact on human health, causing a range of clinical syndromes from self-limited infections to chronic diseases. Screening, diagnosis, and monitoring of these infections rely heavily on both serological and molecular methods. As the performance characteristics of these methods continues to improve and novel treatments become available, laboratories will continue to be tasked to remain up to date on best methods and algorithms for rapid and accurate diagnosis and management of patients infected with these viruses.

Self-assessment questions

1. Which of the following properties is common to all herpesviruses?
   a. Responsible for causing cold sores
   b. Establish latency in specific cell types
   c. Diagnosed with high sensitivity using immunoassay
   d. Viral genome is a single-stranded RNA genome
   e. Viral genome is a single-stranded DNA genome
2. Which of the following assays has the highest sensitivity for diagnosis of HSV meningitis?
   a. IgM and IgG antibodies immunoassays on serum
   b. IgM and IgG antibodies immunoassays on CSF
   c. IgM immunoassays on CSF
   d. PCR assay on CSF
   e. PCR assay on serum
3. Which of the following markers is detectable in patients with a past EBV infection?
   a. VCA IgM
   b. VCA IgG
   c. VCA IgA
   d. EBNA-1 IgG
   e. EA IgG
4. Which of the following is a limitation of CMV antigenemia?
   a. High sensitivity in neutropenic patients
   b. Labor-intensive test
   c. Long turnaround time
   d. Low specificity
   e. High cost
5. Which of the following hepatitis viruses is transmitted through the fecal−oral route?
   a. HCV
   b. HBV
   c. HDV
   d. HEV
   e. HGV
6. Which of the following markers is detectable in an HBV vaccinated person?
   a. HBs antigen
   b. HBs antibodies
   c. Total HBc antibodies
   d. HBc IgM
   e. HBe antibodies
7. Which of the following tests is recommended for initial screening of HIV infection?
   a. HIV-1/2 fourth-generation immunoassay
   b. HIV-1/2 third-generation immunoassay
   c. HIV-1/2, p24 fourth-generation immunoassay
   d. HIV-1 PCR
   e. HIV-1/2 lateral flow immunoassay

Learning objectives

After reviewing this chapter, the reader will be able to:

- List key considerations for specimen collection for microbiology testing.
- Discuss the advantages and limitations of automation in the clinical microbiology laboratory.
- Describe the evolution of microorganism identification methods.
- Discuss the benefits and limitations of molecular microbiology point-of-care testing.
- Summarize currently available multiplex molecular microbiology testing options.

Specimen collection

Specimen collection in clinical microbiology is of utmost importance. The quality of the specimen determines the quality of the results. Proper specimen collection consists of (1) proper collection of the source; (2) proper container selection; and (3) proper transport conditions. Microbiology laboratory staff consists of technicians and technologists who are thoroughly trained on the appropriate processing and testing methodologies; however, even the most skilled microbiologists and the best laboratory practices cannot make up for a poor specimen. Although improperly collected specimens lead to unreliable results, they are received in the microbiology laboratory every day. Thus it is the job of the laboratory to convey information about proper collection techniques and containers to clinicians.

To communicate and highlight the importance of obtaining appropriate specimens for microbiological testing, the Infectious Diseases Society of America and the American Society for Microbiology (ASM) published a guidance document on utilization of the microbiology laboratory, which contains information on optimal test selection, optimal specimen collection approaches, and transport concerns [1]. In addition, the Guide to Specimen Management in Clinical Microbiology, now in its third edition, is available from ASM Press [2]. Both documents are critical resources for additional information regarding management of specimens in microbiology laboratories.

In general, aspirates, fluids, and tissue specimens are preferred over swabs for all microbiology culture testing due to their higher diagnostic yield. However, it is not always possible to obtain an aspirate, fluid, or tissue, so swabs are commonly accepted. Disinfection of the site (if applicable) must be carefully considered during specimen collection. For example, it is imperative to disinfect the skin prior to collection of blood cultures. Otherwise, skin flora may result in a false-positive culture, which can lead to an increase of $2923 to $5812 in hospital costs as well as exposure to unnecessary antimicrobials and increased length of stay [3]. Collection from the appropriate source is also an important consideration. If a nasopharyngeal (NP) swab is the preferred source for a test, it is important to collect a true NP swab, which is not an enjoyable experience for the patient, rather than a nasal swab. For example, *Bordetella pertussis* and many respiratory viruses are primarily found in the nasopharynx, so a properly collected NP swab is essential for detection and diagnosis. A swab of the nares or a mid-turbinate region may cause a false-negative result. Blood cultures and NP swabs are only such two examples to highlight the importance of appropriate source collection.

In comparison with the core laboratory, the microbiology laboratory receives a much wider variety of transport containers, which may include Tupperware containers, Ziploc bags, Mountain Dew bottles, etc. (all of which have been received in a clinical microbiology laboratory). Specimens received in such nonsterile containers are rejected, but the variety of acceptable sterile transport devices can still be overwhelming and collection containers are not standardized between the laboratories due to the extensive number of transport device manufacturers

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00055-7

and variations in devices among manufacturers. One laboratory may use one set of collection devices, while other laboratories have their own sets. A standalone hospital microbiology lab may receive as few as 10−20 different types of containers, consisting of various sterile cups and tubes, preservative tubes, capped syringes, swabs, etc., while the number of collection devices received at the centralized and reference laboratories may be much larger. The variability in specimen collection containers was a major barrier to implementation of total laboratory automation (TLA) for clinical microbiology workflows.

Specimens for anaerobic culture should be submitted under conditions that allow recovery of anaerobes. For example, anaerobic transport containers that contain a semisolid reducing gel may be used for specimens submitted for anaerobic culture. In addition, capped syringes with excess air removed may be used. Dry swabs are not appropriate for anaerobic culture. Anaerobic culture testing should never be performed without an accompanying aerobic culture, unless selective culture for *Clostridioides difficile* is requested; however, this is uncommon. Specimens acceptable for anaerobic culture include aspirates, tissues, and deep wounds. Superficial wounds and other sites with normal anaerobic flora are not acceptable for anaerobic culture.

One of the major shifts in clinical microbiology was the development of the flocked swab in transport media. Historically, tightly wound cotton, rayon, and dacron swabs predominated, with some placed into a liquid or gel transport media while others were not. Traditional swabs performed poorly, because the vast majority of the organisms in the specimen remained trapped in the swab and were not released when the swabs were used to inoculate solid media (Petri dishes). Another drawback of traditional swabs is that if multiple plates need to be inoculated, the majority of the bacteria that are released were released onto the first plate, resulting in inconsistent inoculation across culture media. Compared with traditional swabs, flocked swabs contain fibers that radiate outward from the shaft, which allow for increased release of organisms from the swab. Once the specimen is collected, flocked swabs are placed into transport tubes, which contain liquid transport media. While dry swabs cannot be used for anaerobic culture due to anaerobes drying out and dying, the addition of transport media allows the swabs to be used for anaerobic culture in addition to aerobic culture. The transport media also permits a longer transit time to the lab due to improved specimen stability (24−48 hours). In addition, this setup allows for the release of organisms into the transport media, which can be used for the inoculation of plates rather than inoculating with a swab, allowing for consistent inoculation across culture media. Not only did the development of the flocked swab improve the quality of cultures, it also helped pave the way for automation in microbiology, because it is easier to automate the transfer of transport media to inoculate plates as compared with using a dry swab for plate inoculation. Commercially available flocked swab options include the Copan ESwab and Puritan PurFlock Ultra and HydraFlock swabs.

For urine testing in the microbiology laboratory, urine preservative tubes have become more common and can preserve organisms for up to 24−48 hours during transport. Preservative tubes are more standardized than sterile cups, which are different sizes and have different lid-threading properties. Transport media have been developed for stool, facilitating downstream automation and molecular testing of stool specimens. The shift toward transport media has allowed for improved culture results and support of automation. Although specimen containers have become more amenable to automation, there will always be containers that are not accommodated on automated instrumentation. For additional information, refer to the following section on laboratory automation.

After collection, the specimen should be transported to the laboratory in a timely manner. For off-site laboratories, specimens should be transported to maintain specimen integrity and quality. Excessive transport times may negatively affect results due to either the death of fastidious organisms or overgrowth of nonfastidious organisms. Generally, it is recommended that specimens are received in the laboratory within 1−2 hours after collection unless specimens are in a transport or preservative media, which permits longer transit times. Alternatively, some specimen sources, but not all (e.g., cerebrospinal fluid), can be refrigerated to preserve their quality. Transport time is also important, because the sooner the specimen arrives in the lab, the sooner the culture is inoculated and placed into an incubator. Delays in transport lead to delays in culture results.

Once specimens are received in the laboratory, they are processed in a biosafety cabinet to prevent staff exposure to infectious aerosols, which may be generated during specimen processing, and to prevent contamination from the environment. Only one specimen is processed at a time in order to prevent cross-contamination. This is important to ensure the quality of reported results, both for traditional microbiology and for molecular microbiology. Specimens processed in other areas of the laboratory outside of a biosafety cabinet should not be used for microbiology culture or molecular microbiology testing due to the possibility of false-positive results due to cross-contamination. Shared specimens should be processed initially in the microbiology laboratory prior to other testing (such as Core laboratory testing) or a separate specimen should be obtained.

