Neutral Hydrogels. Flory and Rehner (13) developed the initial depiction of the swelling of cross-linked polymer gels using a Gaussian distribution of the polymer chains. They developed a model to describe the equilibrium degree of swelling of cross-linked polymers. The model postulated that the degree to which a polymer network swells is governed by the elastic retractive forces of the polymer chains and the thermodynamic compatibility of the polymer and the solvent molecules. In terms of the free energy of the system, the total free energy change upon swelling is written as

$$\Delta G = \Delta G_{\text{elastic}} + \Delta G_{\text{mix}}. \quad (3)$$

Here, $\Delta G_{\text{elastic}}$ is the contribution of the elastic retractive forces and ΔG_{mix} represents the thermodynamic compatibility of the polymer and the swelling agent. Upon evaluating each term at equilibrium, the swelling behavior for hydrogels cross-linked in the absence of a solvent can be described by the following equation:

$$\frac{1}{\bar{M}_c} = \frac{2}{\bar{M}_n} - \frac{(v/V_1)[\ln(1 - v_{2,s}) + v_{2,s} + \chi_1 v_{2,s}]}{\left(v_{2,s}^{1/3} - \frac{v_{2,s}}{2}\right)}, \quad (4)$$

where v is the specific volume of the polymer, V_1 is the molar volume of the swelling agent, χ_1 is the polymer solvent interaction parameter, and \bar{M}_n is the molecular weight of linear polymer chains prepared without a cross-linking agent under the same conditions.

In many cases, it is desirable to prepare hydrogels in the presence of a solvent. If the polymers were cross-linked in the presence of a solvent, the elastic contributions must account for the volume fraction density of the chains during cross-linking. Peppas and Merrill (14) modified the original Flory–Rehner to account for the changes in the elastic contributions to swelling. The equilibrium swelling equation for polymer gels cross-linked in the presence of a solvent is

$$\frac{1}{\bar{M}_c} = \frac{2}{\bar{M}_n} - \frac{(v/V_1)[\ln(1 - v_{2,s}) + v_{2,s} + \chi_1 v_{2,s}]}{v_{2,r}[(v_{2,s}/v_{2,r})^{1/3} - (v_{2,s}/2v_{2,r})]}. \quad (5)$$

Here, $v_{2,r}$ is the volume fraction of the polymer in the relaxed state. The relaxed state of the polymer is defined as its state immediately after cross-linking but before swelling or deswelling. By performing swelling experiments to determine $v_{2,s}$, the molecular weight between cross-links can be calculated for a particular gel by using this equation (12).

Ionic Hydrogels. Ionic hydrogels contain pendent groups that are either cationic or anionic. The side groups of

Figure 2. Expansion (swelling) of a cationic hydrogel due to ionization of pendent groups at specific pH values.

anionic gels are unionized below the pK_a , and the swelling of the gel is governed by the thermodynamic compatibility of the polymer and the swelling agent. However, above the pK_a of the network, the pendent groups are ionized, and the gels swell to a large degree due from the development of a large osmotic swelling force due to the presence of the ions. In cationic gels, the pendent groups are not ionized above the pK_b of the network. When the gel is placed in a fluid whose pH is less than this value, the basic groups are ionized, and the gels swell to a large degree (Fig. 2). The swelling behavior of ionic gels is depicted in Fig. 3. Note that this behavior can be completely reversible.

The theoretical description of the swelling of ionic hydrogels is much more complex than that of neutral hydrogels. Aside from the elastic and mixing contributions to swelling, the swelling of an ionic hydrogel is affected by the degree of ionization in the gel, the ionization equilibrium between the gel and the swelling agent, and the nature of the counterions in the fluid. As the ionic content of a hydrogel is increased in response to an environmental stimulus, increased repulsive forces develop, and the network becomes more hydrophilic. The result is a more highly swollen network. Because of Donnan equilibrium, the chemical potential of the ions inside the gel must be

Figure 3. Equilibrium degree of swelling of anionic and cationic hydrogels as a function of the swelling solution pH.

equal to the chemical potential of the ions in the solvent outside the gel (15). An ionization equilibrium is established as a double layer of fixed charges on the pendent groups and the counterions in the gel. Finally, the nature of counterions in the solvent affects the swelling of the gel. As the valence of the counterions increases, they are more strongly attracted to the gel and reduce the concentration of ions needed in the gel to satisfy Donnan equilibrium conditions.

The swelling behavior of polyelectrolyte gels was initially described as a result of a balance between the elastic energy of the network and the osmotic pressure developed as a result of the ions (15–22). In electrolytic solutions, the osmotic pressure is associated with the development of a Donnan equilibrium. This pressure term is also affected by the fixed charges developed on the pendent chains. The elastic term is described by the Flory expression derived from assumptions of Gaussian chain distributions.

Models were developed for the swelling of ionic hydrogels by equating the three major contributions to the swelling of the networks. These contributions are due to mixing of the polymer and solvent, network elasticity, and ionic contributions. The general equation is given as

$$\Delta G = \Delta G_{\text{mix}} + \Delta G_{\text{el}} + \Delta G_{\text{ion}}. \quad (6)$$

In terms of the chemical potential, the difference between the chemical potential of the swelling agent in the gel and outside the gel is

$$\mu_1 - \mu_{1,0} = (\Delta\mu)_{\text{elastic}} + (\Delta\mu)_{\text{mix}} + (\Delta\mu)_{\text{ion}}. \quad (7)$$

The elastic contribution and mixing contributions of weakly charged polyelectrolytes will not differ from those of nonionic gels. However, for highly ionizable materials, ionization effects are significant, and $\Delta\mu_{\text{ion}}$ is important. At equilibrium, the elastic, mixing, and ionic contributions must sum to zero.

The ionic contribution to the chemical potential depends strongly on the ionic strength and the nature of the ions. Both Brannon-Peppas and Peppas (21,22) and Ricka and Tanaka (15) developed expressions to describe ionic contributions to the swelling of polyelectrolytes. Assuming that polymer networks under conditions of swelling behave similarly to dilute polymer solutions, activity coefficients can be approximated as one, and activities can be replaced by concentrations. Under these conditions, the ionic contribution to the chemical potential is described by the following:

$$(\Delta\mu)_{\text{ion}} = RTV_1 \Delta c_{\text{tot}}. \quad (8)$$

Here, Δc_{tot} is the difference in the total concentration of mobile ions within the gel. The difference in the concentration of mobile ions is due to the fact that the charged polymer requires that the same number of counterions remain in the gel to achieve electroneutrality. The difference in the total ion concentration could then be calculated from the equilibrium condition for the salt.

Brannon-Peppas and Peppas (21,22) developed expressions for the ionic contributions to the swelling of polyelectrolytes for anionic and cationic materials. The ionic contribution for an anionic network is

$$(\Delta\mu)_{\text{ion}} = \frac{RTV_1}{4I} \left(\frac{v_{2,s}^2}{v} \right) \left(\frac{K_a}{10^{-\text{pH}} + K_a} \right)^2. \quad (9)$$

The ionic contribution for a cationic network is

$$(\Delta\mu)_{\text{ion}} = \frac{RTV_1}{4I} \left(\frac{v_{2,s}^2}{v} \right) \left(\frac{K_b}{10^{\text{pH}-14} + K_b} \right)^2. \quad (10)$$

In these expressions, I is the ionic strength and K_a and K_b are the dissociation constants for the acid and base, respectively. It is significant to note that this expression has related the ionic contribution to the chemical potential to characteristics about the polymer/swelling agent that are readily determinable (e.g., pH, K_a , and K_b).

The equilibrium swelling of anionic polymer gels that were crosslinked in the presence of a solvent can be described by

$$\begin{aligned} \frac{V_1}{4I} \left(\frac{v_{2,s}^2}{v} \right) \left(\frac{K_a}{10^{-\text{pH}} + K_a} \right)^2 &= [\ln(1 - v_{2,s}) + v_{2,s} + \chi_1 v_{2,s}] \\ &+ \left(\frac{V_1}{v \bar{M}_c} \right) \left(1 - \frac{2\bar{M}_c}{\bar{M}_n} \right) v_{2,r} \left[\left(\frac{v_{2,s}}{v_{2,r}} \right)^{1/3} - \frac{v_{2,s}}{2v_{2,r}} \right]. \end{aligned} \quad (11)$$

The equilibrium swelling of cationic hydrogels prepared in the presence of a solvent is described by the following expression:

$$\begin{aligned} \frac{V_1}{4I} \left(\frac{v_{2,s}^2}{v} \right) \left(\frac{K_b}{10^{\text{pH}-14} + K_b} \right)^2 &= [\ln(1 - v_{2,s}) + v_{2,s} + \chi_1 v_{2,s}] \\ &+ \left(\frac{V_1}{v \bar{M}_c} \right) \left(1 - \frac{2\bar{M}_c}{\bar{M}_n} \right) v_{2,r} \left[\left(\frac{v_{2,s}}{v_{2,r}} \right)^{1/3} - \frac{v_{2,s}}{2v_{2,r}} \right]. \end{aligned} \quad (12)$$

The molecular weights of ionic hydrogels between crosslinks can be calculated by performing swelling experiments and applying Eqs. (11) (anionic gels) or (12) (cationic gels).

Rubber Elasticity Theory

Hydrogels are similar to natural rubbers; they can respond to applied stresses nearly instantaneously (23,24). These polymer networks can deform readily under low stresses. Following small deformations (less than 20%), most gels can also fully recover rapidly from the deformation. Under these conditions, the behavior of the gels can be approximated as elastic. This property can be exploited to calculate the cross-linking density or molecular weight between cross-links for a particular gel.

The elastic behavior of cross-linked polymers has been analyzed using classical thermodynamics, statistical thermodynamics, and phenomenological models. Based on classical thermodynamics and assuming an isotropic

system, the stress–strain behavior of rubbers can be expressed as (23,24)

$$\tau = \frac{\rho RT}{\bar{M}_c} \left(1 - \frac{2\bar{M}_c}{\bar{M}_n} \right) \left(\alpha - \frac{1}{\alpha^2} \right), \quad (13)$$

where τ is the stress, ρ is the density of the polymer, and α is the elongation ratio defined as the elongated length divided by the initial length of the sample.

Similar analysis can be applied to swollen hydrogels when the polymer volume fraction in the network is less than unity. The number of cross-links per unit volume of swollen gels is different from that of unswollen polymer networks. The equation of state for real, swollen polymer gels can be expressed as

$$\tau = \frac{\rho RT}{\bar{M}_c} \left(1 - \frac{2\bar{M}_c}{\bar{M}_n} \right) \left(\alpha - \frac{1}{\alpha^2} \right) \nu_{2,s}^{-1/3}. \quad (14)$$

This equation holds for networks cross-linked in the absence of any diluents. The equation of state of a swollen network cross-linked in the presence of a solvent can be written as (25)

$$\tau = \frac{\rho RT}{\bar{M}_c} \left(1 - \frac{2\bar{M}_c}{\bar{M}_n} \right) \left(\alpha - \frac{1}{\alpha^2} \right) \left(\frac{\nu_{2,s}}{\nu_{2,r}} \right)^{1/3}. \quad (15)$$

For elongation of a polymer network along a single axis, the stress is inversely proportional to the molecular weight between cross-links in the polymer network. Important structural information about polymer networks can be obtained from mechanical analysis under short deformations (26–28).

Network Pore Size Calculation

One of the most important parameters in controlling the rate release of a drug from a hydrogel is the network pore size ξ . This is particularly important for smart gels because pore size changes dramatically as environmental conditions shift. Pore size can be determined theoretically or by using a number of experimental techniques. Direct techniques for measuring this parameter are quasi-elastic laser-light scattering (29) and electron microscopy. Some indirect experimental techniques for determining the hydrogel pore size include mercury porosimetry (30,31), rubber elasticity measurements (26), and equilibrium swelling experiments (12,32). However, indirect experiments allow

calculating the porous volume (mercury porosimetry) and the molecular weight between cross-links (rubber elasticity analysis or swelling experiments).

Based on values for the crosslinking density or molecular weight between crosslinks, the network pore size can be determined by calculating the end-to-end distance of the swollen polymer chains between cross-linking points (12,23,32):

$$\xi = \alpha (r_0^{-2})^{1/2}. \quad (16)$$

In this expression, α is the elongation of the polymer chains in any direction and $(r_0^{-2})^{1/2}$ is the unperturbed end-to-end distance of the polymer chains between cross-linking points. Assuming isotropic swelling of the gels and using the Flory characteristic ratio C_n for calculating the end-to-end distance, the pore size of a swollen polymeric network can be calculated from the following equation (1):

$$\xi = \left(\frac{2C_n \bar{M}_c}{M_0} \right)^{1/2} l \nu_{2,s}^{-1/3} \quad (17)$$

where l is the length of the bond along the backbone chain (1.54 Å for vinyl polymers) and M_0 is the molecular weight of the monomeric repeating units.

CLASSIFICATIONS

Responsive hydrogels are unique. There are many different mechanisms for drug release, and many different types of release systems based on these materials. For instance, drug release in most cases occurs when the gel is highly swollen or swelling and is typically controlled by gel swelling, drug diffusion, or a coupling of swelling and diffusion. However, in a few instances, drug release occurs during gel syneresis by a squeezing mechanism. Drug release can also occur due to erosion of the polymer caused by environmentally responsive swelling.

Another interesting characteristic of many responsive gels is that the mechanism that causes the network structural changes can be entirely reversible. This behavior of a pH- or temperature-sensitive gel is depicted in Fig. 4. The ability of these materials to exhibit rapid changes in their swelling behavior and pore structure in response to changes in environmental conditions lends these materials favorable characteristics as carriers for bioactive agents, including peptides and proteins. This type of behavior may allow these materials to serve as self-regulated, pulsatile drug delivery systems. This type of behavior is shown

Figure 4. Swollen temperature- and pH-sensitive hydrogels may exhibit an abrupt change from the expanded (left) to the collapsed (syneresed) state (center) and then back to the expanded state (right), as temperature and pH change.

Figure 5. Cyclic change of pH, T or ionic strength I leads to abrupt changes in the drug release rates at certain time intervals in some environmentally responsive polymers.

in Fig. 5 for pH- or temperature-responsive gels. Initially, the gel is in an environment in which no swelling occurs. As a result, very little drug release occurs. However, when the environment changes and the gel swells, drug release is rapid. When the gel collapses as the environment changes, the release can be turned off again. This can be repeated through numerous cycles. Such systems could be of extreme importance in treating chronic diseases such as diabetes. Peppas (33) and Siegel (34) have presented detailed analyses of this type of behavior.

pH-Sensitive Hydrogels

One of the most widely studied types of physiologically responsive hydrogels is pH-responsive hydrogels. These hydrogels are swollen from ionic networks that contain either acidic or basic pendent groups. In aqueous media of appropriate pH and ionic strength, the pendent groups can ionize and develop fixed charges on the gel, as shown in Fig. 2 for

an ionic gel. The swelling behavior of these materials has been analyzed in a previous section.

There are many advantages of using ionic materials in neutral networks. All ionic materials exhibit sensitivity to pH and ionic strength. The swelling forces developed in these systems are increased compared to nonionic materials. This increase in swelling force is due to the localization of fixed charges on the pendent groups. As a result, the mesh size of the polymeric networks can change significantly from small pH changes. The drug diffusion coefficients and release rates in these materials will vary greatly as the environmental pH changes.

Temperature-Sensitive Hydrogels

Thermally sensitive polymers comprise another class of environmentally sensitive materials that are being targeted for drug delivery applications. This type of hydrogel exhibits temperature-sensitive swelling due to a change in the compatibility of the polymer/swelling agent across the temperature range of interest. Temperature-sensitive polymers typically exhibit lower critical solution temperatures (LCST), below which the polymer is soluble. Above this temperature, the polymers are typically hydrophobic and do not swell significantly in water (35). However, below the LCST, the cross-linked gel swells to significantly higher degrees because of increased compatibility with water. The rate of drug release of polymers that exhibit this sort of swelling behavior would depend on the temperature. The highest release rates would occur when the temperature of the environment is below the LCST of the gel.

Complexing Hydrogels

Some hydrogels may exhibit environmental sensitivity due to the formation of polymer complexes. Polymer complexes are insoluble, macromolecular structures formed by the noncovalent association of polymers that have affinity for one another. The complexes form due to the association of repeating units on different chains (interpolymer complexes) or on separate regions of the same chain (intrapolymer complexes). Polymer complexes are classified as stereocomplexes, polyelectrolyte complexes, and hydrogen bonded complexes by the nature of the association (36). The stability of the associations depends on such factors as the nature of the swelling agent, the temperature, the type of dissolution medium, the pH and ionic strength, the network composition and the structure, and the length of the interacting polymer chains.

Complex formation in this type of gel results in physical cross-links in the gel. As the degree of effective cross-linking is increased, the network mesh size and degree of swelling are significantly reduced. As a result, the rate of drug release in these gels decreases dramatically when interpolymer complexes are formed.

Materials Sensitive to Chemical or Enzymatic Reaction

More recently, researchers have proposed controlled release devices that can respond to specific chemicals or enzymes in the body (37,38). Under normal conditions, the structure of the hydrogel would be sufficient to prevent drug release. However, in the presence of specific

substances, chemical or enzymatic reactions could occur that may hydrolyze specific groups of the polymer chain and result in an increased pore structure and rate of drug release from the gel. If degradation of the gel occurs, the systems cannot be fully reversible.

In some instances, enzymes can be incorporated in the structure of the hydrogel. In the presence of specific chemicals, the enzyme could trigger a reaction which would change the microenvironment of the hydrogel. Changes in the local microenvironment (such as pH or temperature) could lead to gel swelling or collapse. In these situations, the release rates would be altered significantly. This type of system could be completely reversible.

Magnetically Responsive Systems

Magnetically responsive systems consist of polymers or copolymers that contain magnetic microbeads (39). These systems can be prepared from most polymers; however, the most commonly used copolymer for these systems is the hydrophobic polymer poly(ethylene-co-vinyl acetate). Such systems are not typically classified as hydrogels because they do not swell to any appreciable degree. The drug release mechanism of a typical magnetic system is shown in Fig. 6. The three-dimensional structure of these systems is such that no drug release can occur when no magnetic field is applied. However, when a magnetic field is applied, the microbeads pulsate and allow micropores to form.

Figure 6. Schematic representation of drug release from a magnetically controlled system. Initially, when the field is off (a), no drug release occurs. When the field is turned on (b), the oscillations of the beads creates macropores through which drug release occurs (c). (d) Drug release halts when the field is switched off.

Additionally, the pulsation of the beads “squeezes” the drug out of the gel through these pores. When the field is removed, drug release halts rapidly. Such systems have been targeted for use as pulsatile drug delivery vehicles and, it has been shown, exhibit extremely reproducible behavior.

APPLICATIONS

pH-Sensitive Hydrogels

Hydrogels can respond to pH changes have been studied extensively over the years. These gels typically contain ionizable side groups such as carboxylic acids or amine groups (40,41). The most commonly studied ionic polymers include poly(acrylamide) (PAAm), poly(acrylic acid) (PAA), poly(methacrylic acid) (PMAA), poly(diethylaminoethyl methacrylate) (PDEAEMA), and poly(dimethylaminoethyl methacrylate) (PDMAEMA).

Cationic copolymers based on PDEAEMA and PDMAEMA have been studied by the Peppas and Siegel groups. The Siegel group focused on the swelling and transport behavior of hydrophobic cationic gels. Siegel and Firestone (42,43) studied the swelling behavior of hydrophobic hydrogels of PDMAEMA and poly(methyl methacrylate). Such systems were collapsed in solutions whose pH was higher than 6.6. However, in solutions less than pH 6.6, such systems swelled due to protonation of the tertiary amine groups. The release of caffeine from these gels was studied (44). No caffeine was released in basic solutions; however, in neutral or slightly acidic solutions, steady release of caffeine was observed for 10 days. More recently, Cornejo-Bravo and Siegel (45) investigated the swelling behavior of hydrophobic copolymers of PDEAEMA and PMMA. Additionally, Siegel (46) presented an excellent model of the dynamic behavior of ionic gels.

The Peppas groups studied the swelling behavior of more hydrophilic, cationic copolymers of P(DEAEMA-co-HEMA) and P(DMAEMA-co-HEMA) (47). These gels swelled in solutions less than pH 7 and were in the collapsed state in basic solutions. These materials swelled to a greater degree than those prepared by Siegel. These materials were used to modulate the release behavior of protein and peptide drugs (48). Schwarte and Peppas (49) studied the swelling behavior of copolymers of PDEAEMA grafted with PEG. The permeability of dextrans of molecular weight 4400 and 9400 was studied. The membrane permeabilities in the swollen membranes (pH 4.6) were two orders of magnitude greater than those of the collapsed membranes.

Anionic copolymers have received significant attention as well. The swelling and release characteristics of anionic copolymers of PMAA and PHEMA (PHEMA-co-MAA) have been investigated. The gels did not swell significantly in acidic media; however, in neutral or basic media, the gels swelled to a high degree due to ionization of the pendent acid group (50,51). Brannon-Peppas and Peppas also studied the oscillatory swelling behavior of these gels (52). Copolymer gels were transferred between acidic and basic solutions at specified time intervals. In acidic

solutions, the polymer swelled due to the ionization of the pendent groups. Rapid gel syneresis occurred in basic solutions. Brannon-Peppas and Peppas (53) modeled the time-dependent swelling response to pH changes by using a Boltzman superposition-based model. The pH-dependent release behavior of theophylline and proxiphylline from these anionic gels was also studied (54,55). Khare and Peppas (56) studied the pH-modulated release behavior of oxprenolol and theophylline from copolymers of PHEMA-co-MAA and PHEMA-co-AA. Drug release in neutral or basic media occurred rapidly by a non-Fickian mechanism. The release rate slowed significantly in acidic media. In another study, am Ende and Peppas (57) examined the transport of ionic drugs of varying molecular weight in PHEMA-co-AA. They compared experimental results to a free-volume based theory and found that deviations occurred due to interactions between the ionized backbone chains and pendent acid groups. The swelling and release behavior of interpenetrating polymer networks of PVA and PAA was also investigated (58,59). These materials also exhibit strong pH-responsive swelling. The permeability of these membranes was strongly dependent on the environmental pH and the size and ionic nature of the solute. Recent new studies have used ATR-FTIR spectroscopy to characterize the interactions between polyelectrolytes and solutes (59,60).

Heller et al. (61) studied the behavior of another type of pH-responsive hydrogel. In this work, they evaluated the pH-dependent release of insulin from degradable poly(ortho esters). Other researchers used chitosan (CS) membranes for drug delivery applications. These materials exhibited pH-dependent swelling due to gelation of CS upon contact with anions (62). Interpenetrating networks of CS and PEO have been proposed as drug delivery devices due to their pH-dependent swelling behavior (63,64). More recently, Calvo et al. (65) prepared novel CS-PEO microspheres. These systems were used to provide continuous release of entrapped bovine serum albumin for 1 week. In another study, methotrexate, an anticancer drug, was encapsulated in microspheres of pH-sensitive CS and alginate (66). Zero-order release of the drug was observed from the microspheres in pH 1.2 buffer for more than 1 week. Okano's group (67) studied pH-responsive calcium alginate gel beads. In these systems, modulated release of dextran was achieved by varying the pH and ionic strength of the environmental solution. Such systems may be promising for protein and peptide delivery applications.

An exciting application of pH-sensitive hydrogels is being pursued by Narayani et al. (68). They developed both anionic and cationic hydrogels using either alginate or chitosan as a comonomer with HEMA, respectively. They were able to demonstrate high loading efficiencies of the cancer agent methotrexate.

Temperature-Sensitive Hydrogels

Some of the earliest work on temperature-sensitive hydrogels was done by the Tanaka's group (69). They synthesized using cross-linked poly(*N*-isopropylacrylimide) (PNIPAAm) and determined that the LCST of the PNIPAAm gels was 34.3°C. Below this temperature,

significant gel swelling occurred. The transition about this point was reversible. They discovered that the transition temperature was raised by copolymerizing PNIPAAm with small amounts of ionic monomers. Beltran et al. (70) also worked with PNIPAAm gels containing ionic comonomers. They observed results similar to those achieved by Tanaka.

The earliest investigators who studied PNIPAAm gels discovered that the response time of the materials to temperature changes was rather slow. Future studies focused on developing newer materials could collapse/expand more rapidly. Dong and Hoffman (71) prepared heterogeneous gels containing PNIPAAm that collapsed at significantly faster rates than homopolymers of PNIPAAm. Kabra and Gehrke (72) developed a new method for preparing PNIPAAm gels that resulted in significant increases in the swelling kinetics of the gels. They prepared gels below the LCST to produce a permanent phase separated microstructure in the gels. These gels expanded at rates 120 times faster and collapsed at rates 3000 times faster than homogeneous PNIPAAm gels. Okano's group (73,74) developed an ingenious method for preparing comb-type graft hydrogels of PNIPAAm. The main chain of the cross-linked PNIPAAm contained small molecular weight grafts of PNIPAAm. Under conditions of gel collapse (above the LCST), hydrophobic regions were developed in the pores of the gel that resulted in rapid collapse. These materials could collapse from a fully swollen conformation in less than 20 minutes, whereas comparable gels that did not contain graft chains required up to a month to collapse fully. Such systems show major promise for rapid and abrupt or oscillatory release of drugs, peptides, and proteins.

Thermoresponsive polymers may be particularly useful in a wide variety of drug delivery applications (35,75). Okano et al. (76) studied the temperature-dependent permeability of PNIPAAm gels. They used these gels as "on-off" delivery devices in response to temperature fluctuations. This type of behavior was useful for controlling the release of insulin (77) and heparin (48). These gels were also used as "squeezing" systems (78). More recently, conjugates of PNIPAAm with trypsin have been developed (79). Such systems could be extremely useful in the targeted delivery of enzymes. Another promising application of these systems was explored by Vernon et al. (80). In this work, islets of Langerhans were entrapped by thermal gelation of PNIPAAm for use as a rechargeable artificial pancreas. Fukumori et al. (81,82) also worked with microcapsules coated in a thermosensitive layer comprised of either hydroxypropyl cellulose (HPC) or ethyl cellulose that contained nanoparticles of PNIPAAm hydrogels. These two systems result in two entirely different temperature-sensitive drug release schemes. Drug release occurs readily below the LCST for the the HPC coating due to the more open mesh size. However, above this temperature, the network collapses, hindering solute transport. In the other system, the drug release occurs only at temperatures above the LCST. At these temperatures, the nanohydrogels are collapsed, leaving voids that allow rapid release of solute. These systems, it was, are fully reversible, resulting in an "on/off" release behavior.

Other materials that possess a LCST near physiological conditions have also been pursued. Yuk et. al. (83,84)

proposed another temperature-sensitive comonomer system comprised of DMAEMA and acrylamide (Aam). By changing the comonomer feed ratio, the LCST of these systems varied from 28°C to 50°C. They also developed a mathematical model to describe solute transport as a function of temperature and network swelling kinetics (85). Ogata has also worked on hydrogels composed of the nucleic acid, uracil (86). These hydrogels, it has been shown, rapidly change volume at 35°C.

Another application of thermally sensitive hydrogels is in injectable localized drug delivery systems. Cui and Messersmith (87) used an aqueous solution of sodium alginate and temperature-sensitive liposomes containing Ca^{2+} and a drug. Once the solution is injected, the temperature of the body causes the liposomes to release the calcium ions and the drug. The calcium ions then crosslink the alginate to form a hydrogel, and controlled release of the drug to the surrounding tissue is possible. Hoffman et al. (88) created networks of chitosan grafted with Pluronic side chains. This copolymer system remains a solution until the temperature is raised to 37°C, and the side chains for hydrophobic domains cross-link the network to form a hydrogel.

pH- and Temperature-Sensitive Hydrogels

During the last 10 years, researchers have developed a novel class of hydrogels that exhibits both pH- and temperature-sensitive swelling behavior. These materials may prove extremely useful in enzymatic or protein drug delivery applications. Hydrogels were prepared from PNIPAAm and PAA that exhibited dual sensitivities (89,90). These gels responded rapidly to both temperature and pH changes. Kim's group investigated such systems as carriers of insulin (91) and calcitonin (92). In general, these hydrogels exhibited strong temperature-sensitive swelling behavior only when large amounts of PNIPAAm were in the gel. Cationic pH- and temperature-sensitive gels were prepared using poly(amines) and PNIPAAm (93). These systems were evaluated for local delivery of heparin.

Chen and Hoffman prepared new graft copolymers of PAA and PNIPAAm that responded more rapidly to external stimulus than previously studied materials (94). These new materials exhibited increased temperature sensitivity due to the presence of the PNIPAAm grafts. Such systems were evaluated for prolonged mucosal delivery of bioactive agents, specifically peptide drugs (95).

Brazel and Peppas (96) studied the pH- and temperature-responsive swelling of gels containing PNIPAAm and PMAA. These materials were used to modulate the release of streptokinase and heparin in response to pH and temperature changes (97). Baker and Siegel (98) used similar hydrogels to modulate glucose permeability. However, only large amounts of PNIPAAm were needed to observe large temperature sensitivities. The Peppas group developed novel pH- and temperature-sensitive terpolymers of PHEMA, PMAA, and PNIPAAm (99). These systems were prepared to contain PNIPAAm-rich blocks, and as a result, these materials exhibited strong temperature sensitivity at only 10% PNIPAAm in the gel. Using these materials, they were effectively able to modulate release

Figure 7. The effect of interpolymer complexation on the correlation length ξ and on the effective molecular weight between crosslinks \bar{M}_c , in P(MAA-*g*-EG) graft copolymer networks that have permanent, chemical cross-links (•).

kinetics of streptokinase (100). Cationic pH/temperature-sensitive polymer networks have also been analyzed. Park and Hoffman (101,102) studied gels based on NIPAAm and *NN'*-dimethylaminopropyl methacrylamide (DMAPMAAm), and Gutowska et al. (103,104) looked at networks that consisted of the more commonly used DEAEEMA and NIPAAm. They demonstrated significant pH swelling dependence at 37°C.

A novel approach to pH- and temperature-sensitive drug release was developed by the Orkisz et al. (105). They developed a system that consists of two compartments, one a drug reservoir and the other a pH- temperature-sensitive hydrogel comprised of carboxylic acid functionalized hydroxypropyl cellulose. During periods of neutral pH and low temperature, the gel is swollen and prevents release of the drug from the reservoir. However, when the temperature increases or the pH decreases, the hydrogel barrier collapses, thus allowing drug release. Kaetsu et al. (106–109) also developed a similar technology on a silicon wafer chip. They photoetched pits into the wafer, and these pits were subsequently covered by a layer of polyethylene terephthalate mesh filled with a polyelectrolyte gel. These gels covered the holes in the silicone wafer. Enzymes can be immobilized on the gel and act as the sensing mechanism. When the internal pH of the gel changes, it collapses, thus releasing the drug contained in the hole on the silicone wafer. The advantage of such a system is that a multitude of drug reservoir can be placed on a single chip, thus allowing for localized complex drug delivery.

Complexing Hydrogels

Another promising class of hydrogels that exhibits responsive behavior consists of complexing hydrogels. Osada studied complex formation in PMAA hydrogels (110). In acidic media, the PMAA membranes collapsed in the presence of linear PEG chains due to the formation of interpolymer complexes between the PMAA and PEG. The gels swelled when placed in neutral or basic media. The permeability of these membranes was strongly dependent on the environmental pH and PEG concentration (111). Similar results were observed for hydrogels of PAA and linear PEG (112). Interpenetrating polymer networks of

PVA and PAA that exhibit pH- and weak temperature-sensitive behavior due to complexation between the polymers were prepared, and the release behavior of indomethacin was studied (113,114).

The Peppas group developed a class of copolymer gels of PMAA grafted with PEG (P(MAA-*g*-EG) (115–123). These gels exhibited pH- dependent swelling due to the presence of acidic pendent groups and the formation of interpolymer complexes between the ether groups on the graft chains and protonated pendent groups. Complexation in these covalently cross-linked, complexing P(MAA-*g*-EG) hydrogels resulted in the formation of temporary physical cross-links due to hydrogen bonding between the PEG grafts and the PMAA pendent groups. The physical cross-links were reversible and depended on the pH and ionic strength of the environment. As a result, complexing hydrogels exhibit drastic changes in their mesh size across small pH changes, as shown in Fig. 7. One particularly promising application for these systems is oral delivery of protein and peptide drugs (123). As shown in Fig. 8, these copolymers

Figure 8. Controlled release of insulin *in vitro* from P(MAA-*g*-EG) microparticle simulated gastric fluid (pH 1.2) for the first 2 hours and phosphate buffered saline solutions (pH 6.8) for the remaining 3 hours at 37°C (172).

severely limit the release of insulin in acidic environments like those found in the stomach. However, insulin release occurred rapidly in conditions similar to those in the intestines.

Another form of complexation-dependent drug delivery is in drug-polymer complexation schemes. For example, Hoffman et al. (124,125) made hydrogels of NIPAAm and methacryloyl-polyoxyethyl phosphate. These phosphate-containing networks formed complexes with positively charged proteins such as lysozyme. At pH 7.4, this complex becomes destabilized, thus allowing for a pH- and ionic-strength-dependent release. The advantage of such a system is in the high loading efficiencies possible due to the capacity of the protein to form a polymer complex.

Materials Sensitive to Chemical or Enzymatic Reaction

Major developments have been reported in using environmentally responsive hydrogels as glucose-sensitive systems that could serve as self-regulated delivery devices for treating diabetes. Typically, these systems have been prepared by incorporating glucose oxidase into the hydrogel structure during polymerization. In the presence of glucose, glucose oxidase catalyzes the reaction between water and glucose to form gluconic acid. Gluconic acid lowers the pH of the gel's microenvironment.

The first such systems developed by Kost et al. (126) consisted of glucose oxidase immobilized in hydrogels based on PHEMA and PDMAEMA. These systems exhibited glucose-sensitive swelling. In the presence of glucose, gluconic acid is formed, resulting in a decrease in the local pH. As a result, the cationic-based gels swelled to larger degrees in the presence of glucose due to the production of gluconic acid. Glucose-responsive swelling allowed control of insulin permeation in these membranes by adjusting the environmental glucose concentrations (127,128). The kinetics of gel swelling and insulin release from cationic, glucose-sensitive hydrogels was also studied (129).

Glucose-responsive systems that were based on anionic hydrogels were proposed (130,131). Ito et al. (130) prepared systems of porous cellulose membranes containing an insulin reservoir. The pores of these devices were grafted with PAA chains functionalized by glucose oxidase. In the presence of glucose, the decrease in environmental pH caused the PAA chains to collapse, opening the pores to allow insulin release. More recently, glucose-sensitive complexation gels of P(MAA-*g*-EG) were developed by the Peppas group (131). As the pH decreased in these gels in response to elevated glucose concentrations, interpolymer complexes formed, resulting in rapid gel syneresis. The rapid collapse resulted in insulin release due to a "squeezing" phenomenon.

Other glucose-responsive systems have been developed that take advantage of the formation of complexes between glucose molecules and polymeric pendent groups. Lee and Park (132) prepared erodible hydrogels containing allyl glucose and poly(vinyl pyrrolidone). These systems were crosslinked by the noncovalent associations between concanavalin-A (Con-A) and the glucose pendent groups. In the presence of free glucose, Con-A was

bound to the free glucose, and the gels dissolved due to disruption of the physical cross-links. Newer materials developed by Okano's group exhibited glucose-responsive swelling and insulin release (133–135). These gels were based on phenylboronic acid (PBA) and acrylamides. Another class of glucose-sensitive gels was prepared that contained PBA, PNIPAAm, and PVA (136). These gels allow the release of insulin at physiological pH and temperature.

Similar to the glucose-sensitive hydrogels, Eremeev and Kukhtin made hydrogels that are immobilized by urease instead of glucose oxidase (137). Hence, these networks swell in the presence of urea due to urea hydrolysis.

A number of investigators concentrated on developing environmentally responsive gels that are biodegradable. This can be achieved by a number of synthetic methods. Kopecek and associates (138) developed biodegradable hydrogels by incorporating azo compounds. Bae and associates (139) synthesized very promising biodegradable carriers by preparing eight-arm, star-shaped, block copolymers that contain poly-lactic acid (PLA) and PEO. Another potentially useful biodegradable system is a photo-cross-linked polymer based on poly(L-lactic acid-*co*-L-aspartic acid) (140) which could be prepared *in situ* for delivering anti-inflammatory drugs following surgery.

Kurisawa and Yui investigated several systems that are sensitive to two enzymes. Interpenetrating networks (IPN) of dextran and methacryloyl-glycylglycylglycyl-terminated PEG are hydrogels that degrade only in the presence of both papain and dextranase (141–143). Without both of these enzymes present, the network is not degraded and hence cannot release its solute. Karisawa worked on a similar dual-stimuli system that is an IPN of gelatin and dextran (144,145). In this system, the two enzymes needed for degradation are alpha-chymotrypsin and dextranase.

microworld needs to be bridged naturally by using advanced devices and smart materials. In these respects, it is believed that giant magnetostrictive material (GMM) is one of the most promising materials for satisfying such requirements (Fig. 3).

GIANT MAGNETOSTRICTIVE MATERIALS

INTRODUCTION

The importance of an interface that associates the macro world and the microworld is indicated in Fig. 1. The interface is composed mainly of actuators, sensors, and micro-computers. As shown in Fig. 2, it enables users to feel the microscopic phenomenon as if they were in the macro world.

In life sciences and medical and biological engineering, there are increasing demands for implementing fabrication, assembly, inspection, modification, and/or evaluation at the micron or submicron scale (1,2). To achieve this, the development of new materials and devices that can realize the required functions and movements at a microscopic level becomes mandatory. For instance, great power output, large displacement, and quick response are often required for functional materials, and safety, stability, and flexibility are the primary concern for structural applications. The gap between the macro world and the

Figure 2. An intelligent system proposed for bridging the gap between the macro world and the micro world.

Figure 3. Evolutionary process in a dynamic intelligent system illustrated by unitizing microcomputers, actuators, and sensors, where the GMM plays a very important role.

GIANT MAGNETOSTRICTIVE MATERIALS

What Is a GMM

The magnetostrictive effect is any change in the dimensions of a magnetic material caused by a change in its magnetic state (3). GMMs are a group of materials that produce magnetostriction of more than several thousands ppm (parts per million). GMM was invented by A. E. Clark and his fellow researchers in 1963, when they first discovered the extraordinary magnetostrictive properties of the rare-earth element terbium at an extremely low temperature close to absolute zero. During the next two decades, they found that this giant magnetostrictive behavior exists at room temperature in terbium-iron (TbFe_2) and the magnetic anisotropic compensated alloy $\text{Tb}_x\text{Dy}_{1-x}\text{Fe}_{1.9}$ (or Terfenol-D where $x = 0.3$) for further temperature stability.

GMMs are unique in the sense that their magnetostrictions are as large as 0.2%, and they can sustain external loads as large as 500–600MPa. Unlike conventional materials, the response speed of GMMs is also very fast, of the order of 10^{-6} sec. Other attributes of GMMs include their low impedance and possible noncontact delivery of power. The former, in particular, enables a low voltage drive of GMM which may be of vital significance for applications that are used in inflammable atmospheres. Although there are some drawbacks in GMMs such as expensive material cost, rather poor corrosion resistance, heat generation by the driving coil, and eddy currents at high frequency excitation, however, fairly stable and robust performance can be obtained by choosing driving conditions according to the applications to be used.

Physics of GMMs

GMMs produce large strains up to approximately 2000 ppm in an imposed magnetic field. Magnetostriction is a result of the rotation of small magnetic domains that cause internal strains in the materials. These strains result in a positive expansion of a GMM in the direction of a magnetic field. As the magnetic field is increased, more domains rotate and become aligned until full saturation is achieved. If the magnetic field is reversed, the domains reverse their direction but align again in the field direction and also result in a length increase. The concept of the magnetostrictive effect is sketched in Fig. 4, where the magnetostrain $S(= \Delta l/l)$ is plotted versus the magnetic field H ; here l is the original length of the sample GMM, and the magnetic field intensity $H = nI$, where I is the current through a surrounding coil of N turns across a length l where $n = N/l$.