A Gram stain is performed on the majority of specimens, with the exception of urines, stool, screening

cultures [e.g., Group B *Streptococcus* and methicillin-resistant *Staphylococcus* (MRSA), etc.], and strep throat swabs. A Gram stain can be performed on direct specimens, such as respiratory specimens, fluids, and tissues and on swabs, such as wound swabs. However, Gram stains performed on specimens collected on swabs produce inferior results compared with those performed on direct specimens. The Gram stain provides the clinician with an early result while culture results are pending. In addition to the evaluation of bacteria, Gram stains are analyzed for the presence of white blood cells (WBCs) and squamous epithelial cells (SECs). The presence or absence of WBCs and SECs determines the quality of the specimen. The Gram stain plays a significant role in determining workup for respiratory and wound cultures. As an example, lower respiratory specimens with ≥ 25 SECs per low power field should be rejected and not cultured. The presence of SECs indicates that the specimen is from the oropharynx rather than the lower respiratory tract.

Rejection criteria are essential, and each microbiology laboratory should have a procedure that addresses specimen rejection in order to avoid providing inaccurate results. Examples of rejection criteria that are commonly used are:

- Specimens submitted in nonapproved containers should be rejected.
- Leaking specimens should be rejected.
- Anaerobic culture, if requested, should not be performed if the specimen is not submitted under anaerobic conditions.
- Specimens with excessive transport times (defined by the laboratory, will depend on source) should be rejected.
- Respiratory specimens with ≥ 25 SECs per low power field on Gram stain should be rejected.

Laboratory automation in clinical microbiology

Several components in the clinical microbiology laboratory have been automated during the last few decades. Automation advances include automated blood culture instruments, automated antimicrobial susceptibility testing platforms, automated nucleic acid extraction, and others. Although components of the laboratory were automated, the primary role of the microbiology laboratory—specimen inoculation and culture automation—was not automated until recently due to a number of factors. The wide variety of specimens and specimen collection devices was a key factor as to why the development of TLA in microbiology took so long to become a reality. In addition to the variety of containers, specimens are processed in a variety of manners based on the specimen source and the test ordered. Specimens may be vortexed, centrifuged, minced, or ground. Moreover, once inoculated, plates are incubated in different temperatures under various atmospheric conditions. For decades, it seemed impossible to automate microbiology due to these aforementioned challenges. However, there was increasing need and demand for automation due to a nationwide shortage of medical technologists and due to the consolidation of microbiology

FIGURE 55.1 Components of total laboratory automation in clinical microbiology.

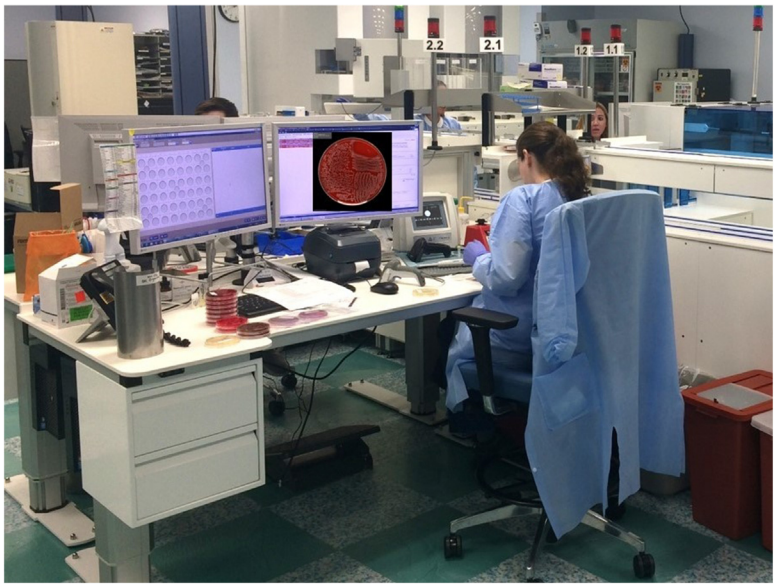

FIGURE 55.2 Total laboratory automation systems present high-resolution images on a computer monitor for technologists to read and interpret.

laboratories, which has resulted in increased workloads. In addition, a greater emphasis has been placed on quality and standardization in healthcare. These factors, along with recent technological advances, led to the rapid evolution of laboratory automation in clinical microbiology. An overview of laboratory automation in clinical laboratories is further described in Chapter 14, Laboratory automation, of this book.

Currently, there are two commercially available laboratory automation systems for clinical microbiology: Becton Dickinson (BD)'s Kiestra TLA and Copan Diagnostic's Walk Away Specimen Processor Laboratory automation system (WASPLab). Both systems automate all steps of the culture process, including specimen inoculation, incubation, and plate imaging (Fig. 55.1). The images are then presented on a computer monitor to technologists who read and interpret the cultures (Fig. 55.2). Both manufacturers are working to automate culture interpretation as well, but it is likely that there will always be a certain degree of human intervention required.

Components of automation

Inoculation unit

The processing components of the systems have been designed to accept multiple types of specimen containers and also allow for "offline" inoculation in case a nonstandard/nonprogrammed container is received. The systems vortex and centrifuge (available with the WASPLab system) specimens, uncap and recap specimen containers, and remove and replace lids on culture plates or broth-based media and inoculate specimens. After samples are added to plates, the systems streak plates according to programmed patterns that are preselected by the laboratory. In addition to processing and inoculation, both systems also prepare Gram stain slides for staining.

Automated track

Once inoculated, plates are transported via automated track lines to automated or "smart" incubators, which can be programed at various temperatures and atmospheric conditions. Plates may then be summoned from the incubators to workbenches via the automated track for further workup by the technologist. Systems may have a unidirectional or bidirectional track. Systems with a unidirectional track allow plates to be summoned to workbenches, assuming workbenches are downstream of the incubators, but plates must be placed in a canister and manually returned to the track upstream of the incubators in order to be returned to the incubator. Systems with a bidirectional track allow plates to be transported back to incubators directly from the workbenches once workup is completed.

Automated "smart" incubators

Prior to automation, plates were stacked in racks and placed in traditional incubators. Plates toward the top of the rack were more exposed to the proper incubation conditions (temperature and atmospheric conditions) compared with plates in the middle and bottom of each rack. In addition, incubator doors were opened and closed each time a plate was added or removed, leading to inconsistency in thermal conditions and other incubator parameters.

"Smart" incubators can automate all forms of aerobic incubation. Plates enter and exit incubators via the

automated track, so incubator doors remain closed throughout the process. This allows the incubators to maintain a constant temperature and environment. In addition, automated incubators contain individual shelves for each plate, which promotes faster, more consistent growth of colonies due to the consistent incubation conditions across all plates. Automated incubators can be programmed at a variety of temperatures and can maintain either an oxygen-rich or a carbon dioxide-enriched environment. Nonfastidious organisms, such as the *Enterobacterales*, grow well in an oxygen-rich environment, while a carbon dioxide environment promotes the growth of fastidious organisms. Moreover, carbon dioxide interferes with the performance of selective culture media. Selective media contain antibiotics and/or inhibitors to suppress the growth of certain organisms. An example is mannitol salt agar, which allows for the growth of *Staphylococcus aureus* while suppressing growth of other organisms. Such media should be incubated in an oxygen-rich environment. It is important to note that current systems do not offer an anaerobic incubator, so anaerobic culture plates must be incubated offline. Inside the incubators, a robotic arm facilitates the movement of the plates, by either placing them on a shelf or removing them for imaging or discarding. The imaging systems are a component either of the incubator or adjacent to the incubator, so plates are removed for a minimal amount of time when imaged.

Imaging

Automation systems are equipped with high-resolution cameras that capture images of plates at defined intervals, which are programmed by the laboratory. Imaging workflows vary based on culture type. Traditionally, technologists would hold plates up toward a light source and at various angles when viewing; this allowed easier detection of certain colony morphologies. Automated systems capture images using various lighting angles, including back lighting, front lighting, and side lighting to mimic manual viewing. Captured images are maintained on the system and can be viewed via remote access. In addition, the captured images allow technologists to go "back in time" when reading cultures. If growth on the second or third day differs from what was reported the first day, the technologist can review the previous days' images for comparison. The storage of image files also creates an opportunity for training of new technologists or to emphasize concepts. Moreover, stored images create an opportunity for quality assurance review.

Workstations

After the images are captured, technologists read plates by viewing the images on a computer rather than viewing the actual plates. Individual plate images can be enlarged to the size of the computer screen and further magnified. Because technologists are never exposed to a plate before viewing an image, imaging could potentially prevent exposure to a select agent (i.e., *Bacillus anthracis*, *Brucella* species, and others) or other highly infectious organisms, such as *Neisseria meningitidis*, based on suspicious growth characteristics. When a plate is viewed, the technologist can virtually mark specific colony morphologies for additional workup processes, which may include identification, antimicrobial susceptibility testing, and subculturing. Additional workup can be completed at the same time by summoning the plate to the workbench or, alternatively, the culture can be added to a queue and batched for workup after viewing is completed.

With the onset of laboratory automation, many microbiology laboratories have adopted a reader/workup workflow where culture images are read by one technologist and annotated for workup and positive cultures are followed up by a second technologist. This differs from the traditional microbiology laboratory, where one technologist would perform all reading and workup for a given culture. The benefit of the reader/workup workflow is that two technologists work together on the same culture, which may lead to improved consistency. This workflow also allows for off-site reading, so technologists could read cultures while in another area of the lab or offsite.

Commercially available systems

The two commercially available laboratory automation systems for microbiology are the Copan WASPLab and BD Kiestra TLA, as mentioned above. Both systems are modular, scalable, and offer automated selection and labeling of media, inoculation, incubation, and plate imaging. The systems interface with the laboratory information system (LIS), and when a specimen barcode is scanned, the LIS is queried and communicates the type of culture that was ordered. The system then selects the corresponding media (previously programmed by the laboratory) based on the type of culture ordered, applies a specimen label to each piece of media and inoculates the specimen.

The WASPLab inoculation unit, the WASP DT, uses 1-, 10-, and 30-μL reusable inoculating loops. Loops are sterilized between the pieces of media or between the specimens, depending on which program the lab selects. The Kiestra inoculation unit, InoculA, uses a pipettor rather than loops for inoculation. The InoculA pipettor can pipette 10−250 μL, and once a specimen is plated, the InoculA uses a single-use sterile magnetic bead to streak each plate. In both cases, specimens must be relatively nonviscous and homogenous for automated inoculation. The Kiestra system has the added consumable cost due to

the single-use nature of the beads, but produces more isolated colonies and more accurate colony counts than the WASPLab [4,5]. Both systems allow for manual inoculation if tissues, viscous specimens, or unusual containers are received. The original WASPLab requires offline manual inoculation and streaking, and plates can subsequently be placed onto the automated track for transport to the incubators. Copan recently developed a robot, called the Collaborative Robot, which can be purchased as a separate unit to assist with manual cultures. Technologists manually inoculate plates, and the Collaborative Robot streaks and places them on the WASPLab automated track. The Kiestra inoculation unit has a biosafety cabinet, in which system-labeled plates are presented for the technologist to inoculate manually. This is referred to as a semiautomated mode and is equivalent to Copan's Collaborative Robot. Once inoculated, the Kiestra system streaks the plates and processes them in the same manner as fully automated specimens. Both systems can create Gram stain slides, although staining and reading of smears are still performed manually.

While both systems have an automated track system, the Kiestra track is bidirectional, while the WASPLab track is unidirectional. The bidirectional track associated with the Kiestra TLA permits plates to be summoned to workbenches and subsequently returned to incubators directly from workbenches. Technologists at WASPLab workbenches can summon plates from incubators, assuming the benches are downstream of the incubators, but must manually place plates on the track upstream of the incubators for return. Both systems have the option of having workbenches that are separate from the automated track. This setup requires manual placement and retrieval of plates, but may be beneficial to labs with a smaller footprint.

Benefits of lab automation and future directions

Improved turnaround times

In traditional microbiology, there is significant variability in the inoculation efficiency between the microbiology staff members. The consistent inoculation of laboratory automation systems results in a higher number of isolated colonies, which are required for identification and susceptibility testing [5,6]. In traditional microbiology, organisms often have to be subcultured to obtain isolated colonies for additional testing, which increases turnaround times. Additionally, staff inoculate several cultures before transporting plates to the incubator, which increases the time the plates are incubated in a suboptimal environment. With automated systems, inoculated plates are transported along the automated track directly to incubators, which provide ideal growth conditions. Moreover, with automation technologists read and interpret images, rather than actual plates, so plates remain in optimal incubation conditions, rather than sitting outside of the incubator for hours at a time.

Due to a combination of the factors listed above, several studies have shown a decrease in the turnaround times of 2−30 hours across multiple culture types on WASPLab and Kiestra [7−11]. However, automation alone is insufficient to improve turnaround times [12]. In addition to automation, workflow changes are required to achieve efficiencies. The majority of laboratories that have implemented automation have also implemented plate reading on the second and/or third shift rather than limiting plate reading to first shift as has traditionally been the case in clinical microbiology laboratories. This allows cultures to be read, as they are ready rather than batching cultures for a single shift.

Automated culture reading

Artificial intelligence (AI) software, PhenoMATRIX, is available for WASPLab. PhenoMATRIX performs automated reading, interpretation, and segregation of cultures into growth versus no growth categories [13,14]. Results are grouped and presented to the technologist for final interpretation and resulting. The software is available for multiple culture types, but each version must be purchased separately. Multicenter studies using chromogenic agar for detection of MRSA and vancomycin-resistant *Enterococcus* (VRE) surveillance cultures demonstrated 100% sensitivity and 89.5%−96% specificity [13,14]. AI software is not currently available for Kiestra but is in development. A proof-of-concept study demonstrated that the Kiestra OPTIS software is able to provide reliable quantitative urine colony counts [15]. In addition to current AI capabilities, there are plans to develop AI that can classify or preliminarily identify organisms based on their morphologies.

TLA for clinical microbiology is still in its early stages. As automation technologies continue to improve, the clinical microbiology laboratory will continue to optimize its operation and workflow. This will result in increased efficiencies that address the shortage of medical technologists, provide a consistent level of care in a healthcare environment that is increasingly focused on quality care, and will continue to improve turnaround times.

Methods for identification of microorganisms

Once an organism is recovered in culture, whether via traditional microbiology or via an automated system, it may

be subjected to a downstream identification method. Such methods include biochemical testing, matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS), or DNA sequencing. DNA sequencing and MALDI-TOF MS can also directly identify a pathogen from a primary specimen.

DNA sequencing

DNA sequencing is the gold standard for microorganism identification. The 16S ribosomal RNA (rRNA) gene is the most common sequencing target for bacteria and is 1542 base pairs (bp) in length. Sequencing the first 500 bp often provides enough differentiation for identification purposes, but certain organism groups require sequencing of the full-length 16S rRNA gene for differentiation, while other genera are homologous across the entire gene and require sequencing of additional genes for differentiation. The additional gene(s) required depends on the genus, and examples include *rpoB, recA, tuf, gyrA gyrB*, and *cpn60.* Many clinical laboratories that perform 16S sequencing only sequence a portion of the 16S rRNA gene, while few sequence the entire 1542 bp. Most clinical laboratories do not perform sequencing of the supplemental genes. Once a sequence is obtained, it is compared with a public or private database for organism identification. Database selection is critical, as some databases are curated and routinely updated and others are static. For more information on selecting an appropriate database, refer to the Clinical and Laboratory Standards Institute (CLSI) MM18 document (Interpretive Criteria for Identification of Bacteria and Fungi by Targeted DNA Sequencing, second edition) [16].

Interpretive criteria are based on the aforementioned CLSI MM18 document [16]; $\geq 97\%$ homology is required for genus-level identification of bacteria, while $\geq 99\%$ homology is required for species-level identification. Less than 95% homology indicates an incomplete database or potentially a novel species. Although 16S rRNA sequencing is the most common, it does not provide sufficient differentiation for particular groups of bacteria, such as *Escherichia coli* and *Shigella* spp., which are essentially the same organism, and *Bordetella* spp. In such cases, sequencing of additional genes or biochemical reactions is required for complete identification.

For yeast and filamentous molds, the most common sequencing targets are the internal transcribed spacer regions (ITS), ITS1 and ITS2. ITS1 and ITS2 are variable regions located between the conserved rRNA genes. ITS2 alone is sufficient for discriminating multiple *Candida* spp. but not for other yeasts or molds. In addition to ITS1 and ITS2, the D1/D2 region of the 28S rRNA gene may be used. A consensus has not been reached in regard to cutoff values for genus- and species-level identification of fungi.

Although DNA sequencing is the gold standard, the methodology is technologically challenging, has a slow turnaround time, is not widely available, and is relatively expensive. Because of these drawbacks, it is not routinely used to identify microorganisms and is more commonly used as a backup or secondary method to other identification methods.

Biochemical/phenotypical methods

Biochemical reactions and phenotypic characteristics have historically been used to identify microorganisms. Initially, biochemical reactions were carried out and analyzed in separate reaction tubes. However, this was burdensome, and some of the reactions required a significant amount of time. Commercial vendors miniaturized biochemical testing, which allowed multiple biochemical reactions to be combined into a panel. Commercial biochemical panels are interpreted manually by the technologist or automatically by an instrument. Examples of manual panels include ThermoFisher's Remel RapID series and bioMerieux's API series (Fig. 55.3). Automated instruments include bioMerieux's VITEK 2 (Fig. 55.4A and B), BD's Phoenix, and Beckman Coulter's MicroScan. For panels that require manual interpretation, the technologist visually determines the reactions and enters the results into a web-based database. Both manual and automated systems compare the reactions to an organism database and provide an identification with a confidence score, which is reported as a percentage.

Biochemical methods are inexpensive and easy to perform, but they are generally slow and have variable performance. Correct genus- and species-level identification rates for aerobic Gram-negative rods are 83% and 75%, respectively [17]. While biochemical methods perform relatively well for commonly isolated aerobic bacteria, they are not reliable for inert, slowly growing or infrequently isolated bacteria, including anaerobes. Correct genus-level identification rates range from 71% to 87%

FIGURE 55.3 A bioMerieux API panel, an example of a miniaturized biochemical identification panel.