As the current I is increased, the magnetic field increases, and the strain $\Delta l/l$ increases to 1400 ppm at a field strength of 1000 Oe. According to the curve in this region, the slope $\Delta S/\Delta H$ is nearly constant across a very wide range of strains. For a larger field, the increase in the curve reaches a plateau where almost all domains are essentially lined up in the direction of the field, and thus there is no further increase in length as the result of saturation. If a negative current is used instead of a positive current starting at $H = 0$, the mirror image curve on the left is followed

Figure 4. Strain versus magnetic field for a GMM (3).

and again there is an expansion of the GMM rod. Thus the negative cycle of a current oscillation also produces a positive expansion, just the same as the positive cycle does. This results in a mechanical motion twice the frequency of the input current. This behavior, if not appropriate, is avoided by introducing a DC biasing field H_0 to expand the GMM rod initially to position Δl_0 which is approximately one-half the total linear expansion limit. As a positive AC current is applied, the magnetic field causes additional expansion. In the negative half of the cycle, the field cancels the DC bias, and the displacement from the neutral position Δl_0 is reduced. The bias may be introduced by a permanent magnet or a DC current that uses a second coil.

Hysteresis should be taken into consideration in being applied into a precision positioning device because the S - H curves are slightly different, depending on whether the magnetic field is increased from zero to saturation or decreased from saturation to zero. The butterfly curves in Fig. 5 illustrate the hysteresis effect. The flux density B versus magnetic field H is shown in Fig. 5a. As H is reduced to zero, there is a remnant flux density value B_0 . In Fig. 5b, the strain S is shown against the flux density B , where no hysteresis is observed. However, when these two curves are combined, the hysteresis turns up in the resulting curve of the strain versus the magnetic field in Fig. 5c. Although the hysteresis effect is relatively small, it could be important in an accurate positioning device. A closed-loop feedback scheme is preferable for such applications.

Dynamics of GMMs

Magnetostriction is a transduction process in which electrical energy is converted into mechanical energy. Reciprocally, GMMs also convert mechanical energy to electrical energy. The material behavior follows a piezomagnetic law (4), and the linear region can simply be expressed by its first-order approximation as

$$B = dT + \mu^T H, \quad H = nI, \quad (1)$$

$$S = s^H T + dH, \quad (2)$$

where, as before, B is the magnetic flux density, H is the strength of the magnetic field, S is the strain, T is the mechanical stress, μ^T is the constant- T permeability corresponding to the slope of the curve in the first quadrant of the B - H curve in Fig. 5(a), s^H is the constant- H elastic modulus or the reciprocal of Young's modulus, d is the piezomagnetic constant corresponding to the slope of the linear region of the S - H curve in Fig. 4, and I is the electric current. The interrelations that are well expressed in Fig. 6, which shows the relationship between the magnetic variables B and H , the mechanical variables S and T , and also the interconnection between the magnetic and mechanical fields.

Note that Eqs. (1) and (2) are valid only if other nonlinear factors such as eddy current loss or nonuniform flux density can be omitted. To accommodate certain degrees of nonlinearity, Carmen and Mitrovic (6) extended Eqs. (1) and (2) by using the Gibbs free energy and representing T

Figure 5. Butterfly curve of S - H .

and H by Taylor series:

$$S = s^H T + \frac{1}{2} d_{m-s} H^2 + \frac{1}{2} s_{m-e} T H^2, \quad (3)$$

$$B = d_{m-s} T H + \mu^T H + \frac{1}{2} s_{m-e} T^2 H, \quad (4)$$

where

$$d_{m-s} = \frac{d_{T=0}}{H_0}, \quad (5)$$

Figure 6. Interrelationships among variables (by ETREMA).

$$s_{m-e} = \frac{dT_{=T_0} - dH_0}{T_0 H_0}, \quad (6)$$

and H_0 is the magnetic field strength under no load. For instance, Carmen and Mitrovic (6) obtained d_{m-s} and s_{m-s} for Terfenol-D ($Tb_{0.3}Dy_{0.7}Fe_{1.93}$) by taking nonlinear terms (7) into account as follows:

$$\begin{aligned} d_{m-s} &= 0.18 \times 10^{-12} \text{ m}^2/\text{A}^2, \\ s_{m-e} &= 0.20 \times 10^{-20} \text{ m}^2/\text{A}^2 \cdot \text{Pa}. \end{aligned}$$

These values show better agreement with reality when the compressive prestress becomes greater than 40 MPa. Compliance and permeability used in the nonlinear constitutive relations [Eqs. (3) and (4)] are

$$\begin{aligned} s^H &= 55 \times 10^{-12} \text{ Pa}^{-1}, \\ \mu^T &= 63 \times 10^{-7} \text{ N/A}^2. \end{aligned}$$

Among these, the most frequently used is the **Joule Effect**, which is responsible for the dimensional change of a

GMM rod when the longitudinal magnetic field varies. If the mechanical stress T is zero, the magnetostrain of a free GMM rod is proportional to the magnetic field to which the GMM is subject, given as

$$\begin{aligned} S &= dH = dnI, \\ B &= \mu^T H = \mu^T nI, \quad \text{for } T = 0. \end{aligned} \quad (7)$$

Therefore, the elongation Δl of a GMM is

$$\Delta l = l \cdot S = dnI = dNI, \quad (8)$$

where N is the number of coil turns over a length l . Equation (8) addresses the way electrical energy is converted to mechanical energy, which is fundamental for designing most GMM actuators. When compressed (a prestress T is applied), a GMM produces significantly more strains. Figure 7 shows strain versus magnetic field up to 20 MPa. It can also be seen that a larger field is necessary to attain a given strain as the prestress is increased. For sinusoidal operation, as described previously, the bias field must be increased somewhat to obtain the same strain.

The inverse Joule effect, also known as the “**Villari effect**,” is the basic principle for sensor design. Equation (1) states that the mechanical stress or the internal strain of a GMM in a biased magnetic field causes a proportional change in the magnetic flux density, which in turn induces voltage changes in a pickup coil that surrounds the GMM rod. Now, suppose that the GMM rod is biased and used as a sensor for sinusoidal input force $F = F_0 \sin \omega t$ at its end. The output voltage V generated at the open circuit, according to Faraday–Noiman’s law, is given as follows:

$$V = -N \frac{d\phi}{dt} = -NA \frac{dB}{dt}, \quad (9)$$

where ϕ is the magnetic flux, A is the cross-sectional area of the GMM rod, and N is the number of turns of the pickup coil. When a circuit is open, $I = 0$, and consequently

Figure 7. S – H curve at different prestress levels.

$H = 0$; the fundamental equation set, Eqs. (1) and (2), are simplified to

$$\begin{aligned} B &= d \cdot T, \\ S &= s^H T, \quad \text{for } H = 0. \end{aligned} \quad (10)$$

Thus, the flux ϕ is determined as

$$\begin{aligned} \phi &= B \cdot A = d \cdot T \cdot A \\ &= d \cdot F, \end{aligned} \quad (11)$$

and the output voltage

$$V = -N \frac{d\phi}{dt} = -d \cdot N \frac{dF}{dt} = -\omega d N F_0 \cos \omega t, \quad (12)$$

where $\omega = 2\pi f$ and f is the frequency of the force imposed. Note that the sensitivity increases as frequency increases. This increase in sensitivity continues up to the first resonance of the GMM rod. If we use the amplitude of the stress T_0 to replace the force amplitude, Eq. (12) is rewritten as

$$V = -\omega \cdot d \cdot n \cdot l \cdot A \cdot T_0 \cos \omega t, \quad (13)$$

which shows that the voltage sensitivity is also proportional to the product of the number of turns per unit length n and the volume $A \times l$ of the GMM rod.

A GMM may also be used to convert a mechanical force or stress to a current rather than a voltage. In this case, a short circuit or very low impedance ($B = 0$) is applied to Eq. (1) to achieve $H = -Td/\mu^T$. As a result, the current I generated for a mechanical stress T is given as

$$I = \frac{H}{n} = -\frac{d}{\mu^T} \cdot \frac{T}{n}, \quad (14)$$

which shows a theoretical basis for designing a GMM power generator.

Other useful GMM effects include

- I. **ΔE Effect:** Young's modulus proportionally changes with the magnetic field H and the acoustic velocity also shows a proportional change in it as well.
- II. **Wiedemann Effect:** At two dimensional change takes place in a GMM ring when a closed magnetic field along its circumference and a longitudinal magnetic field along its axis are superimposed simultaneously. In this case, as shown in Fig. 8, the magnetization changes its direction to a spiral. This combined magnetic field results in a torsional displacement of a GMM (also known as the "**Wertheim Effect**"). Supplying the GMM ring with a twist force in a forcible way induces a current in the surrounding coil, which is called the "**Inverse Wiedemann Effect.**"
- III. **Birkhauzen Effect:** Small discontinuities are observed in the magnetization curve of ferromagnetic materials, which may occur when the magnetizing force is being increased smoothly.

Most GMM applications developed so far have used energy transduction between magnetic and mechanical

Figure 8. Wiedemann effect.

energy. The coupling coefficient is an important factor for a transducer because the square of the coupling coefficient k^2 is equal to the ratio of the energy converted to the total energy stored. For instance, when the coupling coefficient $k = 0$, there is no energy conversion at all, whereas $k = 1$ implies full conversion of energy from one form to another. That is, $0 < k < 1$. The greater the coupling coefficient, the greater the electrical efficiency for a given electrical loss.

The coupling coefficient may be obtained most simply from the fundamental equation set, Eqs. (1) and (2). The procedure is similar to that obtained for the coupling coefficient of a transformer, that is, k^2 is given by the ratio of the cross products:

$$k^2 = \frac{d^2}{\mu^T s^H}. \quad (15)$$

To convert more than half of the electrical energy to mechanical energy, the coupling coefficient has to be at least 0.707. The important physical properties of a GMM are shown in Table 1 in comparison with piezoelectric materials (PZT) and pure nickel. Table 1 shows that a GMM can convert more than 50% of the energy stored, whereas PZT material brings over only about 35%. The 15% difference grants a GMM a significant improvement in the functionality of sensors and actuators.

Table 1. Physical Property Comparison

Property	GMM	PZT	Pure Nickel
Density (10^3 kg/m ³)	9.25	7.49	9.5
Young's modulus (10^{10} N/m ²)	2.5–3.5	7.5	22.5
Electric resistance ($\mu\Omega \cdot \text{cm}$)	60	–	6.6
Saturating strain (ppm)	1500–2000	100	–40
Stress output (kgf/mm ²)	3.0	1.5	0.1
Energy density (J/m ³)	14000–25000	930	30
Coupling coefficient (%)	70–75	65	30
Acoustic velocity (m/s)	1720	3130	4940
Permeability (emu)	4.5–9.3	–	60

Other features of GMM are summarized here. Advantages:

1. Large magnetostriction (more than 2000 ppm)
2. Choice of positive or negative magnetostriction controlled by material compositions
3. High Curie temperature (380°C)
4. Noncontact drive via magnetic field
5. Low voltage drive (due to low impedance)
6. Outstanding energy density, hence large force output
7. Small hysteresis
8. Fast response
9. Controllable temperature characteristics
10. Flexible net shape (if the powder metallurgy method is used)
11. High elasticity, high stiffness
12. Large coupling coefficient

Disadvantages;

1. Necessity for a driving mechanism to supply the magnetic field
2. Joule heat loss from a driving coil
3. Eddy current heat loss under a high-frequency drive
4. Poor corrosion resistance

Other important values of the GMM properties not listed in Table 1 are compressive strength of 800 Mpa, tensile strength of 100 Mpa, thermal expansion rate of $12 \times 10^{-6} \text{ }^{\circ}\text{C}^{-1}$ and saturation magnetization of 10 kG.

GMM MANUFACTURING PROCESS

There are several methods of producing a GMM alloy; four have been used on at least a near-production basis: free stand zone melting (FSZM), modified Bridgman (MB) (8), powder metallurgical compaction (PM), and polymer matrix composites. The unidirectional solidification techniques of FSZM and MB have the advantage of producing rods that have high magnetostrains and power density. In both cases, secondary machining is required to generate complex geometries beyond the right-angle cylinder. The powder techniques can use the powder metallurgical process to produce complex geometries. The composite materials possess substantially high electrical resistivity which would be advantageous in high-frequency applications where eddy current loss is a problem. Of these, the MB and PM are currently the most typical processes for making bulk materials. The process flows of MB and PM are compared in Fig. 9, and a brief description of each process is given here.

Modified Bridgman Method

As noted, The dimensional or structural changes of a GMM are subject to the externally applied magnetic field as well as the material crystal structure, including the

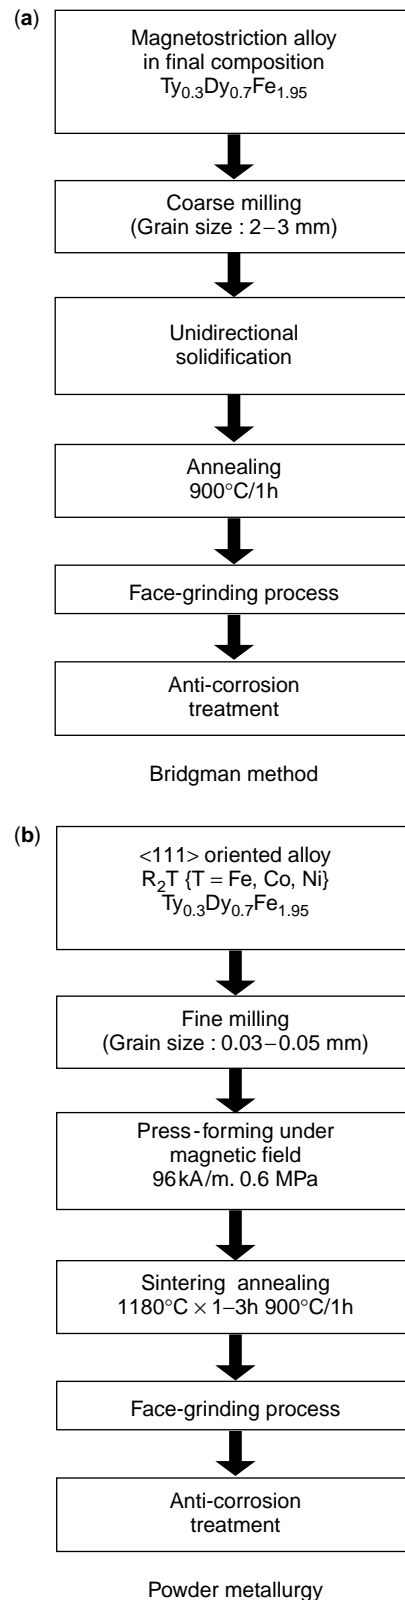

Figure 9. GMM manufacturing processes (10). (a) Bridgman method; (b) powder metallurgy.

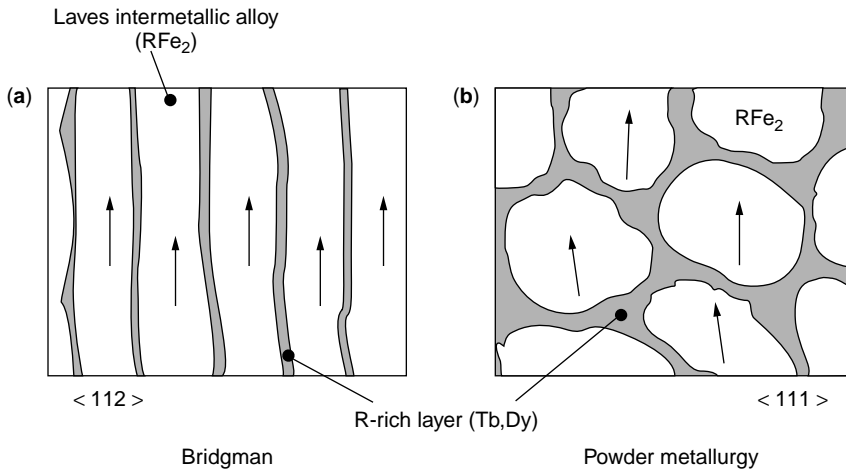

Figure 10. Crystal structure developed.

atomic vacancies, the spin magnetic moment, and the orbital magnetic moment. As a well-established process, the MB method (9) controls the crystal orientation by unidirectionally solidifying the melt of a specified composition. The raw materials used for MB are the Dy, T_y, and Fe grains in the ingredient ratio of 3:7:20 and about 2–3 mm in size. The grains are first melted in a ceramic crucible and then poured via a hole in the bottom of the crucible into preheated molds. The molds are withdrawn from the secondary furnace sections in a standard Bridgman manner. As the material solidifies, the rate of withdrawal and direction of the heat flow are controlled to produce crystallographically aligned drivers. The drivers then go through annealing (900°C/1h), secondary machining, and an anti-corrosion treatment to obtain the final products.

The crystal structures made by different processes are schematically shown in Fig. 10. In a MB ideal driver, the crystal are all aligned to $\langle 112 \rangle$, which is deviated 19° from the rod axis $\langle 111 \rangle$. Because the domains are rotated more fully, the GMM rod potentially risks an initial “jump.” If the rod is not fully aligned, the deviation angle is greater. As a result, the initial “jump” of the domain will not be as great, but the rod normally shows a reduction in magnetostrictive performance.

Powder Metallurgical Method (11)

As shown in the process flow of Fig. 9, the PM process starts with preparation of the alloy composite by milling the alloy ingots to a particle size of 0.03–0.05 mm. Heat treatment is employed before and after the milling process, 14 hours at 950°C for crystal grain homogenization and 2.5 hours for the residual stress relief. Three different types of milled grains that have the following compositions are then blended together and preformed in the presence of a magnetic field of 96 kA/m and under a pressure of 0.6 MPa:

Alloy 1: $Tb_{0.4} Dy_{0.6} Fe_{1.95} + R_2O_3 + R_2C$

Alloy 2: $Dy_2 (Fe_{0.2}Co_{0.5}) + R_2O_3 + R_2C$

Raw material: $Fe + Fe_2O_3$

where, R = Dy, Tb.

The structure developed is obtained in the form of $Tb_{0.3} Dy_{0.7} (Fe_{1.85}Co_{0.06})$. The preformed material is further

sintered under pressure of 6–12 ton/cm² and temperature of 1180°C for 1–3 hours in argon gas at a flow rate of 2 l/min, followed by annealing at 900°C for 1 hour. As shown in Fig. 10, the powder metallurgical GMM takes a polycrystalline form where the main phase RFe₂ grains are wrapped up with the R-rich layer and the oxide impurity is the grain boundary. Because it is formed in the presence of a magnetic field, most of the crystals of the powder metallurgical GMM are oriented in the $\langle 111 \rangle$ direction. Figure 11 is an output chart of X-ray diffraction in which the $\langle 111 \rangle$ oriented crystals amount to 38%. This means that an anisotropic composition has been created in an appropriate crystal orientation along which effective magnetostriction takes place.

Figure 12 compares the *S–H* curves obtained by PM and MB methods. Regardless of the prestress, the magnetostrictions obtained are quite comparable, and so are the hystereses as well. It is particularly noteworthy that there is no initial “jump” observed in the powder metallurgical GMM. The other material properties are summarized in Table 2.

In addition to the manufacturing cost which is as low as one-third that of conventional means, the great advantage of powder metallurgy is the capability of near-net-shape

Figure 11. X-ray diffraction of a GMM made by PM.

Figure 12. Magnetostriction versus applied magnetic field.

forming. Unlike the MB made GMM, which is available only as a right-angle cylinder, the powder metallurgical GMM can be configured into any desired form, as long as the die and mold are applicable.

Apart from the processes mentioned, it is worth noting that thin film GMM using sputtering techniques (12) has recently widened its applications in micromachining, MEMS, and microsystem technology (MST).

APPLICATIONS

Sensor Design

GMM sensors basically transduce mechanical energy to electrical energy. Their design deals with changes in flux density B and the strength of the magnetic field H under

Table 2. Physical Properties of GMM Produced

Property	Bridgman	Power Metallurgy
Density ρ (kg/m ³)	9.20×10^3	7.56×10^3
Elastic E_r (N/m ²) ^a	$3.8\text{--}4.0 \times 10^{10}$	3.7×10^{10}
Modulus E_a (N/m ²) ^a	$5.1\text{--}5.3 \times 10^{10}$	4.2×10^{10}
Bending strength (kg/mm ²)	5.2	4.6

Velocity C_a m/s ^a	2426	2227
Cost	1	1/3

^ar: parallel to anisotropic direction; a: vertical to anisotropic direction.

prestress and basically follows Eqs. (13) and (14). Jiles (13) and Kvarnsjö (14) extended linear Eqs. (1) and (2) to get better agreement with hysteresis:

$$B = 0.5 \sin(\tan^{-1}\{\tan[62^\circ e^{-0.085\sigma(\text{MPa})}] \times e^{C|H_B|}\}) + 3\mu_0 H, \quad (16)$$

where μ_0 is the permeability at zero bias. In an open circuit of $H = 0$, the output voltage is given as

$$\begin{aligned} V &= -N \frac{d\phi}{dt} = -NA \frac{dB}{dt} \\ &= -\frac{NA}{2} \frac{d}{dt} [\sin(\tan^{-1}\{[62^\circ e^{-0.085\sigma(i)(\text{MPa})}] \times e^{C|H_B|}\})] \end{aligned} \quad (17)$$

for a short circuit or very low impedance of $B \approx 0$; on the other hand, the output current is given as

$$I = H \frac{l}{N} = \frac{\sin\{\tan^{-1}[62^\circ e^{-0.085\sigma(i)(\text{MPa})}] \times e^{C|H_B|}\}}{6\mu_0} \frac{l}{N} \quad (18)$$

Vibration Sensor (Accelerometer) (15). Figure 13 shows a schematic drawing of the structure of a vibration sensor

Figure 13. Sectional view of a vibration sensor.

that is 19 mm in diameter and 25 mm long. Three magnetostrictive rods are deployed equally spaced and concentrically. Each rod is surrounded by a pickup coil. As described before, both a mechanical stress bias and a magnetic bias are needed to obtain magnetostriction effectively. This is especially true for applications of reverse transduction because, without magnetic bias, no flux variation would be caused by the varying stress.

A linear model is appropriate for a harmonic small-signal operation around the biased neutral point (H_0, T_0) where H_0 and T_0 are, respectively, the magnetic bias of the permanent magnet and the prestress. When ignoring non-linear factors such as eddy current, hysteresis, and a non-ideal magnetic circuit and leakage, the induced output voltage in an open circuit is given by Eq. (12), which indicates that the induced voltage is proportional to the number of coil turns and the frequency and magnitude of the force amplitude.

Pressure/Force Sensor. Unlike dynamic vibration, static pressure does not cause any change in the flux density of an open circuit. Therefore, there is no output voltage from Eqs. (12) or (13). The static pressure/force sensor requires an alternative design. Because of the coupled nature of the GMM transducer, however, electrical properties are affected by the mechanical boundary conditions on the rod, and likewise, mechanical properties are affected by the boundary conditions on the electrical wires. That is the so-called ΔE effect, which means that a different elastic modulus $1/s^H$ is measured that depends on whether the coil wires are left in an open circuit or a short circuit. The measured permeability and inductance would also be different if the GMM rod is left free or clamped rigidly at its end. The relationship between various parameters is through the coupling coefficient in the form,

$$\mu^S = \mu^T (1 - k^2)$$

and

$$s^B = s^H (1 - k^2). \quad (19)$$

The superscript S means zero strain, the so-called clamped condition, whereas the T indicates a free bar (zero stress). Likewise, the superscript B means zero flux or a short circuit, and H is an open circuit.

When static pressure $T = T_0$ is applied to a GMM rod, the basic Eq. (1) is rewritten as

$$B = dT_0 + \mu^{T_0} \cdot n \cdot I, \quad (20)$$

where $\mu^S < \mu^{T=T_0} < \mu^{T=0}$. Thus, the induced voltage is,

$$V = -NA \frac{dB}{dt} = -n^2 \cdot \mu^{T_0} \cdot l \cdot A \cdot \frac{dI}{dt}. \quad (21)$$

To obtain the output voltage, an AC current $I = I_0 \sin \omega t$ is needed to excite the pickup coil. The detecting voltage is given by

$$V = -n^2 \cdot \mu^{T_0} \cdot l \cdot A \cdot I_0 \cdot \omega \cdot \cos \omega t \quad (22)$$

which is can be represented by its virtual value $n^2 \cdot l \cdot A \cdot I_0 \cdot \omega \cdot \mu^{T_0} / \sqrt{2}$. The sensitivity of the measured virtual value

Figure 14. Structure of pressure/force sensor.

is proportional to the product of the square of the number of turns per unit length n , the volume of the GMM rod $l \cdot A$, the excitation current I_0 , and its frequency $\omega = 2\pi f$. The variation in the virtual voltage responding to the applied stress T_0 is subject to the permeability μ^{T_0} . For instance, the difference in the virtual voltage between the free bar and the bar undergoing T_0 is

$$\Delta V = \frac{n^2 \cdot l \cdot A \cdot I_0 \cdot \omega}{\sqrt{2}} (\mu^{T=0} - \mu^{T=T_0}). \quad (23)$$

Figure 14 shows the structure of a pressure/force sensor 100 mm in diameter and 50 mm long. The GMM rod deployed is a right cylinder shape $\phi 6 \times 25$ mm and coated with 30 μm of Teflon at its ends. The rod is surrounded by the bias coil which is sized about OD = 100 mm, ID = 30 mm and is produced by 1180 turns of $\phi 1.0$ mm UEW wire. Seated in between the GMM rod and bias coil is the pickup coil, which uses $\phi 0.2$ wire wound in 570 turns and formed to OD = 7.7 mm and ID = 6.5 mm.

Figure 15 shows the measured virtual voltage as the force varies from 20 to 200 kgf/cm² at 400 Oe bias and 5 V, 1 kHz AC current for the excitation.

Figure 15. Performance of pressure/force sensor.

Figure 16. Torque sensor.

Torque Sensor (16). The design of a torque sensor is based on the principle of the inverse Wiedemann effect. As schematically shown in Fig. 16, a torque sensor is simply structured by a set of jigs where torque is applied and a GMM ring is sandwiched. The dimensions of the GMM ring used are OD = 25 mm, ID = 20 mm, and L = 15 mm. Using the Bridgman method, it is difficult to give the GMM a shape other than a cylinder or rectangular solid. On the other hand, the geometry of a powder metallurgical GMM is subject only to which molds are applied. This creates great flexibility in shaping GMM products. Using the recently developed MEMS technology like micromolding, a GMM element is also available on a micrometer scale.

A toroidal coil is made by winding 300 turns of $\phi 0.3$ mm wire around the GMM ring. It is used to generate a magnetic field circumferentially and also as the pickup coil to sense the voltage variation induced by the torque applied. A solenoid coil, which is made of 400 turns of $\phi 0.3$ mm wire, is placed outside the GMM ring to apply a vertical magnetic bias. In addition, four strain gauges are placed on the periphery of the GMM ring in 0° , 45° , 90° and 135° directions to monitor the twist strain applied to the GMM ring by torque. When a torque T_r is applied to a tube like the GMM ring, the sharing stress τ in the sensor is given as

$$\tau = r \frac{T_r}{I_p}, \quad (24)$$

where I_p is the polar moment of the inertia of area for the GMM ring expressed by $\pi(OD^4 - ID^4)/32$. Equation (24) indicates that the sharing stress τ increases proportionally with radius r and reaches its maximum when the radius becomes $r = OD/2$. The varied stress, however, can be simply represented by the average sharing stress at $r = (OD + ID)/2$ if $(OD - ID)$ is relatively small.

Like the scheme of pressure/force sensor, the sharing stress causes a change in the permeability of the GMM rod, which in turn induces an output voltage in the pickup coil. For such a torque sensor, similarly, the pickup coil requires an AC excitation current, and the output voltage is evaluated by its virtual value. In an experiment carried out under 200 N preload, 5 V and 1 kHz excitation current, it was found that the mechanical torque also changed

the permeability μ^T of the GMM material, which in turn changed the flux density.

Applied torque varying from 0 Nm to 1 Nm in 0.2 Nm increments and the corresponding outputs are plotted in Figure 17. The linearity is quite acceptable except that a little hysteresis exists.

Power Generator (17). When converting mechanical energy to electrical energy, a GMM can also output a current rather than voltage. Equation (14) theoretically describes the relationship between the mechanical stress and generated current and shows the possibility of building a GMM power generator.

Figure 18 is a drawing of a prototype that stores the electrical energy generated by mechanical force in a condenser. The GMM rod used for this device is 6 mm in diameter and 50 mm long and is preloaded at 0.2 MPa. The impact F is delivered directly to the rod via the movable yoke. The bias coil has 2560 turns and generates a 24-kA/m magnetic field and an 800-mA DC current. When a 36-g steel ball drops 10 cm to hit the movable yoke, the GMM rod generates 27 V from a 300-turn pickup coil, 86 V from 900 turns, and 700 V from 6750 turns.

The voltage induced by the impact is, as shown in Fig. 19a, a kind of AC current, thus needs to be rectified

Figure 17. Torque applied versus voltage induced.

Figure 18. GMM power generator.

to waveform (b) before being stored in the condenser. In this case, each impact induces 45 V, equivalent to 2.2 mJ. The ratio of converted energy to the total kinetic energy of the steel ball is about 5%. Figure 20 shows the step of energy storage done by every impact of the steel ball falling from 15 cm above. The electrical energy after 20 impacts is sufficient to flash the strobe light of a compact camera (Fig. 21).

Figure 19. Voltage induced by impact.

Figure 20. Process of energy storage.

Actuator Design

If only positive displacements are required, no magnetic bias is required. However, a bias is needed for linear actuation. The magnetic bias is normally introduced by permanent magnets or a DC bias current. In the sample curve of Fig. 4, a field of 500 Oe (40 kA/m) is chosen as a bias because it is midway between the minimum and maximum fields. This field $H_0 = nI$ where n is the number of turns per unit length and I is the DC current. Thus, for a current of 4 A, 10,000 turns per meter are necessary.

The performance of a GMM actuator is significantly improved under compressive mechanical bias (preload or prestress). The compressive bias also allows the material to be subjected to greater tension and to sustain its strength under shock. A compressive bias is normally given by using a high-strength stainless bolt. A simple arrangement using one bolt is illustrated in Fig. 22 where the

Figure 21. Camera strobe light flash.

Figure 22. Mechanical bias.

two end pieces on the rods also provide a closed magnetic path.

An actuator is a device that puts things into motion. The cross-sectional view of a general giant magnetostriction actuator is shown in Fig. 23. The actuator is composed mainly of a magnetostrictive rod, yokes and a driving coil to make a magnetic circuit, and two permanent magnets to impose a bias magnetic field. SS41 steel is used for the yoke, and SmCo for the permanent magnet. A water-cooling device, made of a copper tube 2 mm in diameter, is also incorporated to isolate the heat between the driving coil and the magnetostrictive rod.

The distribution of magnetic flux in the magnetostrictive rod in connection with the bias condition is an important factor to be considered in designing an actuator. Figure 24 shows the distribution of magnetic flux at the inside of the solenoid coil in the various cases; (A) magnetic flux generated by the solenoid coil only, (B) magnetic flux generated by the SmCo magnet, and (C) magnetic flux in a

Figure 23. GMM actuator.

Figure 24. Distribution of magnetic flux.

rod under the real driving condition, which is computed by MAGNA code under the following conditions:

1. The permeability of a magnetostrictive rod is constant irrespective of driving conditions.
2. The permeability of both the permanent magnets for bias and the solenoid coil can be adjusted under any driving condition.

Each magnetic flux is shown by both curves of (A) (B) and (C) in Fig. 24 and depends on the distance from the center of the coil in the direction of the coil axis. On the other hand, the distribution of magnetic flux in a magnetostrictive rod is quite uniform under real conditions, as shown by curve. This result means that the displacement coefficient is almost constant in every position of the magnetostrictive rod.

It is also important in designing an actuator to note that the displacement hysteresis of the giant magnetostrictive rod depends remarkably on the bias magnetic field generated by the permanent magnet. The bias magnetic field dependence of the displacement hysteresis is shown in Figure 25, which is obtained for a full stroke $\pm 1 \mu\text{m}$.

Figure 25. Bias magnetic dependence of displacement hysteresis.

Figure 26. Linear positioner: (a) Cross-sectional view; (b) external view.

The hysteresis decreases markedly as the bias magnetic field increases. Therefore, the bias magnetic field should be properly selected to restrain the hysteresis.

Positioner (18). A DC field causes a GMM rod to extend by a specific displacement. Based on the dynamics of the GMM actuator mentioned before, an actuator has been designed to position the cutting tool for a diamond lathe. As shown schematically in Fig. 26, the positioner consists of a GMM rod, a solenoid coil for actuation, a Belleville spring for the mechanical preload, a set of permanent magnets and yoke for magnetic bias, and an output piston. The GMM rod is shaped into a cylinder of $\phi 6 \text{ mm} \times 40 \text{ mm}$ and is mechanically compressed by the Belleville spring under a 6-MPa preload. The magnetic bias applied is 400 Oe. A solenoid coil that has 1500 turns, can generate a 500-Oe magnetic field for every 1A of current input. The photo in Fig. 26 is an external view of the GMM positioner.

The response of the GMM positioner, at 100 nm/step, 15 nm/step, and 3 nm/step is shown in Figure 27. It confirms that the GMM positioner can deliver a large displacement ($40 \mu\text{m}$) without any assistance from the magnifier, while maintaining a resolution as fine as 3 nm. The GMM positioner is used to control the depth of cut (DOC) to achieve ductile mode cutting/grinding of hard, brittle materials such as silicon substrates, glasses, and ceramics.

Linear actuators are basically transduction devices but are usually confined to operation at low frequencies and produce greater motions than acoustic transducers. Accordingly, the design considerations for linear actuators may be somewhat different from acoustic transducers.

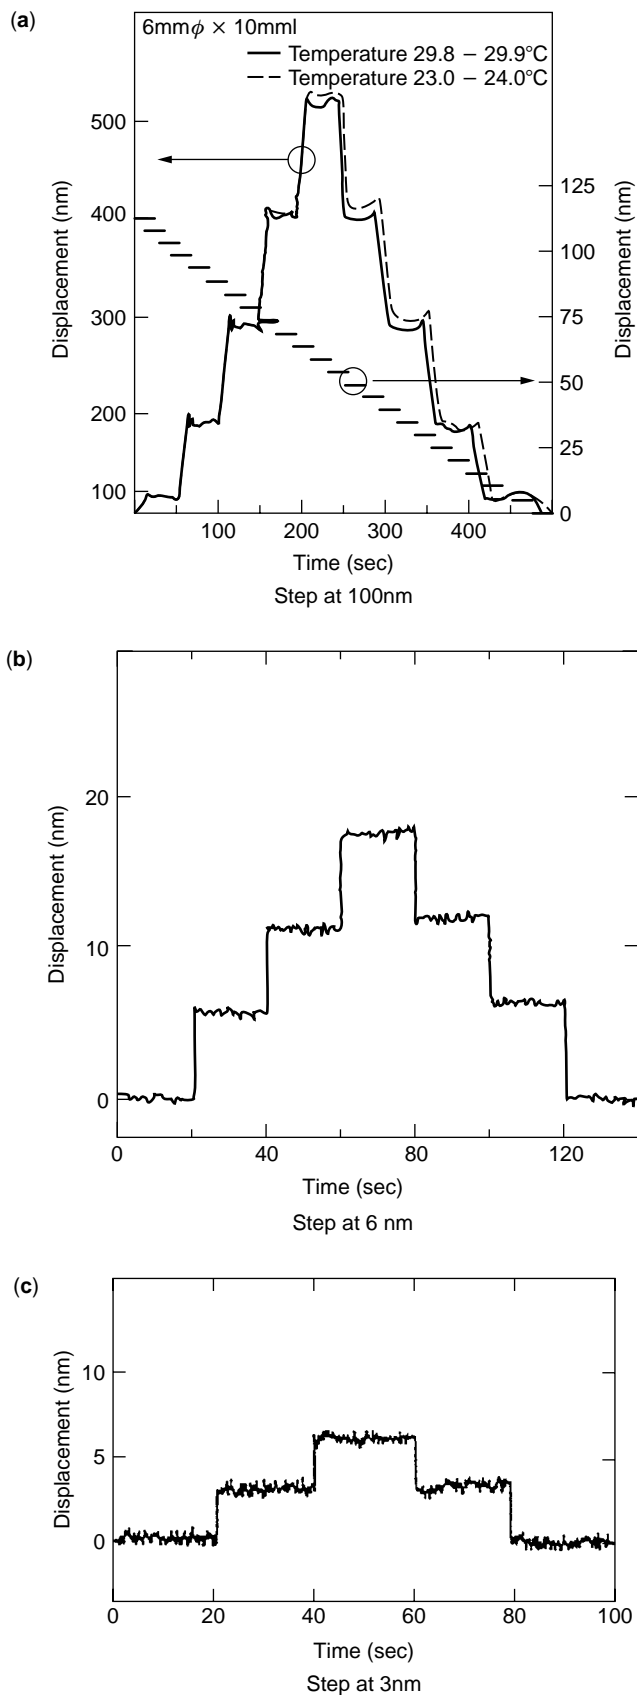

Figure 27. Step response of the positioner: (a) Step at 100 nm; (b) step at 6 nm; (c) step at 3 nm.

Figure 28. Machining application (19).

Increasing the length of the GMM rod increases the total displacement for a given current, and increasing the cross-sectional area increases the force of the rod for a given current. Therefore, the total work done by a GMM rod is proportional to the product of the force and the displacement, which is in turn subject to the volume of the GMM rod.

Other applications of a linear actuator include the active positioner (Fig. 28), which is used for nonround shape generation and counterchattering, the smart wing (Fig. 29) (19), which dynamically changes wing shape according to the flying speed to reduce petrol consumption, and the hydraulic actuator (Fig. 30), which is modularized and delivers high power output.

Pump (20). A GMM pump has been developed for a medical/biological application in delivering a microliter flow of liquid. As shown in Fig. 31, it consists of a GMM rod, a solenoid coil for magnetic field generation, a Belleville spring for preload, an external yoke for magnetic bias, a piston, check valves, and chambers. The GMM rod is shaped into a cylinder of $\phi 12 \text{ mm} \times 50 \text{ mm}$ and seats in the center of the solenoid coil. It is compressed by a Belleville

Figure 29. Smart wing (19).

spring with a 6-MPa preload against the external yoke. The coil, which has 5200 turns, is 50 mm long and 28.5 mm in diameter. For every ampere current input, the coil generates a 1.2-kA/m magnetic field.

Unlike a rotary pump driven by a motor, the GMM pump operates by converting its magnetostrain directly into reciprocating motion for the plunger. Figure 32 shows the operating cycle of the pump. When AC power input is in a sine wave form, the magnetic field generated is also synchronized to the sine wave. As the magnetic field (current) increases in (1), the GMM rod is expanded to push the piston, allowing the pump to discharge. When the magnetic field (current) decreases in (2), the GMM rod contracts. Meanwhile the Belleville spring pushes the piston back and makes the pump charge the liquid. Because the GMM rod responds positively to a negative magnetic field, the pump repeats the discharge-and-charge in the second half cycle (3) and (4). For every cycle of the input sine wave current, therefore, the pump reciprocates twice.

The flow rate Q_{th} (m^3/min) and the outlet pressure P_{th} (Pa) of the pump are, respectively, given as

$$Q_{th} = 120 \cdot f \cdot S_p \cdot \Delta L \quad (25)$$

$$P_{th} = P_m \cdot S_m / S_p \quad (26)$$

where f is the current frequency, S_p is the cross sectional area of the piston, ΔL is the piston stroke, and, P_m , S_m are the created stress and the cross-sectional area of the GMM rod. The actual measured flow rate–outlet pressure is plotted in Fig. 33 for the operating conditions of $H = 32 \text{ kA/m}$ and $f = 50 \text{ Hz}$. The test was carried out continuously for 10 days (4.3×10^7 cycles), and no failure or damage was found in the powder metallurgical GMM pump.

Figure 30. Hydraulic application (19).

Figure 31. GMM pump.

Suppression (11). The GMM material is characterized by high power, large displacement, and fast response, as well as safety, long life and flexibility, which are often required by an aerospace structure. Vibration suppression for an aerospace structure has been explored as one application of a giant magnetostrictive actuator. A prototype of the vibration suppression device is shown schematically in Fig. 34. The beam is made of aluminum, the first resonant frequency is about 3 Hz or lower, and the acceleration at the tip is 1G or less. The beam is held vertically by a single-end supporter. The mass is added to the beam tip accordingly. Before starting suppression, necessary excitation is applied to the device. The suppression device consists of a pair of giant magnetostrictive actuators, electronic equipment for control, and a measuring instrument. A pin hinge is built in the beam supporter. The controllable force around the pin hinge is generated by the paired giant magnetostrictive actuator. Parameters measured include acceleration of the beam tip, strain of the beam root, and displacement of the magnetostrictive actuator; and any of them can be used as an input signal to be fed back to the control system.