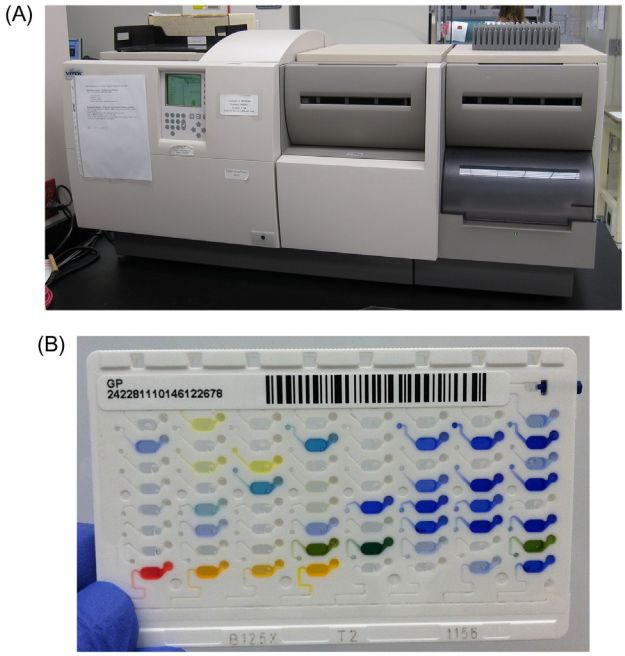

FIGURE 55.4 (A) VITEK 2 instrument and (B) VITEK 2 Gram-positive identification panel are shown. Each well on the identification panel represents a unique biochemical reaction.

for anaerobes, while correct species-level identification rates are a mere 50% to 60% [18–21]. Identification rates for infrequently isolated aerobic bacteria are even more dismal and have been reported to be 52% for genus level and 34% for species level [17]. During the past decade, biochemical methods are being replaced by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS), which is discussed in the following section.

Mycobacteria should be cultured in a biosafety level 3 or BSL2 + (BSL2 plus BSL 3 practices) laboratory due to the potential aerosolization of *Mycobacterium tuberculosis* (MTB). Mycobacteria were traditionally identified by biochemical methods. However, this process required weeks for the slowly growing mycobacterial species, including MTB. Improvements in time to identification were made with the implementation of high-performance liquid chromatography (HPLC), DNA probes, MALDI-TOF MS, and polymerase chain reaction (PCR) for MTB complex. Biochemical methods and HPLC are no longer recommended due to their poor performance and slow turnaround times compared with newer methods [22]. Although DNA probes provide a same day turnaround time once growth is detected, they are labor-intensive and only available for four species: MTB complex, *Mycobacterium avium* complex, *Mycobacterium kansasii*, and *Mycobacterium gordonae*. In addition to routine bacteria, MALDI-TOF MS is also replacing traditional methods for identification of mycobacteria.

Yeasts have historically been identified using biochemical methods, which require up to 72 hours. The phenotypic methods commonly employed by clinical laboratories for yeast identification have variable accuracy, with most methods performing well for common species; however, accuracy may decrease with infrequently encountered isolates [23–27]. One of the notable drawbacks of biochemical methods for yeast testing is the misidentification of *Candida auris* [28]. *C. auris* has gained international attention due to isolates frequently demonstrating multidrug resistance. Molds, on the other hand, have historically been identified using macroscopic and microscopic morphologies. The surface color and texture of the mold colony, the color of the reverse of the colony, and the microscopic morphology using lactophenol cotton blue (LPCB) tape preparation are combined to identify the mold. LPCB tape preparation is performed by touching a piece of clear tape to the top of the mold colony and applying it to a microscope slide with a drop of LPCB dye, which stains the fungal elements and allows visualization. MALDI-TOF MS is replacing biochemical methods for yeast. MALDI-TOF MS has also been applied to mold identification. However, there are some drawbacks specific to molds, which have resulted in limited usage compared with other organism groups and are discussed in the following section.

Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry

MALDI-TOF MS is a rapid and inexpensive method for identification of bacteria, acid-fast bacilli (*Mycobacterium* spp.), yeasts, and molds in the clinical microbiology laboratory. MALDI-TOF MS uses proteomic profiling to assign and identification, which primarily includes ribosomal proteins due to their relative abundance. Thus MALDI-TOF MS is the closest identification to the gold standard of 16S ribosomal DNA sequencing. MALDI-TOF MS measures proteins in the range of 2–20 kilodaltons. Bruker's Biotyper system (Fig. 55.5A) and bioMerieux's VITEK MS (Fig. 55.5B) are the two commercially available MALDI-TOF MS instruments available in the United States for microorganism identification. The Bruker is a bench top model, while the VITEK MS is a larger floor model. Both systems have Food and Drug Administration (FDA)-cleared in vitro diagnostic (IVD) organism libraries as well as more comprehensive research use only (RUO) libraries. Although the majority of clinically encountered bacteria and yeast can be identified using the IVD libraries, many laboratories have validated RUO libraries for clinical use to provide complete coverage of organism identification. Mycobacteria and

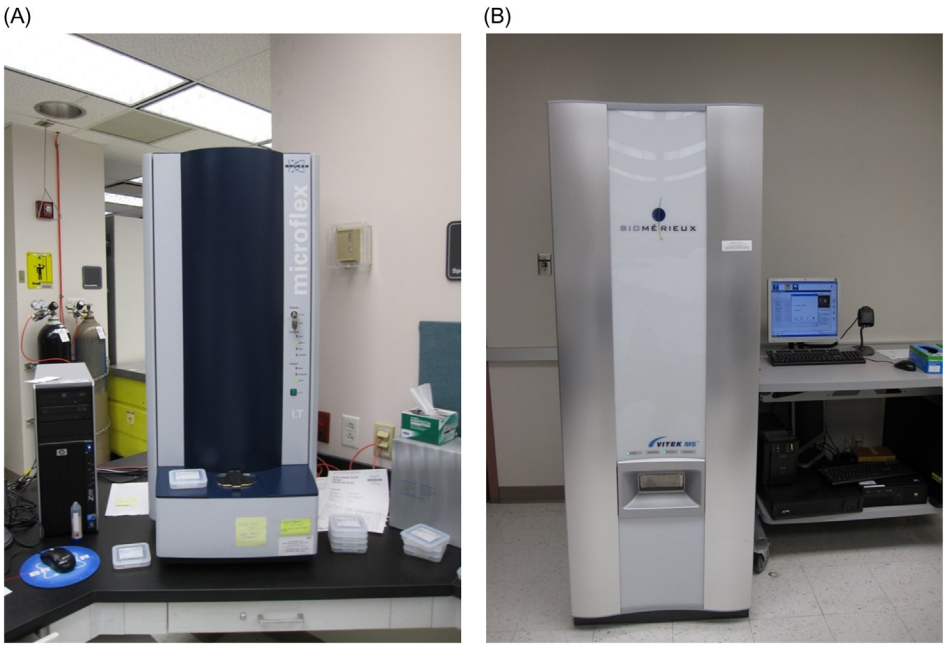

FIGURE 55.5 (A) Bruker's Biotyper system and (B) bioMerieux's VITEK MS are the two commercially available matrix-assisted laser desorption/ionization time-of-flight mass spectrometry instruments available in the United States for microorganism identification.

molds are included in the most recent VITEK MS IVD library v.3.0, while the Bruker has RUO mycobacterial and mold libraries that must be purchased separately from the bacterial library.

For bacteria and yeasts, a thin layer of organism is applied to the target plate using a toothpick or inoculation loop and 1 μL of formic acid overlay may be added, depending on the organism group. The organism ± formic acid is subsequently overlaid with matrix (α-cyano-4-hydroxycinnamic acid), allowed to dry, and subjected to MALDI-TOF analysis. The process is more complicated for mycobacteria and molds, which require extraction and inactivation prior to MALDI-TOF MS analysis. Of note, both commercially available laboratory automation systems are developing modules that will automate inoculation of MALDI-TOF targets. Once the organism's mass spectrum is obtained, it is compared with the manufacturer's library/database, and a confidence score is provided. The Bruker uses a logarithmic scale, where, per the manufacturer, a score ≥ 1.7 is sufficient for genus-level identification and a score of ≥ 2.0 is sufficient for species-level identification. Some laboratories have validated lower thresholds off-label for species-level identification. The VITEK MS system reports, on the other hand, identifications with a percent confidence score up to 99.9%.

MALDI-TOF MS has a turnaround time of approximately 40 minutes for identification of bacteria and yeasts [8,29]. This is a significant improvement compared with 1.5−72 hours for traditional biochemical methods [8,29]. In addition to a faster turnaround time, MALDI requires less organism mass. A single isolated colony is sufficient for MALDI-TOF MS analysis, while biochemical methods require sufficient colonies to create a 0.5−3 McFarland turbidity standard, depending on the organism group.

MALDI-TOF MS has demonstrated excellent performance for aerobic bacteria with genus- and species-level identification rates of 98.6% and 96.5% for Gram-positives and 98.5% and 96.8% for Gram-negatives [30]. One of the biggest improvements over biochemical methods is the identification of anaerobes. Genus- and species-level identification rates for anaerobes by MALDI-TOF MS have been reported to be 98.5% and 85.8%−97.4%, as compared with 71%−87% and 50%−60%, respectively, by biochemical methods [18−21,30]. Approximately 60% of College of American Pathologists (CAP)-accredited laboratories are using MALDI-TOF MS for the identification of bacteria (CAP DEX-B 2019 survey).

MALDI-TOF MS has a few limitations with regard to bacterial identification. It is unable to separate *E. coli* and *Shigella* spp., which are essentially the same organism. The technology also has challenges with discrimination and accurate detection of *Streptococcus pneumoniae* and *Streptococcus mitis/oralis* group due to the high degree of relatedness between the two organisms; however, this has improved with the release of updated libraries. MALDI-TOF MS typically does not identify or misidentifies select agents, such as *Brucella* spp., *B. anthracis, Burkholderia pseudomallei*, etc. even when they are present in the library being used [31]. Therefore, it is imperative that microbiology technologists are familiar with recognizing select agents and recognizing common misidentifications by MALDI-TOF MS. It is essential that technologists are

aware of the limitations and maintain competency for recognizing patterns and questioning things that do not fit. For microorganisms not identified by MALDI-TOF, DNA sequencing should be used if identification is necessary.

A recent CAP proficiency testing survey (E-B 2019) revealed that 20% of laboratories are using MALDI-TOF MS for identification of mycobacteria. MALDI-TOF MS performs well for mycobacteria, although more hand-on time is required than bacteria and yeast. The Bruker extraction/inactivation method requires approximately 1 hours, while the VITEK MS extraction method requires 30−60 minutes. However, a recent study published a method that requires only 10 minutes, decreasing the hands-on time and turnaround time [32]. Species-level identification rates are 84.7%−100% [32−34].

Notable drawbacks of MALDI-TOF are that it cannot differentiate members of the MTB complex nor can it differentiate *Mycobacterium abscessus* complex to subspecies-level (*M. abscessus* subsp. *abscessus, M. abscessus* subsp. *bolletii* and *M. abscessus* subsp. *massiliense*). The former is significant because *Mycobacterium bovis*, a member of the MTB complex, is intrinsically resistant to pyrazinamide, a first-line drug for tuberculosis treatment. The latter is significant, because *M. abscessus* subsp. *abscessus* and *M. abscessus* subsp. *bolletii* have a functional *erm* gene, encoding macrolide resistance, whereas *M. abscessus* subsp. *massilience* has a nonfunctional *erm* gene. MALDI-TOF MS also cannot differentiate *Mycobacterium chimaera* from *Mycobacterium intracellulare*. While this is normally not a concern, sequencing should be performed if the infection is associated with cardiothoracic surgery, as there is currently a global outbreak of *M. chimaera* associated with heater-cool units [35].

Currently, 48% of CAP-accredited laboratories are using MALDI-TOF MS for identification of yeasts (CAP F-B 2019 survey). Several studies have demonstrated species-level identification rates of 83%−99% (reviewed in [36]), and the majority of yeasts require formic acid overlay or extraction with formic acid and acetonitrile for successful identification. MALDI-TOF MS identification of molds, on the other hand, has been less widespread. While 48% of laboratories are using MALDI-TOF MS for yeasts, only 5% are using it for molds (CAP F-B 2019 survey). There are no molds in the most recent FDA-cleared library (IVD Claim 4) for Bruker, and there are 79 species in the recent VITEK MS library (v3.0). The RUO libraries for both instruments, however, contain numerous species. Although libraries are available, there are two issues with identification of molds. Mold colonies are not homogeneous the way bacterial, mycobacterial, or yeast colonies are. Protein expression varies across mold colonies, with a subset of proteins being more highly expressed at the inner portion of the colony, whereas another subset of proteins may be more highly expressed at the outer edge of the colony, etc. Thus the sampling location has a significant impact on which proteins are present in the spectra. Moreover, in the case of the Bruker, the original mold library was created using molds that had been grown in broth rather than on plates. Although the broth method standardizes protein expression, molds are not grown in broth in clinical laboratories.

The difficulty in mold identification is demonstrated by publications reporting 78%−83.5% identification to genus level and 54%−79% identification to species level (reviewed in [36]). Some laboratories have created their own user-developed libraries, either for all molds or for a particular subset of molds. User-developed libraries have demonstrated species-level identification rates of 89%−98% [36]; however, many labs do not have the capacity to create their own library. A recent study evaluating the VITEK MS v3.0 library demonstrated 86.6% correct identification to the species level [37]. If only the species present in the library were included, 91% were correctly identified to species level. These are the most promising data using a commercially developed library thus far. MALDI-TOF MS identification of molds is an ongoing area of research.

Beyond colony identification

To date, the majority of studies evaluating MALDI-TOF MS have focused on identification of organisms growing on solid media; a smaller number of studies have evaluated MALDI-TOF MS analysis on positive blood culture broth. An initial extraction is required when testing positive blood cultures to eliminate interfering substances, including blood and broth. Time to identification ranges from 30 minutes to 2 hours, depending on the method used. Of note, this method applies to bacteria and yeasts, which grow well in routine blood culture bottles. Mycobacteria and molds are rarely recovered in routine blood culture bottles and require alternative methods for detection. Correct identification rates vary based on which extraction method is utilized but appear most optimized with the use of a commercially available Sepsityper kit (Bruker-Daltonics) or saponin [38−42]. The majority of studies have evaluated the Bruker Biotyper for this analysis. One drawback is that MALDI-TOF cannot accurately identify multiple species in polymicrobial blood cultures, though it frequently identifies the predominant organism from mixed cultures [43−46]. The issue with polymicrobial specimens has also been reported with molecular methods [47,48].

MALDI-TOF MS has been shown to correctly identify 84%−99% of Gram-negative bacteria from positive blood culture broth, with most studies reporting rates from 90% to 99% (reviewed in [49]). The rate varies from

65% to 96% for Gram-positive bacteria, with most studies reporting identification rates of 80% [49]. In regard to the identification of yeasts, one study showed concordance rates of 95.9% for *Candida albicans* and 86.5% for non-*albicans Candida* species [50].

Rather than using lysis or extraction methods, some labs have opted to test microcolonies or "scum" growth. Positive blood culture broth is inoculated to solid media and incubated, and MALDI-TOF MS analysis is performed after 2−6 hours of incubation. Although the turnaround time is longer than the extraction methods, this method is less labor-intensive and fits better into a laboratory workflow. Species-level identification rates have been reported to be in the range of 81.8%−95.5% [49]. Anaerobes and slow growing bacteria have lower identification rates, and polymicrobial cultures cannot be differentiated after 2−6 hours of growth.

Direct identification from urine via MALDI has also been investigated. One study used diafiltration and concentration to obtain bacterial identification in 2−3 hours. Detection limits were 5×10^4 to 10^6 colony forming units/mL [51]. A second study inoculated urine into broth media, incubated the broth for 3 hours, and checked the density. If the density was ≥ 0.3 on the McFarland turbidity scale, the broth was centrifuged, and the bacterial pellet was used to spot the MALDI target. The study demonstrated 96.5% sensitivity and 71.4% specificity [52]. Neither workflow is ideal for a clinical microbiology laboratory, so MALDI-TOF MS of urine cultures is not widely performed. In addition, urine cultures have a high rate of contamination and are often polymicrobial in nature, further limiting the utility of this method.

Point-of-care microbiology

Point-of-care (POC) testing generally refers to testing that is performed near the site of patient care (such as a physician office, clinic, or hospital unit) by nonlaboratory trained individuals. POC tests often have a rapid turnaround time, providing actionable results that facilitate immediate patient management decisions. This advantage is particularly pronounced in the emergency department and in cases where the traditional laboratory is off-site. A more expanded definition of POC testing may include testing performed in small laboratories that serve as a satellite laboratory for a main central laboratory. Centralization of laboratory testing, where a large centralized laboratory performs the majority of testing for hospitals and clinics within a region, has led to increased turnaround times for results when transport times are taken into account. Smaller satellite laboratories may be staffed by general laboratory technologists without specialized microbiology training. Testing performed in these types of laboratories may confer the turnaround time benefits of POC testing by eliminating or reducing transit times while offering an expanded menu of assays. In this context, many rapid sample-to-answer microbiology tests may be considered POC tests, such as syndromic multiplex molecular testing platforms. For remote clinics or hospitals, simple and rapid POC assays are essential for optimal patient management.

Most POC tests receive waived status by the United States FDA. Laboratories or clinics exclusively performing waived tests are required to obtain a Certificate of Waiver, which is issued by the Centers for Medicare and Medicaid Services under Clinical Laboratory and Improvement Amendments of 1988 (CLIA). Waived tests are considered low risk for errors, are performed using simple and straightforward protocols, require minimal instrument maintenance, and require minimal training for test interpretation. Although these assays are simple, appropriate quality control and user training is essential to preventing diagnostic errors.

POC microbiology testing has historically been limited to lateral flow immunoassays (LFAs). LFA tests are performed on a lateral flow strip and are often double-antibody sandwich assays. A capture antibody is immobilized on the membrane and the clinical specimen is flowed over the strip. The target antigen, if present, is bound by conjugate-labeled antibodies, such as colloidal gold-labeled antibodies, and the target antigen−antibody complex binds the immobilized capture antibody, producing a visible line. The sample flows further along the membrane where excess conjugate binds the control antibodies, producing a visible control line. For some assays, digital analyzers have been introduced to eliminate the subjective nature of visual interpretation of LFA assays. Examples of LFA POC tests in use include assays for the diagnosis of *S. pyogenes* [Group A *Streptococcus* (GAS)], infectious mononucleosis, influenza A/B viruses, respiratory syncytial virus (RSV), HIV-1 and HIV-2, and adenovirus.

Although LFA assays are rapid, inexpensive, and simple, these assays have variable clinical performance and often suffer from suboptimal sensitivity. Metaanalysis of the diagnostic accuracy of rapid antigen tests for GAS found a sensitivity of 86% and specificity of 95%, although the reported sensitivities in the included studies were highly variable, ranging from 44% to 98% [53]. Owing to the low sensitivity of these tests, negative rapid GAS tests are reflexed to culture for confirmation testing.