The vibration suppression experiment was carried out with the prototype device without the feedback control, but

Figure 32. Operating cycle of GMM pump.

inputting a proper sine waveform corresponding to the resonance frequency and in the opposite phase of the vibration detected from the signal of the accelerometer. The control was continued until the vibration (the maximum acceleration) was constantly below a specified level. The beam was first excited from standstill by applying a sine waveform current (maximum 3A) that had the first-order frequency of the beam to the magnetostrictive actuators. The suppression was then started from the steady state of vibration, by

Figure 33. Flow rate versus outlet pressure (measured).

Figure 34. Prototype for space structure suppression.

giving the actuators a maximum 4-A current whose phase was inverted from that of the input current. To compensate for the phase deviation taking place during suppression, the phase of the suppression current was corrected every few seconds according to information from the accelerometer. Figure 35 shows the history of the acceleration at the

Figure 35. An example of a vibration suppression experimental result: (a) Acceleration of top of the beam; (b) input current to the actuator.

Figure 36. Ultrasonic transducer.

tip of the beam and the suppression current input to the actuators. The beam tip acceleration dramatically decreased about 10 seconds after suppression started.

Vibration Source (19). Another major application of a GMM actuator is as a vibration source, where the GMM rod is operated at its resonant frequency by properly selecting the AC driving current. There are two resonances in magnetostrictive transducers: the maximum and the minimum impedance resonance f^B , which occur under an open circuit and a short circuit, respectively. For a free bar of length l_1 the fundamental half wavelength resonance frequency conditions are $f^{Hl_1} = 845 \text{ kHz} \cdot \text{mm}$ or $f^{Bl_1} = 1225 \text{ kHz} \cdot \text{mm}$. For a free 2.5-inch GMM bar, the resonant frequency would be 13.32 kHz for an open circuit and 19.28 kHz for a short circuit. Operation at these frequencies would lead to considerable eddy current loss and reduced permeability and coupling coefficient. The critical frequency for GMM is written as $f_c = 0.0687/D^2$ where D is in meters. For a $D = 6.35\text{-mm}$ diameter rod, the critical frequency is 1.7 kHz. Reducing the eddy current losses is achievable either by increasing the length or reducing the diameter of the rods.

An ultrasonic transducer developed by ETREMA Products Inc. is shown in Figure 36. This transducer uses a $\phi 75 \text{ mm} \times 100 \text{ mm}$ Terfenol-D rod and can be continuously operated at $20 \text{ kHz} \pm 1 \text{ kHz}$ and output power of 6 kW. In the unloaded condition, the output displacement is $20 \mu\text{m}$ peak to peak at resonance.

This kind of vibration source has wide application in aerospace, medicine, sonochemical processing, and the naval and petroleum industries. Some of the commercialized products are listed here:

- Active noise and vibration control system
- Ultrasonic device
- Ultrasonic knives
- Surgical/dental tool
- Speakers—audio/warning system
- Cleaning device
- Hearing assistance/diving communication

HEALTH MONITORING (STRUCTURAL) USING WAVE DYNAMICS

DARRYLL J. PINES
University of Maryland
College Park, MD

INTRODUCTION

The extraction of the modal parameters of a structure for model-based damage detection methods has received a considerable amount of attention in the literature (1). Many of these model-based methods are widely used for problems of structural health monitoring of aerospace, civil, and mechanical systems. However, studies have shown that these methods have many limitations, including sensitivity to model uncertainty, changes in boundary conditions, insensitivity to incipient structural defects, and sensor and actuator placement (2,3). To counter these inherent problems, attention has focused on the development of alternative modeling approaches to describe the vibratory motion of structures under external excitation. One such approach is to represent the response of a structure in terms of the superposition of traveling waves that can traverse individual elements of a structure and reflect off boundaries to establish standing waves from constructive interference. These standing waves constitute the resonance or reverberant response of the structure and lead to reverberated transfer functions (RTF) from force excitation of sensor outputs. Common attributes of such frequency domain responses are characteristic pole-zero patterns for collocated and noncollocated transfer functions. Using these frequency response functions, many methods (4) have been developed to obtain modal properties of a variety of structures. However, often neglected in the process is that these RTF responses are comprised of the steady-state superposition of incident and reflected traveling waves propagating along the structure. These traveling wave components can be used to identify local damage in structural systems.

The idea of identifying damage using the scattering of transient structural waves (5,6) is directly related to the dereverberated response of a structure. Whereas the reverberated transfer function (RTF) of a structure measures the response when travelling waves interfere constructively and destructively with each other, the dereverberated transfer function (DTF) is a measure of the steady-state response of a structure when incident waves do not reflect off internal or external boundaries. Thus, the characteristic pole-zero behavior commonly found in RTF responses is suppressed in favor of the mean or “backbone” response of the RTF transfer function. The DTF response essentially represents the steady-state incident power that flows through the structure from each actuator to each sensor.

Initial attempts to suppress broadband vibration of structural waves involved adhoc feed-forward and local feedback control laws (7–12). MacMartin and Hall

(9) found that the optimal collocated feedback controller had noncausal properties that were not physically realizable by using conventional analog electronic components. However, many researchers (11,12) have developed a series of approximate collocated controllers that were physically realizable but not optimal in terms of energy dissipation. Such collocated controllers, it was demonstrated experimentally reduce the resonant response of uniform structures across a fairly broad frequency range that involves several modes of a structure. These approximate controllers were later used in an initial study (13) to infer the presence of delamination damage qualitatively in several tapered composite rotorcraft flexbeam specimens using the DTF response. This article develops the precise mathematical formalism for determining the matched terminating controllers required between successive nonuniform structural elements to obtain the DTF from the RTF response at every degree of freedom (DOF). The DTF is used to infer the presence and location of damage by examining the relative phase lag error between successive degrees of freedom. A damage index method is introduced to quantify the amount and type of damage (mass or stiffness) that occurs in a particular structural element. One-dimensional examples illustrate that the presence, location, and amount of local damage can be determined in discrete and continuous structures.

In the next section of this article, the concept of dereverberation is introduced, followed by a discussion of the way to obtain the DTF response of discrete and continuous structural elements. In the following section, the DTF response is obtained from simulated nonuniform discrete and continuous structures. Finally, in the last section, a damage detection method using the DTF response and a phase damage index method illustrate the effectiveness of the approach.

DEREVERBERATED TRANSFER FUNCTIONS OF STRUCTURAL ELEMENTS

Discrete Spring-Mass Elements

Discrete spring-mass structures can be constructed from two types of elements: symmetrical and asymmetrical (14). A symmetrical element is shown in Fig. 1a. It has identical masses m at both ends of the element connected by a spring whose stiffness is k in the middle. An asymmetrical element, shown in Fig. 1b, has only one mass attached to either end of the spring. A generic spring-mass element is shown in Fig. 1c. Note that when $m_1 = m_2$, the generic elements are symmetrical. When $m_1 = 0$, they are asymmetrical elements. This section introduces an approach for obtaining dereverberated transfer functions for asymmetrical spring-mass elements and for generic spring-mass elements.

Asymmetrical Spring-Mass Element. The equations of motion of the asymmetrical spring-mass element shown in

Figure 1. Discrete spring-mass elements: (a) symmetrical (b) asymmetrical (c) generic.

Fig. 1b are

$$\begin{cases} k(x_1 - x_2) = F_1 \\ m\ddot{x}_2 + k(x_2 - x_1) = F_2. \end{cases} \quad (1)$$

Assuming a solution of the following form:

$$x_n(t) = Ae^{i\omega t - n\mu} \quad n = 1, 2, \quad (2)$$

where n is the DOF of interest, leads to the following expressions for the wave numbers μ_l and μ_r :

$$\begin{aligned} \mu_l = \mu &= \cosh^{-1} \left(\frac{2k - m\omega^2}{2k} \right), \\ \mu_r = -\mu &= -\cosh^{-1} \left(\frac{2k - m\omega^2}{2k} \right). \end{aligned} \quad (3)$$

The subscripts l and r refer to the leftward and rightward propagation coefficients. Therefore, the spectral representations for the longitudinal displacements of each degree of freedom are

$$\begin{aligned} \hat{x}_1(\omega) &= W_{rp}(\omega)e^{-\mu} + W_{lp}(\omega)e^{\mu}, \\ \hat{x}_2(\omega) &= W_{rp}(\omega)e^{-2\mu} + W_{lp}(\omega)e^{2\mu}. \end{aligned} \quad (4)$$

Assuming that energy is input from the left where $F_1 \neq 0$, a controller can be added at the right to extract energy. The control force is designed to have the form $F_{2c} = G_d x_2$ and must satisfy two objectives: (1) equilibrium of forces at degree of freedom x_2 , and (2) prevent energy reflection between the elements. Therefore, the control force F_{2c} , must satisfy the following equations:

$$F_{2m} + F_{2c} = 0,$$

and

$$W_{lp}(\omega) = 0, \quad (5)$$

where F_{2m} is the motion-dependent force. From the first part of Eq. (5),

$$m\ddot{x}_2 + k(x_2 - x_1) + G_d x_2 = 0. \quad (6)$$

Transformed into the frequency domain, Eq. (6) becomes

$$-m\omega^2 \hat{x}_2 + k(\hat{x}_2 - \hat{x}_1) + \hat{G}_d \hat{x}_2 = 0. \quad (7)$$

Now let us substitute Eq. (5) in Eq. (7) and set $W_{lp} = 0$. After some algebra, the control gain is determined to be

$$\hat{G}_d = m\omega^2 - k + ke^{\mu}. \quad (8)$$

If the RTF matrix of an asymmetrical element is available, transfer functions \hat{x}_1/\hat{F}_1 and \hat{x}_2/\hat{F}_1 can be dereverberated by using the following expression:

$$\begin{bmatrix} \hat{x}_1 \\ \hat{F}_1 \\ \hat{x}_2 \\ \hat{F}_1 \end{bmatrix}_{DTF} = \left(\text{RTF}^{-1} + \begin{bmatrix} 0 & 0 \\ 0 & \hat{G}_d \end{bmatrix} \right)^{-1} \begin{bmatrix} 1 \\ 0 \end{bmatrix}. \quad (9)$$

RTF and DTF responses of \hat{x}_1/\hat{F}_1 and \hat{x}_2/\hat{F}_1 are shown in Fig. 2a, b, respectively. As expected, the effect of the control force F_{2c} , is to remove the resonance and antiresonance from the response. The control gain for the asymmetrical structural elements are plotted versus ω in Fig. 2c. Note that this compensator has an unusual magnitude and phase behavior that is not consistent with conventional linear pole-zero representations. The magnitude of behavior for the compensator has a derivative type characteristic up until the cutoff frequency. However, the phase is not necessarily equal to 90° . Thus, such a compensator would be difficult to implement by using conventional electronic components.

Generic Structural Elements. Considering the generic element shown in Fig. 3a, energy is input from the left in terms of $F_1 \neq 0$. A control force F_{2c} is applied at the right end to prevent energy reflection. This generic element can be separated into two parts, shown in Fig. 3b.

The first part of Fig. 3b displays the force boundary condition. The equation of motion at DOF x_1 is given by

$$F_1 = m_1 \ddot{x}_1 + F_w, \quad (10)$$

where F_w , is the force that generates a wave propagating through k_2 and m_2 . The control force $F_{2c} = G_d x_2$ prevents energy that arrives at m_2 from being reflected. From the discussion in the previous section, the controller gain G_d is determined only by parameters m_2 and k_2 . The control gain is independent of F_w , which means that it is independent of m_1 . m_1 , joined by F_1 , determines the speed and amplitude of energy passing through the element but has nothing to do with the controller applied at the right end to obtain the nonresonant transfer functions. If the conventional

Figure 2. Asymmetrical element: $k_2 = 1 \times (1 + 0.00001i)$; $m_2 = 1$. (a) RTF and DTF responses of \hat{x}_1/\hat{F}_1 ; (b) RTF and DTF responses of \hat{x}_2/\hat{F}_1 ; (c) control gain \hat{G}_d .

reverberated transfer function matrix (RTF) of the generic element is known, transfer functions \hat{x}_1/\hat{F}_1 and \hat{x}_2/\hat{F}_1 can be dereverberated using the following expression:

$$\begin{bmatrix} \hat{x}_1 \\ \hat{F}_1 \\ \hat{x}_2 \\ \hat{F}_1 \end{bmatrix}_{\text{DTF}} = \left(\text{RTF}^{-1} + \begin{bmatrix} 0 & 0 \\ 0 & \hat{G}_d \end{bmatrix} \right)^{-1} \begin{bmatrix} 1 \\ 0 \end{bmatrix}. \quad (11)$$

The DTF responses \hat{x}_1/\hat{F}_1 and \hat{x}_2/\hat{F}_1 that correspond to different m_1 and m_2 values are shown in Fig. 4.

Continuous Structural Elements

Although discrete spring-mass structural elements can be used to model a variety of complex structures, continuous structural elements are also being used to model structures

Figure 3. Generic structural element.

Figure 4. DTF responses of generic elements.

such as space trusses, rotor blades, and buildings. In this section, models of rod and beam elements are developed. Using the concept of the virtual controller, the dereverberated response is obtained for continuous rod and beam spectral elements.

Uniform Rod Element. A uniform rod element is shown in Fig. 5. The equation of motion for a rod is given by

$$EA \frac{\partial^2 u(x, t)}{\partial x^2} - \rho A \frac{\partial^2 u(x, t)}{\partial t^2} = f(x, t). \quad (12)$$

Transformed into the frequency domain, Eq. (12) becomes

$$EA \frac{\partial^2 \hat{u}(x, \omega)}{\partial x^2} + \rho A \omega^2 \hat{u}(x, \omega) = \hat{f}(x, \omega). \quad (13)$$

The spectral representation (15) for the longitudinal deflection of the rod is given by

$$\hat{u}(x, \omega) = W_{rp}(\omega) e^{-i\mu x} + W_{lp}(\omega) e^{-i\mu(L-x)}, \quad (14)$$

where $\mu = \omega \sqrt{\rho A / EA}$ is the longitudinal wave number. Assume that energy is input from the left end where $F_1 \neq 0$. As the incident energy arrives at the right end, a control force $F_{2c} = G_r u_2$ is designed to satisfy two objectives: (1) equilibrium of forces at the right end and (2) prevent

Figure 5. Uniform rod element.

energy reflection at the right end. Therefore, the control force must satisfy

$$F_{2m} + F_{2c} = 0,$$

and

$$W_{lp}(\omega) = 0, \quad (15)$$

where $F_{2m} = EA \frac{\partial \hat{u}}{\partial x} |_{x=L}$ is the motion-dependent force. After some algebra, the control gain is determined as

$$\hat{G}_r = i\mu EA. \quad (16)$$

If the RTF matrix of a uniform rod element is available, the dereverberated transfer functions \hat{u}_1 / \hat{F}_1 , \hat{u}_2 / \hat{F}_1 can be obtained by using the following expression:

$$\begin{bmatrix} \hat{u}_1 \\ \hat{F}_1 \\ \hat{u}_2 \\ \hat{F}_1 \end{bmatrix}_{\text{DTF}} = \left(\text{RTF}^{-1} + \begin{bmatrix} 0 & 0 \\ 0 & \hat{G}_r \end{bmatrix} \right)^{-1} \begin{bmatrix} 1 \\ 0 \end{bmatrix}. \quad (17)$$

The DTF and RTF responses of \hat{u}_1 / \hat{F}_1 , \hat{u}_2 / \hat{F}_1 are shown in Fig. 6.

It should be pointed out that transfer functions \hat{u}_1 / \hat{F}_2 , \hat{u}_2 / \hat{F}_2 are not dereverberated by Eq. (17). These transfer functions can be dereverberated by

$$\begin{bmatrix} \hat{u}_1 \\ \hat{F}_2 \\ \hat{u}_2 \\ \hat{F}_2 \end{bmatrix}_{\text{DTF}} = \left(\text{RTF}^{-1} + \begin{bmatrix} \hat{G}_r & 0 \\ 0 & 0 \end{bmatrix} \right)^{-1} \begin{bmatrix} 0 \\ 1 \end{bmatrix}. \quad (18)$$

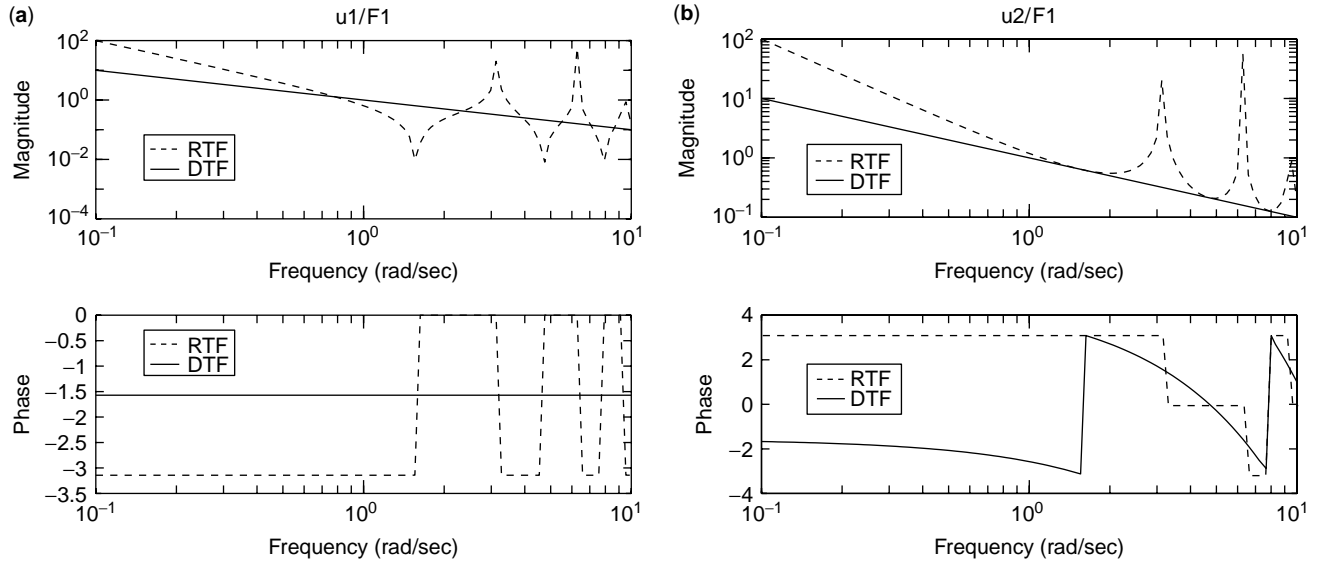

Figure 6. RTF and DTF responses of uniform rod element where $EA = 1 \times (1 + 0.000001i)$, $\rho A = 1$, $L = 1$. (a) \hat{u}_1/\hat{F}_1 , (b) \hat{u}_2/\hat{F}_1 .

Uniform Beam Element. A uniform beam element is shown in Fig. 7. The equation of motion for a Bernoulli–Euler beam is given by

$$EI \frac{\partial^4 v(x, t)}{\partial x^4} + \rho A \frac{\partial^2 v(x, t)}{\partial t^2} = f(x, t). \quad (19)$$

Transformed into the frequency domain, Eq. (19) becomes

$$EI \frac{\partial^4 \hat{v}(x, \omega)}{\partial x^4} - \rho A \omega^2 \hat{v}(x, \omega) = \hat{f}(x, \omega). \quad (20)$$

The spectral representation for the beam's flexural vibration is

$$\begin{cases} \hat{v} = W_{rp} e^{-i\mu x} + W_{re} e^{-\mu x} + W_{lp} e^{-i\mu(L-x)} + W_{le} e^{-\mu(L-x)} \\ \hat{\theta} = W_{rp}(-i\mu)e^{-i\mu x} + W_{re}(-\mu)e^{-\mu x} + W_{lp}(i\mu)e^{-i\mu(L-x)} \\ \quad + W_{le}(\mu)e^{-\mu(L-x)}. \end{cases} \quad (21)$$

where v is vertical displacement and θ is angular displacement. $\mu = (\frac{\rho A}{EA} \omega^2)^{1/4}$ is the bending wave number.

Different sign conventions lead to different expressions of nodal displacements and nodal forces. The sign convention applied here is shown in Fig. 7. Nodal displacements are given by

$$\begin{bmatrix} v_0 \\ \theta_0 \\ v_1 \\ \theta_1 \end{bmatrix} = \begin{bmatrix} 1 & 1 & e^{-i\mu L} & e^{-\mu L} \\ -i\mu & -\mu & i\mu e^{-i\mu L} & \mu e^{-\mu L} \\ e^{-i\mu L} & e^{-\mu L} & 1 & 1 \\ -i\mu e^{-i\mu L} & -\mu e^{-\mu L} & i\mu & \mu \end{bmatrix} \begin{bmatrix} W_{rp} \\ W_{re} \\ W_{lp} \\ W_{le} \end{bmatrix}. \quad (22)$$

Nodal forces $F_0 = EI \frac{\partial^3 v}{\partial x^3} |_{x=0}$, $M_0 = -EI \frac{\partial^2 v}{\partial x^2} |_{x=0}$, $F_1 = -EI \frac{\partial^3 v}{\partial x^3} |_{x=L}$, and $M_1 = EI \frac{\partial^2 v}{\partial x^2} |_{x=L}$, are given by

$$\begin{bmatrix} F_0 \\ M_0 \\ F_1 \\ M_1 \end{bmatrix} = EI \mu^2 \begin{bmatrix} i\mu & -\mu & -i\mu e^{-i\mu L} & \mu e^{-\mu L} \\ 1 & -1 & e^{-i\mu L} & -e^{-\mu L} \\ -i\mu e^{-i\mu L} & \mu e^{-\mu L} & i\mu & -\mu \\ -e^{-i\mu L} & e^{-\mu L} & -1 & 1 \end{bmatrix} \begin{bmatrix} W_{rp} \\ W_{re} \\ W_{lp} \\ W_{le} \end{bmatrix} \quad (23)$$

Assuming that energy is input from the left, control forces

$$\begin{bmatrix} F_{1c} \\ M_{1c} \end{bmatrix} = G_{br} \begin{bmatrix} v_1 \\ \theta_1 \end{bmatrix} \quad (24)$$

are applied at the right end to satisfy the following equations:

$$\begin{bmatrix} F_{1c} \\ M_{1c} \end{bmatrix} + \begin{bmatrix} F_1 \\ M_1 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix},$$

Figure 7. Uniform beam element.

and

$$\begin{bmatrix} W_{lp}(\omega) \\ W_{le}(\omega) \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}. \quad (25)$$

Solving for the control gain matrix leads to

$$\hat{G}_{br} = \begin{bmatrix} (i-1)EI\mu^3 & iEI\mu^2 \\ iEI\mu^2 & (1+i)EI\mu \end{bmatrix}. \quad (26)$$

Using this matrix control law, the dereverberated transfer functions can be obtained from

$$\begin{bmatrix} \frac{\hat{v}_0}{\hat{F}_0} & \frac{\hat{v}_0}{\hat{M}_0} \\ \frac{\hat{\theta}_0}{\hat{F}_0} & \frac{\hat{\theta}_0}{\hat{M}_0} \\ \frac{\hat{v}_1}{\hat{F}_1} & \frac{\hat{v}_1}{\hat{M}_1} \\ \frac{\hat{\theta}_1}{\hat{F}_1} & \frac{\hat{\theta}_1}{\hat{M}_1} \end{bmatrix}_{DTF} = \left(\text{RTF}^{-1} + \begin{bmatrix} 0_{4 \times 4} & 0_{4 \times 4} \\ 0_{4 \times 4} & \hat{G}_{br} \end{bmatrix} \right)^{-1} \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 0 \\ 0 & 0 \end{bmatrix}. \quad (27)$$

The DTF and RTF response for \hat{v}_0/\hat{F}_0 , $\hat{v}_0/\hat{M}_0 \dots \hat{\theta}_1/\hat{F}_0$, $\hat{\theta}_1/\hat{M}_0$ are shown in Fig. 8.

If the energy is from the right, different control forces

$$\begin{bmatrix} F_{0c} \\ M_{0c} \end{bmatrix} = \hat{G}_{bl} \begin{bmatrix} v_0 \\ \theta_0 \end{bmatrix} \quad (28)$$

The control gains are given by

$$\hat{G}_{bl} = \begin{bmatrix} (i-1)EI\mu^3 & -iEI\mu^2 \\ -iEI\mu^2 & (1+i)EI\mu \end{bmatrix}. \quad (30)$$

The dereverberated transfer functions are obtained from

$$\begin{bmatrix} \frac{\hat{v}_0}{\hat{F}_1} & \frac{\hat{v}_0}{\hat{M}_1} \\ \frac{\hat{\theta}_0}{\hat{F}_1} & \frac{\hat{\theta}_0}{\hat{M}_1} \\ \frac{\hat{v}_1}{\hat{F}_1} & \frac{\hat{v}_1}{\hat{M}_1} \\ \frac{\hat{\theta}_1}{\hat{F}_1} & \frac{\hat{\theta}_1}{\hat{M}_1} \end{bmatrix}_{DTF} = \left(\text{RTF}^{-1} + \begin{bmatrix} \hat{G}_{bl} & 0_{4 \times 4} \\ 0_{4 \times 4} & 0_{4 \times 4} \end{bmatrix} \right)^{-1} \begin{bmatrix} 0 & 0 \\ 0 & 0 \\ 1 & 0 \\ 0 & 1 \end{bmatrix}. \quad (31)$$

Remember that the controllers attached at both ends of rod elements are the same. But for a beam, the controller gain matrices \hat{G}_{br} and \hat{G}_{bl} have a sign difference in the off-diagonal terms because the sign convention that was used for the beam did not create a symmetrical element stiffness matrix.

DTF RESPONSES OF NONUNIFORM STRUCTURES

Discrete Spring-Mass Structures

Energy Is Input from the End. A five DOF spring-mass structure is shown in Fig. 9. The properties of this structure are listed in Table. H. Complex stiffness is used to add a small amount of damping to the structure and to overcome potential numerical problems. The right end of this structure is fixed, and the left end is free. Energy is input from the left in terms of $F_1 \neq 0$. The reverberated transfer function matrix RTF of this structure is given by

$$\begin{bmatrix} \hat{x}_1 \\ \hat{x}_2 \\ \hat{x}_3 \\ \hat{x}_4 \\ \hat{x}_5 \end{bmatrix} = \text{RTF} \begin{bmatrix} \hat{F}_1 \\ \hat{F}_2 \\ \hat{F}_3 \\ \hat{F}_4 \\ \hat{F}_5 \end{bmatrix} = \begin{bmatrix} k_1 - m_1\omega^2 & -k_1 & 0 & 0 & 0 \\ -k_1 & k_1 + k_2 - m_2\omega^2 & -k_2 & 0 & 0 \\ 0 & -k_2 & k_2 + k_3 - m_3\omega^2 & -k_3 & 0 \\ 0 & 0 & -k_3 & k_3 + k_4 - m_4\omega^2 & -k_4 \\ 0 & 0 & 0 & -k_4 & k_4 + k_5 - m_5\omega^2 \end{bmatrix}^{-1} \begin{bmatrix} \hat{F}_1 \\ \hat{F}_2 \\ \hat{F}_3 \\ \hat{F}_4 \\ \hat{F}_5 \end{bmatrix}. \quad (32)$$

are applied at the left end to satisfy the following equations:

$$\begin{bmatrix} F_{0c} \\ M_{0c} \end{bmatrix} + \begin{bmatrix} F_0 \\ M_0 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix},$$

and

$$\begin{bmatrix} W_{rp}(\omega) \\ W_{re}(\omega) \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}. \quad (29)$$

To obtain the dereverberated transfer functions with respect to external force F_1 , the structural part to the right of mass m_5 will be ignored for two reasons. First, the original wave has already passed all DOFs after it arrives at m_5 . Structural components behind m_5 along the wave length will be ignored because DTF deals with the incident wave. Second, the fixed boundary condition should be ignored; otherwise, it will generate a reflected wave. The control scheme to obtain DTF responses is shown in Fig. 10. F_w is derived from the force boundary condition at the left. Local controllers are used to match the impedance of adjacent elements. There is no energy reflection at the interface

Figure 8. RTF and DTF responses: (a) \hat{v}_0 / \hat{F}_0 ; (b) $\hat{\theta}_0 / \hat{F}_0$; (c) \hat{v}_1 / \hat{F}_0 ; (d) $\hat{\theta}_1 / \hat{F}_0$; (e) \hat{v}_0 / \hat{M}_0 ; (f) $\hat{\theta}_0 / \hat{M}_0$; (g) \hat{v}_1 / \hat{M}_0 ; (h) $\hat{\theta}_1 / \hat{M}_0$.

Figure 8. Continued.

of different elements. Mathematically, the dereverberated transfer functions for $\hat{x}_1/\hat{F}_1, \hat{x}_2/\hat{F}_1 \dots \hat{x}_5/\hat{F}_1$ can be found by using the following expression:

$$\begin{bmatrix} \hat{x}_1 \\ \hat{F}_1 \\ \hat{x}_2 \\ \hat{F}_1 \\ \hat{x}_3 \\ \hat{F}_1 \\ \hat{x}_4 \\ \hat{F}_1 \\ \hat{x}_5 \\ \hat{F}_1 \end{bmatrix}_{\text{DTF}} = \left(\text{RTF}^{-1} + \begin{bmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & G_{2d} - G_{3d} & 0 & 0 & 0 \\ 0 & 0 & G_{3d} - G_{4d} & 0 & 0 \\ 0 & 0 & 0 & G_{4d} - G_{5d} & 0 \\ 0 & 0 & 0 & 0 & G_{5d} - k_5 \end{bmatrix} \right)^{-1} \begin{bmatrix} 1 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}, \quad (33)$$

where $G_{id} = m_i \omega^2 - k_{i-1} + k_{i-1} e^{\mu_i}$ and $\mu_i = \cosh^{-1} \left(\frac{2k_{i-1} - m_i \omega^2}{2k_{i-1}} \right)$. Now, we know the DTF responses of $\hat{x}_1/\hat{F}_1, \hat{x}_2/\hat{F}_1 \dots \hat{x}_5/\hat{F}_1$. For damage detection, we are more interested in how an individual element affects a wave passing through it. This is demonstrated by DTF responses $\frac{\hat{x}_{i+1}}{\hat{x}_i}, (i = 1, 2, \dots, 4)$ of successive degrees of freedom. These transfer function responses are shown in Fig. 11.

$$\text{RTF} = \begin{bmatrix} k_1 - m_1 \omega^2 & -k_1 & 0 & 0 & 0 \\ -k_1 & k_1 + k_2 - m_2 \omega^2 & -k_2 & 0 & 0 \\ 0 & -k_2 & k_2 + k_3 - m_3 \omega^2 & -k_3 & 0 \\ 0 & 0 & -k_3 & k_3 + k_4 - m_4 \omega^2 & -k_4 \\ 0 & 0 & 0 & -k_4 & k_4 + k_5 - m_5 \omega^2 \end{bmatrix}^{-1}. \quad (34)$$

Energy Is Input from the Middle. A five-DOF spring-mass structure that has energy input at the middle ($F_3 \neq 0$) is

shown in Fig. 12a. Spring stiffness k_5 and the fixed end will be ignored to obtain DTF responses. Hence, this structure can be thought of as constructed from two parts, shown in

Fig. 12b. Each part reveals the path of an incident wave propagating in both directions, respectively. Adding these two parts together, an alternate structure is used to obtain the DTF of the original structure with respect to input F_3 (see Fig. 12c).

The RTF response of the original structure shown in Fig. 12a is given by

Note that the alternate structure is different from the original structure in two ways: (1) the spring attached to

where off-diagonal elements of this banded matrix are zero.

The conventional reverberated transfer function matrix *RTF* can be obtained experimentally and satisfies

Assuming that the energy is input from the middle of the beam where vertical force $F_3 \neq 0$, dereverberated transfer functions $\frac{v_0}{F_3}$, θ_0/F_3 , v_1/F_3 , θ_1/F_3 , \dots , v_5/F_3 , and θ_5/F_3 can

$$\text{RTF} = \begin{bmatrix} K_1^1 & K_2^1 & & & & & \\ K_3^1 & K_4^1 + K_2^2 & K_2^2 & & & & \\ & K_3^2 & K_4^2 + K_1^3 & K_2^3 & & & \\ & & K_3^3 & K_4^3 + K_1^4 & K_2^4 & & \\ & & & K_3^4 & K_4^4 + K_1^5 & K_2^5 & \\ & & & & K_3^5 & K_4^5 & \\ & & & & & & \end{bmatrix}^{-1} \quad (38)$$

Table 2. Properties of the Beam Structure

Element Number	1	2	3	4	5
EI	$4 \times (1 + 0.0001i)$	$1 \times (1 + 0.0001i)$	$10 \times (1 + 0.0001i)$	$2 \times (1 + 0.0001i)$	$3 \times (1 + 0.0001i)$
ρA	2	1	5	3	1
Length	2	3	3	1	1

Consider the fixed-free beam shown in Fig. 17. The left end of the beam is fixed, and the right end is free. Energy is input into this beam by $F_3 \neq 0$. The conventional reverberated transfer function matrix of this five-element beam can be obtained experimentally. The inverse of the RTF is the dynamic stiffness matrix of the beam.

$$\text{RTF}^{-1} = \begin{bmatrix} K_4^1 + K_1^2 & K_2^2 & & & 0 \\ K_3^2 & K_4^2 + K_1^3 & K_2^3 & & \\ & K_3^3 & K_4^3 + K_1^4 & K_2^4 & \\ & 0 & K_3^4 & K_4^4 + K_1^5 & K_2^5 \\ & & & K_3^5 & K_4^5 \end{bmatrix}. \quad (40)$$

As previously shown for the free-free beam, the vertical displacement and angular displacement of each node are fed back into local controllers to generate control forces that can eliminate wave reflection at each node. Controllers can be attached at all nodes except for the node at the fixed end of the fixed-free beam. The DTF responses with respect to input F_3 can be obtained from the following expression:

$$\begin{bmatrix} \frac{v_1}{F_3} \\ \frac{\theta_1}{F_3} \\ \frac{v_2}{F_3} \\ \frac{\theta_2}{F_3} \\ \frac{v_3}{F_3} \\ \frac{\theta_3}{F_3} \\ \frac{v_4}{F_3} \\ \frac{\theta_4}{F_3} \\ \frac{v_5}{F_3} \\ \frac{\theta_5}{F_3} \end{bmatrix}_{\text{DTF}} = \left(\text{RTF}^{-1} + \begin{bmatrix} -K_4^1 + G_{2l} & & & & \\ & G_{3l} - G_{2l} & & & \\ & & 0_{2 \times 2} & & \\ & & & G_{4r} - G_{5r} & \\ & & & & G_{5r} \end{bmatrix} \right)^{-1} \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 1 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}, \quad (41)$$

where K_4^1 can be obtained because the physical properties of the first element are known. The RTF and DTF responses are shown in Fig. 18

Comparing the expressions in Eqs. (39) and (41), the difference between the free-free beam and the fixed-free beam

Figure 17. Fixed free beam that has five elements.

dereverberated responses depends on the way the boundary conditions are treated. A controller is needed for the free-free beam to extend the free end to infinity. However, for the fixed-free beam, element 1 is ignored, and element 2 needs to be extended to the left to infinity. To achieve this, K_4^1 is the affecting part from element 1, and G_{2l} is from element 2.

DAMAGE DETECTION APPROACH BASED ON DTF RESPONSE

Detecting the Presence and Location of Damage

In the previous section, collocated noncausal controllers were developed to obtain the DTF responses for discrete

spring-mass structural elements and spectral rod and beam finite elements. In this section, a methodology for detecting damage in one-dimensional structures is developed based on the characteristic changes in the undamaged DTF responses. For an undamaged structure, collocated

Figure 18. DTF and RTF response of fixed-free beam structure: (a) v_1/F_3 ; (b) v_2/F_3 ; (c) v_3/F_3 ; (d) v_4/F_3 ; (e) v_5/F_3 .

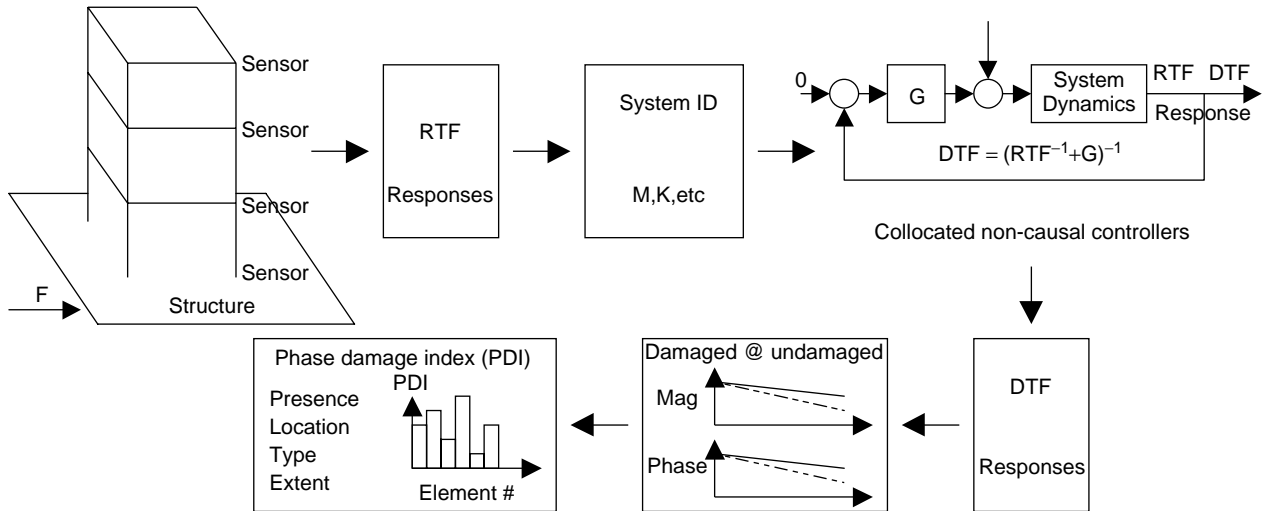

Figure 19. Damage detection methodology based on the DTF response.

noncausal controllers can be developed based on an identified model of the structural system. Implementing these noncausal controllers off-line in a computer will yield the DTF response from each actuator to each sensor. To infer the presence of damage, these undamaged controllers can be repeatedly applied to the identified RTF responses of a structural system. Thus, as damage appears in the structure, its presence will be revealed in the magnitude and phase plots of the DTF responses. Therefore, by tracking relative magnitude and phase errors between the undamaged and damaged structure's DTF response, it is possible to infer both the presence and location of damage. Furthermore, to determine damage in a particular structural element, one needs only to track the transmission of incident energy through the structure. This can be done by computing the ratio of the DTF responses for sequential degrees of freedom. This damage detection methodology is illustrated in Fig. 19.

Using examples of a free-free and fixed-free beam, the concept of a phase damage index is introduced following to illustrate how the presence, location, type, and amount of damage can be determined. This approach is later demonstrated on a model of a civil building structure.

Free-Free Beam. Consider the free-free beam structure previously shown in Fig. 14. Energy is input at node 3 where external force $F_3 = 0$. Figure 20 shows the DTF responses for the following transmission ratios of sequential degrees of freedom ($v_1/v_0, v_2/v_1, v_3/v_2 \dots$). The solid line refers to the undamaged case, and the dashed line refers to the damaged case. Each part of the figure displays the respective magnitude and phase response of the transmission ratio. It is assumed that damage in the form of a loss of stiffness is simulated in element number 3. Careful inspection of Fig. 20 allows two observations: First, in the case of stiffness damage, the phase of the DTF response will wrap around $-\pi$ earlier than in the undamaged case. Secondly, there is not a significant change in the DTF magnitude response due to damage in the structure.

To explain these observations in more detail, one has to consider the effect of damage on the structure's wave propagation response. When a leftward propagating wave passes through a damaged element such as element number 3, the effect of a stiffness loss is to increase the wave number and slow down the propagation of the transmitted wave. This introduces an additional phase lag in the DTF response. Undamaged structural elements have no effect on propagating the transmitted wave. In terms of the magnitude response, the noncausal controllers are designed to prevent wave reflection at the interfaces between structural elements. However, when damage occurs, wave reflection is not prevented because the controllers can no longer provide a match terminating boundary condition at each end. Nevertheless, because the simulated damage is small, the magnitude of the DTF displays modest sensitivity to damage. Therefore, a phase damage index (PDI) has been developed to locate the element that contains the damage. The PDI is based on the relative phase error from successive DOFs and is given by

$$\text{PDI}_i = \sum_{\omega_l \leq \omega \leq \omega_u} \left| \text{phase} \left[\left(\frac{v^i}{v^{i-1}}(\omega) \right)_{\text{DTF}}^{\text{undamaged}} \right] - \text{phase} \left[\left(\frac{v^i}{v^{i-1}}(\omega) \right)_{\text{DTF}}^{\text{damaged}} \right] \right|, \quad (42)$$

where $i = 1, 2, \dots, 5$ and refers to the i th element. ω_l, ω_u are the lower and upper bounds of the frequency range of interest. Computing the value of the PDI for each structural element indicates which element is damaged. This is evident from the PDI computed for the free-free beam example described earlier in this section. Note that the PDI is significantly larger for element number 3 in which simulated stiffness damage was assumed (see Fig. 20). Figure 21 displays the PDI for assumed stiffness damage in each of the five structural elements. Note that in all cases, the PDI that has the largest absolute value indicates, the structural element in the free-free beam example that is damaged.