Rapid influenza diagnostic tests (RIDTs) are immunoassays that detect influenza viral antigens. Several metaanalyses have evaluated the sensitivity of RIDTs, reporting a pooled sensitivity of 51%−68% and lower sensitivity for adult patients compared with pediatric patients due to the relatively lower viral load [54−56]. When seasonal influenza activity is high, the negative predictive value of RIDTs is low, due to the substantial

number of falsely negative results. Because of these poor performance characteristics, the Centers for Disease Control and Prevention recommends that all negative samples be tested by a more sensitive assay, although adherence to this recommendation is likely low. Further, antiviral therapy is commonly not withheld based on a negative RIDT alone, particularly if there is a high clinical suspicion for influenza illness. Conversely, when influenza activity is low to moderate, the positive predictive value of RIDTs is poor. Due to low sensitivity for the detection of influenza viruses, especially novel or emerging influenza viruses, in 2017 the FDA reclassified RIDTs from class I to class II devices, which requires these devices meet minimum criteria for sensitivity and specificity [57].

Development of POC molecular techniques has the potential to meet the clinical need for highly sensitive, rapid POC microbiology diagnostics. The first POC molecular test to be granted a CLIA waiver was the Alere i influenza A & B test (Alere Inc.), which received waived status in 2015. Subsequently, Abbott purchased Alere and renamed the Alere i to the infectious disease (ID) NOW platform. It is CLIA-waived for influenza A/B virus, RSV, and GAS testing, with results reported in 2−15 minutes. The ID NOW system uses strand displacement amplification technology, where target nucleic acid is amplified in an isothermal reaction using a nicking endonuclease and a strand-displacing DNA polymerase in addition to target primers. Fluorescently labeled molecular beacon probes are used to monitor amplification in real time. Three additional molecular platforms have subsequently received CLIA-waived status. The Cobas Liat (Roche Diagnostics) is CLIA-waived for influenza A/B virus, RSV, and GAS testing, with results in 15−20 minutes. Amplification occurs using real-time PCR technology and results are interpreted based on real-time detection of fluorescently labeled probes. The GeneXpert Xpress platform (Cepheid) is CLIA-waived for influenza/RSV and GAS testing, with results in 18−30 minutes. The Xpress system uses real-time PCR and fluorescently labeled probes for the amplification and detection of target nucleic acid. The Accula system (Mesa Biotech) is CLIA-waived for influenza and RSV detection, with results in 30 minutes. The Accula system uses reverse-transcription PCR technology to amplify target RNA, which is then complexed to oligonucleotide probes conjugated to dye-labeled microspheres. Using technology similar LFAs, the amplicon-microsphere complex is flowed across a detection membrane where complementary oligonucleotide capture probes are bound. Hybridization of capture probes to the amplicon-microsphere complex is visualized on the membrane as a colored line. Additional molecular POC assays are currently under development and in clinical trials.

Molecular POC tests have demonstrated clinical performance characteristics similar to molecular testing performed in the clinical microbiology laboratory. GAS molecular POC assays have a reported sensitivity of 99%−100% and specificity of 91%−97% when compared with culture [58,59]. POC molecular assays for RSV and influenza A/B viruses also demonstrate high sensitivity. Reported sensitivity of the Liat is >97% for influenza A virus, influenza B virus, and RSV targets [60−63]. Similarly, evaluation of the GeneXpert influenza A/B assay demonstrated high sensitivity (>96%) and specificity (>97%) for both influenza A and influenza B viruses [63,64]. Studies of the Alere i have reported lower sensitivity for all targets when compared with the Liat, with overall influenza A/B sensitivity as low as 64% in one study, although the majority of studies report sensitivities >90% [60,63−66]. Metaanalysis of the reported diagnostic accuracy of influenza POC nucleic acid amplification tests found a pooled sensitivity 92% for influenza A virus and 95% for influenza B virus [67]. This was a marked increase compared with the pooled sensitivity of newer generation influenza antigen immunoassays, which had a pooled sensitivity of 80% for influenza A virus and 77% for influenza B virus.

Risk of contamination is a significant concern for molecular POC assays, as amplicon contamination can lead to false-positives and pseudooutbreaks. Because these tests are performed by nonlaboratory staff that are inexperienced in performing highly sensitivity laboratory assays, proper training and quality control, such as frequent testing of the setup area for target contamination, are essential. In addition, improved test utilization education and stewardship strategies are a focus across all areas of laboratory medicine. As increasingly expensive and sensitive tests are introduced, education on which patients are appropriate to test will be essential. For example, overdiagnosis of pediatric patients colonized with GAS is a concern, as up to 26% of healthy children may be colonized with GAS [68,69]. Testing only patients with clinically significant signs and symptoms of GAS is imperative to prevention of overdiagnosis.

A drawback of molecular POC testing is increased cost per test compared with traditional antigen tests. Benefits that may offset cost increases include the potential for improved antibiotic and antiviral use. In the cases of GAS, patients that tested antigen-negative but culture-positive would potentially receive results and antibiotic therapy 1−2 days sooner if molecular testing was used. In addition, molecular GAS POS testing does not require reflex of negative results to culture, reducing the workflow burden in the clinical microbiology laboratory and simplifying the overall operational process. In the cases of influenza A/B testing, the increased negative predictive value of molecular testing over antigen testing during influenza virus season may facilitate appropriate use of antiviral medications and judicious use of antibiotics.

Molecular POC platforms will allow for expansion of the POC microbiology test menu. Numerous assays are currently in development and many are currently CE-marked for use in European laboratories. Promising new assays include HIV-1 viral load testing and diagnostic assays for sexually transmitted infections. In 2019 the first assay for molecular POC STI detection received FDA 510(k) clearance. The binx *io* platform is a rapid molecular assay for the diagnosis of *Chlamydia trachomatis* and/or *Neisseria gonorrhoeae* from clinician or self-collected vaginal swab specimens, with results in less than 30 minutes.

Introduction of molecular microbiology into the POC testing environment represents a paradigm shift and has led to increased versatility, scope, and availability of POC rapid testing. POC molecular testing is also accompanied by an increase in cost per test, which may limit uptaking these assays, especially if viewed independent of changes to cost utilization of other resources, such as administration of antibiotics.

Syndromic-based multiplex molecular testing

Introduction

Multiplex testing was developed for the detection of pathogens associated with clinical syndromes of the bloodstream, respiratory, gastrointestinal, and central nervous systems (CNS). Since their introduction, these panels have become increasingly common with improved workflows and decreased turnaround times. Syndromic-based testing has streamlined ordering workflows, as providers need to select only one test order to analyze the most common organisms causing a specific syndrome. Moreover, some platforms offer flexibility in ordering, allowing the provider to order more specific targets based on clinical presentation, which can help limit unnecessary testing and costs. Molecular syndromic testing is more rapid than conventional microbiology methods, reducing time to diagnosis and, if the result is acted upon, potentially reducing time to appropriate therapy.

Early multiplex testing platforms, such as the Luminex xTAG, had cumbersome workflows and testing was often batched and performed once per day or once per shift. Subsequently, sample-to-answer platforms were developed and have replaced many of the older platforms. Sample-to-answer platforms require minimal set time, leading to simplified workflow as compared with traditional microbiology methods. A major limitation to adoption of multiplex testing is cost, as these panels incur an increased cost to both the laboratory as well as the patient compared with conventional methods. Institutional savings outside the clinical laboratory may be observed if utilization of these panels results in reduced antibiotic use, decreased length of stay, and promotion of appropriate infection prevention and control isolation precautions. In order to maximize institutional and patient benefits, multiplex testing should optimally be performed 24 hours per day and 7 days per week. In addition, test results are most optimally acted upon when accompanied by an antimicrobial stewardship intervention, either via direct contact with a member of an institutional antimicrobial stewardship team or via laboratory comments appended to results. Finally, test utilization strategies specific to each panel and patient population should be adopted to minimize inappropriate costly testing and target these assays to patients who will see the most benefit. Antimicrobial stewardship and test utilization opportunities specific to each syndromic panel are discussed below.

Currently, sample-to-answer multiplex testing platforms are commercially available via several vendors, including BioFire Diagnostics, the Luminex Corporation, and GenMark Diagnostics. GenMark panels are offered on the ePlex system, with a throughput of up to 96 samples within 8 hours. Following an amplification step, target DNA is hybridized to a signal probe, which reacts with a capture probe attached to a gold electrode. Application of voltage leads to electrochemical detection of the target DNA/signal probe complex. Current panels available on the ePlex instrument include respiratory pathogen and blood culture identification (BCID) panels. BioFire panels are offered on the FilmArray system. The FilmArray 2.0 is a single-bay instrument that is scalable by connecting up to eight instruments to a single processing computer. The FilmArray Torch is a fully integrated system with up to 12 modules in a tower configuration. In the FilmArray cartridge, nucleic acid is extracted and purified, followed by a nested PCR reaction and then a single-plex reaction for each target. Target detection is determined by endpoint melting curve analysis. BioFire currently has the largest menus of available panels, with testing available for infections of the upper respiratory, lower respiratory, gastrointestinal, and CNSs, as well as BCID. Luminex panels are performed on the Verigene system, consisting of a Verigene Processor and a Verigene reader. Specimen processing and target detection is performed on the Verigene Processor using a microarray format and gold nanoparticle probe-based technology. The test cartridge is then read by the Verigene reader, which offers scalable reading. Syndromic panels available on the Verigene system include respiratory, gastrointestinal, and BCID panels.

Respiratory panels

The differential diagnosis for upper respiratory infections is often broad, with nonspecific clinical signs and symptoms. Most illness is cause by viral infections, which do

not have targeted individual FDA-approved/cleared assays. Multiplex molecular testing for respiratory pathogens was first approved in 2008. Most panels target common respiratory viruses, with some including atypical bacterial targets (e.g., *Chlamydophila pneumoniae, Mycoplasma pneumoniae*, and *Bordetella* species). NP swabs are the only approved specimen type for these panels, although many laboratories have performed validation studies to allow for testing of lower respiratory specimens such as bronchoalveolar fluid. Several multiplex panels designed to detect respiratory pathogens have been FDA-cleared, including more traditional assays such as Luminex xTAG Respiratory Viral Panel (RVP; Luminex Corporation), the Luminex xTAG RVP Fast (Luminex Corporation), and the Luminex xTAG Respiratory Pathogen Panel (RPP; Luminex Corporation); newer sample-to-answer assays such as FilmArray Respiratory Panel (RP; BioFire Diagnostics) and RP2; Verigene Respiratory Pathogens Flex test (Luminex Corporation); and ePlex RPP (GenMark Diagnostics). Panels include 8−20 respiratory pathogen targets and turnaround time ranges from 1 to 8 hours.

Clinical evaluations of syndromic respiratory panels have demonstrated overall sensitivities >85% and specificities >99% [70−73]. However, suboptimal performance characteristics have been described for specific targets on individual panels. In one study, the FilmArray RP exhibited a sensitivity of 57% for adenovirus and 77% for influenza B virus when compared with a reference standard [70]. A redesign of the FilmArray RP, the RP2, has improved sensitivity for both adenovirus and influenza B virus [73]. The xTAG RVP Fast demonstrated <50% sensitivity for the detection of influenza B virus [70,74]. The xTAG-RPP demonstrated lower sensitivity for human coronaviruses OC43 (67%) and HKU1 (67%) than other assays [72]. Low sensitivity for viral pathogens with treatment options, such as influenza B virus, may negatively affect patient outcome; for this reason, a higher sensitivity assay should be used for the primary diagnosis of these viruses. For viruses not historically detected by traditional testing and for which no targeted therapy is available (such as coronaviruses), the impact of missed diagnosis is unclear. Nonetheless, many of these older assays have been supplanted by newer versions of sample-to-answer assays with improved overall sensitivity.

Implementation of multiplex respiratory testing has demonstrated clinical and financial benefits. Studies have documented a decreased mean time to diagnosis compared with conventional testing [75−77]. In addition, because multiplex panels include pathogens for which targeted testing is not routinely available (e.g., coronaviruses), use of multiplex panels increased the overall number of patients with a microbiological diagnosis [76]. Additional benefits include decreased use of antibiotics in viral illness, decreased admission rates, and decreased length of stay [75,76]. Although clinical benefits are promising, cost of implementation of multiplex panels is a significant concern. Mahony et al. [78] performed a cost evaluation of the xTAG RVP assay compared with conventional methods and determined that multiplex testing was cost-effective if the prevalence of respiratory viral illness was >11%. Availability and turnaround time of targeted assays in addition to the specific patient population (e.g., immunocompromised, pediatric, etc.) must be considered when evaluating the utility of multiplex respiratory pathogen tests.

The FilmArray Pneumonia (PN) panel received FDA approval/clearance in 2018. The PN panel includes targets for eight respiratory viruses, 18 bacteria, and seven antimicrobial resistance markers. This panel is approved for bronchoalveolar lavage (BAL), mini-BAL, sputum, and endotracheal aspirates. For 15 of the 18 bacterial targets, the target is reported as a semiquantitative result, which allows for interpretation of the results in a similar manner as traditional quantitative culture. Positive targets are reported within a 1 log bin, ranging from $<10^4$ to $\geq 10^7$ copies/mL. At the time of this writing, no peer-reviewed studies have been published on the performance of the PN panel.

Gastroenteritis panels

Traditional diagnostic testing for infectious diarrhea has included bacterial culture, antigen detection, microscopy, and targeted molecular tests. These assays require that clinicians select the appropriate test and misordering may lead to missed diagnoses. In addition, traditional testing for gastroenteritis (GI) pathogens in the microbiology laboratory is time-consuming, often requiring multiple days, and involves complicated workflows. Detection of some pathogens, such as *Giardia lamblia*, may require collection of multiple samples for maximum sensitivity. Advantages of syndromic panel testing for the diagnosis of diarrheal illness include decreased turnaround time, increased sensitivity, and, in some cases, decreased cost. Three multiplex assays are currently FDA-approved/cleared for the detection of enteric pathogens: Luminex xTAG Gastrointestinal Pathogen Panel (GPP; Luminex Corporation), FilmArray Gastrointestinal Panel (GIP: BioFire Diagnostics), and Verigene Enteric Pathogens Panel (Luminex Corporation). These multiplex tests detect 9−22 targets and on-instrument time is 1−5 hours. All panels detect the most common bacterial pathogens associated with GI (*Campylobacter* spp., *Salmonella* spp., *Shigella* spp., *Vibrio* spp., *Yersinia enterocolitica*, and Shiga toxin). The Luminex GPP and FilmArray GIP additionally detect enterotoxigenic *E. coli, E. coli* O:157, and *C. difficile*. The FilmArray GIP is the only assay that

detects enteropathogenic and enteroaggregative *E. coli* as well as *Plesiomonas shigelloides*. No multiplex GI panel detects *Aeromonas* species, an additional possible bacterial cause of infectious diarrhea. Of the viral causes of infectious diarrhea, all panels detect norovirus GI/II and rotavirus A. The Luminex GPP also detects adenovirus 40/41, while the FilmArray GIP also detects adenovirus 40/41, astrovirus, and sapovirus. Finally, the Luminex GPP and FilmArray GIP also include parasitic species, with the GPP detecting *Cryptosporidium* species, *Entamoeba histolytica*, and *G. lamblia* and the GIP detecting *Cryptosporidium* species, *E, histolytica*, *G. lamblia*, and *Cyclospora cayetanensis*. Stool submitted in Cary-Blair transport media is the acceptable specimen for all panels.

Multiplex panels offer significant sensitivity increases over conventional testing methods. Across multiple studies, all panels detect an enteric pathogen in 20%−50% of specimens, compared with detection of a pathogen in 8%−18% of samples tested by traditional methods [79−82]. Increased overall detection is likely due to increased sensitivity for specific targets as well as increased number of targets tested. The most commonly detected organisms are *C. difficile*, enteropathogenic *E. coli*, *Salmonella* species, norovirus, rotavirus, sapovirus, and *Cryptosporidium* species [79−82]. Sensitivity of all targets is generally >90%, although reduced sensitivities have been reported for *Salmonella* and *Y. enterocolitica* for the Luminex GPP and *Campylobacter*, *Salmonella*, and rotavirus for the Verigene EP [81,83,84]. Evaluation of multiplex molecular GI panels has repeatedly demonstrated that detection of >1 target is more frequent than previously appreciated. Codetections were observed in 16% of specimens tested by the BioFire GI Panel [79]. Among specimens with >1 targets detected, enteroaggregative and enteropathogenic *E. coli* were commonly detected [79−81].

Implementation of multiplex testing for the detection of GI pathogens has been associated with financial, clinical, and infection control benefits. In addition to increases in sensitivity and detection of coinfections, results are available in <6 hours when GI panel testing is performed, in contract with culture-based methods which require several days before a result is available. Although multiplex testing is associated with increased costs to the clinical laboratory when compared with traditional testing methods, in hospitalized patients, these costs may be offset by reduced overall institutional costs [85]. Improvement in utilization of patient isolation precautions associated with implementation of GI panel testing, including both increasing numbers of patients in appropriate isolation as well as discontinuing isolation precautions for patients with negative GI panel results, has important cost, patient satisfaction, and infection control implications [85,86]. Consideration should be given to test utilization and interpretation strategies when implementing syndromic GI testing for optimal cost and clinical utility.

Blood culture identification panels

Early antimicrobial administration is an important predictor of morbidity and mortality associated with sepsis. Diagnosis of bacteremia and fungemia is predicated on appropriate collection of blood cultures, with at least two sets of aerobic and anaerobic blood culture bottles filled with 10 mL of blood per bottle or 5 mL of blood per bottle for pediatric bottles. Blood cultures are incubated for five days on a continuously monitored blood culture instrument. When a bottle signals positive, a Gram stain is performed and the results are immediately called to the clinical care team. The blood culture broth is then inoculated to solid media and organism identification and antimicrobial susceptibility testing is performed on culture growth, requiring an additional 18−48 hours. From the time of initial positivity, workup of positive blood culture bottles requires 48−72 hours before the report is finalized. Multiplex molecular testing of positive blood culture bottles may decrease both the time to organism identification and time to preliminary antimicrobial susceptibility results.