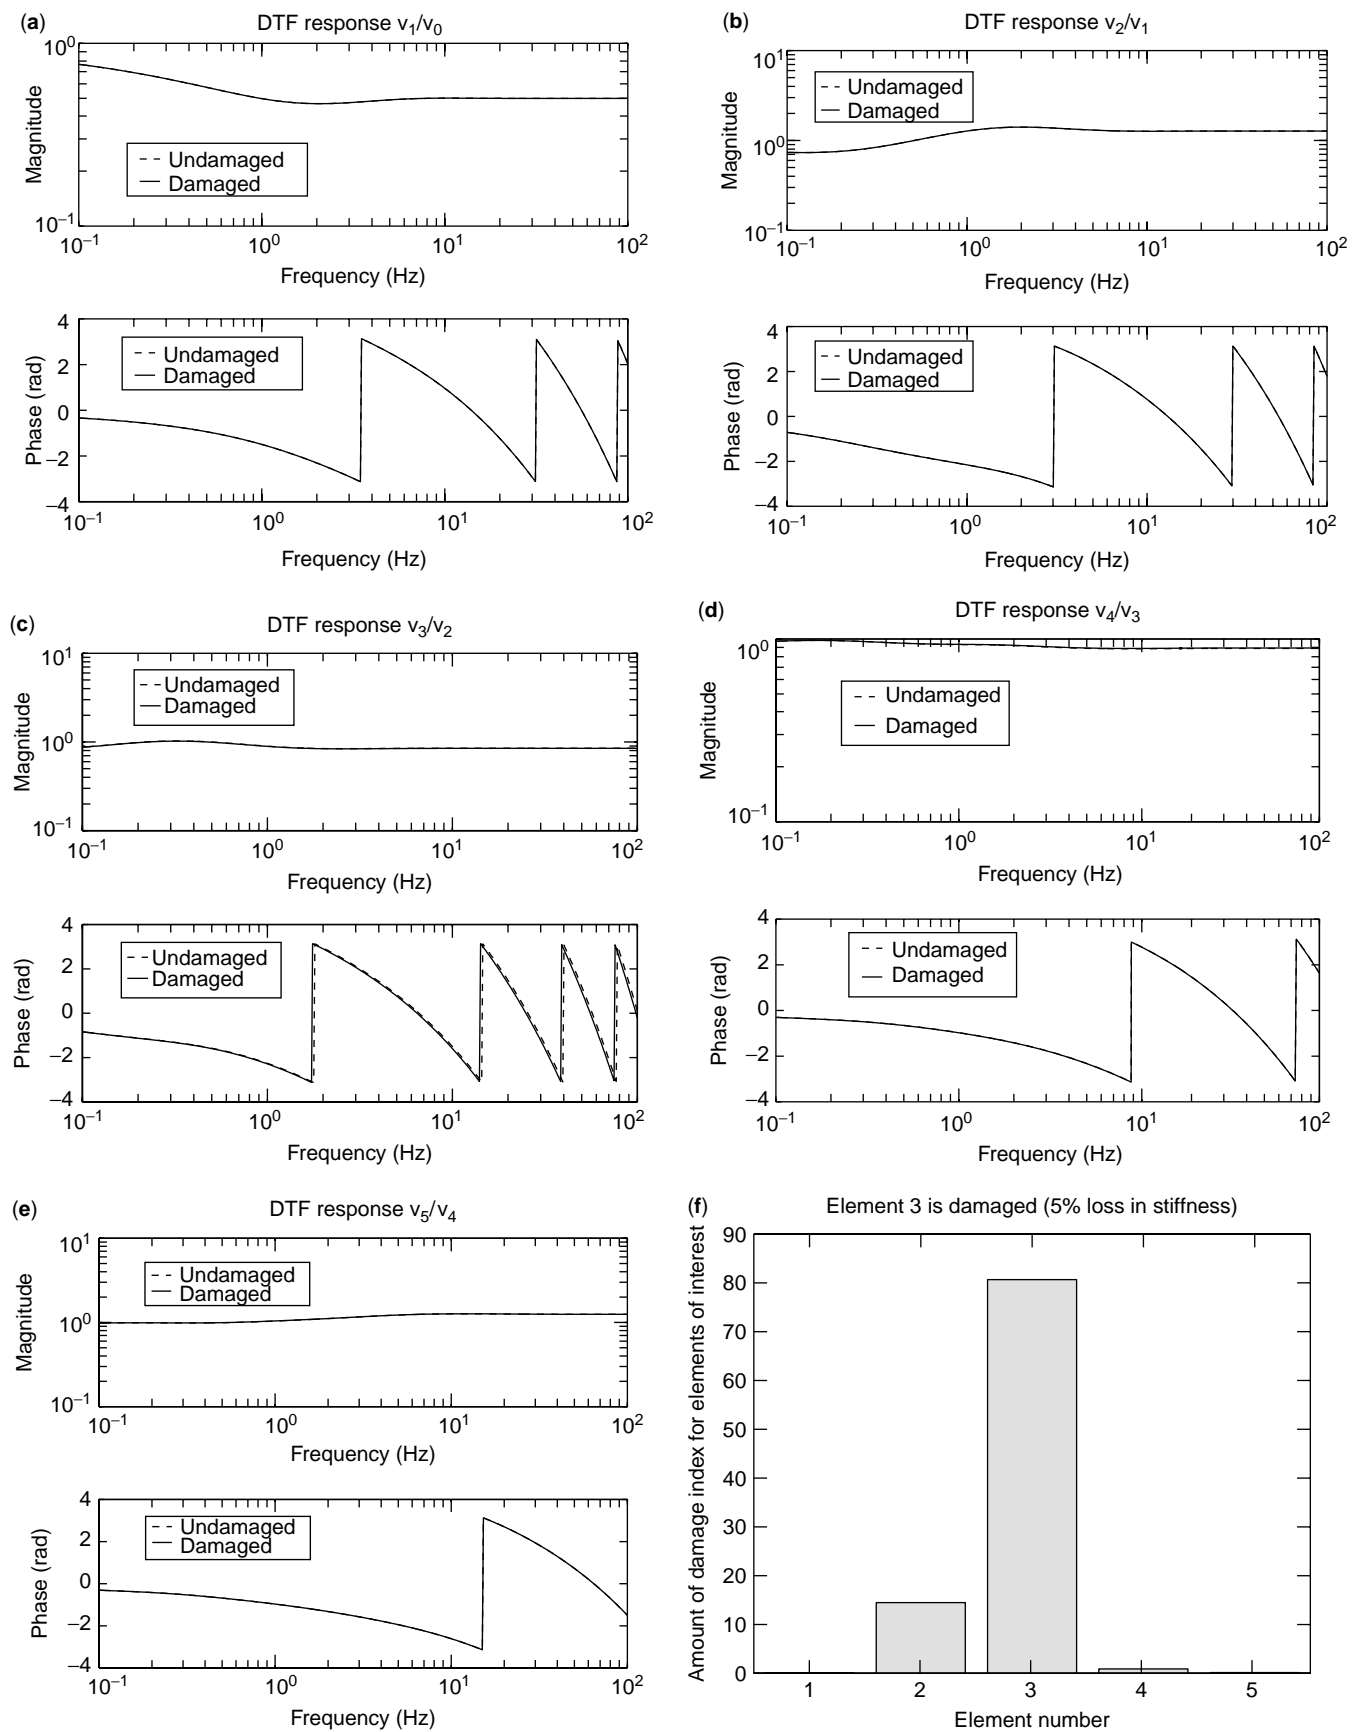

Figure 20. Element 3 is damaged in terms of 5% loss of stiffness. (a) DTF response v_1/v_0 ; (b) DTF response v_2/v_1 ; (c) DTF response v_3/v_2 ; (d) DTF response v_4/v_3 ; (e) DTF response v_5/v_4 ; (f) damage index vs. element number.

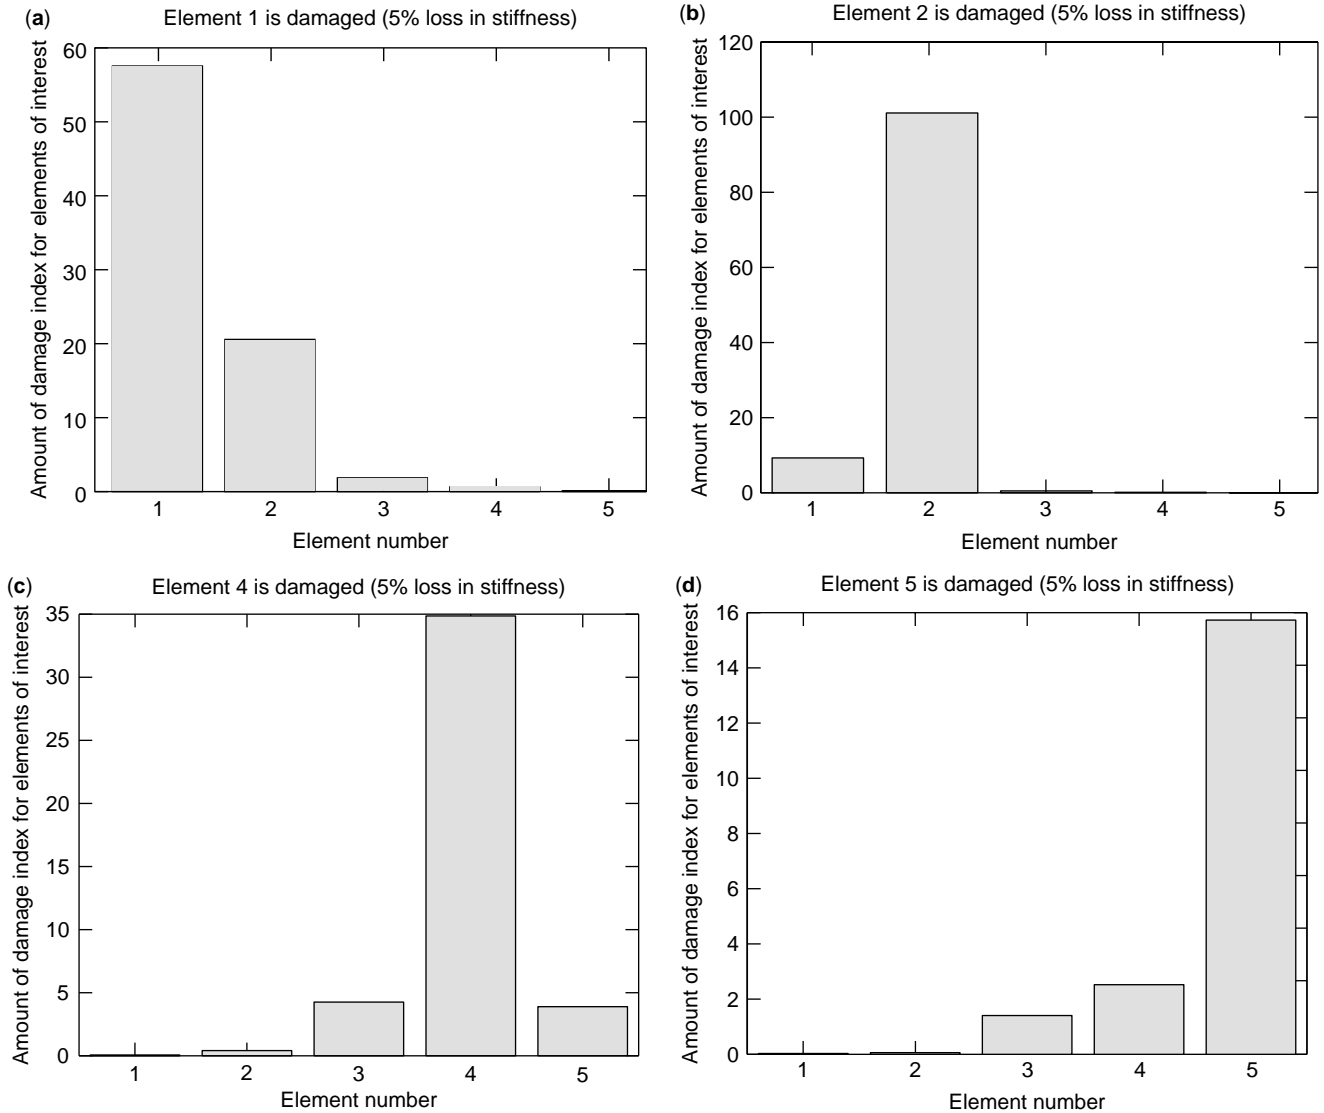

Figure 21. Damage index vs. element number. (a) Element 1 is damaged (5% stiffness loss). (b) Element 2 is damaged (5% stiffness loss). (c) Element 4 is damaged (5% stiffness loss). (d) Element 5 is damaged (5% stiffness loss).

Fixed-Free Beam. For a fixed-free beam, $\begin{pmatrix} v_0 \\ \theta_0 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}$. Only $i = 2, 3, 4, 5$ can be substituted in Eq. (42), and four damage indices, $PDI_2, PDI_3, PDI_4, PDI_5$, can be formulated. They are associated with elements 2, 3, 4, and 5, respectively. Five damage cases are simulated. Figure 22a shows damage indexes versus element number when element 1 is damaged. Remember that no damage index is formulated for element 1. However, from Fig. 22a, the index for element 2, PDI_2 , is large. This implies that damage occurred in element 1, demonstrated by the damage index of element 2. Of course, from Fig. 22b, damage in element 2 leads to a blowup of PDI_2 , too. Therefore, if the damage index of element 2, PDI_2 , exhibits some large value, both element 1 and element 2 need to be checked to see whether they are damaged. The damage indexes of elements 3, 4, and 5 can locate the damage of the associated elements as shown in Fig. 22c–e.

Damage Type and Extent

Most structural damage can be categorized as mass or stiffness related. In stiffness loss, the phase curve of the DTF response of a damaged structure tends to wrap at π or $-\pi$ earlier than in the undamaged case. In mass loss, the phase of the DTF response of a damaged structure tends to wrap later than in the undamaged case. This pattern in the phase behavior of stiffness or mass damage is primarily a result of the way wave number variations affect the transmission properties of an incident wave through a structural element. Thus, by simply examining the phase behavior of undamaged and damaged DTF responses, it is possible to ascertain the type of damage, albeit stiffness or mass. In addition, damping effects can also be identified.

Although the type of damage in a structural system can be determined from the phase response of the DTF,

Figure 22. Damage indices vs. element number. (a) Element 1 is damaged (5% stiffness loss). (b) Element 2 is damaged (5% stiffness loss). (c) Element 3 is damaged (5% stiffness loss). (d) Element 4 is damaged (5% stiffness loss). (e) Element 5 is damaged (5% stiffness loss).

Figure 23. Fixed-free beam; the fifth element is damaged.

determining the extent of damage in a structural element is a bit more difficult. The phase damage index (PDI) described before represents a qualitative measure of damage in a structure. However, by conducting a numerical study of the structural model identified, one can simulate structural damage in each structural element and correlate the PDI with percentage damage. Thus, a lookup table or curve-fitted database can be developed for each structural element to provide an estimate of the amount of damage in that element. Figure 23 displays such a correlation for the

fixed-free beam example developed earlier. Note that the PDI increases as structural damage increases in the structural element of interest. Similar trends exist for other elements.

DAMAGE DETECTION IN A BUILDING STRUCTURE USING DTF

Consider the discrete three-DOF model of the three-story framed building structure displayed in Fig. 24. The properties of the structure are given in Table 3. The equation of motion for the building structure is

$$M\ddot{X} + KX = q \quad (43)$$

or

$$\begin{bmatrix} m_1 & 0 & 0 \\ 0 & m_2 & 0 \\ 0 & 0 & m_3 \end{bmatrix} \begin{Bmatrix} \ddot{x}_1 \\ \ddot{x}_2 \\ \ddot{x}_3 \end{Bmatrix} + \begin{bmatrix} k_1 + k_2 & -k_2 & 0 \\ -k_2 & k_2 + k_3 & -k_3 \\ 0 & -k_3 & k_3 \end{bmatrix} \begin{Bmatrix} x_1 \\ x_2 \\ x_3 \end{Bmatrix} = \begin{Bmatrix} k_1 x_g \\ 0 \\ 0 \end{Bmatrix} \quad (44)$$

Transformed into the frequency domain and assuming that $x = Xe^{i\omega t}$, Eq. (44) becomes

$$[-M\omega^2 + K]X = Q \quad (45)$$

Figure 24. (a) Framed building structure. (b) Discrete three-DOF model.

Table 3. Properties of the structure

Mass	$m_1 = 16.7676$	$m_2 = 16.7676$	$m_3 = 16.7676$	unit: kg
Stiffness	$k_1 = 9158.7$	$k_2 = 13084$	$k_3 = 36635$	unit: N/m

**Figure 25.** Summing asymmetrical spring-mass elements to construct a building structure.

or

$$\begin{bmatrix} k_1 + k_2 - m_1\omega^2 & -k_2 & 0 \\ -k_2 & k_2 + k_3 - m_2\omega^2 & -k_3 \\ 0 & -k_3 & k_3 - m_3\omega^2 \end{bmatrix} \begin{Bmatrix} X_1 \\ X_2 \\ X_3 \end{Bmatrix} = \begin{Bmatrix} -k_1\omega^2 X_g \\ 0 \\ 0 \end{Bmatrix}. \quad (46)$$

From Eq. (46), note that energy is input into the building structure from ground motion by $F_1 = -k_1\omega^2 X_g(\omega)$ or $k_1 \ddot{X}_g(\omega)$.

A model of the three-DOF three-story building structure in Fig. 24 can be constructed by simply adding three asymmetrical spring-mass elements (see Fig. 25). The DTF of the whole building structure can be obtained by first adding a virtual controller to the right end of element 1, then adding elements 2 and 3 that have similar virtual controllers attached to both ends. This process is shown in Fig. 26. The control architecture is shown in Fig. 27. The controller gains G_{1r} , G_{2l} , G_{2r} , G_{3l} , G_{3r} are obtained by using Eq. (8) and substituting different k , m , and μ values for the different structural elements. The RTF and DTF are shown in Fig. 28.

Considering the structure shown in Fig. 26, energy is input from the left end of the structure. After passing element 1, controller G_{1r} will prevent the energy from being reflected back into element 1. A portion of the energy will continue transmitting into element 2. At the end of element 2, controller G_{2r} acts like controller G_{1r} to ensure that no energy is reflected back. The same effect will be achieved by controller G_{3r} . The result is that wave reflection does

not occur across the structure. If damage is present in a structural element, the idealized local controllers can not prevent reflection.

Damage in civil structures is usually categorized as stiffness loss. The following damage case studies simulate one-quarter damage loss for each stiffness of the three-DOF three-story building. This study attempts to show the characteristic change in the DTFs before and after damage. Further, a methodology is developed to locate damage. Six sets of figures are displayed for each case study, and each figure has two parts: the magnitude and phase of a particular DTF response. Emphasis is placed on examining the incident path of energy traveling through the structure. As the energy is transmitted across a damaged structural element, either the magnitude or the speed of wave propagation will change compared to the undamaged element. This change in local structural properties is revealed in the magnitude and phase plot of the DTF response.

Case Study: One-Quarter Stiffness Loss for k_1

Considering k_1 damaged in terms of stiffness loss, the energy is still input from the left end of the structure. Remember that G_{1r} is determined by m_1 and k_1 . The controller gains G_{1r} can prevent wave reflection perfectly at element 1. But for the damaged element, we do not know how much change there is in k_1 . If we still use G_{1r} as a virtual controller for the damaged element, wave reflections will occur at the end of element 1. The DTF response of \ddot{x}_1/\ddot{x}_g will change before and after damage, as is illustrated in Fig. 29 a. Strictly speaking, \ddot{x}_1/\ddot{x}_g is no longer the DTF after damage because a wave is reflected back into element 1. But that is not the case for elements 2 and 3. Controller gains G_{2r} and G_{3r} will do their jobs perfectly. This leads to identical DTF responses of \ddot{x}_2/\ddot{x}_1 , \ddot{x}_3/\ddot{x}_1 , and \ddot{x}_3/\ddot{x}_2 , illustrated in Fig. 29d–f before and after damage.

Now, consider Fig. 29a. In the low-frequency range, the DTF phase of an undamaged element is smaller than that of a damaged element. This means that the wave number of an undamaged element is smaller than that of a damaged element. The reason for the increased wave number is either stiffness loss and/or mass increase. Mass increase is unlikely in the event of damage in a civil structure. Thus, the cause of damage is assumed to be stiffness.

**Figure 26.** Applying controllers to obtain the DTF of a building structure.

Figure 27. Control architecture.

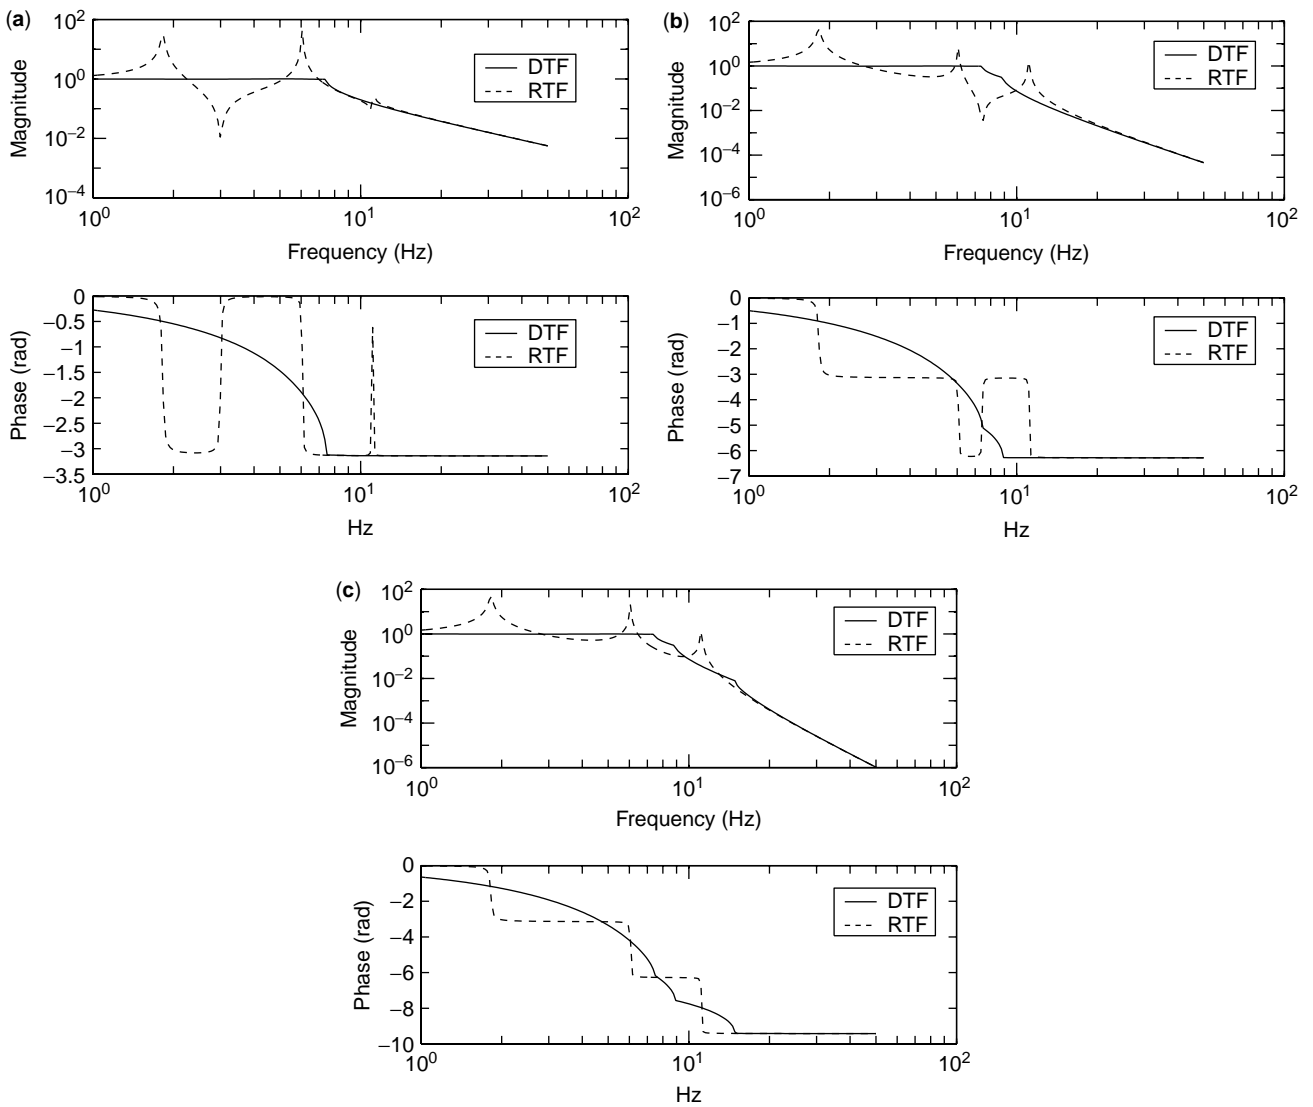

Figure 28. RTF and DTF response of a building structure: (a) \dot{x}_1/\dot{x}_g ; (b) \dot{x}_2/\dot{x}_g ; (c) \dot{x}_3/\dot{x}_g .

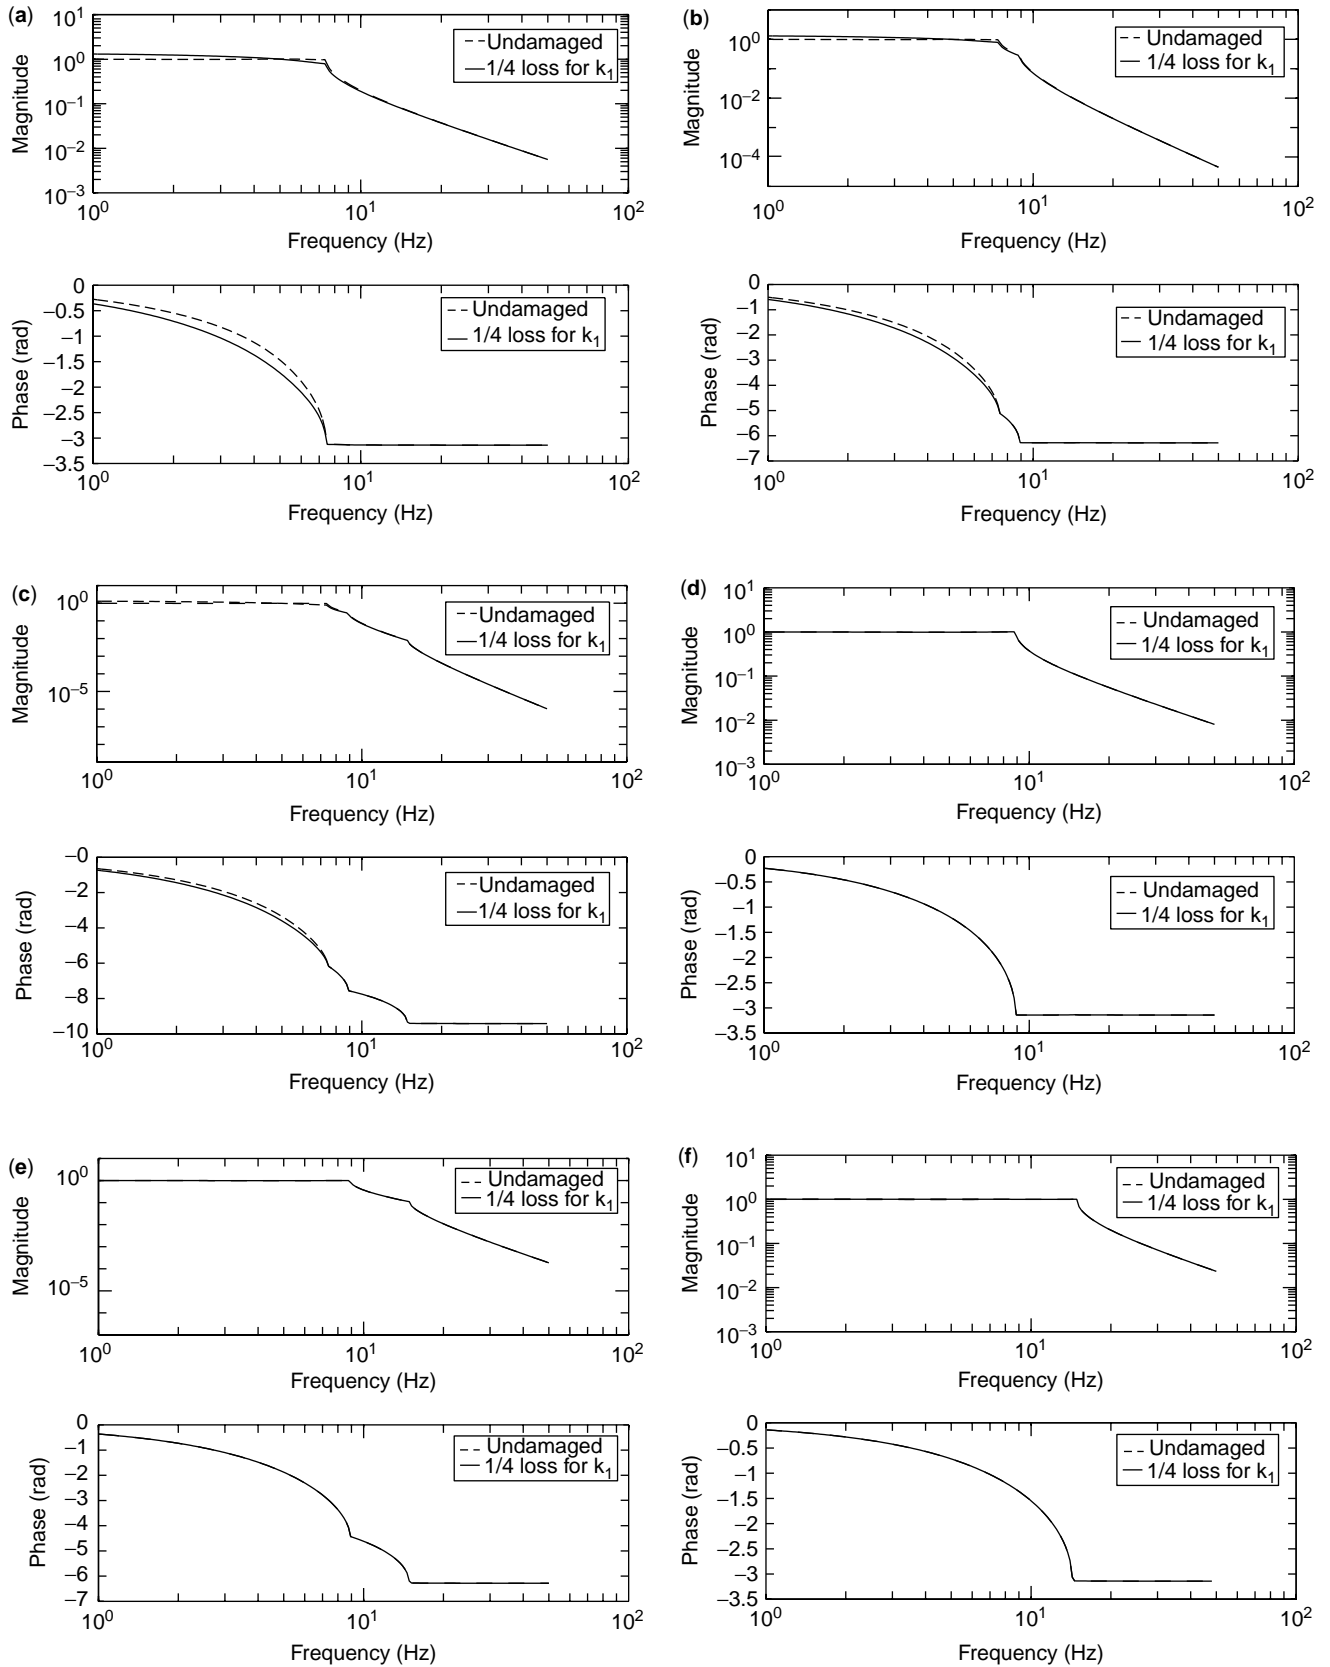

Figure 29. DTF response: (a) \ddot{x}_1/\ddot{x}_g ; (b) \ddot{x}_2/\ddot{x}_g ; (c) \ddot{x}_3/\ddot{x}_g ; (d) \dot{x}_2/\dot{x}_1 ; (e) \ddot{x}_3/\dot{x}_1 ; (f) \ddot{x}_3/\ddot{x}_2 .

Figure 30. DTF response: (a) \dot{x}_1/\dot{x}_g ; (b) \ddot{x}_2/\ddot{x}_g ; (c) \ddot{x}_3/\ddot{x}_g ; (d) \ddot{x}_2/\dot{x}_1 ; (e) \ddot{x}_3/\dot{x}_1 ; (f) \ddot{x}_3/\ddot{x}_2 .

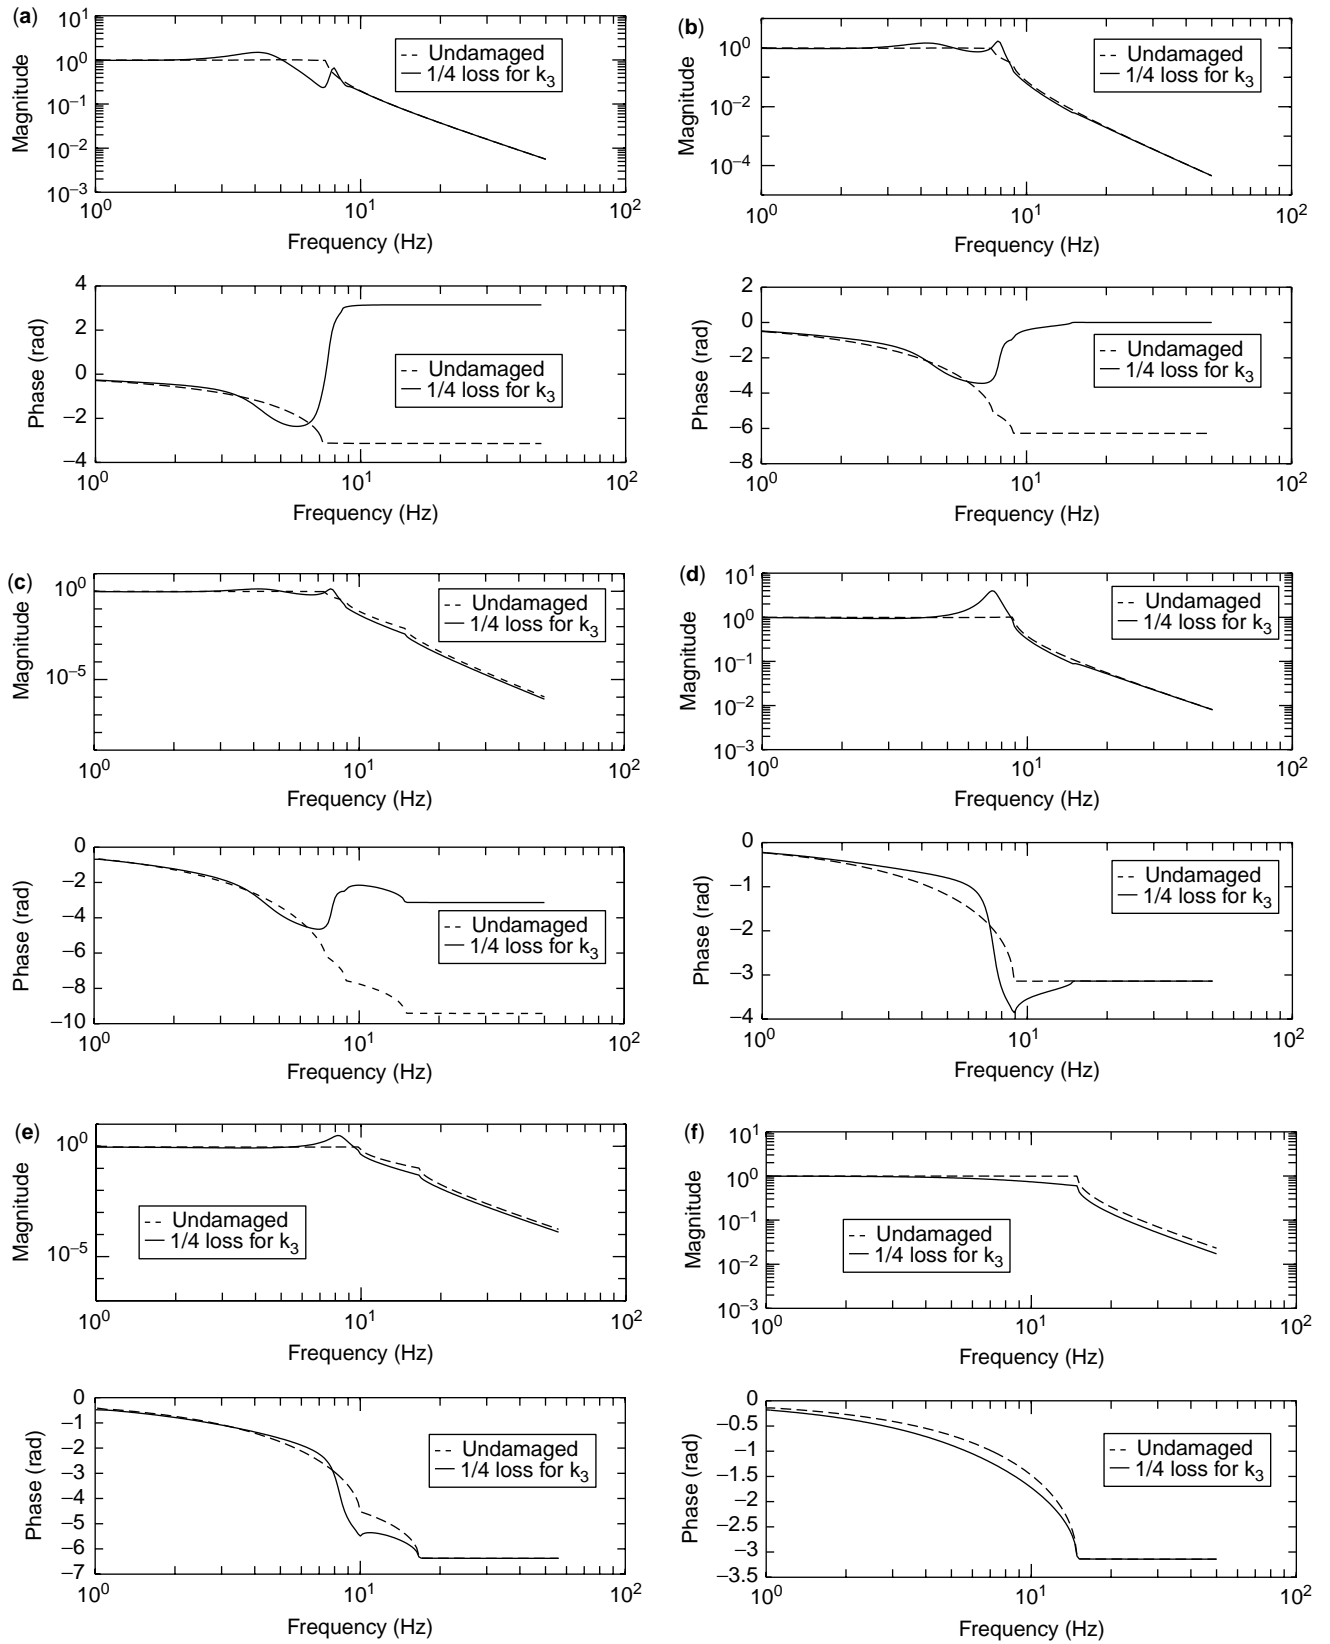

Figure 31. DTF response: (a) \dot{x}_1/\dot{x}_g ; (b) \dot{x}_2/\dot{x}_g ; (c) \dot{x}_3/\dot{x}_g ; (d) \dot{x}_2/\dot{x}_1 ; (e) \dot{x}_3/\dot{x}_1 ; (f) \dot{x}_3/\dot{x}_2 .