Currently, several assays have received FDA approval/clearance for testing positive blood culture bottles. The FilmArray BCID panel tests for 19 bacterial targets (Gram-positive and Gram-negative), five yeast targets, and four resistance genes. The Luminex Verigene assay is divided into two panels based on Gram stain results. The Gram-positive blood culture (BC-GP) panel tests for 12 Gram-positive bacterial targets and three resistance genes. The Gram-negative blood culture (BC-GN) panel contains eight Gram-negative bacterial targets and six resistance markers. The GenMark ePlex system offers three panels. The Gram-positive panel contains 20 bacterial targets and four resistances gene; the Gram-negative panel tests for 21 bacterial targets and six resistance genes; and the fungal panel tests for 15 fungal targets. Finally, the Accelerate Pheno system (Accelerate Diagnostics) uses gel electrofiltration and fluorescence in situ hybridization for the identification of six Gram-positive bacteria, eight Gram-negative bacteria, or two yeast targets within 90 minutes and subsequent phenotypic susceptibility testing within 7 hours. The Accelerate Pheno system is the only multiplex system that offers phenotypic susceptibility testing.

Performance characteristics of multiplex molecular testing have been evaluated across multiple studies. Implementation of molecular testing of positive blood culture bottles reduced time to organism identification by 20−30 hours [87,88]. In monomicrobial positive blood

culture bottles, an organism was correctly identified in 90%–100% of bottles [48,87–89]. In addition, select resistance genes have been incorporated into these panels for a preliminary indication of antimicrobial resistance, including *mecA* detection for the preliminary identification of MRSA species, *vanA/B* detection for the preliminary identification of VRE species, $bla_{CTX\text{-}M}$, the most commonly detected extended spectrum beta-lactamase in *Enterobacterales*, and the five most common carbapenemase genes detected in the United States. Assays from each manufacturer have different combinations of genetic resistance markers. Assessment of performance characteristics of the susceptibility markers on each panel have shown high rates of agreement between assay detection and conventional testing and/or sequencing [47,48,89].

False-positive results have been reported using the FilmArray BCID, possibly due to microbial DNA contamination of blood culture broth. *P. aeruginosa* DNA has been detected in bioMerieux BacT/Alert standard anaerobic bottles when tested by the FilmArray BCID [87]. Moreover, false identification of *Candida parapsilosis* and *Proteus* species has been reported using BD Bactec blood culture bottles when testing by the FilmArray BCID. The Verigene BC-GN and BC-GP assays, on the other hand, have not been affected by contaminating DNA in blood culture bottles, because the assays do not include an amplification step. Due to the possibility of false-positive target detection, results from molecular testing should be correlated with the bottle Gram stain and discordant results warrant further testing and investigation.

Numerous studies have evaluated the clinical impact of implementation of rapid BCID. Differences in study population, individualized institutional practices, and study design lead to differences in outcome metrics across studies. Decreased time to appropriate antibiotic therapy was observed in most studies following implementation of rapid blood culture panels [90–96]. In addition, some but not all studies have demonstrated decreased length of hospital stay and decreased overall institution costs [90,94,96]. No mortality benefit was noted following implementation in most clinical studies; however, a few studies reported a statistically significant reduction in 30-day mortality rate [95,96].

Maximum impact of these panels is appreciated when results are coupled with antibiotic stewardship interventions, providing real-time guidance to clinicians to promote optimization of antibiotic choice and dose [97,98]. Antibiotic stewardship interventions may include real-time communication of BCID results from the microbiology laboratory to a member to the antimicrobial stewardship team (such as an ID pharmacist or ID physician). In such interventions, real-time antibiotic decision support is then provided to the primary clinical team by an ID expert. While real-time in-person interventions are likely to result in optimal antibiotic therapy, institutions may not have sufficient resources to implement fully these labor-intensive interventions. Alternatively, laboratories may release BCID testing results with evidence-based antibiotic stewardship recommendations in the form of comments appended to test results. Such comments should be carefully crafted in consultation with ID specialists. Although BCID reporting comments provide decision support and are more easily implemented compared with real-time expert advice, comments do not provide individualized guidance and are easily overlooked by physicians. Ultimately, improved communication between primary clinical providers, antibiotic experts, and the clinical microbiology laboratory is essential for optimal utilization of BCID panel results and improved patient care.

Meningitis and encephalitis panel

Infections of the CNS are associated with significant morbidity and mortality. Establishing a specific diagnosis is integral to administering appropriate therapy, as the etiologic agents of meningitis and encephalitis vary. Clinical presentation may be nonspecific, with many patients experiencing headache, alternated mental status, and potentially nuchal rigidity. WBC count and differential in cerebrospinal fluid, in addition to protein and glucose concentrations, may be indicative of the infecting agent. In the cases of bacterial meningitis, WBC counts are typically elevated with a neutrophilic predominance. Moreover, CSF protein concentrations are usually elevated and glucose concentrations are usually below normal limits. In the cases of viral meningitis, WBC counts are also elevated, with a lymphocytic predominance, although neutrophils may be present early in infection. Protein concentration is normal to elevated and glucose concentrations are generally normal. In the cases of fungal or tubercular CNS infections, WBC counts are elevated with lymphocytosis, protein concentrations are normal to elevated, and glucose concentration is normal to low. Traditional microbiologic testing of CSF is necessary to determine the infecting agent. Bacterial meningitis is generally diagnosed by Gram stain and bacterial culture. Viral meningitis requires molecular testing of CSF for the diagnosis of enterovirus and herpes simplex virus 1 and 2 (HSV-1 and HSV-2). In some cases of viral CNS infections, such as in cases of vector-borne encephalitis, serological testing may be warranted. Tubercular and fungal CNS infections are diagnosed by molecular and culture-based methods and, in the case of cryptococcal meningitis, by antigen detection in the CSF. Molecular detection of CNS pathogens may allow for a more rapid diagnosis, especially in the cases of bacterial meningitis. In addition, molecular testing is less likely to be affected

by prior antimicrobial therapy that may affect culture sensitivity.

At this time, only one panel has received FDA approval/clearance for the diagnosis of CNS infections, the FilmArray Meningitis/Encephalitis (ME) panel (BioFire Diagnostics). This panel tests for 14 pathogens, including enterovirus, human parechovirus, HSV-1 and -2, cytomegalovirus, human herpesvirus 6, varicella zoster virus, *E. coli* K1, *Haemophilus influenzae, Listeria monocytogenes, N. meningitidis, Streptococcus agalactiae*, *S. pneumoniae*, and *Cryptococcus neoformans/gattii*. Several studies have evaluated the performance of the ME Panel and found high overall positive and negative agreement rates. In a large prospective evaluation of CSF specimens, the authors found 84.4% and >99.9% positive and negative agreement between the FilmArray ME Panel and conventional microbiology testing [99]. In a smaller study of pediatric patients, authors found 92.5% positive agreement and 96.2% negative agreement [100].

False-positive results from these panels are a matter of concern and prevention of contamination during specimen collection and handling is integral to appropriate utilization of the FilmArray ME Panel. Several studies have documented concerning rates of *S. pneumoniae* false-positive detection [99,101]. For these reasons, many laboratories have placed testing restrictions on these panels. In some cases, a laboratory director may opt to evaluate CSF parameters prior to performing the FilmArray ME Panel. Alternatively, some laboratory directors may evaluate all positive results prior to release to clinicians. False-negative results are also concerning. Cases of false-negative results for cryptococcal meningitis have been documented when compared with cryptococcal culture results [101,102]. Finally, some studies have reported false-negative HSV-1 and HSV-2 results, possibly due to viral burden below the panel limit of detection in Refs. [100] and [101].

Additional studies are necessary to determine the clinical and economic benefits of syndromic panel testing for the diagnosis of meningitis and encephalitis. Pre-/postintervention studies evaluating the impact of FilmArray ME Panel testing on length of stay and duration of antibiotic treatment have shown variable results, with reduced length of stay documented in one study but not observed in another [103,104]. Similar to outcome studies associated with other syndromic panels, it is likely that antibiotic stewardship intervention at the time of result reporting will be helpful in realizing the maximum impact of these results.

Conclusion

The clinical microbiology laboratory has undergone a period of rapid growth and evolution during the past 10–15 years. Significant strides in advancement continue to be made as more rapid and automated technologies obtain FDA-clearance.

Self-assessment questions

1. What is the primary benefit of flocked vs. traditional swabs?
   - **a.** Flocked swabs are larger and allow for collection of a greater number of organisms
   - **b.** Flocked swabs allow a greater number of organisms to be released from the swab
   - **c.** Specimens collected using flocked swabs can be transported at any temperature
   - **d.** Flocked swabs are less expensive
2. Which of the following is not a component of current microbiology laboratory automation systems?
   - **a.** Specimen inoculation
   - **b.** Automated track
   - **c.** Anaerobic incubation
   - **d.** Digital imaging
3. Which of the following is the gold standard method for identification of microorganisms?
   - **a.** PCR
   - **b.** Biochemical methods
   - **c.** MALDI
   - **d.** DNA sequencing
4. Clinics in your hospital system perform rapid influenza diagnostic tests for the detection of influenza A and B viral antigens, which have a low negative predictive value (NPV) during influenza virus season. Which test performance characteristic is associated with the low NPV of influenza antigen testing?
   - **a.** High cross-reactivity with other viruses
   - **b.** Poor reproducibility
   - **c.** Poor sensitivity
   - **d.** Poor specificity
5. Several multiplex molecular panels are commercially available for syndromic-based microbiology diagnosis. Which of the following infections *cannot* be diagnosed by a syndromic-based test?
   - **a.** Central nervous system infection
   - **b.** Gastrointestinal infection
   - **c.** Prosthetic joint infection
   - **d.** Upper respiratory infection

Answers

1. b
2. c, anaerobic incubation
3. d, DNA sequencing
4. c, Poor sensitivity
5. c, Prosthetic joint infection