Now, it is evident that the damage occurs at element 1 in terms of stiffness loss. This led to the malfunction of controller G_{1r} . Using Eqs. (4) and (8), reducing the value of k_1 to k_{1r} , a new controller G_{1r} will be found to obtain a perfect DTF response for each element. Thus, the damage extent, $\Delta k_1 = k_1 - k_{1r}$, can be obtained.

Case Study: One-Quarter Stiffness Loss for k_2

From Fig. 30f, \ddot{x}_3/\ddot{x}_2 is identical before and after damage. This shows immediately that the damage happened at element 2. Now, only the DTF response of \ddot{x}_2/\ddot{x}_1 needs to be examined. This is shown in Fig. 30d. Applying similar reasoning, as earlier, a stiffness loss for k_2 is concluded.

Case Study: One-Quarter Stiffness Loss for k_3

From Fig. 31, no identical DTF before and after damage shows up. This shows that G_{3r} did not perform correctly. The wave reflection at the right end of the structure degrades all DTFs. We can conclude that damage must have happened at element 3, and the same reasoning leads to a stiffness loss for k_3 .

SUMMARY AND CONCLUSIONS

This article has introduced a wave propagation approach for computing the DTF responses of nonuniform structures. By using DTF responses, boundary effects are ignored in favor of the incident path that the energy takes to travel through a structure. It has been shown that the DTF responses, associated with an individual element, are sensitive to physical parameter changes which are directly in the load path from the input force to the measured sensor response. The DTF provides direct information regarding the source, location, and amount of damage.

HIGHWAYS

KAMBIZ DIANATKHAH
Lennox Industries
Carrollton, TX

INTRODUCTION

The number of automobiles has increased dramatically as a result of population and job growth during the past several decades. During the same period, the commuting distance has also increased (1). This in turn has resulted in congestion in many suburban areas. This increase in traffic flow translates into higher cost for accident expenses, a rise in fuel consumption, and air pollution. The Department of Transportation has estimated that the volume of traffic will increase by 50% in next 25 years (2). The loss of time and productivity and health issues caused by increased carbon monoxide and dioxide are the predominant factors that call for building smart highway systems.

SMART MATERIALS

Smart material technology is progressively becoming one of the most important new research areas for engineers, scientist, and designers. Increased use of smart materials will undoubtedly influence our daily lives fundamentally in the near future. Presently, the emergence of smart materials and smart structures has resulted in new applications that change the way we think about materials, sensors, actuators, and data processing. Smart materials are defined as materials whose properties alter predictably in response to external stimuli. Smart materials can be divided into several categories:

1. Shape-memory alloys: Polymers or alloys that remember their original shape under an applied load and temperature through phase transformation. Typical alloys are Ti–Ni (Nitinol) and TiNi–Cu (K-alloy).
2. Piezoelectric materials where strain results from an applied load or voltage (electric field), for example, polyvinylidene fluoride (PVDF) polymer.

3. Electrorheological fluids that change their viscosities according to the intensity of an electric field.
4. Photochromic glasses whose transparency changes with the intensity of light (photographic lens).

In this article, the advantages of smart materials are described for application to smart highways, structures and intelligent transportation systems (ITS). Through the application of new technology, there is potential to integrate multiple modes of travel and to focus on demand as well as transportation supply throughout the world. The field of smart highways and structures consist of many areas of innovation in developing superhighways, bridges, modern cars that have built-in computer-aided navigation equipment, and a central control unit within each highway system to assist in traffic management.

OBJECTIVES OF SMART HIGHWAYS

The objectives of building smart highways are safety, low maintenance, and conveyance. By building smart highways, more vehicles can be on the road thereby reducing congestion and eliminating the need for building additional lanes. For safety, computers installed in an automobile will perform all driving tasks, and this will enhance safety because most traffic fatalities are due to human error. For general safety purposes, the following are required for a modern highway: (1) piezo MTLs that connect to electric heaters and therefore, do not ice up, (2) "glow in the dark" surface material, and (3) standards for traffic flow. Maintenance is a major issue in establishing engineering design parameters for estimating the life of the road versus replacement cost. The convenience features of smart highways should include optical sensors on-site, cars that have Global Positioning System (GPS)/road maps and bar code road signs, and autopilot features. Environmental issues also play a critical role in designing a smart highway system. Finally, development of road surfaces that can break down pollutants such as nitrogen oxide gas, will be a major focus of future research for metropolitan areas such as Los Angeles and Denver that have high pollution.

Smart Structures

Smart structures are nonbiological physical structures that have the following attributes: (1) a definite purpose and (2) means and an imperative to achieve that purpose.

The functional aspects of a smart highway are to integrate the normal design features and provide means of controlling traffic to optimize the traffic flow and human safety. Smart highway structures are designed for normal and abnormal events. Normal design conditions are dead-weight, thermal expansion and cyclic traffic loads (3). A smart structure is a subset of many intelligent structures that is complex and made of innovative materials, control laws, and communications. Smart structures have sensors and or actuators to help them function. Smart structures generally should be light, take advantage of new computer technology, integrated sensors, actuators, and contain some sense of intelligence to attain structural performance capabilities.

America's bridges have deteriorated during the past two decades due to lack of funding and neglect. Many collapses have occurred on shorter spans during this period, and many are also riddled with cracks and weak spots. Concrete bridges have been more susceptible to failures than steel because their flaws are often less apparent. Because bridges are a critical part of any highway system, particularly a modern one, continuous monitoring and innovative technology are required to construct and modernize bridges to modern standards. In the construction of modern bridges and structures, smart materials must be capable of warning of potential failures for operations or of enhancement by structural health monitoring of civil infrastructures and marine structures.

The most significant areas of concern for smart structures are performance, cost, sensing technology, engineering integration, structural stress and the need for wireless technology. Smart structures provide useful tangible benefits, and adaptability is achieved by knowing the limits, constraints, and compatibility with existing designs, methodologies, and the ability to learn. The drawbacks of building smart structures lie in the capital intensive nature of the projects, lack of understanding what data to collect and how to interpret the data, lack of an integrated team approach, reluctance to change, lack of consistency, and dealing with regulations. Major areas of concern in design, construction, and maintenance are monitoring and evaluating structures of bridges, soil, and concrete as a result of stress or natural disasters such as earthquakes that will also be a major factor in constructing an intelligent highway system. Monitoring a bridge by fiber-optic deformation sensors or Doppler vibrometers to detect disbonded composites is currently being studied to prevent catastrophic failures(1,4).

Monitoring the structural integrity of highways and bridges for safety and ease of repair presents an emerging field of study to find new ways to support the infrastructure of these systems. Smart materials are beginning to play an important role in civil engineering designs for dams, bridges, highways, and buildings. Sensors embedded throughout a concrete and composite structure can sense when any structural area is about to degrade and notify maintenance personnel to prepare for repair or replacement. Smart materials will be used to improve reliability, longevity, performance, and reduce the cost of operating smart highways and structures (5). The application of sensors and actuators, diagnostic monitoring, structural integrity/repair, damage detection, and active hybrid vibrational control will be the major areas of discussion in building intelligent highways and structures using smart materials. A smart structure using smart technology may include the use of fiber-reinforced (FR) concrete and optical-fiber sensors. Glass or carbon fibers in a cement matrix (6) are used instead of steel to increase the strength of concrete. Steel tends to corrode in salt, water, and corrosive deicing compounds, but reinforced concrete is not susceptible.

Shape-memory alloys that are important elements of intelligent (smart) materials can be used to build smart sensing structures, for example, a damping device made of shape-memory alloys can absorb seismic energy and

reduce its force. Due to its unique properties, this type of alloy can return a bridge to its original position after seismic activity (7). Optical-fiber sensors can also be embedded in composite beams along their length to monitor any stresses from traffic loads, cold, and wind. The change in wavelength of light reflections from optical sensors is compared to a set of baseline wavelength data (6). Old bridges can also be reconstructed and reequipped with small amounts of carbon fibers in the concrete mix and by using an electrode at each end of the bridge and measuring its resistance. Should developing cracks disintegrate the fibers that can conduct electricity thereby increasing the electrical resistance. The fractures can also be correlated with reduction in the strength of steel and concrete and also to determine whether serious damage has occurred (8).

Materials technology, specifically, the use of composites and shape-memory alloys in new structures and highways will have a great impact on human society, including the creation of new industries, extension of the women frontier to space, high-speed transportation, and earthquake-resistant and disaster-preventing construction.

A major area of focus in building a smart highway structure is the road pavement smoothness that creates better driving conditions and increases the life of the road (9). Equipment for road smoothness in all states will be required to set a minimum standard. The quality of cement and concrete also plays a significant role in developing a high quality road. Paving material quality plays an important role in durability and safety of roads. Use of recycled materials and polymer-modified binders have been considered for the durability of paving systems in some California highways (10), compared with traditional asphalt pavement. The major obstacles to using recycled or polymer material in pavement materials are extreme loads introduced by heavy trucks that may impact the integrity of the road and the driving performance of the truck.

However, these new materials cost far less than ordinary asphalt and may also assist in design, construction, and easier maintenance of the roads. Another concern that recycled materials and polymers must address is the material's performance in variable weather conditions and major fluctuations in temperature.

Highway fatalities have declined about 20% within the past decade from 47,000 to 41,000 annually as a result of safety improvement (9). Road condition plays a critical role in highway safety.

Liability issues and cost-effectiveness will be significant factors in the development of modern highways in upcoming years. A successful, low-cost system for modern automobiles that can reduce fatalities will be a key initial step to globalization of this system.

Sensors

Sensors must have properties that enable them to detect small changes in a structure (8), that is, changes in strain and capability for a measurable output signal. The response time of a sensor is a critical issue in monitoring crack growth within a structure; although it will not be as critical in observing stiffness changes from fatigue.

Piezoelectric ceramics are a common type of embedded sensor and are used for noise and vibrational sensing (II). Mechanical and viscoelastic properties and compatibility with the surrounding structure are the primary factors in selecting a sensor because it is usually embedded in a polymeric composite. Polymers at high frequency and low temperatures are stiff due to lack of molecular motion and because they are in a glassy state (8). At high temperatures, polymers are glassy due to high viscosity because atoms can move more easily. The behavior of a polymer is a function of T_g , the glass transition temperature at which a polymer is in a glassy state. The strain properties of a polymer are directly related to the state of the polymer.

As mentioned previously, carbon fibers are used as reinforcement in smart structures for strain sensing (9) and can replace the need for strain gauges and optical sensors. However, the important factor in considering carbon fibers is their electromechanical properties, namely, the electrical resistivity of the fibers under load in composite, polymer, and concrete structures. The electrical resistivity and the modulus of elasticity are affected by tensile and compressive forces (9).

Fiber-optic sensors can provide information on any strain fluctuations as a result of stress and early warning of a flaw in a joint or within the concrete. Fiber-optic sensors, as related to smart structures, can reduce the risk of failure in an aging infrastructure. Although fiber-optic sensors are not smart and lack actuating capability, they are the predominant technology that is discussed in relation to smart structures. Structures instrumented with fiber-optic sensors can respond to or warn of impending failure and indicate the health of a structure after damage. Applications include the instrumentation of bridges, highways, dams, storage tanks, oil tankers, and buildings. Systems that can measure strain or vibration have been tested in the United States and Germany. The cost and complexity of such optical systems and the limited benefit will make this a slow market to develop. Larger scale and longer term demonstrations will be required to gain acceptance from the engineering community.

Vibrational measurements could provide information on any earthquake activity within a region or the deterioration of a structure. Electromagnetic sensors that take advantage of steel's magnetic permeability as a function of its internal stress also present tools for monitoring bridge cables and prestressed concrete structures (12). In this method, the internal stresses of highly elastic steel are measured by determining its permeability, which can be measured indirectly by its inductance (12). Strain sensors will be a key tool for monitoring crack initiation sites and a good indicator of structural failure. Typical sensors, in addition to the those mentioned before, include strain gauge sensors, displacement transducers, accelerometers, anemometers, electrical time domain reflectometry (for stress/strain sensing), and temperature sensors.

Many highway systems enforce weight restrictions on large truck to reduce road damage. The use of weight in-motion sensors such as piezoelectric polyvinylidene fluoride (PVDF) polymer can reduce the damage caused by heavy trucks. This type of polymer embedded in elastomeric

material placed in a groove on the highway can detect the weight of a passing vehicle and translate the weight into a voltage output (13). The disadvantages of this type of sensor are temperature variation and physical damage under extreme loads.

SMART HIGHWAYS

A smart highway system consists of sensors, computers, and communication tools to enable all driving functions to work. The smart highway program is designed to make travel smoother on highways by quickly alerting motorists to traffic accidents, icy stretches of road, and other hazards, and by posting the best alternate routes. Today's highway systems are long, steep grades and sharp curves that present problems especially for high traffic volume and bad weather conditions. More than half of all traffic accidents occur during foggy, rainy, icy, and snowy conditions. More than two-third of truck accidents occur on curves or slopes. One way to reduce traffic accidents is to use advanced communication systems via satellites and place warning signs. The following must be considered in building a smart highway:

- Traffic control centers assisted by a computer networking system where controllers adjust traffic flow. In this center, video-image signals, which are sent by cameras and video cameras, mounted on poles and building, are converted to digital maps.

- Construction of many ramp meters where traffic lights are installed in critical entrance ramps to control the flow of merging traffic.

- Placement and design of narrow poles that support signs and light on fixed objects such as a bridge (14) for safety enhancement.

- Installation of hundreds of sensors in the pavement to count cars as they pass and to estimate and transfer this information to the control center.

- Broadcast of critical traffic information to alert drivers to slow down ahead and advise an alternate route.

- Automatic toll collection where sensors read optical cards on dashboards.

- Sufficient safety enhancement.

In addition to building and monitoring highways systems, control centers that are assisted by computer-networking system are also required to manage traffic and construct intelligent transportation systems. Central units are a way to communicate to drivers and law enforcement officers to reduce routine accidents by improving visibility at night or in bad weather by early warning to drivers (15).

An intelligent highway system that has an electronic communication system should be capable of the following tasks: (1) automatically regulate the flow of traffic, (2) provide drivers with up-to-the-minute information, (3) perform most driving tasks, (4) ease carpooling, and (5) manage and guide commercial fleets (14).

To build a modern highway, loop detectors and video cameras will be installed in critical areas to monitor traffic flow, speed of vehicles, and identify bottlenecks to a central communication headquarters. An intelligent highway system will consist of information processing, communications, control, and electronics to transmit critical information to drivers.

Satellites flying in low orbit will be required to transmit data to a central unit. Satellites must have a broad range and can collect, monitor, store, and selectively transmit data to process information.

Smart highways could also be used for smart public transportation, allowing bus drivers control over passenger traffic, manage traffic flow, and reduce delays. Smart transit systems can be organized for expensive share-ride taxis and to assemble carpools and vanpools for daily operation (16), for smart goods movement systems to assist companies to transport goods more cheaply and with less energy and resource use, using streamlined truck inspections and better routing through traffic and linking road-rail transport systems. Computer process technology can also be used to improve manufacturer information and communications to reduce the need for long-distance shipping and provide faster delivery systems to encourage purchases from home or local stores.

To minimize fuel consumption and improve fuel efficiency, formulas must be developed based on factors such as the lane miles of roadway, vehicle miles traveled, the level of mail routes, the population and the size of the state in square miles and transmitted to a central computer system.

ADVANCED AUTOMOBILES

In conjunction with smart highways, smart vehicles will provide complete control of nearly all driving functions. The major tasks of driving consist of navigation, braking, steering, throttle control, and avoiding accidents; the vehicle will automatically control traffic light management. Most automated driving tasks have already been implemented in pilot vehicles by major auto manufacturers.

Today's automobiles carry more advanced semiconductor technologies than they did in the early 1980s. Until now, chip technology has been used to enhance the performance of engines and to control airbags and antilock brake systems. However, navigation systems such as the global satellite (GPS) systems will dominate the new generation of telecommunication advances in congested traffic areas. Modern car manufacturers have developed navigation systems to pinpoint a driver's location and are also developing systems that activate warnings for avoiding objects in the blind spots. Collision avoidance units are also under development to steer, brake, or accelerate a vehicle automatically (15). A unique feature of the modern automobile is the card key for opening car doors and driver information identification that will enable identifying a car's speed and taking care of tolls. The microchip-embedded card that is slightly thinner than a normal credit card can operate within three feet of the vehicle. A Siemens Smart Card is

already available as an option on new the Mercedes-Benz S-Class.

Personal communicators and computers are presently under development to receive data from Global Positioning Satellite (GPS) signals. Receivers work with embedded systems and translate and correlate data with multiple satellites to determine the positioning of vehicles. A video screen using GPS signals can determine the location on a road or within a city map. In combination with sensors, computers will be able to monitor traffic and road conditions and even control the distance between cars for increased safety.

To build smarter highways and structures, we may also need to build smarter and more sophisticated automobiles. Smart sensors and devices can be used to control traction, steering, and suspension and monitor tire pressure and sense and orient a car automatically to road conditions. Sensors that can control the speed, vibration, and temperature of vehicles could be used in conjunction with road sensors to optimize most critical functions of an automobile. Sensors could also be used in the rear and front of a vehicle to warn drivers that they are getting too close to another vehicle or are being approached too closely by another automobile in addition to lane changing. Optical sensors, based on the misbonding effect and speckle phenomenon technology, can be used to identify a vehicle type and its speed and also to monitor traffic flow and count vehicles on the road. These sensors can be placed inside the asphalt layer of the road surface (17). The major area of focus for automobiles besides safety is the use of sensors for automation and using exotic materials such as composites to substitute for steel to improve fuel efficiency. The use of new materials such as composites provides a multitude of potentials and degrees of freedom for materials design that involve increased strength, creating new functions and expanding to multiple functionalities. Smart materials consist of composites that indicate exactly the direction of the future development of materials engineering and represent a change from "supporting" to "working" to build up a new materials application system that integrates structures, functions, and information.

Smart sonic traffic sensors placed on acoustic sensors is another alternative (18) to magnetic-loop sensors to detect vehicles from the sounds that they make. More sophisticated cruise control could be tied in with sensors to reduce or increase speed instantaneously to avoid accidents. General Motors and Ford have tested computerized navigation systems to pinpoint a driver's location and to warn drivers of potential obstacles by using detection systems to steer clear of objects in blind spots and avoid collisions.

Modern automobiles for smart highways also being considered where by drivers can take their hands off the wheel and eyes off the road enabling advanced cruise controls take charge of the driving (19). Smart highways and uniform speed are the major requirements for this futuristic idea before such cars can be used. In addition to cruise control features, this type of vehicle is equipped with radar fields. Sensors emit a beep if the car is about to hit something. This type of technology is currently available

in the Ford Windstar and some other commercial vans (19).

The combination of sensors and the advanced cruise control will enable vehicles to take charge of most routine driving tasks. Examples of modern cars under consideration include General Motors Buick Division where magnetic pegs are inserted on the road and vehicles are then capable of riding on their own. Front sensing radar plays a key role in maintaining the distance from other cars; one of the key features of this type of automobile is communication between cars equipped with similar technology. Mitsubishi has also built a futuristic car where the vehicle had dual mode driving capability; the first mode is the traditional driving mode where the driver is in command. In the second mode, the driver uses the passenger seat, and the car uses sensors and HR6 technology to take complete care of all driving tasks. This type of vehicle is equipped with the latest communication tools where the driver can monitor the traffic and weather conditions, access the Internet, and check e-mail. In the automatic mode, the vehicle body turns into an aerodynamic type. Mitsubishi has also developed cars that have multiple sensors to detect steep roads, curves, and hazardous signs, and the vehicle adjusts after detecting any upcoming warning sign. Ford also uses a new technology of light beam output where the size and the shape of the beam are calibrated with the speed and the type of road, and radar is installed in the vehicle. This technology provides ideal speed control for safety and fuel efficiency. Jaguar progress has been in night vision technology where infrared technology gives the driver the ability to monitor any object that cannot be observed during darkness. Mercedes-Benz in cooperation with Boeing is also developing a limousine equipped with the latest electronic features that can drive on its own and is also equipped with GPS technology.

The future car for the twenty-first-century will look like a rolling recreation room and a source of entertainment as manufacturers progress in developing new technology. This in turn will reduce traffic commuting between home and office and also will require far less attention from drivers. Future automobiles will be designed to represent true mobility rather than a transportation tool. The new generation of cars will possess more revolutionary and innovative electronic features to ease driving tasks and access communication networks for weather, news, the worldwide web, and satellite or cellular networks. Thus far, the United States has lagged behind other industrialized nations; in 1998, of all vehicles equipped with navigation systems, less than 5% were purchased in the United States and more than 90% were sold in Europe and Japan, where there is higher demand for communication technology.

Recent developments in automobile manufacturing consist of using a laptop computer to interface with all sensors to warn and control the devices in a car. The new laptop computers offer ample processing power and disk space and can operate on 12 Vdc power. On new futuristic cars, the laptop computer is likely to become standard, and the cost of remaining associated hardware is expected to fall significantly in the near future.

Global Positioning System (GPS)

GPS is a technology for improving the accuracy of positioning information. Greater accuracy is potentially useful in such ways as improving the accuracy of maps, enhancing search and rescue efforts, improving navigation on crowded highways and waterways, and helping planes land in bad weather. Present technology has made it possible to improve greatly the accuracy of global positioning information available from satellites. This technology, called Differential Global Positioning Systems, allows pilots, surveyors, and others using satellite positioning information to determine their positions on earth to within a few meters—or even a few centimeters. Normal GPS can provide latitude and longitude, speed, and direction of travel. GPS is beneficial to improve safety for trucks by installing receivers and sensors in the trailer section. The load of the truck then can be monitored in addition to determining tax and fuel rates (9). The driver can also receive real-time traffic and navigational information.

The development of a central GPS unit for nationwide use is critical for managing multiple functions for entire smart highways within all states. This system could be used on land as well as in the air and on the sea. Development of common equipment standards, technical feasibility and accessibility, and organizational structures will be the key issues for coordinating this system. Global positioning data can presently be provided from a network of Department of Defense (DOD) satellites. Planes, boats, vehicles, and mapping and survey teams can determine their positions on earth by using equipment that receives and interprets signals from these satellites. For smart highway applications, the satellites provide a signal that is accurate to about 100 meters without the use of GPS. Coordination between the federal government and local states may be needed to enhance joint development or sharing of Differential Global Positioning Systems equipment, facilities, and information for future use. The limitation of existing GPS technology lies in highly populated areas that have large buildings and trees. GPS is not functional inside a tunnel or any enclosed area (16). Present GPS technology relies on a satellite signal whose signal is received and translated by a receiver (9). The system works perfectly in an uninhabited area where it may not be as useful.

The price of a GPS system has fallen dramatically in recent months provided that the automobile is equipped with a portable computer. Earthmate sells for less than \$180 and is a high-performance, easy-to-use receiver that links to the satellite navigation technology of the Global Positioning System (GPS).

UPDATE ON SMART HIGHWAY PROJECTS UNDER CONSTRUCTION

Major smart highway development has been underway in the states of California and New Jersey. Thus far, major problems consist of major delays in completing construction and some minor accidents due to the extreme weight of signs that require support. New Jersey's Route 80 from the George Washington Bridge to its connection with 287 in Morris County and Routes 95, 23, 46, 4, 17, 202, 287,

and 280 use radar, pavement sensors, and closed circuit TV and cameras. This highway system was designed to provide real-time information about traffic, ice, upcoming accidents, and weather (20). Besides major construction delays, problems appear to be the variable sizes of signs throughout the highway that make reading them difficult. Another obstacle is a potential design flaw where the strengths of structure may be underestimated for strong storms and abnormal weather conditions. Most of the problems thus far have been related to scheduling, lack of coordination for use, and timing of installation. It appears that a pilot smart highway may be required where extreme weather conditions are present before additional major superhighway construction begins. Chrysler Corporation has developed vehicles, particularly large trucks for smart highways, that are presently being tested without any drivers. However, the company is not betting that any major smart highway projects will be started soon. Chrysler believes that there are many old cars on the road that may interfere with the general concept of fully automated highways. This presents a case for a two-tier highway system, one for modem vehicles and one for cars that are not equipped with smart computers. The associated costs and capital for building new highways must be considered relative to potential revenues. Another dilemma concerns turning over the control of human lives on such highways to a major corporation or the government (20).

SMART HIGHWAYS IN JAPAN

Japan has been far ahead of most industrialized nations in developing and using smart materials; therefore, it is beneficial to review the recent progress of smart cars and highways that is a model for the rest of the world.

Traffic fatalities in Japan are approximately 14,000 per year (21) at an annual cost of \$120 billion. Population density is also 12 times higher than that in the United States. Therefore, the benefits of constructing an ITS system will have a tremendous impact on productivity. The total annual budget for an intelligent transportation system is estimated at 700 million, proportionally higher than that in the United States (21). Japan has more than 3800 miles of toll roads and development is underway to automate a toll collection system fully.

Although traffic control systems have been used in Japan for a number of years to ease traffic, the major objective in automating a traffic system in Japan by using a smart highway system is for safety enhancement and reduction of traffic fatalities. Another objective is to enhance communication between vehicles, particularly commercial vehicles and public transit, by using a central traffic management system. Today, Japan has more than 112 miles of smart highways, which consist of 2,077 vehicle detectors to monitor the number of vehicles and speed. These smart roads also have graphic displays and television cameras. Presently, Japanese auto manufacturers offer 40 different models of navigation systems; approximate sales are one million units per year.

In Japan, ITS development began in the 1960s and 1970s by construction of a road system, the Electronic

Route Guidance Systems similar to those in the United States and Germany (21). In the 1980s, due to microprocessing technology development and the lower cost of computer chips, work has been under way to set up a system for communicating between the road and the automobile. The final phase will be implementation of smart highway and smart cars to build an intelligent transportation system (ITS). Although United States lags behind Japan in smart highway development, the implementation of fully automated highways has not yet materialized in Japan or Europe.

SUMMARY

Fully automated highways may still be a long-range vision, but one must recognize the tremendous social and cost implications of converting our basic transportation structure to a more interactive, customer-oriented "smart" system. The critical obstacles besides cost are whether the public really wants some level of external control over its driving behavior, even if that control means increased safety and efficiency. As for cost, a fully implemented "smart" highway or transit system is probably akin to building another interstate system, not to mention the increased cost of smart vehicles to consumers. Although ITS will probably be implemented incrementally, the areas that need to be considered are social and cost implications for the public and agreement on some long-range vision of an ITS futuristic design. Congress and local states will make the final decision; however, because the United States reliance on cars is expected to continue for at least the next 50 years, development of smart cars and smart highways will be required to reduce the traffic and improve safety.

Future operational prototypes of smart highways have been decided; the actual test and evaluation phase nationwide is planned between 2002 and 2006 (22). The challenge for future intelligent transportation systems (ITS) will be to maximize safety and efficiency and reduce traffic congestion and associated costs. Auto manufacturers have already begun to build collision avoidance devices, electronic brakes, and steering and sensors to automate driving. Future evaluation of ITS will be based on reduction of traffic and accidents, energy efficiency, and reduction of cost and travel time compared to the present highway system.

ACKNOWLEDGMENTS

I thank Professor James Harvey, who introduced me to the field of smart materials and structures and encouraged me to broaden my knowledge in this field. I also express my gratitude to Mary B. Taylor who read the manuscript and contributed and suggested great futuristic ideas on how to build smarter highways and structures.

HYBRID COMPOSITES

DAZHI YANG
ZHONGGUO WEI
Dalian University of Technology
Dalian, China

INTRODUCTION

Smart materials, or intelligent materials systems, are concepts developed in the late 1980s. Technologically, smart materials could be said to integrate actuators, sensors, and controls with a material or structural component. Scientifically, they can be defined as material systems with intelligence and life features that reduce mass and energy and produce adaptive functionality. The development of smart materials has been inspired by biological structural systems and their basic characteristics of efficiency, functionality, precision, self-repair, and durability. As is well known, few monolithic materials presently available possess these characteristics. Accordingly, smart materials are not singular materials, rather, they are hybrid composites or integrated systems of materials.

Presently, no materials possessing high-level intelligent have been developed. Only some smart hybrid composites that can receive or respond to a stimulus, including temperature, stress, strain, an electric field, a magnetic field, and other forms of stimuli have been developed and studied by materials scientists. These smart hybrid composites are developed by incorporating a variety of advanced functional materials, such as shape memory materials, piezoelectric materials, fiber-optics, magnetostrictive materials, electrostrictive materials, magnetorheological fluids, electrorheological fluids, and some functional polymers. Smart hybrid composites provide tremendous potential for creating new paradigms for material-structural interactions, and they demonstrate varying success in many engineering applications, such as vibration control, sound control, quiet commuter aircraft, artificial organs, artificial limbs, microelectromechanical systems among a variety of others.

Shape-memory materials (SMMs) are one of the major elements of smart hybrid composites because of their unusual properties, such as lie shape-memory effect (SME), pseudoelasticity, or large recoverable stroke (strain), high damping, capacity, and adaptive properties which are due to the reversible phase transitions in the materials. To date, a variety of alloys, ceramics, polymers and gels have been found to exhibit SME behavior. Both the fundamental and engineering aspects of SMMs have been investigated extensively and some of them are presently commercial materials. Particularly, some SMMs can be easily fabricated into thin films, fibers or wires, particles and even porous bulks, enable them feasibly to be incorporated with other materials to form hybrid composites.

SHAPE MEMORY ALLOY FIBER/METAL MATRIX COMPOSITES

The basic design approaches for the SMA fiber/metal matrix composite can be summarized five steps: (1) The SMA fiber/metal matrix composites are prepared and fabricated by using conventional fabrication techniques; (2) the as-fabricated composites will be heated to high temperatures to shape memorize the fibers or to undergo some specific heat treatment for the matrix material, if necessary; (3) since SMAs have much lower stiffness at martensite stage or readily yield at the austenitic stage just above the martensitic transformation start temperature (M_s), the composites are then cooled to lower temperatures, preferably in martensite state; (4) the composites are further subjected to proper deformations at the lower temperature to enable the martensite twinning or the stress-induced martensitic transformation to occur; and (5) the prestrained composites are then heated to higher temperatures, preferably above the austenite finish temperature A_f , wherein martensite detwinning or the reverse transformation from martensite to austenite takes place, and the TiNi fibers will try to recover their original shapes and hence tend to shrink, introducing compressive internal residual stresses in the composites. This design concept can also be applied to polymer matrix composites containing SMA fibers and to the metal matrix composites containing SMA particles.

The internal residual stress in both the fiber and the matrix, and the composite macroscopic strains as a function of external variables such as temperature and applied load or prestrain have been calculated within nonlinear composite models using Eshelby's formulation. As expected, depending on the fiber pretreatment and distribution, as well as the boundary conditions, varying levels of compressive residual stresses can be generated in the matrix of the SMA composite during heating process, resulting in a large negative thermal expansion. For a given SMA fiber reinforcement, the matrix compressive residual stress increases with increasing volume fraction and prestrain of the SMA fibers within a limited range, and optimal prestrain and fiber volume fraction values can be found. In addition, the magnitude of the internal residual stress is limited by the flow strength of both the SMA fibers and the matrix material.

Apart from the dependence on the volume fraction and prestrain, the yield stress of the composite increases with increasing temperature within a limited temperature range. This is because the contributing back stress in the Al matrix induced by stiffness of TiNi fibers and the compressive stress in the matrix originate from the reverse transformation process from the "soft" martensite to the parent phase (austenite) with a several times higher stiffness. For the austenite phase fiber, the critical stress to induce the martensitic transformation shows a strong positive dependence on temperature, as demonstrated in the Clausius-Clapeyron equation and temperature-stress-strain curves of SMAs.

In agreement with modeling predictions, with increasing fiber volume fraction and prestrain, a more significant strengthening effect of the composite by the SMA fibers was observed. It was found that the Young's modulus and tensile yield stress increase with increasing volume fraction of fibers. The crack propagation rate as a function of the apparent stress intensity factor in the composites was measured and a drastic drop of the propagation rate (i.e., crack-closure effect) was observed after the composite was heated to higher temperatures ($>A_f$). The enhancement of the resistance to fatigue crack propagation was suggested to be ascribed to the combination of compressive residual stress, higher stiffness of the composite, the stress-induced martensitic transformation and the dispersion of the mechanical strain energy at the crack-tip.

The SMA fiber-reinforced MMCs also exhibit other improved properties. For instance, the damping capacity of the TiNi fiber/Al matrix composite was measured and the results indicated that the damping capacity of the composite in the temperature range 270 to 450 K was substantially improved over the unreinforced aluminum. The composite was also expected to show high wear resistance.

SHAPE MEMORY ALLOY FIBER/POLYMER MATRIX COMPOSITES

Depending on the SMA fiber pretreatment, distribution configuration, and host matrix material, a variety of hybrid polymer matrix composites can be designed that may actively or passively control the static and/or dynamic

properties of composite materials. Passively, as in the SMA fiber/Al matrix composites, the shape memory alloy fibers are used to strengthen the polymer matrix composites, to absorb strain energy and alleviate the residual stress and thereby improve the creep or crack resistance by stress-induced martensitic transformations. The embedded SMA fibers are usually activated by electric current heating, and hence they undergo the reverse martensitic transformation, giving rise to a change of stiffness, vibration frequency, and amplitude, acoustic transmission or shape of the composite. As a result structural tuning modal modification or vibration and acoustic control can be accomplished through (1) the change in stiffness (inherent modulus) of the embedded SMA elements or (2) activating the prestrained SMA elements to generate a stress (tension or compression) that will tailor the structural performance and modify the modal response of the whole composite system just like tuning a guitar string. The two techniques are termed active property tuning (APT) and active strain energy tuning (ASET), respectively. In general, APT requires a large volume fraction of SMA fibers that are embedded without prior plastic elongation and do not create any large internal forces. While ASET may be equally effective with an order of magnitude by a smaller volume fraction of SMA fibers that are active, however, and impart large internal stresses throughout the structure.

Usually the embedded or bonded shape memory alloy fibers are plastically elongated and constrained from contracting to their “normal” length before being cured to become an integral part of the material. When the fibers are activated by passing current through them, they will start to contract to their normal length and therefore generate a large, uniformly distributed shear load along the length of the fibers. The shear load then alters the energy balance within the structure and changes its modal response. Shape memory alloy fibers can also be embedded in a material off the neutral axis on both sides of the beam in an antagonist–antiantagonist pair. Alternative interaction configurations include creating “sleeves” within the composite laminates and various surface or edge attachment schemes.

Advanced composites such as graphite/epoxy and glass/epoxy composites offer high strength and stiffness at a low weight and moderate cost. However, they have poor resistance to impact damage because they lack an effective mechanism for dissipating impact strain energy such as plastic yielding in ductile metals. As a result the composite materials dissipate relatively little energy during severe impact loading and fail in a catastrophic manner once stress exceeds the composite’s ultimate strength. Typically damage progresses from matrix cracking and delamination to fiber breakage and eventual material puncture. Various approaches to increase the impact damage resistance, and specifically the perforation resistance, of the brittle composite materials have been attempted. The popular design concept is to form a hybrid that utilizes the tougher fibers to increase the impact resistance and also the stiffer and stronger graphite fibers to carry the majority of the load. The hybrids composed of the graphite/epoxy with Kevlar[®], Spectrag[®], and S-glass fibers have demonstrated modest improvements in impact resistance. Among

various engineering materials, high strain SMAs have a relatively high ultimate strength. They can absorb and dissipate a large amount of strain energy first through the stress-induced martensitic transformation and then through plastic yielding. Accordingly, the impact resistance of the graphite/epoxy composites may be improved by hybridizing them with SMA fibers. Paine and Rogers have developed the concept and demonstrated that under certain load conditions the impact energy absorbing ability of graphite and glass composites can be effectively improved by hybridizing the composites with TiNi SMA fibers. Hybrid composites with improved impact and puncture resistance are very attractive because of their great potential in military and commercial civil applications.

Generally, the shape memory hybrid composite materials can be manufactured with conventional polymer matrix composite fabrication methods, by laying the SMA fibers into the host composite prepreg between or merging with the reinforcing wires and then using either hot press or autoclave and several different types of cure cycles. Previously the few attempts to incorporate embedded TiNi wires directly into a polymer matrix composite proved unsuccessful due to manufacturing difficulties and problems associated with interfacial bonding. To avoid the interface bonding issue, SMA wires were alternatively incorporated into polymer matrix by using coupling sleeves. Both thermoset and thermoplastic composites have been addressed. Comparatively, fiber-reinforced thermoplastics offer some substantial advantages over fiber-reinforced thermosets because of their excellent specific stiffness, high fracture toughness, low moisture absorption, and possible fast and cost-effective manufacturing processes. However, the high process temperatures can be problematic for the embedding of SMA elements. The thermoplastic processing must be performed at higher temperatures, typically between 423 and 673 K. Whereas the thermoset processing cycle of the composites is in the relatively low temperature range of RT – 443 K. The thermoplastic processing cycle has some effect on the microstructure of the SMA fibers as manifested in the change in transformation temperatures and peak recovery stress: the transformation temperatures of the SMA shift upward while the peak recovery stress drops as a result of the thermoplastic processing. The thermoset processing only mildly affects the transformation characteristics of SMA fibers.

However, some dynamical properties of SMA fibers could be significantly affected. Much of previous research on the SMA hybrid composites utilized the one-way shape memory effect, especially in the applications that require recovery stress of the SMA. Much care should be taken to prevent shape recovery of the prestrained SMA fibers or wires during the composite cure cycle. The complexity of manufacturing the SMA composites can be greatly simplified by using the two-way shape memory effect. That is, the SMA wires will be trained to exhibit the two-way shape memory effect prior to embedding in the matrix.

Void content is one of the pressing issues in manufacturing the SMA hybrid composites. Voids in composite materials significantly affect the material integrity and behavior. Their presence in the SMA composites will not only lead to property degradation of the host composite material, but

the efficiency of activation and the level of interfacial bonding between the SMA fibers and host matrix will also be sacrificed. In the hot press composites with graphite/epoxy laminates and embedded TiNi fibers, the average void content was found to be 10.20%. Voids were shown to be concentrated near the embedded TiNi wire locations. Additionally, the interfacial bonding was quite poor. The void content can be reduced as low as 1.29% by autoclave stage curing.

Another concern is the interfacial bonding. In the SMA hybrid composites, the maximum interfacial adhesion between the SMA wire and the polymer matrix is desired because most applications require maximum load transfers, and a strong interfacial bond also increases the structural integrity of the final composite. To improve the interfacial bonding, various surface treatments of SMA fibers have been examined involving the introduction of a coupling interphase. The pullout test was used to qualitatively compare the interfacial adhesion. Five kinds of TiNi fibers—that is, untreated, nitric acid-etched, handsanded, sand-blasted, and plasma-coated—and two kinds of host matrix materials—that is, graphite/epoxy and PEEK/carbon (APC-2) composites—were examined. The pullout test results indicated that in the TiNi fiber/APC-2 system, a brittle interface failure without friction occurred, resulting in overall lower peak pullout stress levels. In the TiNi fiber/GR/EP system, however, strong mechanical interaction or friction between the TiNi fiber and GR/EP composite occurred. As a result the fiber pull-out stress levels show a dependence on the adhesion between TiNi fibers and host composite, and on the average, the peak pull-out stresses are significantly higher than those in the APC-2 composites. Generally, sand-blasting of TiNi fibers increases the bond strength while handsanding and acid cleaning actually decrease the bond strength. Surprisingly, it was found that plasma coating of the fibers did not significantly alter the adhesion strength. The in-situ displacements of embedded SMA wires were also measured and the resulting stresses were induced in the matrix by using heterodyne interferometry and photoelasticity, respectively. As expected, the constraining effect of the matrix increases with increasing bond strength, causing a decrease in the displacement of SMA wire and a corresponding increase in the interfacial shear stress induced in the matrix.

SMA PARTICULATE / ALUMINUM MATRIX COMPOSITES

Particulate-reinforced metal matrix composites (MMCS) have attracted considerable attention because of their feasibility for mass production, promising mechanical properties, and potential high damping capacity. In applications not requiring extreme loading or thermal conditions, such as automotive components, the discontinuously reinforced MMCs have been shown to offer substantial improvements in mechanical properties. In particular, discontinuously reinforced Al alloy MMCs provide high damping and low density and allow undesirable mechanical vibration and wave propagation to be suppressed. As in the fiber-reinforced

composites, the strengthening of the composites is achieved through the introduction of compressive stresses by the reinforcing phases, due to the mismatch of the thermal expansion coefficient between the matrix and reinforcement. The most frequently used reinforcement materials are SiC, Al₂O₃, and graphite (Gr) particles. Although adding SiC and Al₂O₃ to Al matrix can provide substantial gains in specific stiffness and strength, the resulting changes in damping capacity may be either positive or negative. Graphite particles may produce a remarkable increase in damping capacity, but at the expense of elastic modulus. More recently, Yamada et al. have proposed the concept of strengthening the Al MMCs by the shape-memory effect of dispersed TiNi SMA particles. The strengthening mechanism is similar to that in the SMA fiber reinforced composites: the prestrained SMA particles will try to recover the original shape upon the reverse transformation from martensite to parent (austenite) state by heating and hence will generate compressive stresses in the matrix along the prestrain direction, which in turn enhances the tensile properties of the composite at the austenitic stage. In the light of the well-known transformation toughening concept, some adaptive properties such as self-relaxation of internal stresses can also be approached by incorporating SMA particles in some matrix materials. Since SMAs have a comparatively high loss factor value in the martensite phase state, an improvement in the damping capacity of the SMA particulates-reinforced composites is expected at the martensite stage. Accordingly, SMA particles may be used as stress or vibration wave absorbers in paints, joints, adhesives, polymer composites, and building materials.

Shape-memory particulate-reinforced composites can be fabricated by consolidating aluminum and SMA particulates or prealloyed powders via the powder metallurgical route. SMA particulates may be prepared with conventional processes, such as the atomization method and spray or rapid solidification process which can produce powders with sizes ranging from micrometers to millimeters. However, few reports on the production of SMA particles are recorded in the open literature. Recently, Cui has developed a procedure to prepare Ti–Ni–Cu SMA particulates through hydrogenating-ball milling-dehydrogenating. The ternary TiNiCu alloys, where there is a substitution of Ni by Cu by up to 30 atomic %, are of particular interest for their narrow hysteresis, large transformation plasticity, high shock absorption capacity, and basic shape-memory effect. Owing to their unique properties, the ternary Ti–Ni–Cu alloys have shown some promise as smart materials with actuation, sensing, and adaptive strengthening characteristics. When the content of Cu exceeds 15 at%, the ternary alloys become very brittle and hence more easily broken down into particulates by ball milling. Although it was reported previously that Cu–Zn–Al alloy powders had been prepared from commercial Cu–Zn and Al powders, using the mechanical alloying technique, there was no physical evidence to prove that thermoelastic martensitic transformations occurred in the as-received powders. As a matter of fact, most of the attempts to prepare the TiNi and Cu-based SMA particulates by ball milling were

unsuccessful due to the complex mechanical alloying reactions and contaminations during the process.

In an exploratory attempt, a $\text{Ti}_{50}\text{Ni}_{25}\text{Cu}_{25}$ alloy was prepared in a high-frequency vacuum induction furnace. The ingot was homogenized at 1173 K for 10 h. The bulk specimens were cut from the ingot. Chips with a size of about $0.1 \times 3 \times 30$ mm from the ingot were hydrogenated at 673 K for 5.8 h in a furnace under a hydrogen atmosphere, then the chips were ball milled in a conventional planetary ball mill, the weight ratio of balls to chips being 20 : 1. The vials were filled with ether and the rotational speed of the plate was kept constant during the milling. The milled powders were then dehydrogenated in a vacuum furnace at 1073 K for 10 minutes at a vacuum of 10^{-3} Pa. The X-ray diffraction and transmission electron microscopy (TEM) observations indicated that the as-received Ti–Ni–Cu particulates, similar to the bulk counterpart, possessed a mixture structure of B19 and B19' martensites. Differential scanning calorimetry (DSC) results demonstrated that the particulates exhibit excellent reversible martensitic transformations, though the peak temperatures were slightly altered when compared to the bulk material. The Ti–Ni–Cu/Al composite was prepared from 99.99% Al powders of 2 to 3 μm in size and the Ti–Ni–Cu powders of about 30 μm in size. The volume ratio of the Ti–Ni–Cu powder to Al powder was 3 : 7. The powders were mixed in a mixer rotated at 50 RPM for 10 h. The consolidation of the mixed powders was achieved by hot isostatic pressing (HIP) at 793 K for 10 minutes, the relative density of the compact being 98.5%.

The DSC measurements of the Ti–Ni–Cu/Al composite showed evidence the occurrence of the thermoelastic martensitic transformations, just as demonstrated in the Ti–Ni–Cu bulk and particles. These preliminary results suggest that it is feasible to produce some adaptive characteristics within the composite through the shape-memory alloy particulates.

CERAMIC PARTICULATE / SMA MATRIX COMPOSITES

In a shape-memory alloy matrix, dispersed second-phase particles may precipitate or form during solidification or thermal (mechanical) processing, thereby creating a native composite. The martensitic transformation characteristics and properties of the composites can be modified by control the particles, as demonstrated in Ti–Ni(Nb), CuZn–Al, and Cu–Al–Ni–Mn–Ti alloys. Alternatively, the presence of a ceramic second phase within the SMA matrix may lead to a new composite with decreased density and increased strength, stiffness, hardness, and abrasion resistance. Compared with common ceramic/metal composites, a higher plasticity may be expected for this composite because the stress-induced martensitic transformation may relax the internal stress concentration and hence hinder cracking. Previously, Al_2O_3 particle reinforced CuZnAl composites were prepared with conventional casting method, and this kind of composite was suggested to be suitable for applications requiring both high damping and good wear resistance. Using explosive

pressing of the powder mixture, a TiC/TiNi composite was prepared. In the sintered TiC/TiNi composite it was found that the bend strength, compression strength, and stress intensity factors were significantly higher than those for TiC/Ni and WC/Co composites. With increasing TiC content, the hardness and compressive strength increase, while the ductility and toughness decrease. More recently, Dunand et al. systematically investigated the TiNi matrix composites containing 10 vol% and 20 vol% equiaxed TiC particles, respectively. The composites were prepared from prealloyed TiNi powders with an average size of 70 μm and TiC particles with an average size of about 40 μm , using powder metallurgy technique. The TiC particles modify the internal stress state in the TiNi matrix, and consequently, the transformation behavior of the composite: the B2-R transformation is inhibited; the characteristic temperatures A_s and M_f are lowered, while the M_s temperature remains unchanged; and the enthalpy of the martensitic transformation is reduced. Unlike composites with matrices deforming solely by slip, the alternative deformation mechanisms, namely twinning and stress induced transformation, are expected to be operative in the TiNi composites during both the overall deformation of the matrix and its local deformation near the reinforcement, thereby resulting in the pseudoelasticity and rubberlike effect. Compared to unreinforced TiNi, the range of stress for formation of martensite in the austenitic matrix composite is increased, and the maximum fraction of the martensite is lowered. For both the austenitic and martensitic matrix, a strengthening effect can be observed: the transformation or twinning yield stress is increased in presence of the dispersed TiC particles. However, for the austenitic matrix, the transformation yield stress is higher than predicted by Eshelby's load transfer theory, due to the dislocations created by the relaxation of the mismatch between matrix and particles. In contrast, for the martensitic matrix, the twinning yield stress and the apparent elastic moduli are less than predicted by Eshelby's model because of the twinning relaxation of the elastic mismatch between matrix and reinforcement. Besides the elastic load transfer, the thermal, transformation, and plastic mismatches resulting from the TiC particles are efficiently relaxed mainly by localized matrix twinning, as revealed by neutron diffraction measurements. As a result the shape memory capacity, that is, the extent of strain recovery due to detwinning upon unloading, is scarcely affected by the presence of up to 20 vol% ceramic particles.

MAGNETIC PARTICULATE / SMA MATRIX COMPOSITES

Giant magnetostrictive materials $(\text{Tb}_y\text{Dy}_{1-y})_x\text{Fe}_{1-x}$, (Terfenol–D) provide larger displacements and energy density, and superior manufacturing capabilities, as compared to ferroelectrics. However, their applications have been limited by the poor fracture toughness, eddy current losses at higher frequencies, and bias and prestress requirements. More recently, composite materials based on Terfenol–D powders and insulating binders have been developed in Sweden. These composites broaden the

useful range of the Terfenol-D material, with improved tensile strength and fracture toughness, and potential for greater magnetostriction and coupling factor. Most recently, Ullakko has proposed a design concept to embed Terfenol-D particles within a shape memory alloy matrix to create a ferromagnetic shape memory composite with combination of the characteristics of shape memory alloys and magnetostrictive materials. The Terfenol-D particles will be elongated by about 0.1% when applying a magnetic field. The generated force is high enough to induce the martensitic transformations in the matrix at appropriate temperatures. Therefore, the orientation and growth of the martensite plates may be controlled by the magnetic field, and by the distribution and properties of the Terfenol-D particles embedded in the matrix. The magnetic control of the shape-memory effect through the magnetostrictive inclusions may be used independently, or simultaneously with the thermal control to achieve optimal performance. Experimentally, a Terfenol-D/Cu-Zn-Al composite was prepared using Cu-Zn-Al SMA and Terfenol-D (15 wt%) powders with the shock wave compaction method. However, the magneto(visco)elastic response and thermomechanical properties of the composite have not been reported. It is probable that this kind of composite is not suitable as an active actuator material due to some technical limitations.

As an alternative, the high passive damping capacity of the magnetic powders/SMA matrix composites may be utilized. It is known that Cu-Zn-Al SMAs have high damping capacity at large strain amplitudes due to thermoplastic martensitic transformations, but their stiffness is inadequate for some structural applications. The ferromagnetic alloys, including Terfenol-D, Fe-Cr, Fe-Cr-Al, and Fe-Al, are known to have relatively high strength as well as high damping capacity in the range of small strain amplitudes, and low damping capacity in the range of large strain amplitudes. In principle, the combination of Cu-Zn-Al matrix and ferromagnetic alloy inclusions should yield high damping capacity over a wide range of strain amplitudes, and higher stiffness than that of the monolithic Cu-Zn-Al alloys. Accordingly, three kinds of metal matrix composites were fabricated from prealloyed Cu-26.5 wt% Zn-4.0 wt%Al powders (as a matrix) and rapidly solidified Fe-7 wt%Al, Fe-20 wt%Cr, and Fe-12 wt%Cr-3 wt%Al alloy flakes (30 vol%), respectively, by powder metallurgy processing. The interfaces between the Cu-Zn-Al matrix and the flakes in the consolidated composites were delineated and were free of precipitates or reaction products. In all of the three composites, the damping capacity with the strain in the range from 1.0×10^{-4} to 6.0×10^{-4} was found overall to show substantial improvements. In particular, the Fe-Cr flakes/Cu-Zn-Al composite demonstrated the highest overall damping capacity and exhibited an additional damping peak at strain 165×10^{-6} .

SMA/SI HETEROSTRUCTURES

The development of shape-memory alloy thin films for microelectromechanical systems (MEMS) is one of the most

important engineering applications of shape-memory alloys during the past decade. Owing to the extensive use in IC microfabrication technologies, silicon is particularly preferable as the substrate to fabricate and pattern SMA thin films in batches. TiNi, Ti-Ni-Cu, and other kinds of SMA films have been deposited onto both single-crystal silicon and polysilicon substrates.

From a thermodynamical point of view, TiNi is unstable compared to Si. As a result interface diffusion and chemical interactions may occur, and Ti and Ni silicides may be formed on postdeposition annealing, especially at higher temperatures, of the SMA films. A thin buffer layer of Nb or Au can prevent the interdiffusion. In particular, a buffer layer of SiO₂ has been proven an effective diffusion barrier and an excellent transition layer favoring the interface adherence.

The delamination of the deposited SMA films from Si arising from the evolution of the intrinsic residual stress must be prevented. Wolf and Heuer reported that the adherence of TiNi with bare Si wafer can be improved if it has been cleaned and etched with a buffered oxide etchant (H₂O + NH₄F + HF) prior to deposition. Also modest heating of the substrate under vacuum to around 473 K, prior to deposition, can minimize contamination and improve adherence. Krulevitch et al. also reported that in-situ heated Ti-Ni-Cu SMA films adhere well to bare silicon. The adherence of TiNi film with both bulk SiO₂ and thermal oxide coated Si (SiO₂/Si) were reported to be excellent. A 50 to 300 nm thick layer of TiNi with parent B2 phase, which remains untransformed, was observed adjacent to the interface. The untransformed interlayer, which may be due to the effect of the strong (110) B2 texture, contributes to the interface adherence by accommodating the strain through a gradient or by absorbing the elastic energy. In some cases, electrical isolation of the film is needed. Wolf and Heuer reported that deposition of a 0.1 μm polysilicon layer on SiO₂ prior to deposition of TiNi resulted in a well-bonded interface.

The structure of the composite films should be properly designed to achieve optimal performance. Owing to the mechanical constraints via the interface, the substrate stiffness, determined by the film/substrate thickness ratio, has a significant effect on the transformation characteristics of the SMA layer and on the output energy of the composite's multiple layers. The optimum SMA film thickness for maximum cantilever deflection depends on the relative stiffness of the SMA film and the underlying beam. The behavior of the film depends on the film thickness and approaches bulk behavior as the film becomes a few micrometers thick. However, more compliant actuating films must be slightly thicker for maximum tip deflection. Up to now, some novel microdevices using the SMA/Si diaphragm have been patterned and fabricated, such as microvalves and microactuators, the micro robot arm, and the microgripper.

SMA/PIEZOELECTRIC HETEROSTRUCTURES

An ideal actuation material would display a large stroke, high recovery force and superior dynamical response.

Shape-memory alloys exhibit large strokes and forces but suffer from a slow response. Ferroelectric ceramics are very sensitive to applied stresses through the direct piezoelectric effect and generate powerful forces by means of the converse piezoelectric effect. The ceramics are characterized by excellent dynamical response (on the order of microseconds), but their displacements are quite small (on the order of a few micrometers) due to their small strain magnitude ($<10^{-3}$). There are a large number of ferroelectric ceramics, but the most widely investigated and currently applied for thin film technology are the titanate and niobate (with oxygen octahedral structure) types, such as lead titanate (PbTiO_3), lead zirconate titanate (PZT), lead lanthanum zirconate (PLZT), barium titanate (BaTiO_3), and strontium titanate (SrTiO_3). Ferroelastic SMAs combined with ferroelectric piezoelectric ceramics have yielded hybrid heterostructures that have the optimum characteristics of both materials.

Piezoelectric thin films can be fabricated with various techniques such as sputtering, chemical vapor deposition (CVD), and sol-gel processing. The sol-gel process of piezoceramics has had increasing applications because the chemical composition can be controlled precisely. Of particular concern here is whether the amorphous piezoelectric materials can be synthesized on SMA, and vice versa. Chen et al. first successfully deposited thin films of PZT and PLZT with 0.6 and 1.4 μm thickness, respectively, onto TiNi SMA foils by the sol-gel process and multistep spin-on coating techniques (\cdot). The amorphous films were annealed at temperatures above 773 K to obtain the perovskite phases. The dielectric constant and loss tangent at 100 kHz of the TiNi/PZT composite film were about 700 and 0.03, respectively, comparable to that of the bulk ceramics. The PZT films were found adhere well to the TiNi alloy for strains as large as 0.4%, and their ferroelectric properties remain unchanged during repeated cycling through the shape-memory transformation. However, considerable cracking was observed when the diaphragms subjected to a strain of 0.5%. Jardine et al. and Alam et al. also successfully deposited the thin films of PZT, BaTiO_3 , and SrTiO_3 onto commercially available TiNi SMA bulk and thin films by sol-gel and spin-on techniques or with pulsed laser deposition method, though the quality of the multilayer composites was not that desired.

Both types of the amorphous thin films will be crystallized simultaneously if, deposited on amorphous SMA films. Therefore, the fabrication steps must be minimized so as not to promote degradation of performance due to second phases and chemical interactions via diffusion. The composite's multilayers were annealed at various temperatures ranging from 723 to 973 K and a suitable crystallization temperature was found at about 873 K. Although the heterostructures have good SME and piezoelectric properties, the cracking of the piezoceramic thin film layer remains a critical problem. Generally, a thicker PZT film causes more cracks than a thinner film, whereas a smooth surface roughness and a slow cooling rate after annealing will favor the bond of the PZT film with the TiNi SMA substrate. An effective method to lessen cracking is to deposit a buffer layer of TiO_2 onto TiNi SMA foil and then

deposit the piezoelectric film onto the TiO_2/TiNi substrate. Nevertheless, how to accommodate the stress and dynamical coupling of the dissimilar material layers remains a problem that must be solved before SMA films can be used for actuation applications.

Alternatively, the ferroelastic/ferroelectric heterostructures may be effective for active suppression of high amplitude acoustic waves and shock waves. After coupling TiNi SMA to PZT via a TiO_2 layer, the final composite material was found to sense and actuate to dampen structural vibration without the use of external control. The mechanism of the active damping can be explained by considering an approaching stress wave. The stress wave propagates through the TiNi SMA, producing a stress-induced martensitic transformation where some of the mechanical energy is converted into heat. The wave further produces a voltage across the first ferroelectric layer that can be used to produce an out-of-phase stress wave by the second ferroelastic layer and in turn attenuate the stress wave. A mechanical metallic impedance buffer (e.g., Al, Ti, and TiNi) is used to provide time for the counterstress actuation to occur.

SMA/TERFENOL-D HETEROSTRUCTURES

Magnetostrictive materials with either crystalline or amorphous structure provide higher counterforces and up to 20 times higher strains than piezoelectric ceramics. Of the magnetostrictive materials presently available, the compounds Terfenol-D ($\text{Tb}_x\text{Dy}_{1-x}\text{Fe}_2$) have the largest magnetostriction and magnetization at room temperature, the strain output being up to 0.2% when subjected to up to 2500 oersteds (Oe), and in some cases approaching 1%. The alloys are analogous to electrostrictive materials in that they respond quadratically to an applied field. The optimum performance of Terfenol-D is achieved with the combination of a bias field plus a bias compressive stress. The superior properties of Terfenol-D have attracted increasing attention to the use of this material in both bulk and thin film form, applied for actuation.

Terfenol-D films can also be fabricated with the conventional magnetron sputtering techniques. Su et al., Quandt et al., and other researchers have successfully deposited Terfenol-D films of various thicknesses onto Si/SiO₂ substrates by DC magnetron sputtering. The thin films deposited at room temperature are amorphous and the crystallization temperatures are much high (>903 K). However, it should be reminded that the as-received amorphous Terfenol-D films are excellent ferromagnetic materials. The amorphous films show a sharp increase in the magnetostriction at low magnetic fields and no hysteresis during cycling of the field, whereas the crystalline films exhibit magnetostrictive hysteresis loops and large remanence and coercivity, which limit their application. Since the amorphous Terfenol-D films do not need annealing at elevated temperatures to address undesirable chemical interactions or diffusion, the fabrication of hybrid composite films appears to be easy and simple. For instance, the Terfenol-D films can be grown on crystalline TiNi SMA

bulk or deposited films annealed before the sputtering of the Terfenol-D films. Su et al. proposed the concept of a Terfenol-D/NiTi/Si composite in which the ferroelastic actuation can be triggered by magnetic field. Although the Terfenol-D/SiO₂/Si and TiNi/SiO₂/Si composites have been fabricated and characterized, no further report on

the successful fabrication of Terfenol-D/TiNi hybrid composite films are recorded in the open literature. Surely this is a interesting and exciting subject that needs further investigations, and of course, some technical challenges such as their interface compatibility still remain ahead.

MAGNETS, ORGANIC/POLYMER

JOEL S. MILLER

Columbus, OH

INTRODUCTION

Magnetism has enabled the development and exploitation of fundamental science, ranging from quantum mechanics, to probing condensed matter chemistry and physics, to materials science. The control of magnetism has resulted in the availability of low-cost electricity and the use of electric motors, leading to the development of telecommunications devices (microphones, televisions, telephones, etc.), and to magnetic storage for computers. Magnets, due to their myriad properties, are suitable components in sensors and actuators, and hence they must be considered the key components in smart materials and systems of the future.

Magnetic materials known from time immemorial are comprised of either transition or rare-earth metals, or their ions with spins residing in d- or f-orbitals, respectively, such as Fe, CrO_2 , SmCo_5 , $\text{Co}_{17}\text{Sm}_2$, and $\text{Nd}_2\text{Fe}_{14}\text{B}$. These materials are prepared by high-temperature metallurgical methods, and generally, they are brittle. In the late twentieth century many metal and ceramic materials were replaced with lightweight polymeric materials. The polymeric materials were designated primarily for structural materials, but examples also abound for electrically conducting and optical materials. More recently, new examples of magnetic materials (1) have been reported. Undoubtedly, in this millennium there will be commercialization of these organic and polymeric magnets (2).

Magnetism is a direct consequence of the coupling of unpaired electron spins. Independent, uncoupled electron spins, as shown in Fig. 1(a), lead to paramagnetic behavior. Strong coupling of the aligned spins, Fig. 1(b), can lead to a substantial magnetic moment and a ferromagnet, while that of opposed spins, Fig. 1(c), to an antiferromagnet as the net moments cancel. In contrast, the incomplete cancellation of spins can lead to a net magnetic moment and a ferrimagnet, Fig. 1(d), or a canted antiferromagnet also termed a weak ferromagnet, Fig. 1(e).

Figure 1. Two-dimensional spin alignment for (a) paramagnet, (b) antiferromagnet, (c) ferromagnet, (d) ferrimagnet, and (e) canted antiferromagnet behavior.

Figure 2. Structure of 4-nitrophenyl nitronyl nitroxide, which orders as a ferromagnet at 0.6 K (a), and a dinitroxide that orders as a ferromagnet at 1.48 K (b).

The recently discovered magnets with spins residing in p-orbitals (organic magnets) have added the following properties to those in the repertoire that already can be attributed to magnets: solubility, modulation of the properties via organic chemistry synthetic methods, and low-temperature (nonmetallurgical) processing, enhancing their technological importance and value for the smart materials or systems.

A few organic nitroxides order ferromagnetically below a T_c of 1.5 K. These include a phase of 4-nitrophenyl nitronyl nitroxide reported by M. Kinoshita et al. (1b) with a T_c of 0.6 K, Fig. 2(a), and a phase of dinitroxide reported by A. Rassat et al. (3) with a T_c of 1.48 K, Fig. 2(b). Each of these molecules can crystallize into more than one polymorph, four for the former and two for the latter (4). However, in each case only one of the possible polymorphs magnetically orders as a ferromagnet. These examples of organic magnets, albeit with very low T_c 's, are crystalline solids, and not polymers.

Organic magnets possessing unpaired electron spins in both p- and d-orbitals also have been reported (1a,c). These include ionic decamethylferrocenium tetracyanoethanide, $[\text{FeCp}_2^*][\text{TCNE}]$ ($T_c = 4.8$ K; $\text{Cp}^* = \text{cyclopentadienide}$, $[\text{C}_5(\text{CH}_3)_5]^-$; $\text{TCNE} = \text{tetracyanoethylene}$), Fig. 3, exhibiting the first evidence for magnetic hysteretic behavior in an organic magnet, as reported by J.S. Miller and A.J. Epstein (5,6). $[\text{Fe}^{\text{III}}\text{Cp}_2^*][\text{TCNE}]^-$ has an alternating $\cdots\text{D}^+\text{A}^-\text{D}^+\text{A}^-\cdots$ ($\text{D} = [\text{FeCp}_2^*]^+$; $\text{A} = [\text{TCNE}]^-$) structure in the solid state, Fig. 4. The observed 16,300 emu Oe/mol saturation magnetization, M_s , is in excellent agreement with the calculated value of 16,700 emu Oe/mol for single crystals aligned parallel to the chain axis. Hysteresis loops with a coercive field of 1 kOe are observed at 2 K (Fig. 5) (1a,5,6).

D and A each have a single spin ($S = \frac{1}{2}$). Above 16 K the magnetic susceptibility behaves as expected for a 1-D ferromagnetically coupled Heisenberg chain with $J/k_B = 27$ K (6). Below that temperature, the susceptibility

Figure 3. Molecular structures of FeCp_2^* (a), TCNE (b), and TCNQ (c).

Figure 4. Crystal structure of $[\text{FeCp}_2^*][\text{TCNE}]$ showing the orbitals possessing the largest density of unpaired electrons.

diverges as $(T - T_c)^{-\gamma}$ as anticipated for a 1-D Heisenberg-like system approaching a 3-D magnetically ordered state. Spontaneous magnetization below the 4.8 K ordering temperature follows $(T_c - T)^\beta$ with $\beta \sim 0.5$. Hysteresis loops are well defined with coercive field $H_{cr} = 1$ kG at 2 K (Fig. 5) indicating substantial pinning of the domain walls.

Replacement of Fe by Cr (7) and Mn (8) as well as substitution of TCNE with TCNQ (9–11). [7,7,8,8-tetracyano-*p*-quinodimethane, Fig. 3(c)], leads to ferromagnets with T_c reduced for TCNQ substitution and enhanced when Mn is utilized, Table 1 and Fig. 6. Partial substitution of spinless ($S = 0$) $[\text{CoCp}_2^*]^+$ for ($S = 1/2$) $[\text{FeCp}_2^*]^+$ in $[\text{FeCp}_2^*][\text{TCNE}]^-$ leads to a rapid reduction of T_c as a function of the fraction of spinless sites ($1 - x$) occurs, such as 2.5% substitution of $[\text{FeCp}_2^*]^+$ sites by $[\text{CoCp}_2^*]^+$ decreases T_c by 43% (12).

D. Gatteschi, P. Rey and co-workers (1c) demonstrated and more recently H. Iwamura and co-workers (13) have shown that covalent polymers comprised of bis (hexfluoroacetylacetonate) manganese(II) (Fig. 7) and nitroxides bound to the Mn(II) sites order as ferrimagnets. Using more complex nitroxides Iwamura and co-workers have prepared related systems with T_c 's ~ 46 K. Using TCNE electron-transfer salts of Mn^{II}-(porphyrin)'s, such as $[\text{MnTPP}][\text{TCNE}]$ (TPP = *meso*-tetraphenylporphinato),

Figure 5. 2 K hysteresis loops with a coercive field, H_{cr} , of 1 kOe for $[\text{FeCp}_2^*][\text{TCNE}]$.

Fig. 8, (14) magnets ($T_c = 13$ K) (15) based on metallo-macrocycles also can be prepared. Both the $[\text{TCNE}]^-$ and the nitroxide each have one spin; however, the Mn(II) in the former 1-D polymeric chain has five spins ($S = 5/2$), while the Mn(III) in the latter polymeric chain has four spins ($S = 2$). In both cases, the Mn and organic spins couple antiferromagnetically, leading to ferrimagnetic ordering. The solid state motif is distinctly different than that for $[\text{MnCp}_2^*][\text{TCNE}]^-$ (Fig. 4) as $[\text{TCNE}]^-$ does not coordinate to the M in the latter system. Thus, the bonding of $[\text{TCNE}]^{\bullet-}$ to Mn is a model for the bonding of $[\text{TCNE}]^{\bullet-}$ to V in the $\text{V}[\text{TCNE}]_x(\text{solvent})$ room temperature magnet (16).

As a consequence of the alternating $S = 2$ and $S = \frac{1}{2}$ chain structure, the $[\text{MnTPP}]^+[\text{TCNE}]^-$ 1-D chain system, which forms a large family of magnets, is an excellent model system for studying a number of unusual magnetic phenomena. This includes the magnetic behavior of mixed quantum/classical spin systems (17a), the effects of disorder (17b), and the role of classical dipolar interaction (in contrast to quantum mechanical exchange) in achieving magnetic ordering (17c). Because of the single ion anisotropy for $[\text{MnTPP}]^+$ and the large difference in orbital overlaps along and between chains,

this class of materials often undergoes lattice- and spin-dimensionality crossovers as a function of temperature (17d). Metamagnetic-like behavior is noted for many members of this family at low temperature with unusually high critical fields, H_c , and unusually high coercive fields, H_{cr} , as large as ~ 2.7 T (17e). These metamagnetic-like materials are atypical as they exhibit hysteresis with very large coercive fields, H_{cr} , also as high as ~ 2.7 T, and may have substantial remanent magnetizations (Fig. 9).

V(TCNE)_xY(SOLVENT) ROOM TEMPERATURE MAGNETS

Reaction of V(C₆H₆)₂ and TCNE in a variety of solvents, such as dichloromethane and tetrahydrofuran, leads to loss of the benzene ligands and immediate formation of V(TCNE)_xyCH₂Cl₂ ($x \sim 2$; $y \sim \frac{1}{2}$). Because of its extreme air and water sensitivities as well as insolubility, compositional inhomogeneities within and between preparations occur. The structure remains elusive. This material, however, is the first ambient temperature organic- or polymer-based magnet ($T_c \sim 400$ K) (16). The proposed structure has each V being octahedrally coordinated with up to 6 ligands (N's from different TCNE's), and each TCNE is reduced and is either planar or twisted and bound to up to four V's.

Figure 9. Metamagnetic and hysteresis with 27,000 Oe critical, H_c , and coercive, H_{cr} , fields at 2 K.

Magnets made in dichloromethane have a three-dimensional magnetic ordering temperature, T_c , of ~ 400 K, which exceeds its ~ 350 K decomposition temperature, and hence can be attracted to a SmCo₅ magnet at room temperature. Recently, solvent-free thin magnetic films on a variety of substrates, such as silicon, salt, glass, and aluminum, have been prepared, Fig. 10 (18).

The inhomogeneity in the structure is expected to lead to variations in the magnitude, not sign, of the exchange between the V^{II} ($S = \frac{3}{2}$) and [TCNE]⁻ ($S = \frac{1}{2}$), and the disorder should result in a small anisotropy (16).

V(TCNE)_x prepared in CH₃CN has larger disorder and a lower $T_c \sim 135$ K, which enables the quantitative study of

Figure 10. Photograph of ca. 5 μ m coating of the V[TCNE]_x magnet on a glass cover slide being attracted to a Co₅Sm magnet at room temperature in the air (18).

Figure 11. Idealized structure of $\text{Fe}_4^{\text{III}}[\text{Fe}^{\text{II}}(\text{CN})_6]_3 \cdot x\text{H}_2\text{O}$, Prussian blue with $\cdots\text{Fe}^{\text{III}}-\text{N}\equiv\text{C}-\text{Fe}^{\text{II}}-\text{C}\equiv\text{N}-\text{Fe}^{\text{III}}\cdots$ linkages along each of the three unit cell axes.

its critical behavior. Near T_c , a modified equation-of-state approach can be used to obtain the approximate critical exponents for this disordered magnet. A critical isotherm can be determined by plotting $M(H)$ against H at varying temperatures, with M proportional to $H^{1/\delta}$ at T_c . Using this analysis, we determine that $\delta = 4$ and $T_c = 135$ K for the typical $\text{V}(\text{TCNE})_x \cdot y \text{CH}_3\text{CN}$ sample being studied. With T_c and δ determined, exponents β_α and γ_α (for the random anisotropy model) can be determined directly by analyzing isothermal plots of $(H/M)^{1/\gamma_\alpha}$ versus M^{1/β_α} . Given β_α and δ , all of the $M(H, T)$ data in the vicinity of T_c can be collapsed onto a single set of curves for plots of $\ln(M/|t|^{\beta_\alpha})$ versus $\ln(H/|t|^{\beta_\delta})$, where $t = |T - T_c|$; one curve corresponds to $T > T_c$ and the other curve corresponds to $T < T_c$ (19a). Similar results can be obtained for $\text{V}(\text{TCNE})_x \cdot y \text{C}_4\text{H}_8\text{O}$ with $T_c = 205$ K and some different critical exponents (19b). Evident in the analysis of high-temperature magnetization of $\text{V}(\text{TCNE})_x \cdot y \text{CH}_2\text{Cl}_2$ is the important role of random magnet anisotropy (19c).

$\text{M}(\text{TCNE})_2 \cdot x(\text{CH}_2\text{Cl}_2)$ (M = Mn, Fe, Co, Ni) HIGH ROOM TEMPERATURE MAGNETS

New members of the family of high- T_c organic-based magnets $\text{M}(\text{TCNE})_2 \cdot x(\text{CH}_2\text{Cl}_2)$, (M = Mn, Fe, Co, Ni; TCNE = tetracyanoethylene) have been prepared (20). X-ray diffraction studies on powder samples show that these materials are partially crystalline and isomorphous. These materials have T_c 's of 97, 75, 44, and 44 K, respectively. Field-cooled and zero-field-cooled magnetization studies suggest that while the Mn (21) system is a reentrant spin glass, the Fe (22) system is a random anisotropy system. Both systems exhibit complex behavior below T_c . For example, hysteresis curves for the Fe compound, taken at 5 K, are constricted, with a spin-flop shape, indicating

Figure 12. Temperature-dependent magnetization of the amorphous film of $\text{Cr}^{\text{III}}[\text{Cr}^{\text{III}}(\text{CN})_6]_{0.98}[\text{Cr}^{\text{II}}(\text{CN})_6]_{0.02}$, zero field cooled (+) and field cooled in 5 Oe (\circ), -5 Oe (\bullet), 10 Oe (\square), and -10 Oe (\blacksquare) after 2 minutes of oxidation at -0.2 V upon warming in a 5 Oe field (25).

ferrimagnetic behavior, and field- and zero-field-cooled magnetization studies reveal magnetic irreversibilities below T_c for both compounds. Static and dynamic scaling analyses of the dc magnetization and ac susceptibility data for the Mn compound show that this system undergoes a transition to a 3-D ferrimagnetic state at T_c , followed by a reentrant transition, to a spin glass state at $T_g = 2.5$ K. For M = Fe, the results of static scaling analyses are consistent with a high- T transition to a correlated sperimagnet, while below about 20 K, there is a crossover to sperimagnetic behavior.

HEXACYANOMETALLATE MAGNETS

Although rigorously not organic magnets, several materials termed molecule-based magnets are prepared by the same organic chemistry methodologies and have been

Figure 13. Sample of a $\text{V}[\text{Cr}(\text{CN})_6]_y \cdot z\text{H}_2\text{O}$ magnet ($T_c = 372$ K) attracted to a Teflon coated magnet at room temperature in the air (27a).

Table 2. Summary of the Critical Temperatures, T_c , and Coercive Fields, H_{cr} , for Representative Organic-Based Magnets

Magnet	M_s , (emuOe/mol)	T_c (K)	H_{cr} (Oe)	Reference
α -1,3,5,7-Tetramethyl-2,6-diazaadamantane- N,N' -dioxyl (Fig. 2b)	11,000	1.48	<0.1	(3)
β -2-(4'-Nitrophenyl)-4,4,5,5-tetramethyl- 4,5-dihydro-1H-imidazol-1-oxyl-3- N -oxide (Fig. 2a)	5600	0.6	8	(1b)
$[\text{Fe}^{\text{III}}\text{Cp}_2^*][\text{TCNE}]$ (Figs. 3a, b; 4)	16,300	4.8	1000	(1a,5,6)
$\text{Mn}^{\text{II}}(\text{hfac})_2\text{NITEt}$ (Fig. 7)	20,000	7.8	320	(1c)
$[\text{MnTPP}][\text{TCNE}]\cdot 2\text{C}_6\text{H}_5\text{CH}_3$ (Fig. 8)	17,000	13	24,000	(15,17)
$\text{V}[\text{TCNE}]_x\cdot y\text{CH}_2\text{Cl}_2$ ($x \sim 2; y \sim 0.5$)	10,000	~ 400	15	(16b)

Figure 14. Folded soft iron rods (staples) are shown attracted to a SmCo_5 permanent magnet (*left*). The soft iron rods hang freely when a pellet of $\text{V}(\text{TCNE})_x\cdot y(\text{CH}_2\text{Cl}_2)$ at room temperature shields the magnetic field.

reported to magnetically order in many cases. Prussian blue, $\text{Fe}^{\text{III}}[\text{Fe}^{\text{II}}(\text{CN})_6]_3\cdot x\text{H}_2\text{O}$, possesses a 3-D network structure, with $\dots \text{Fe}^{\text{III}}-\text{N}\equiv\text{C}-\text{Fe}^{\text{II}}-\text{C}\equiv\text{N}-\text{Fe}^{\text{III}}\dots$ linkages along each of the three unit cell axes, Fig. 11. It is a prototype structure that stabilizes both the ferro- and ferrimagnetic orders. Replacement of iron with other spin-bearing metal-ions leads to strong magnetic coupling and magnetic ordering with high T_c 's. Examples include ferromagnetic $\text{CsNi}^{\text{II}}[\text{Cr}^{\text{III}}(\text{CN})_6]\cdot 2\text{H}_2\text{O}$ ($T_c = 90$ K) (23) and ferrimagnetic $\text{CsMn}^{\text{II}}[\text{Cr}^{\text{III}}(\text{CN})_6]\cdot \text{H}_2\text{O}$ ($T_c = 90$ K) (24) as well as thin films ($\leq 2\mu\text{m}$), both oxidized and reduced, of $\text{Cr}^{\text{III}}[\text{Cr}^{\text{III}}(\text{CN})_6]_{0.93}[\text{Cr}^{\text{II}}(\text{CN})_6]_{0.05}$ ($T_c = 260$ K) (25) that exhibit negative magnetization, Fig. 12. Verdager and co-workers (48) report that ferrimagnetic $\text{V}_{0.42}^{\text{II}}\text{V}_{0.58}^{\text{III}}[\text{Cr}^{\text{III}}(\text{CN})_6]_{0.86}\cdot 2.8\text{H}_2\text{O}$ magnetically ordered above room temperature ($T_c = 315$ K). Further studies of this class of materials (26) have led to an enhancement of the T_c to about 100°C (373 K), Fig. 13 (27).

USES OF ORGANIC/POLYMERIC MAGNETS

The magnetic (Table 2) as well as chemical/physical properties of organic/polymer magnets, especially in conjunction with other physical properties, may well lead to their use in smart materials in the future (2). Applications include the next generation of electronic, magnetic, and/or photonic devices ranging from magnetic imaging to data storage and to static and low-frequency magnetic shielding and magnetic induction. Particularly promising is the applications, in static and low-frequency magnetic shielding and magnetic induction (2b), as relatively high initial permeabilities have been reported for the $\text{V}(\text{TCNE})_x\cdot y(\text{solvent})$ materials. Combined with their low density (~ 1 g/cm³),

relatively low resistivity ($\sim 10^4$ ohm-cm), and low power loss (as low as ~ 2 erg/(cm³ cycle), these properties suggest that magnetic shielding will have future practical applications especially for devices requiring low weight. The feasibility of using $\text{V}(\text{TCNE})_x\cdot y(\text{CH}_2\text{Cl}_2)$ in magnetic shielding applications is demonstrated in Fig. 14. Other potential applications include photoinduced magnetism based on recent studies of Prussian blue-like materials (28,29). Studies of the effects of light on the zero-field cooled and field-cooled behavior show the importance of disorder and defects in stabilizing the photoinduced magnetic phenomena (29).

ACKNOWLEDGMENT

The authors gratefully acknowledge the extensive contributions of their collaborators, students, and post-doctoral associates in the studies discussed herein. The authors also gratefully acknowledge the continued partial support by the Department of Energy Division of Materials Science (Grant Nos. DE-FG02-86ER45271.A000, DE-FG03-93ER45504, and DEFG0296ER12198) as well as the National Science Foundation (Grant No. CHE9320478).

MAGNETORHEOLOGICAL FLUIDS

ALISA J. MILLAR HENRIE

Brigham Young University
Provo, UT

J. DAVID CARLSON

Lord Corporation
Cary, NC

INTRODUCTION

Magnetorheological (MR) materials are a class of materials whose rheological properties may be rapidly varied by applying a magnetic field. This change is in proportion to the magnitude of the magnetic field applied and is immediately reversible. MR material behavior is often modeled by the Bingham plastic model. Advances in the application of MR materials are parallel to the development of advanced MR materials. These applications include brakes, dampers, and shock absorbers.

DEFINITION

Magnetorheological materials are a class of material whose rheological properties may be rapidly varied by applying a magnetic field. Most commonly, these materials are fluids that consist of micron-sized, magnetically polarizable ferrous particles suspended in a carrier liquid. When exposed to a magnetic field, the suspended particles polarize and interact to form a structure aligned with the magnetic field that resists shear deformation or flow. This change in the material appears as a dramatic increase in apparent viscosity, or the fluid develops the characteristics of a semisolid state. The magnitude of this change is controlled

by the strength of the magnetic field and is immediately reversed upon removing the magnetic field. In addition to fluids, magnetorheological materials also include magnetic field responsive gels, foams, powders, greases, and elastomers.

HISTORY

Jacob Rabinow made advances in early magnetorheological research while at the National Bureau of Standards in the 1940s and early 1950s (1,2). Rabinow's early work on MR fluids eventually led to a host of devices and products based on dry magnetic powders, for example, the magnetic, powder brake. Interest in MR fluids languished until the early 1990s when advancements in MR material composition and the advent of readily available digital control electronics fostered renewed interest. Magnetorheological materials share much in common with their counterpart, electrorheological (ER) materials. These are materials that change their behavior in an electric field. This phenomenon was first documented by Duff in the 1800s, (3), but its potential was not realized until Willis Winslow began working with electrorheological fluids in 1938 (4). Winslow also contributed to early research on MR materials and combined electromagnetorheological materials.

Research in magnetorheology has gone forward in three main areas; developing advanced materials, characterizing the mechanism that causes the MR effect, and applications of MR materials. Advancement in these areas is necessary for the development of mechanical systems that will optimize MR materials. Descriptions of MR compositions, basic models of the MR phenomenon, characteristics of common MR materials, and popular MR applications follow.

COMMON NOMENCLATURE

Some terms commonly used with magnetorheological materials include

Rheology—the study of the deformation and flow of matter

H = Magnetic field strength (a/m) (1 a/m = $4\pi \times 10^{-3}$ oersted)

B = Magnetic flux density (tesla) (1 tesla = 10^4 gauss)

$\dot{\gamma}$ = Shear rate (s^{-1})

τ = Shear stress (Pa)

τ_y = Yield stress (Pa)

η_a = Apparent viscosity (Pa · s) = $\tau / \dot{\gamma}$

η_p = Plastic viscosity (Pa · s) = $d\tau / d\dot{\gamma}$

MATERIAL CHOICE

Common Materials

Magnetorheological materials usually consist of micron-sized (3–8 μm) magnetizable particles suspended in a

liquid. A typical MR fluid consists of 20–40% by volume of relatively pure iron particles suspended in a carrier liquid such as mineral oil, synthetic oil, water, or glycol. A variety of proprietary additives similar to those found in commercial lubricants are used to discourage gravitational settling and promote particle suspension, enhance lubricity, change initial viscosity, and inhibit wear.

Some materials exhibit both MR and ER behavior and react in both magnetic and electric fields. In fact, almost all MR fluids exhibit some ER response due to moisture and mobile ions in the native oxide surface layer on virtually all ferrous particles. For more information on commercially manufactured MR fluids, see (5).

BASIC COMPOSITION

A simple MR fluid may be constructed by mixing fine iron powder (3–8 μm) into mineral oil at approximately one part filings to three parts oil by volume. Stir the mixture with a plastic or wooden implement until a consistent mixture is obtained. Place the mixture in a plastic or glass container (a 50–100 ml beaker works well). A horseshoe magnet or two bar magnets can be used to observe the MR effect. Stir the mixture to observe its viscosity and the way it feels. Now, place the container between the two poles of the magnet, and stir it again. The mixture should feel stiff. If you look closely, you can see the particle structure form between the two poles of the magnet (6).

THEORY

Currently, there is no universally accepted theory for the causes of the MR effect. However, it is generally agreed that the change in properties is due to the realignment of particles in the fluid to form fibrils, or long strands of suspended particles, that resist shear (Fig. 1). It is believed that the observed alignment of particles is related to the displacements and torque produced in the medium by the field and the translational motion and relocation of particles to positions that have local minimum potential energy. This results in an increase in viscosity and an increase in the shear strength of the material. A Bingham plastic model is often considered sufficient to model MR devices:

$$\tau_{\text{total}} = \tau_y(H) + \eta_p \dot{\gamma}, \quad (1)$$

where τ_{total} is the total shear stress of the material, τ_y is the yield stress as a function of the magnetic field, H is the magnetic field strength, η_p is the plastic viscosity or post yield viscosity, and $\dot{\gamma}$ is the shear strain rate in the fluid. Apparent viscosity η_a is defined as the total shear stress divided by the shear rate:

$$\eta_a = \frac{\tau_{\text{total}}}{\dot{\gamma}}. \quad (2)$$

Figure 1. Suspended magnetizable particles align in a magnetic field. The MR fluid will then resist a certain amount of shear before the chains begin to break. This yield point increases as magnetic field strength increases until the magnetic saturation point is reached. This results in the solid feel of MR materials.

Figure 2. Bingham plastic behavior. Graph (a) shows that the apparent viscosity η is very large until a certain shear rate, dv_x/d_y , is obtained. This shows that the fluid acts as a solid and does not flow until a certain threshold stress, the yield stress, is exceeded. Graph (b) shows that yield stress τ is a function of shear rate and that Bingham plastics experience shear thinning. The yield stress of the material τ_y is the y intercept of the linear regression curve fit of shear stress vs. shear rate. Yield stress τ_y increases as magnetic field increases.

The apparent viscosity of a Bingham plastic material increases dramatically at a low shear rate. At a very high shear rate, the magnitude of the apparent viscosity approaches that of the plastic viscosity, as shown in Fig. 2. Although plastic viscosity is sometimes observed to be a weak function of magnetic field strength, it is often assumed that it is constant for constant magnetic field strength (typically 0.10 to 0.70 Pa · s) (7).

The Bingham plastic model indicates that the material property that changes as magnetic field strength increases is the yield stress τ_y , where flow of the material is initiated. Ideally, below a certain threshold of stress, a Bingham plastic does not flow at all. Beyond this threshold, the flow rate increases in proportion to the applied stress minus the threshold stress (Fig. 2a). Plastic viscosity η_p is the slope of a linear regression curve fit to a measured stress versus shear strain data set, and the yield stress τ_y of an MR fluid is the y intercept of that same linear regression curve (Fig. 2b).

MR PROPERTIES

Magnetorheological materials are useful because the change in their material properties is so large (Fig. 3). Typical magnetorheological materials can achieve yield

Figure 3. One example of a change in the effective modulus of elasticity (E_{MR} vs. magnetic field strength (H_0)) for a specific MR material.

strengths up to 50–100 kPa at magnetic field strengths of about 150–250 kA/m. For low strains prior to yield, the shear modulus of a MR fluid also shows a very large increase in an applied magnetic field. MR materials eventually reach a saturation point where increases of magnetic field strength do not increase the yield strength of the MR material. This typically occurs around 300 kA/m. MR materials have been developed that are stable in temperature ranges from -40 to 150°C . There are slight changes in the volume fraction and hence slight reductions in the yield strength at these temperatures, but they are small. The MR effect is immediately reversible if the magnetic field is reduced or removed. Response times of 6.5 ms have been recorded (8).

Magnetorheological materials exhibit some advantages over typical ER materials. Unlike ER materials, they are not sensitive to impurities, and thus MR materials are candidates for use in dirty or contaminated environments. They are also unaffected by the surface chemistry of surfactants as ER materials are. The power (1–2 amps or 50 watts) and voltage (12–24V) requirements for MR material activation are relatively small compared with ER materials (8).

Other MR properties that have also been explored include the following. Ginder and Davis (7) investigated the effect of magnetic saturation on the strength of MR

materials by using finite element analysis. It was found that wall roughness on contact with the fluid is important for yield strengths, especially in low magnetic fields (9,10). Size and size distribution of the suspended particles also affect the change in properties of the MR fluid when placed in a magnetic field (11,12). The combined effect of magnetic and electric fields on magnetoelectrorheological materials has also been explored (13). Tang and Conrad conducted a series of systematic experiments to characterize the rheology of MR fluids from technological and scientific viewpoints (14).

APPLICATIONS

Because the state of MR materials can be controlled by the strength of an applied magnetic field, it is useful in applications where variable performance is desired. Many smart systems and structures would benefit from the change in viscosity or other material properties of MR materials. Beginning with the commercialization of MR fluid rotary brakes for use in aerobic exercise equipment in 1995, application of magnetorheological material technology in real-world systems has grown steadily. The past few years have witnessed a blossoming commercialization of MR fluid technology. MR fluid technology has been embraced by a number of manufacturers for inclusion in a diverse spectrum of products that are now commercially available (15):

- linear MR dampers for real-time active vibrational control systems in heavy duty trucks
- linear and rotary brakes for low-cost, accurate, positional and velocity control of pneumatic actuator systems
- rotary brakes to provide tactile force-feedback in steer-by-wire systems
- linear dampers for real-time gait control in advanced prosthetic devices
- adjustable shock absorbers for NASCAR oval and dirt track racing

Other applications that are near commercialization include

- low-cost MR sponge dampers for washing machines (16,17)
- very large MR fluid dampers for seismic damage mitigation in civil engineering structures (17)
- large MR fluid dampers to control wind-induced vibrations in cable-stayed bridges (18)
- real-time controlled shock absorbers and struts for domestic automobiles

MR materials are also being considered for use in compliant mechanism design to change the compliance of flexible members. This behavior can be modified as a function of time resulting in a variably compliant mechanism (19). More applications are being considered and it is likely that,

as MR materials continue to improve, many more applications will be forthcoming.

MAGNETOSTRICTIVE MATERIALS

MARCELO J. DAPINO
Ohio State University
Columbus, OH

INTRODUCTION

Magnetostrictive materials are a class of smart materials that can convert energy between the magnetic and elastic states. For this reason, magnetostrictive materials and devices based on these materials are often referred to as *transducers*. Due to the bidirectional nature of this energy exchange, magnetostrictive materials can be employed for both actuation and sensing. Alloys based on the transition metals iron, nickel, and cobalt in combination with certain rare-earth elements are currently employed in actuator and sensor systems in a broad range of industrial,

biomedical, and defense applications. Because magnetostriction is an inherent property of ferromagnetic materials, it does not degrade over time as do some poled piezoelectric substances. In addition, newer magnetostrictive materials provide strains, forces, energy densities, and coupling coefficients that compete favorably with more established technologies such as those based on piezoelectricity. As evidenced by the ever-increasing number of patented magnetostrictive systems, transducer designers are finding new opportunities to employ magnetostrictive materials in a wide variety of applications ranging from stand-alone transducers to complex smart structure systems.

A number of design and modeling issues, however, complicate the implementation of magnetostrictive materials in certain applications in which other smart material technologies are currently favored. For instance, due to the required solenoid and related magnetic circuit components, magnetostrictive transducers are usually larger and bulkier than their piezoelectric or electrostrictive counterparts. Hence, they are employed primarily in applications that require high strains and forces but where weight is not an issue. One additional consideration is that the most technologically advanced magnetostrictive materials are costly to manufacture. Advanced crystalline materials are manufactured by employing sophisticated crystal growth techniques that produce directional solidification along the drive axis of the transducer material. The manufacturing process also includes precision machining of laminations, final diameters, and parallel ends of cut-to-length drivers, as well as thorough quality assurance and performance evaluation throughout the process. These technological and cost-related problems have been mitigated to some extent through the advent of new manufacturing techniques that have enabled more capable magnetostrictive materials in various forms, including amorphous or crystalline thin films, magnetostrictive particle-aligned polymer matrix composite structures, and sintered powder compacts suitable for mass production of small irregular shapes. From the perspective of modeling and control, magnetostrictive materials exhibit nonlinear effects and hysteretic phenomena to a degree which other smart materials, for instance electrostrictive compounds, do not. These effects are particularly exacerbated at the moderate to high drive level regimes in which magnetostrictive materials are most attractive. These issues have been addressed through recent modeling techniques, and as new applications are developed, model accuracy and completeness will almost surely follow.

The term magnetostriction is a synonym for magnetically induced strain, and it refers to the change in physical dimensions exhibited by most magnetic materials when their magnetization changes. Magnetization, defined as the volume density of atomic magnetic moments, changes as a result of the reorientation of magnetic moments in a material. This reorientation can be brought about by applying either magnetic fields, heat or stresses. The linear magnetostriction $\Delta L/L$ that results from applying a longitudinal magnetic field on a sample of length L , illustrated in Fig. 1, is the most commonly employed attribute of the magnetostrictive principle in actuator applications.

Though most ferromagnetic materials exhibit linear magnetostriction, only a small number of compounds that contain rare-earth elements provide "giant" magnetostrictions in excess of 1000×10^{-6} . These large magnetostrictions are a direct consequence of the strong magnetomechanical coupling that arises from the dependence of magnetic moment orientation on interatomic spacing. When a magnetic field is applied to a magnetostrictive material, the magnetic moments rotate to the direction of the field and produce deformations in the crystal lattice and strains in the bulk material. Referring again to Fig. 1 which pertains to a material that has positive magnetostriction, note

Figure 1. Joule magnetostriction produced by a magnetic field H . (a) H is approximately proportional to the current i that passes through the solenoid when a voltage is applied to it. (b) The rotation of magnetic dipoles changes the length of the sample, and (c) curve $\Delta L/L$ vs. H obtained by varying the field sinusoidally.

that the sample elongates irrespective of the direction of rotation of the magnetic moments. A symmetrical magnetostriction curve is obtained when the field is cycled, as depicted in Fig. 1b,c. If stress is applied instead, the material deformations lead to magnetic moment reorientation and a subsequent change in the magnetization M . This magnetization change can be detected through the voltage induced in a sensing solenoid wrapped around the sample, which provides a mechanism for sensing. In applications, either one sensing solenoid or a plurality of them arranged along the length of the driver can be placed inside of the driving coil. Alternatively, it is possible to employ only one solenoid to drive the magnetostrictive material and sense its magnetization changes. This configuration exhibits the major disadvantage that additional signal processing hardware is required to extract the sensing voltage from the driving signal.

This article provides an overview of magnetostrictive materials in the next section, followed by a description of the physical origin of magnetostriction and a discussion of material behavior. The subsequent section is devoted to linear magnetostriction, and other magnetostrictive effects are discussed in the following section. Finally, a discussion of current transducer designs and modeling techniques is presented.

MATERIALS OVERVIEW

The study of magnetostriction began in 1842 when James P. Joule first observed that a sample of iron changes in length when magnetized by a magnetic field. Subsequent work using other materials such as nickel, cobalt, and their alloys led to numerous applications, including telephone receivers, hydrophones, scanning sonar, fog horns, oscillators, and torque sensors. During World War II, sonar transducer were driven primarily by nickel, which exhibits saturation magnetostrictions of about 50×10^{-6} . A breakthrough in magnetostrictive materials occurred in 1963 when the largest-known magnetostrictions in the rare-earth elements terbium and dysprosium were discovered. The strains in these elements are of the order of $10,000 \times 10^{-6}$, or three orders of magnitude larger than those of nickel, but they are achieved exclusively at cryogenic temperatures. The temperature limitation and the fact that the field of piezoelectricity was gaining technical maturity hindered the development of magnetostrictive materials and led, in the early 1970s, to a search for a new class of transducer materials capable of high room temperature strains. Highly magnetostrictive rare earths (R), principally samarium (Sm), terbium (Tb), and dysprosium (Dy), were combined with the magnetic transition metals nickel, cobalt, and iron by direct compound synthesis and by rapid sputtering into amorphous alloys. In contrast to the normal Curie temperature behavior of the R-Ni and R-Co compounds, R-Fe compounds exhibit an *increase* in the Curie temperature as rare-earth concentration increases. Consequently, huge room temperature magnetostrictions up to $3,000 \times 10^{-6}$ were achieved, particularly in the TbFe₂ compound. However, because the

magnetostriction originates in the strain dependence of magnetic anisotropy, the large magnetostriction in these compounds is obtained at the expense of large anisotropies. This poses a technological limitation since impractically large fields of more than 2 MA/m are needed to bring these compounds to technical saturation.

Partial substitution of dysprosium for terbium in the TbFe₂ system resulted in improved magnetostriction and anisotropy properties. The resulting pseudobinary compound Tb_{0.3}Dy_{0.7}Fe_{1.9-1.95} has been available commercially since the 1980s under the name Terfenol-D (Ter = terbium, Fe = iron, N = Naval, O = Ordnance, L = Laboratory, D = dysprosium). The highest room temperature magnetostriction for Terfenol-D is $1,600 \times 10^{-6}$ at a moderate saturation field of 0.16 MA/m, but even larger magnetostrictions up to $3,600 \times 10^{-6}$ are possible when the material is employed in transducers driven at resonance. The utility of Terfenol-D as a rugged, high-power transducer driver has been increasingly recognized in recent years. At present, Terfenol-D is used in active noise and vibration control systems; low-frequency underwater communications (sonar); linear and rotational motors; ultrasonic cleaning; machining and welding; micropositioning; and detecting motion, force, and magnetic fields. Terfenol-D is currently available in a variety of forms, including monolithic rods (1,2), particle-aligned polymer matrix composites (3-5), and thin films (6,7). Because of the large magnetostrictive anisotropy and strong magnetoelasticity, Terfenol-D and other pseudobinary rare-earth-iron compounds can be synthesized to exhibit a broad range of properties (8).

A second new magnetostrictive material based on amorphous metal was introduced in 1978, produced by rapid cooling of iron, nickel, and cobalt alloys together with one or more of the elements silicon, boron, and phosphorus. These alloys are known commercially as Metglas (metallic glass) and are commonly produced in thin-ribbon geometries. Because of the extremely high coupling coefficients ($k > 0.92$), Metglas is a prime candidate for sensing applications in which a mechanical motion is converted into an electrical current or voltage (2).

The latest materials science research on magnetostrictive materials includes the development of new compounds to minimize magnetic anisotropy and hysteresis and new manufacturing techniques to produce Terfenol-D thin films efficiently (9). Substantial advances have been achieved in the quaternary compounds Terfenol-DH, which are produced by substituting holmium for terbium and dysprosium (10). In addition, new manufacturing techniques are enabling the production of multilayered driver rods which will lead to reduced dynamic losses, thus facilitating operation over a broad frequency spectrum into the megahertz range. Ferromagnetic shape-memory alloys are another class of smart materials which hold much promise due to the large strains that they can provide. The nickel-titanium alloy commercially known as Nitinol features large recoverable strains of the order of $60,000 \times 10^{-6}$, but it suffers from inferior dynamic response. The possibility of combining the desirable aspects of shape memory with magnetostriction through actuating an SMA in a magnetic

Figure 2. In highly magnetostrictive materials, the spin moment m_{spin} and orbital moment m_{orbit} are strongly coupled. When the spin moment rotates to align with the external field H , the orbital moment rotates along with it and produces considerable lattice deformation.

field is currently being investigated. Promising candidate materials are the Ni_2MnGa system and the Fe-based Invars, which exhibit, in principle, the desired characteristics. Further details on the Ni–Mn–Ga alloys can be found in (11,12).

PHYSICAL ORIGIN OF MAGNETOSTRICTION

Magnetic coupling within atoms can be of two forms, spin–spin and spin–orbit interactions. In ferromagnetic materials, the spin–spin coupling that keeps neighboring spins parallel or antiparallel to one another within domains can be very strong. However, this exchange energy is isotropic because it depends only on the angle between adjacent spins, not on the direction of the spins relative to the crystal lattice.

Magnetostriction is due mainly to spin–orbit coupling, which refers to a kind of interaction between the spin and orbital motion of each electron. This type of coupling is also responsible for crystal anisotropy. Referring to Fig. 2, when a magnetic field is applied and an electron spin tries to align with it, the orbit of that electron also tends to be reoriented. But because the orbit is strongly coupled to the crystal lattice, the orbit resists the rotation of the spin axis. Thus, the energy required to rotate the spin system of a domain away from the preferred orientations is the energy required to overcome spin–orbit coupling. Spin–orbit coupling is weak in most ferromagnetic materials, as evidenced by the fact that a moderate field of a few thousand kiloamperes per meter suffices to rotate the spins. Spin–orbit coupling in rare-earth metals is much stronger by about an order of magnitude. When a magnetic field rotates the spins, the orbital moments rotate, and considerable distortion, and hence magnetostriction, results (13).

MATERIAL BEHAVIOR

Magnetic Anisotropy

Magnetic anisotropy refers to the dependence of magnetic properties on the direction in which they are measured. It can be of several kinds, including crystal, stress, shape,

and exchange anisotropy. Of these, however, only crystal anisotropy is intrinsic to the material, whereas the other types are externally induced.

In crystalline materials, the magnetic moments do not rotate freely in response to applied fields, but rather they tend to point in preferred crystallographic directions. This phenomenon is called magnetocrystalline (or crystal) anisotropy, and the associated anisotropy energy is that required to rotate the magnetic moments away from their preferred direction. Crystal anisotropy energy and linear magnetostriction are closely related. If anisotropy is independent of the state of strain, there will be no linear magnetostriction (14). In rare-earth elements, for instance, large strains are a direct consequence of the huge strain dependence of magnetic anisotropy (8). Under the action of a magnetic field, measurable strains result from the deformations that the crystal lattice undergoes to minimize the energy state of the material.

When a sinusoidal magnetic field is applied to a material that has sufficiently large anisotropy, the resulting magnetization curve is not smooth due to the presence of magnetic moment “jumping.” For example, Fig. 3a,b shows the magnetization and magnetostriction of the alloy $\text{Tb}_{0.67}\text{Dy}_{0.33}$, which has substantial magnetic anisotropy. The discontinuity in both curves near a field value of 40 kA/m occurs because the magnetic moments abruptly enter or leave low energy directions. Elements that have

Figure 3. (a,b) Magnetization and magnetostriction jumps in $\text{Tb}_{0.67}\text{Dy}_{0.33}$, a material that has large anisotropy. (c), (d) The same measurements are much smoother in a material that has near zero anisotropy such as $\text{Tb}_{0.6}\text{Dy}_{0.4}$ (36).

Figure 4. Crystallographic orientations in monolithic Terfenol-D. The square brackets represent the indexes of particular directions such as the edges of a cube: $[100]$, $[010]$, $[001]$, $[\bar{1}00]$, $[0\bar{1}0]$, and $[00\bar{1}]$, in which $\bar{1}$ denotes -1 . The entire set of directions is designated by any one direction in angular brackets, for instance, $\langle 100 \rangle$. Finally, planes of a form are designated by rounded brackets, such as the six faces of a cube: (100) , (010) , (001) , $(\bar{1}00)$, $(0\bar{1}0)$, and $(00\bar{1})$.

opposite anisotropies are often alloyed together to reduce the jumping and associated nonlinearities in material behavior. Such a material is shown in Fig. 3c,d. In this case, the same system but in a different composition ($\text{Tb}_{0.6}\text{Dy}_{0.4}$) exhibits a much smoother response to the applied field.

Accurate models for crystal anisotropy and its relationship to the magnetization process exist for simple cases of cubic and hexagonal crystals (15,16), but models of complex crystal structures often rely on simplifying assumptions that reduce the problem to the simpler cases. For instance, it is often useful to assume operating regimes in which stress anisotropy dominates crystal anisotropy, thus enabling the modeling of highly complex cases such as that of Terfenol-D whose crystals are grown in dendritic twin sheets oriented in the $[11\bar{2}]$ direction, as shown in Fig. 4 and discussed in (1). Terfenol-D has a large and positive magnetostrictive coefficient of $\lambda_{111} = +1,600 \times 10^{-6}$, so a compressive stress applied along the $(11\bar{2})$ direction produces a significant decrease in the internal energy of the crystal at *right angles* to the applied stress. On the other hand, although the anisotropy coefficient of Terfenol-D varies significantly, depending on temperature and stoichiometry ($K_1 = -4$ to -50 kJ/m^3 [3,17]), it is sufficiently large to resist such energy changes by favoring alignment in the $\langle 111 \rangle$ directions. Then, it is inferred that a sufficiently large compressive stress will raise the elastic energy above that of the crystal anisotropy, shifting the

preferred orientation of domains to the $\langle 111 \rangle$ magnetic easy axes that are perpendicular to the $[11\bar{2}]$ direction. Under such compressive stress, the population density in these two orientations increases, and a magnetic field applied in the $[11\bar{2}]$ direction produces nearly isotropic 90° rotations because the energy wells of crystal anisotropy have been effectively removed from the path of the rotations. In addition, under compression, as large populations of magnetic moments align normally to the stress direction, the demagnetized length decreases to a minimum, and the saturation magnetostrictive potential increases to a maximum. The 90° rotations subsequently provide the maximum possible magnetostrictions. To summarize, in materials that have positive magnetostrictions like Terfenol-D, the stress anisotropy generated by compression effectively improves the magnetoelastic state that leads to enhanced magnetostrictions. The manner in which this is implemented in transducer applications is discussed later. In nickel, which has a negative magnetostrictive coefficient, the effect is reversed, and enhanced magnetoelasticity is obtained from tensile stresses. Further details regarding crystal anisotropy can be found in (18–20).

Domain Processes and Hysteresis

The changes in magnetization that result from an applied magnetic field can be either reversible or irreversible. Reversible changes in magnetization are energetically conservative and occur for small field increments in which the material can return to the original magnetic state upon removing the field. Irreversible magnetizations are dissipative because external restoring forces are needed to return the magnetism to its original state, for example, when large fields are applied. In applications, both types of mechanisms contribute to the magnetization process. Magnetization, either reversible or irreversible, can be explained by considering two related mechanisms: the rotation of magnetic moments and the movement of domain walls. The presence of domain walls lies in the domain structure characteristic of ferromagnetic materials below their magnetic phase transition temperature or Curie temperature, T_c (see Table 1 for values of T_c for several magnetostrictive materials). When a ferromagnetic material is cooled below its Curie temperature, the magnetic moments become ordered across volumes, called domains, that contain large numbers of atoms. The domain structure can be observed under a microscope, and it typically consists of 10^{12} – 10^{15} atoms per domain. The transition regions between neighboring domains are called domain walls. All of the moments of each domain are aligned parallel, producing a spontaneous magnetization M_s , but without a field, the direction of M_s varies from domain to domain, so that the bulk magnetization in the material averages zero. This is illustrated by the randomly oriented regions of Fig. 5a.

When a small magnetic field H is applied, as depicted in Fig. 5b, domains oriented favorably to the field grow at the expense of the remaining domains, and the main magnetization mechanism is domain wall motion. As the field is increased (see Fig. 5c), entire domains rotate to align

with the easy $[11\bar{1}]$ axis. This produces a burst region in the magnetization versus field (M - H) and strain versus field (ϵ - H) curves by virtue of which small field changes produce large magnetization or strain changes. In the final stage shown in Fig. 5d, the material acts as a single domain as magnetic moments rotate coherently from the easy axis to the direction of the field. This produces saturation of the magnetization. Typical magnetization and strain loops shown in Fig. 6 illustrate the burst region and saturation effects. From a design perspective, magnetic biasing described later is used to center operation in the burst region for optimum performance.

For low magnetic field levels, partial excursions in the M - H or ϵ - H curve are observed that are approximately linear. However, hysteresis is always present, particularly when the materials are employed at high field levels such

as those of Fig. 6. The hysteresis can be attributed to the irreversible impediment to domain motion by pinning sites, such as when domain walls move across twin boundaries in Terfenol-D. Modeling hysteresis and nonlinear behavior is currently a focal point in designing and controlling magnetostrictive materials. Extensive details on the topic of ferromagnetic hysteresis can be found in (14,21,22).

Material Properties

Strains are generated by magnetostrictive materials when magnetic moments rotate to align with an applied field. This phenomenon is governed by an energy transduction process known as magnetomechanical coupling that is intrinsically bidirectional and that facilitates both actuating and sensing mechanisms in a material. From a design

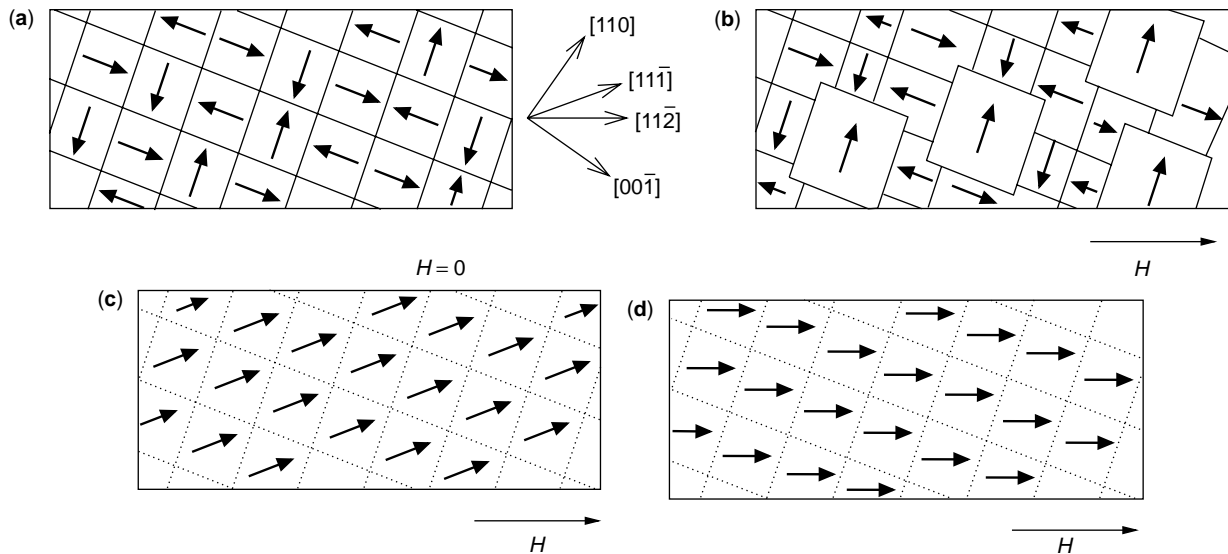

Figure 5. Domain processes in the $(1\bar{1}0)$ plane of single crystal Terfenol-D under the application of a field H along the $[11\bar{2}]$ axis: (a) demagnetized specimen, (b) partial magnetization by domain-wall movement, (c) from partial magnetization to the knee of the magnetization curve by irreversible domain magnetization rotation into the $[11\bar{1}]$ axis, and (d) from the knee of the magnetization curve to technical saturation by reversible (coherent) rotation to the $[11\bar{2}]$ axis (21).

Figure 6. Relative magnetization M/M_s and total strain ε as a function of magnetic field H in a magnetostrictive material.

standpoint, the linear coupling coefficient k that quantifies the conversion efficiency between mechanical and elastic energies must be close to unity. Significant magnetic moment rotation occurs only when a domain structure is present, that is to say, in the ferromagnetic state below the Curie temperature T_c . Hence, the material must be designed so that its Curie temperature is well above the operating temperature range. In smart structure systems, large forces are often involved that the magnetostrictive material must support. The stiffness of the material is quantified by the elastic modulus E . The material must have a large value of E to support large forces. Finally, the magnetostrictive material must feature a large saturation magnetization M_s (or, equivalently, a large saturation induction B_s), and the magnetic anisotropy must be small.

Shown in Table 1 is a list of nominal properties for several magnetostrictive materials of interest. Note that the magnetomechanical coupling responsible for diverse material properties is a highly complex function that depends on quantities such as magnetic field, stress, temperature, and frequency. These quantities are collectively known as “operating conditions” and typically vary during device operation. It has been demonstrated that small variations in operating conditions often produce large changes

in material properties (23). Efficient transducer design requires accurately assessing how material properties behave under varying operating conditions.

LINEAR MAGNETOSTRICTION

Linear or Joule magnetostriction pertains to the strain produced in the field direction and is the most commonly used magnetostrictive effect. Because linear magnetostriction occurs at constant volume, there must be a transverse strain of sign opposite to that of the linear magnetostriction,

$$\lambda_{\perp} = -\frac{\lambda}{2}.$$

Isotropic Spontaneous Magnetostriction

It was mentioned earlier that when a ferromagnetic material is cooled through its Curie temperature, a transition from paramagnetism to ferromagnetism takes place, and magnetic moments become ordered giving rise to spontaneous magnetization M_s within domains. This process is also accompanied by a strain which is known as *spontaneous* magnetostriction λ_0 . It is possible to derive a useful relationship between λ_0 and *saturation* magnetostriction λ_s . To that end, we consider an isotropic material in the disordered state above T_c , which is therefore modeled by spherical volumes, as shown in Fig. 7a. As the material is cooled below T_c , spontaneous magnetization M_s is generated within magnetic domains along with the corresponding spontaneous magnetostriction λ_0 . The domains are represented in Fig. 7b by ellipsoids that have spontaneous strain e . Because the material is isotropic, the magnetic domains are oriented randomly; each bears an angle θ with respect to the direction of measurement. Net magnetization is consequently zero, and the length in the

Figure 7. Schematic diagram illustrating the magnetostriction of a ferromagnetic material: (a) paramagnetic state above T_c ; (b) after it has been cooled through T_c ; and (c) after it has been brought to saturation by a field H .

direction of interest is given by (13)

$$e(\theta) = e \cos^2 \theta. \quad (1)$$

Then, the average domain deformation at the onset of spontaneous magnetostriction can be obtained by integration in all possible directions,

$$\lambda_0 = \int_{-\pi/2}^{\pi/2} e \cos^2 \theta \sin \theta d\theta = \frac{e}{3}.$$

Spontaneous magnetostriction λ_0 is homogeneous in all directions, so that the material has changed its dimensions but not its shape. When a magnetic field is applied, the domains rotate and become aligned either parallel to the field or perpendicular to it, depending on whether the material exhibits positive or negative magnetostriction. Assuming positive magnetostriction, the domains will rotate into the field direction, as depicted in Fig. 7c. Near saturation, the material will be a single domain, and the total strain will be e . Then, the total available saturation magnetostriction is given by the difference between e and λ_0 ,

$$\lambda_s = e - \lambda_0 = \frac{2}{3} e = 2 \lambda_0. \quad (2)$$

This expression provides a method of measuring the spontaneous strain λ_0 by measuring λ_s . Methods to determine λ_s are discussed next.

Saturation Magnetostriction

Assuming again for simplicity that the medium is isotropic, saturation magnetostriction at an angle θ to the direction of the field is given by (13)

$$\lambda_s(\theta) = \frac{3}{2} \lambda_s \left(\cos^2 \theta - \frac{1}{3} \right), \quad (3)$$

where $\lambda_s(\theta)$ is the saturation magnetostriction at an angle θ to the field and λ_s is the saturation magnetostriction along the direction of magnetization.

The saturation magnetostriction is then calculated from the difference between the maximum magnetostriction when the field is parallel to a given direction ($\lambda_{s\parallel}$) and that when the field is perpendicular to the given direction ($\lambda_{s\perp}$). Substituting $\theta = 0^\circ$ and $\theta = 90^\circ$ in Eq. (3) gives

$$\lambda_{s\parallel} - \lambda_{s\perp} = \lambda_s + \frac{1}{2} \lambda_s = \frac{3}{2} \lambda_s, \quad (4)$$

which defines λ_s independently of the demagnetized state.

Magnetostriction data from Clark (8) taken from polycrystalline $\text{Tb}_x\text{Dy}_{1-x}\text{Fe}_2$ samples are reproduced in Fig. 8. The data points correspond to $\lambda_{s\parallel} - \lambda_{s\perp}$ at room temperature and field values of $H = 10$ kOe (0.8 MA/m) and $H = 25$ kOe (2 MA/m). Near $x = 0.3$, the magnetostrictive curve shows a peak in accordance with the near zero magnetic anisotropy observed at this composition. From the magnetostrictive value at the peak, about 1600×10^{-6} ,

Figure 8. Magnetostriction of polycrystalline $\text{Tb}_x\text{Dy}_{1-x}\text{Fe}_2$ at room temperature (8).

Eq. (4) gives $\lambda_s = 1000 \times 10^{-6}$ which is a widely employed value for the saturation magnetostriction of Terfenol-D.

Anisotropy is present to some degree in all magnetic materials, and therefore, the saturation magnetostriction needs to be defined relative to the axis along which the magnetization lies. One exception is nickel, whose magnetostriction is almost isotropic (see Table 2). Recognizing that there are two independent magnetostriction constants λ_{100} and λ_{111} for cubic materials, the saturation magnetostriction, assuming a single crystal, single domain material is given by a generalization of Eq. (3) for isotropic materials:

$$\lambda_s = \frac{3}{2} \lambda_{100} \left(\alpha_1^2 \beta_1^2 + \alpha_2^2 \beta_2^2 + \alpha_3^2 \beta_3^2 - \frac{1}{3} \right) + 3 \lambda_{111} (\alpha_1 \alpha_2 \beta_1 \beta_2 + \alpha_2 \alpha_3 \beta_2 \beta_3 + \alpha_3 \alpha_1 \beta_3 \beta_1), \quad (5)$$

where λ_{100} and λ_{111} are the saturation magnetostrictions along the $\langle 100 \rangle$ and $\langle 111 \rangle$ axes of the crystal. Cosines α_i

Table 2. Magnetostrictive Coefficients of Cubic Crystal Materials

Material	$\lambda_{100} (10^{-6})$	$\lambda_{111} (10^{-6})$
Nickel	-46	-24
Iron	21	-21
Terfenol-D	90	1600

($i = 1, 2, 3$) define the direction along which the magnetic moments are saturated, and cosines β_i define the direction in which the saturation magnetization is measured. The saturation magnetostriction in the field direction is obtained by using $\alpha_i = \beta_i$ in Eq. (5), which leads to

$$\lambda_s = \lambda_{100} + 3(\lambda_{111} - \lambda_{100})\left(\alpha_1^2\alpha_2^2 + \alpha_2^2\alpha_3^2 + \alpha_3^2\alpha_1^2\right). \quad (6)$$

Note that Eqs. (5) and (6) apply only to single domain materials. In the saturated state, the whole specimen consists of a single domain whose magnetization M_s is aligned parallel to the applied field. However, when a domain structure is present such as in polycrystals, the magnetostriction can be calculated only by averaging the effects, unless the domain structure is known specifically. Note that different domain configurations can give the same bulk magnetization and different magnetostrictions (see Fig. 9). So, assuming that there is no preferred grain orientation, Eq. (6) simplifies further and becomes

$$\overline{\lambda_s} = \frac{2}{5}\lambda_{100} + \frac{3}{5}\lambda_{111}.$$

Extensive magnetostriction data on the R-Fe₂ compounds can be found in (8), and calculations of λ_s in different crystallographic structures such as cubic, hexagonal, and polycrystalline can be found in (2,13,16,21).

Magnetostriction below Saturation

Although saturation magnetostriction λ_s can be determined by employing the methods previously discussed, magnetostriction between the demagnetized state and saturation is structure sensitive, so general constitutive

Figure 9. Demagnetized specimen featuring a 180° domain wall in the (a) horizontal or (b) vertical direction. The length of the specimen is different in either case, even though the magnetization is the same.

relationships for magnetostriction are not feasible. However, an explicit solution exists when strains are due primarily to 90° domain rotations. In practice, these rotations occur in (1) a single crystal that has uniaxial anisotropy in which the field is applied in a direction perpendicular to the easy axis or (2) a polycrystalline material in which the magnetic moments have been completely aligned in a direction perpendicular to the applied field, such as Terfenol-D under extreme compression or nickel under tension. The latter implies that perpendicular stress energy is sufficient to dominate crystal anisotropy, as discussed earlier. For that regime, combining Eqs. (1) and Eq. (2) gives

$$\lambda = \frac{3}{2}\lambda_s \cos^2 \theta, \quad (7)$$

where θ is the angle between the M_s vectors and the field direction. Recognizing that the bulk magnetization in the field direction is given by $M = M_s \cos \theta$, Eq. (7) becomes

$$\lambda = \frac{3}{2}\lambda_s \left(\frac{M}{M_s}\right)^2, \quad (8)$$

which provides a quadratic relationship between magnetization and magnetostriction. It has been shown that this expression is sufficiently accurate in a broad range of transducer regimes in which high mechanical preloads are employed to optimize transducer performance (24). A generalized version of this equation has been given in (25), and more elaborate models of magnetostrictive hysteresis have been presented in (19,26–28). Additional effects such as stress dependences have been also considered (25,29). Finally, the dependence of the magnetostriction of the R-Fe₂ compounds on temperature has been discussed in (8).

OTHER MAGNETOSTRICTIVE EFFECTS

Linear magnetostriction is just one of several manifestations of a more general phenomenon, the coupling between the magnetic and elastic states in a material. These effects are briefly discussed following and are summarized in Table 3.

Villari Effect

The Villari effect, also known as the magnetomechanical effect, are the changes in magnetization that a magnetostrictive material undergoes when subjected to an applied uniaxial stress. This effect pertains to the transduction of energy from the elastic to the magnetic state and is inverse of Joule magnetostriction. Furthermore, the Villari effect exhibits many of the attributes of the direct magnetostrictive effect inasmuch as its physical origin also lies in magnetoelastic coupling. The Villari effect has been the object of much study, given its relevance in applications such as nondestructive evaluation and sensing. Extensive theoretical and experimental details can be found in (25). The effect of stress on magnetostrictive materials in particular has been discussed in (30).

Table 3. Magnetostrictive Effects

Direct Effects	Inverse Effects
Joule magnetostriction Change in sample dimensions in the direction of the applied field	Villari effect Change in magnetization due to applied stress
ΔE effect Magnetoelastic contribution to magnetocrystalline anisotropy	Magnetically induced changes in elasticity
Wiedemann effect Torque induced by helical anisotropy	Matteucci effect Helical anisotropy and emf induced by torque
Magnetovolume effect Volume change due to magnetization (most evident near the Curie temperature)	Nagaoka–Honda effect Change in the magnetic state due to a change in volume

ΔE Effect

The elasticity of magnetostrictive materials is composed of two separate but related attributes, the conventional stress–strain elasticity that arises from interatomic forces and the magnetoelastic contribution due to the rotation of magnetic moments and the ensuing strain that occur when a stress is applied. The latter contribution, known as the ΔE effect, is quantified by $\Delta E = (E_s - E_0)/E_0$, where E_0 is the minimum elastic modulus and E_s is the elastic modulus at magnetic saturation. Because the strain produced by magnetic moment rotation adds to the non-magnetic strain [see Eq. (9)], the material becomes softer when the moments are free to rotate. This is illustrated in Fig. 10. Note that the material becomes increasingly stiff as saturation is approached and magnetic moment mobility decreases. The ΔE effect is small in nickel ($\Delta E = 0.06$) but is quite large in Terfenol-D (ΔE up to 5) and certain transverse-field annealed $\text{Fe}_{81}\text{B}_{13.5}\text{Si}_{3.5}\text{C}_2$ (Metglas 2605SC) amorphous ribbons ($\Delta E = 10$). The ΔE effect of Terfenol-D can be advantageously employed in tunable vibration absorbers and broadband sonar systems (31).

**Figure 10.** Magnetoelastic modulus of $\text{Tb}_{0.3}\text{Dy}_{0.7}\text{Fe}_2$ under various stresses (79).

Wiedemann Effect

A current-carrying ferromagnetic or amorphous wire produces a circular magnetic field in a plane perpendicular to the wire, and the moments align predominantly in the circumferential direction. When an axial magnetic field is applied, some of the moments align helically and create a helical magnetic field. The twist observed in the wire is called the Wiedemann effect. The inverse Wiedemann effect, known as the Matteucci effect, is the change in axial magnetization of a current-carrying wire when it is twisted. Further details can be found in (2).

Magnetovolume Effect

The volume of a magnetostrictive material remains virtually unchanged during normal operation, but in certain extreme regimes, the volume of the material may change in response to magnetic fields. This anomalous volume change is called the volume magnetostriction or Barret effect. The effect has little applicability in smart structure systems. For instance, the magnetostriction curve of nickel rapidly reaches -35×10^{-6} at only 10 kA/m, but the fractional volume change is only 0.1×10^{-6} in a much larger field of 80 kA/m. In the alloy Invar (36% nickel–64% iron), the fractional volume change at the Curie temperature, which is slightly above room temperature, compensates for the intrinsic thermal expansion and gives a compound that has nearly zero thermal expansion at room temperature. The inverse of the Barret effect, the Nagaoka–Honda effect, is the change in magnetic state caused by a volume change (2,14).

MAGNETOSTRICTIVE TRANSDUCERS

One advantage of magnetostrictive transducers over other types of transducers is that they can be driven by conventional low impedance amplifiers, particularly at frequencies well below resonance; in this case, the low impedance of a magnetostrictive transducer means that driving voltages can be low. This can prove useful in medical applications and in general can greatly simplify amplifier design. Figure 11 shows the measured complex electrical impedance frequency response function $Z_{ee} = V/I$ of a Terfenol-D transducer designed following the generic

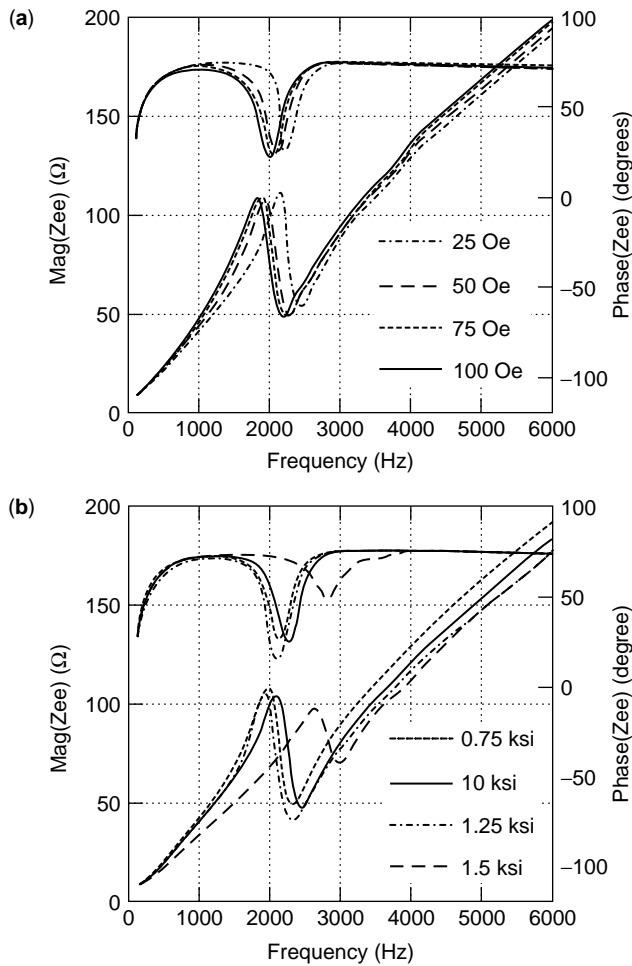

Figure 11. Total electrical impedance Z_{ee} versus frequency, expressed as magnitude and phase: (a) bias condition of 5.2 MPa, 24 kA/m (0.75 ksi, 300 Oe), and varied ac drive levels; (b) constant ac drive level of 8 kA/m (100 Oe) and varied bias conditions (79).

configuration indicated in Fig. 12 (32,33). This transducer consists of a cylindrical magnetostrictive rod, a surrounding copper-wire solenoid, a preload mechanism that consists of a bolt and a spring washer, magnetic couplers, and a barrel-like permanent magnet that provides bias magnetization. Specific design details depend on the particular smart structure application; however, this configuration depicts the basic components needed to extract maximum performance from a magnetostrictive material.

Because magnetostriction is produced by the rotation of magnetic moments, a magnetostrictive transducer driven by an ac magnetic field vibrates at twice the drive frequency, and the motion occurs in only one direction. This is illustrated in Fig. 13, where the solid lines represent the unbiased input and corresponding strain output. The dashed lines demonstrate the performance improvements achieved by applying a magnetic bias. In the biased regime, the frequency of the input is preserved, the output is bidirectional, and the ratio of output per input is substantially larger. To center operation accurately around the

Figure 12. Cross section of a typical magnetostrictive transducer.

desired bias point, a permanent magnet is often employed in combination with a static field generated by passing a dc current through the solenoid. Note that exclusive permanent magnet biasing has the advantage of substantial power savings, but it has the disadvantage of added bulk and weight. Conversely, dc currents produce considerable power losses through ohmic heating but facilitate savings in bulk and weight. Magnetic biasing can be alternatively provided by magnets located in series with the rod or rods; this design is known as a stacked-magnet configuration. The stacked-magnet configuration can improve the magneto-mechanical coupling up to 5% for large rods ($L > 20$ cm, $D > 2.5$ cm) compared to the barrel-magnet configuration. However, collateral problems such as saturation effects and resonance frequency shifts are common in stacked-magnet designs. Carefully designed transducers must provide efficient magnetic flux closure within the circuit formed by the rod itself, the couplers, and the permanent magnets.

Figure 13. Effect of magnetic bias on the strain produced by a magnetostrictive transducer.

Finally, although modern magnetostrictive materials such as Terfenol-D are manufactured so that their magnetic moments are nearly perpendicular to the rod axis, a static stress (mechanical preload) is nevertheless, required to achieve full alignment of all of the moments. The moments of a mechanically free rod are aligned randomly, and the rod produces only about half of its maximum magnetostriction because the moments initially aligned with the rod axis do not contribute to the magnetostriction. Furthermore, the stress anisotropy generated by the static compression (or tension for materials of negative magnetostriction) enhances the overall magnetoelastic state, as described previously. Note that in designs that employ linear washers for preloading, the stress in the magnetostrictive rod can vary significantly relative to the nominal preload during dynamic transducer operation. By virtue of the magnetomechanical coupling, this can have a profound impact on the performance of the magnetostrictive transducer and driving electronics by affecting the magnetic state and, through it, the electrical regime (see Fig. 11). The effects of mechanical preload and magnetic bias on the performance of a Terfenol-D transducer have been studied in (34). A second reason for employing a mechanical preload is to avoid operating the rod in tension, particularly when driving brittle materials such as Terfenol-D ($\sigma_t = 28 \text{ MPa}$, $\sigma_c = 700 \text{ MPa}$) at or near mechanical resonance.

Actuator Applications

The number of actuator applications based on magnetostrictive materials, mainly Terfenol-D, is continuously increasing as a consequence of the high energy density, high force, broad frequency bandwidth, and fast response that these materials provide. Even though the cost of Terfenol-D is high at present, the range of applications is likely to continue increasing as manufacturing techniques are perfected and prices decline. Actuators designed according to the configuration shown in Fig. 12 have been employed in these applications: sonar, chatter control for boring tools, high-precision micropositioning, borehole seismic sources, geological tomography, hydraulic valves for fuel injection systems, deformable mirrors, hydraulic pumps, bone-conduction hearing aids, exoskeletal telemanipulators, self-sensing actuators, degassing in manufacturing processes such as rubber vulcanization, and industrial ultrasonic cleaning. Four main application subgroups of current transducer designs are discussed here: sonar transducers, linear motors, rotational motors, and hybrid smart material transducers. The reader is directed to (1,2) for more complete details.

Sonar Transducers. Efficient sonar transducers must produce high mechanical power at low frequencies and often have the additional constraint that a broad frequency bandwidth or equivalently, a low quality factor Q , must be attained. Although nickel was widely employed in sonar applications during World War II, it has a low magneto-mechanical coupling coefficient of $k = 0.30$ which typically demands a high Q to achieve good efficiencies. In

contrast, the newer giantmagnetostrictive materials have much higher coupling coefficients of more than $k = 0.70$ which makes it possible to operate the transducer at low Q and attain high power output simultaneously. For example, a Terfenol-D Tonpitz transducer similar to that depicted in Fig. 14a can produce a bandwidth of 200 Hz at a resonance frequency of 2 kHz ($Q = 10$) and a source level of 200 dB ref. $1 \mu\text{Pa}$ at 1 m (35). Another Terfenol-D transducer reportedly produces a maximum output of 206 dB

Figure 14. Magnetostrictive sonar transducers: (a) Tonpitz, (b) flextensional, and (c) square ring.

ref. $1 \mu\text{Pa}$ at 1 m and operates across a broad usable bandwidth of 5–50 kHz (36). Other designs employ the linear motion of cylindrical magnetostrictive rods to flex a surrounding shell or to induce radial vibrations in a tube or ring, as shown in Fig. 14b,c. Further details and references are provided in (37).

Linear motors. Direct coupling between the load and the magnetostrictive element in Fig. 12 implies that the net load displacement is limited by magnetostriction. For instance, an 11.4-cm Terfenol-D actuator provides maximum displacements of about 0.2 mm. This displacement level is sufficient for many vibration control applications, but certain applications such as flow control valves or aircraft flap positioners typically require much larger strokes.

The fact that Joule magnetostriction takes place at constant volume is employed in the Kiesewetter motor to displace loads beyond the maximum strain normally achievable by a Terfenol-D rod. This motor (38) consists of a cylindrical Terfenol-D rod that fits snugly inside a stiff stator tube when no magnetic field is applied. Several short coils surround the stator to produce a magnetic field profile that sweeps along the Terfenol-D rod. When one of the coils is energized, for instance, coil 1 in Fig. 15a, the section of rod directly exposed to the magnetic field elongates and shrinks. As the field is removed, the rod clamps itself again inside the stator but at a distance d to the left of the original position. As the remaining coils are energized sequentially and the magnetic field profile is swept, the rod moves in a direction opposite to the sweeping field. The direction of motion is changed by inverting the sequence in which the coils are energized. From a design perspective, the total displacement is limited only by the length of the Terfenol-D rod, whereas the speed of motion is proportional to the sweeping frequency and the magnetostriction of the rod. Other factors that affect the smoothness and speed of the motor are the number of traveling pulses, the spacing between excitatory coils, the stiffness of the Terfenol-D material, and skin effect degradation due to eddy currents. The Kiesewetter motor is self-locking when unpowered, which is an important attribute for many robotic applications.

A proof-of-concept Kiesewetter motor presented in (39) produces 1000 N of force and 200 mm of useful stroke at a speed of 20 mm/s; it is intended for uses such as control of coat weight and fiber distribution in the paper industry and valve operation and precision positioners for the machine tool industry. An improved design presented in (40) addresses some of the technical problems of the Kiesewetter motor, particularly the degradation of fit between the stator and the rod caused by wear and thermal expansion. Furthermore, this revised design enables rotary motion in a way that is otherwise impossible to achieve by using the original Kiesewetter design.

Another variant of the inchworm principle is shown in Fig. 15b. This motor consists of translating clamps, fixed position clamps, pusher transducers, and a load shaft. By coordinating the clamping and unclamping actions of the clamps with the action of the pushing transducers, it is possible to induce bidirectional motion of the load shaft. The load rating is limited by the frictional force between the clamps and the load shaft. Note that the inchworm principle can

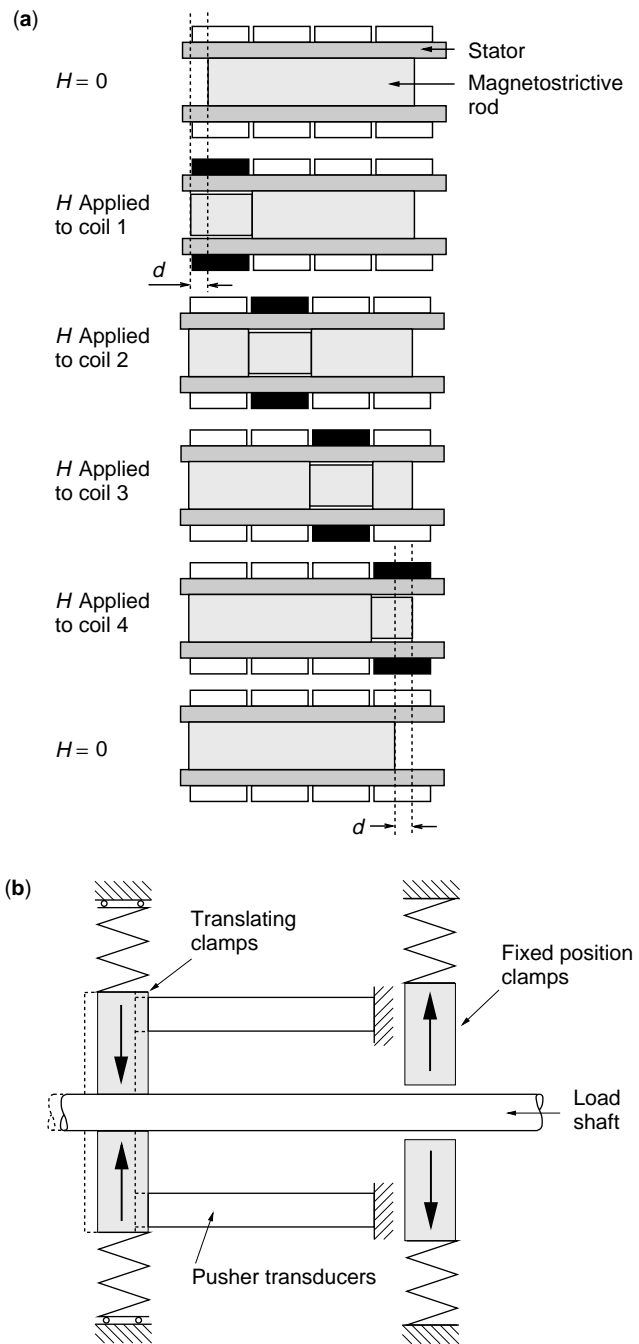

Figure 15. (a) The Kiesewetter inchworm motor. Black rectangles indicate energized coils; white rectangles indicate inactive coils. (b) Inchworm linear motor.

also be implemented by using other smart materials such as piezoelectric stacks (41) or a combination of piezoelectric and magnetostrictive elements, as shown later.

Piezoelectric transducers are often preferred for ultrasonic power generation in the megahertz range, but certain applications in the low-ultrasonic range benefit from the ruggedness and lack of depoling mechanisms of magnetostrictive materials. For instance, nickel is extensively used in applications such as degassing liquids (20–50 kHz)

Figure 16. Schematic diagram of an ultrasonic Terfenol-D device consisting of a quarter-wave transducer coupled to a quarter-wave titanium waveguide and a half-wave acoustic horn. Different tool tips can be used as needed.

and cleaning dental or jewelry pieces (more than 50 kHz). A surgical ultrasonic tool based on Terfenol-D was developed recently that reportedly provides enhanced power and displacement output compared to existing piezoelectric tools; it is also lighter, more compact, and can deliver a 600-V, 1-MHz signal to cauterize bleeds without affecting its surgical function. In this device, illustrated in Fig. 16, a laminated quarter-wavelength Terfenol-D rod is coupled to a quarter-wavelength titanium waveguide that provides the resonant subassembly to which a half-wavelength acoustic horn is attached. The acoustic horn has an amplification factor from 15–30; thus, it provides extreme accelerations and energy concentration at the tip of the tool (42,43). Other current or potential uses for this transducer design include industrial cleaning, sonic cell disruption and sterilization, friction welding, and treatment of diverse chemical and biological processes (1).

Rotational Motors. Smart material motors based on the magnetostrictive principle are potentially simpler and more reliable than conventional hydraulic or electromagnetic systems. The inchworm technique has been employed in a rotational motor that produces a torque of 3 Nm at a speed of 0.5 rpm (44). Another inchworm type device also provides a speed of 0.5 rpm but produces a very high torque of 12 Nm and precision microsteps of $800 \mu\text{rad}$ (45). Despite the great positional accuracy and high holding torques, the current inchworm-type rotational motors tend to lack efficiency. Much of the efficiency limitation has been overcome in the resonant rotational motor proposed by Claeysen et al. (46). Two linear Terfenol-D actuators are used to induce elliptical vibrations in a circular ring that acts as a stator and transmits the vibrations to rotational rotors pressed against the ring. The prototype reportedly provides a maximum torque of 2 Nm at a maximum speed of 17 rpm.

The field of ultrasonic rotational motors has aroused much research and commercial interest. These motors are employed in a wide range of applications from autofocusing camera lenses to robotic manipulators. A rotational actuator developed by Akuta (44) employs Terfenol-D to achieve a relatively high speed of 13.1 rpm and a maximum torque

Figure 17. Rotational ultrasonic motor (44).

of 0.29 Nm. As depicted in Fig. 17, this motor employs two Terfenol-D exciter rods to induce rotations in the shaft.

Hybrid Magnetostrictive/Piezoelectric Devices. Given their technological interest, hybrid smart material actuators can be considered a separate class independently of whether they are intended for sonar, linear, or rotational applications. Because magnetostrictive materials are inductive and piezoelectric elements are capacitive, it is advantageous to combine both types of materials in the same device, so that a resonant electric circuit is formed. When driven at resonance, such a device behaves like a purely resistive load and only the energy that is effectively converted to mechanical motion or lost to inner losses needs to be supplied externally. This greatly simplifies amplifier design and helps to attain high efficiencies.

The hybrid device has been demonstrated that overcomes the difficulties involved in achieving motion at only one end of a Tonpitz piston-type sonar transducer; it consists of a quarter-wavelength stack of piezoelectric Navy type I ceramic rings joined to a quarter-wavelength Terfenol-D composite tube [see Fig. 18a and (47)]. The inherent 90° phase shift between the magnetostrictive and piezoelectric velocities in combination with the quarter-wavelength design of the elements ensures addition at one end and cancellation at the other. The device is *mechanically* unidirectional, but it becomes *acoustically* unidirectional only under array-baffled operation. The measured front-to-back pressure ratio is 5 dB for the device alone and 15 dB under array-loaded conditions. The concept of hybrid piezoelectric/magnetostrictive transduction has also been implemented for linear inchworm motors (48,49) and rotational motors (50). For example, the prototype presented in (48) has the configuration shown in Fig. 15b, but the clamping is done by piezoelectric stacks, and the translation is provided by Terfenol-D rods. The intrinsic 90° phase lag between the two types of elements provides natural drive timing for the inchworm, and the direction of motion

Figure 18. Hybrid magnetostrictive/piezoelectric transducers: (a) sonar projector (47); (b) rotational motor (50).

is easily reversed by changing the magnetic bias on the Terfenol-D elements. This motor achieves a zero-load speed of 25.4 mm/s and a stall load of 115 N.

The hybrid magnetostrictive/piezoelectric rotational motor illustrated in Fig. 18b follows the proof-of-concept transducer presented in (50). A piezoelectric stack clamps a piece of friction material onto the rotating disk, and two magnetostrictive rods move the clamp tangentially to the disk to produce rotational motion. As indicated before, the sequence of the motion is determined by the natural timing of the piezoelectric and magnetostrictive responses. The device produces a speed of 4 rpm at excitatory voltages from 30–40 V and frequencies from 650–750 Hz.

Sensor applications

Magnetostrictive materials are being employed in a wide variety of sensor designs as evidenced by the growing number of publications and patents. In this overview, the term sensor is used in a broad sense to indicate the attributes of magnetostrictive materials that facilitate generation of electrical signals in response to mechanical excitations, such as force, strain, and torque, or magnetic excitations such as magnetic fields. By virtue of the magnetoelastic coupling, changes in the magnetoelastic state through these parameters (or a combination of them) produce measurable change in magnetization anisotropy. To complete the sensing mechanism, a pick-up coil is often wrapped

around the magnetostrictive material to detect magnetization changes; this effectively provides a mechanism for conversion of energy from magnetic to electrical regimes. The principle that links the magnetization with the voltage V generated across a pick-up coil is the Faraday–Lenz law of electromagnetic induction:

$$V = -NA \frac{dB}{dt},$$

in which N and A are, respectively, the number of turns and constant cross-sectional area of the coil and B is the magnetic induction that quantifies the magnetization state through the relationship $B = \mu_0(H + M)$ (21). Alternatively, interferometric techniques can be employed to detect the changes in wave speed that occur when the magnetostrictive material changes its properties in the presence of external excitations, for instance, the stiffness changes associated with the ΔE effect described earlier.

An overview of sensor designs is presented next. The main principles that enable operation of the sensors are emphasized. The list is not comprehensive, but it shows that a huge number of alternative designs can be devised based on the fundamental operation principles presented here. Further details can be found in the references provided.

Torque sensors. Magnetostrictive noncontact torque meters have been devised based on the principle that the torque applied to a shaft generates stresses of opposite sign, $+\tau$ and $-\tau$, oriented $\pm 45^\circ$ from the shaft axis. If the shaft is magnetostrictive or has a magnetostrictive amorphous ribbon bonded to it, the magnetic properties along the directions of $+\tau$ and $-\tau$ change as discussed previously. These properties can be measured either differentially by a set of perpendicular coils, as shown in Fig. 19a, or through a single Hall effect or similar magnetic field intensity sensor (51). This kind of sensor can be employed, for instance, in fly-by-wire steering systems for the automotive and aerospace industries. Additional details and references can be found in (2).

Another class of noncontact torque meters relies on the changes in permeability exhibited by a magnetostrictive material subjected to torsional stress. In particular, applications that require less sensitivity can benefit from the elevated mechanical strength that magnetic steels or alloys provide. One example is shown in Fig. 19b, where the working torque on a drill bit is detected by two sensing coils connected in series, one located over the flutes and the other over the shank (the permeability of the shank is less sensitive to changes in torque than the flutes.) A coil provides the ac magnetic field excitation, and the sensor's proportional output is the differential voltage generated by the sensing coils as the permeability of the bit changes due to the applied torque (52).

Deformational and Position Sensors. Transverse-field annealed magnetostrictive ribbons or wires make very sensitive strain gauges. A sensor of this kind has been made from strips of Metglas 2605SC transverse annealed for 10 min in a 208 kA/m (2.6 kOe) magnetic field at 390°C

Figure 19. Magnetostrictive noncontact torque sensors: (a) Differential reading in directions oriented $\pm 45^\circ$ from the shaft axis and (b) differential reading of the permeability changes experienced by a drill bit subjected to a torque.

and rapidly cooled in a saturation field (53). The sensor responds to the changes in the permeability of the ribbon, which by virtue of the magnetomechanical coupling depends in turn on the state of strain in the material. Defining a dimensionless gauge factor as the fractional change in the measured parameter (in this case permeability) divided by the change in strain, $F = (\partial\mu/\partial S)/\mu$,

Figure 20. Magnetostrictive waveguide position sensor.

this sensor has an F value equal to about 250,000, which compares extraordinarily well with resistive strain gauges ($F = 2$) and semiconductor gauges ($F = 250$). One problem encountered in using this device is that normal thermal expansion can saturate the sensor. This problem can be overcome by bonding the material using a highly viscous liquid, although this limits operation to ac regimes.

A position detector can be made by using a magnetostrictive material as an acoustic waveguide. This device, shown in Fig. 20, consists of a permanent magnet that is connected to the target and rides along the length of the waveguide, an emitter/receiver head that sends and receives either an acoustic or current pulse down the waveguide, and a damper that prevents unwanted wave reflections. The sensor's operating principle is rather simple; the magnet interacts with the magnetostrictive waveguide and locally changes its material properties. These material property changes can be detected in different ways. In one version, the stiffness discontinuity produced by the magnet (ΔE effect, see earlier) partially reflects an acoustic pulse sent by the emitter. In a second version, the emitter sends a continuous current pulse down the waveguide that produces a circumferential magnetic field that interacts with the axial field from the magnet. The resulting helical field produces a twist in the wire (Wiedemann effect) that travels back to the receiver head. In both versions, the transit times of the original and reflected pulses provide a measure of the location of the magnet along the waveguide. This sensor can be used for measuring fluid levels by connecting the magnet to a float or for generic position sensing of up to 50 m at ± 1 mm accuracy (2).

Magnetometers. If the magnetostriction of a given material is known as a function of magnetic field, the problem

Figure 21. Hybrid magnetostrictive/piezoelectric magnetic field sensors. When a magnetic field is applied to one of these sensors, the magnetostrictive material strains, which either (a) generates a voltage across the piezoelectric plate or (b) induces an emf in a surrounding pick-up coil that can be extracted from the alternating carrier emf produced as the piezoelectric plate resonates.

of measuring the magnetic field reduces to one of measuring length. The length can be measured by a laser interferometer, optic fiber, strain gauge, capacitor, or another calibrated material such as a piezoelectric compound. For example, a very simple design consists of two slabs of magnetostrictive and piezoelectric materials bonded together (Fig. 21a). When a magnetic field is applied to the magnetostrictive material, it strains and induces a proportional voltage in the piezoelectric material. In another version, shown in Fig. 21b, a magnetometer is realized by bonding a field-annealed metallic glass ribbon onto a resonating PZT plate by using a viscous fluid. An alternating voltage is applied to the PZT plate, which generates a longitudinal stress field. By using proper bonding techniques, the dynamic stress in the metallic ribbon is congruent with that in the PZT, and the static component is filtered out by the viscous fluid. By virtue of the Villari effect, these dynamic stresses create an oscillating electromotive force (emf) in the surrounding pick-up coil. When exposed to low-frequency magnetic fields, a low-frequency emf is generated in the coil that is extracted from the carrier emf by conventional phase sensitive detection techniques. The measured detection limit can reach 6.9×10^{-6} A/m at 1 Hz (54), which compares with that of fluxgate magnetometers.

Figure 22. Magnetostrictive force sensor based on the Villari effect.

Another type of magnetometer consists of a magnetostrictive film bonded to an optic fiber. When the sensor is exposed to magnetic fields, the magnetostrictive material deforms and induces a deformation in the optic fiber. This causes changes in the optical path length of laser beams that pass through the optic fiber and can be detected by an interferometer (55). Highly sensitive metallic glass ribbons have been employed in devices so designed that yield quasi-static resolutions from 1.6×10^{-3} – 8.0×10^{-3} A/m (56). Finally, a diode laser interferometer has been used to detect changes in the length of a Terfenol-D rod that are produced when a magnetic field is applied (57). A maximum sensitivity of 160×10^{-6} A/m was achieved, although certain non-linear dependences were observed that make it critical to operate the sensor within its optimum mechanical preload range.

Force Sensors. By employing the Villari effect, it is possible to realize a simple and rugged force sensor from either crystal or amorphous magnetostrictive materials. The magnetostrictive attribute that provides the operating principle for such a sensor is the dependence of magnetization on the state of stress in a material. To illustrate, the design in Fig. 22 consists of two magnetostrictive elements, one surrounded by an excitation coil and the other surrounded by a pick-up coil, and two rigid end plates. In one mode of operation, an ac voltage is applied to the excitation coil that generates a magnetic flux in the sensor and a corresponding voltage in the sensing coil. As a force is applied, the magnetostriction in the elements produces a change in the magnetic flux that is detected as a proportional voltage change in the pick-up coil. In a second mode of operation at constant flux, the excitation voltage is allowed to change to maintain a constant pick-up coil output voltage. The change in excitation voltage is then related to the change in the applied force. Compared to conventional force sensors such as those based on strain gauges, this sensor is simpler, more rugged, and requires simpler electronics. A similar Villari effect sensor based on amorphous ribbons has been discussed in (58). Numerous other designs have been discussed or patented, including

percussion sensors, pressure sensors, and force sensors based on magnetoelastic strain gauges. The reader is directed to (2) for further details and references.

Transducer Models

Fundamental models of the performance of magnetostrictive materials used in smart structure systems are particularly difficult to develop. The difficulty lies in the coupling between regimes and the strong nonlinear dependence of material behavior on operating conditions and the hysteresis inherent in the materials. Notwithstanding, models based on physical principles are necessary to optimize transducer design and control, particularly considering that first-principles models provide the ability to *scale the results* in a sense that empirical models typically do not. These include magnetization models based on Preisach, Stoner–Wohlfarth, Jiles–Atherton, and micromagnetic theories, as well as domain rotation and higher order magnetostrictive models. However, comprehensive models for designing and controlling integrated smart structure systems must address the interaction between the magnetostrictive material’s elastic, magnetic, thermal, and electrical regimes and the dynamics of the underlying structure. This can include elastic dynamics and also acoustics attributes. Following is an overview of models that have been employed to design and control magnetostrictive transducers. The reader is directed to the references for more comprehensive details on individual modeling techniques.

Piezomagnetic Constitutive Equations. Piezomagnetic models analogous to those classically employed for piezoceramics can prove useful for low drive level applications where hysteresis is minimal and behaviors are quasi-linear. Neglecting thermal effects, the total strain ε of a magnetostrictive material includes two contributions: (1) the magnetostriction λ produced by the rotation of magnetic moments as they align with externally applied magnetic fields and (2) a purely elastic component $\varepsilon = s\sigma$ of the kind found in conventional nonmagnetic materials. Analogously, the magnetic induction B consists of two contributions: (1) a magnetomechanical component dependent on the stress and (2) the constant-stress magnetic constitutive law $B = \mu H$. From these considerations, the constitutive linearized equations that describe magnetostriction or piezomagnetism can be written in differential form, as follows:

$$\begin{aligned}\Delta\varepsilon &= s^H \Delta\sigma + d \Delta H, \\ \Delta B &= d^* \Delta\sigma + \mu^\sigma \Delta H,\end{aligned}\quad (9)$$

where ε is the total strain in the magnetostrictive material, s^H is the compliance at constant field H , d and d^* are the piezomagnetic coefficients, σ is the stress, B is the magnetic induction, and μ^σ is the magnetic permeability at constant stress.

The ratio of fundamental constants $k^2 = d^2 / (s^H \mu^\sigma)$ for this one-dimensional linearized case provides a formulation which has been of value in describing the magnetomechanical coupling coefficient k of magnetostrictive

materials. This coupling coefficient provides a measure of the conversion efficiency between magnetic and mechanical energies. Specifically, the magnetomechanical coupling coefficient squared represents the fraction of maximum stored magnetic energy that can be converted into elastic energy or conversely, the fraction of maximum stored elastic energy that can be converted into magnetic energy. It has been shown (59) that k can be expressed in terms of suitable internal energies,

$$k = \frac{U_{me}}{\sqrt{U_e U_m}},$$

in which $U_{me} = (1/2)Hd^*\sigma$ is the magnetic energy due to elastic energy, $U_e = (1/2)s\sigma^2$ is the elastic internal energy and $U_m = (1/2)\mu H^2$ is the magnetic internal energy. Note that these expressions for k are based on the intrinsic assumption of piezomagnetic reciprocity, that is, $d = d^*$ and $U_{me} = U_{em} = (1/2)dH\sigma$. In that sense, these expressions must be employed strictly within the linear operating regimes in which the reciprocity assumption is sufficiently accurate. Typical values of the coupling constant are provided in Table 1. Further details can be found in (1,8).

The piezomagnetic model given by Eq. (9) has been augmented by adding saturation phenomena, temperature dependences, and the quadratic relationship between the magnetization and free strains given by Eq. (8). This higher order anhysteretic model has been described elsewhere (4). Like the original formulation from which it derives, this augmented model has the advantage of simplicity in addition to adding certain nonlinear features. In this model, however, complete nonlinear phenomena or hysteretic effects can be addressed only by using complex model parameters. Furthermore, this model addresses material attributes primarily but disregards important transducer effects such as the electrical and dynamic regimes. These effects have been addressed to some degree by coupling the piezomagnetic equations (9) with transducer models such as the linearized canonical equations for electromechanical transducers,

$$\begin{aligned}V &= Z_e I + T_{em} v, \\ F &= T_{me} I + z_m v,\end{aligned}\quad (10)$$

that describe the behavior of a “black box” analog of a transducer system that consists of two coupled electrical and mechanical regimes (60,61). In these equations and Fig. 23,

Figure 23. Schematic representation of an electromechanical transducer.

V and I are the voltage and current in the coil, Z_e is the blocked electrical impedance (electrical impedance that is observed when the mechanical system is prevented from moving), F and v are force and velocity on the mechanical side, z_m is the mechanical impedance, and T_{em} and T_{me} represent transduction coefficients that describe the electromechanical coupling. Although this model is phenomenological, certain loss mechanisms based on physical effects such as eddy currents have also been incorporated (1).

Magnetization Models. Magnetization plays a fundamental role in both the magnetostriction that arises from the rotation of magnetic moments (actuator mode) and the change in magnetic anisotropy that occurs when the material strains (sensor mode). From a modeling perspective, the hysteretic phenomena that arise as magnetic moments rotate in response to magnetic fields, stresses, or thermal energy are often the primary magnetization attribute that needs to be quantified. Models for magnetization hysteresis in ferromagnetic materials range from micromechanical models to phenomenological characterizations. Micromechanical models (28,62) describe the coupled magnetoelastic interactions through first-principles formulations that involve the elasticity, thermodynamics, and the electromagnetic energy states. This can lead to highly accurate results at the magnetic domain level, but the large number of parameters required currently prohibits implementing micromechanical models at the system level. The Preisach model has been extensively used to characterize the magnetization of ferromagnetic materials, and more recently of magnetostrictive materials as well (63–66). This model approximates the multivalued hysteretic map by employing a parallel collection of operators. This method has the advantage of intrinsic generality, but typically it requires identifying a large number of nonphysical parameters, and it does not employ or provide insights regarding the dynamics of the system. One advantage of this method is that the Preisach operator can be inverted to facilitate linear control design. Domain rotation models include the classical anisotropic formulation of Stoner and Wohlfarth (18) and later extensions to include cubic anisotropies (67) and compressive loading effects (19). A more complete generalization includes anisotropy, magnetoelastic, and field energies in all three spatial directions (20). Although model results agree well with measured data, identifying the fractional occupancies that define the participation of different easy axes in the total magnetization is rather complex. The domain wall theory of Jiles and Atherton has provided accurate results in ferromagnetic (68), magnetostrictive (30,69), and ferroelectric (70–72) materials. This model is constructed from a thermodynamic difference between the magnetic energy available to magnetize a material and the energy lost as domain walls attach to and detach from inclusions or pinning sites in the material. This yields a set of differential equations that depend on five physical parameters which quantify reversible, irreversible, and total magnetization changes. In the limit when domain wall pinning goes to zero, the Jiles–Atherton model reduces to Langevin’s anhysteretic function, although alternative anhysteretic models that employ

the Isin spin relation have been studied (72). Finally, the Jiles–Atherton model has been employed in combination with Eq. (8) to map the H – λ constitutive relationship (24), and later with dynamical transducer effects to provide a set of reciprocal constitutive relationships among H , M , ε , and σ (30,69). This modeling approach has proven useful in inverse compensation designs (73), characterization of collocated actuation and sensing in transducers (74), and quantification of the ΔE effect in magnetostrictive materials (75).

CONCLUDING REMARKS

Magnetostrictive materials are a class of smart materials that can convert energy between the magnetic and elastic states. The phenomenon of magnetostriction is ultimately due to the coupling between magnetic moment orientation and interatomic spacing, or magnetomechanical coupling. This type of coupling provides a mechanism for bidirectional conversion of energy between magnetic and elastic regimes which is attractive for actuator and sensor systems because it does not degrade in time and it provides almost immediate response. Newer materials such as Terfenol-D or amorphous metallic ribbons exhibit a unique combination of high forces, strains, energy densities, operating bandwidths, and coupling coefficients that justify their use in an ever-increasing number of applications ranging from micropositioners to vibration control systems for heavy machinery. The excellent performance of magnetostrictive materials is sometimes obscured by the large magnetic hysteresis losses and substantial nonlinear effects exhibited by these materials when operated at the high regimes in which their attributes become more prominent. In this sense, realizing the full potential of magnetostrictive materials presents rigorous engineering challenges in a way that other less capable smart materials do not. However, as evidenced by the increasing number of patented devices based on magnetostrictive principles, designers continue to overcome these challenges and make advances in designing, modeling, and controlling magnetostrictive transducers. Furthermore, clever transducer designs are possible solely due to the rich performance space that arises from the otherwise undesirable nonlinear characteristics of these materials. As material advances continue, it is expected that magnetostrictive device designers will find new magnetostrictive solutions for an ever-growing variety of transducer applications.

MICROROBOTICS, MICRODEVICES BASED ON SHAPE-MEMORY ALLOYS

YVES BELLOUARD

Institut de Systèmes Robotiques
Ecole Polytechnique Fédérale de Lausanne
Switzerland

INTRODUCTION

For the past few years, consumer products such as computers, mobile phones, and cameras have drastically decreased in size and their functionalities have increased. In addition, mini-invasive techniques in surgery have led to a growing need for small, highly reliable components that can go through arteries or veins. In general, there are nearly no highly technological products that do not benefit from miniaturization. However, one cannot simply scale down electrical or mechanical components from “macroscale” because physical forces do not scale down at the same amplitude. Therefore, the efficiency of actuators depends on their size. Consequently, there is a need for new actuating technologies adapted to the microworld

that can replace usual actuators such as electromagnetic motors. Among these technologies, smart materials such as piezoceramics, magnetostrictive, electrostrictive, and shape-memory materials are of particular interest. This article describes the use of shape-memory alloys (SMA) for microengineering applications.

In the first part, a brief description of SMA properties is given. The second part addresses some usual design principles. Finally, a literature survey and a concept of monolithic microdevices concludes the article.

SHAPE-MEMORY ALLOYS (SMA): A SUMMARY OF THEIR PROPERTIES

Properties of SMA: A Brief Description

Three main functionalities can be associated with the martensitic transformation: the shape-memory effect, superelasticity, and high damping capability. Special care is taken to describe the shape-memory effect, which is the essence of the SMA actuator. For a thorough understanding, the reader may refer to other sections of this encyclopedia. General books about SMA material may also be consulted (1–3).

The shape-memory effect. This happens when a material, previously deformed in martensite—the low-temperature phase—recovers its original shape when heated up to the austenite—the high-temperature phase. Figure 1 illustrates the shape-memory effect. The graph on the left side represents the stability zone for the two phases in a stress–temperature representation. According to the Clausius–Clapeyron relationship between stress and temperature, the oblique lines indicate the boundary between phases and the transition period. The martensitic transformation occurs across a given range of temperature (M_s to M_f , from austenite to martensite and A_s to A_f , from martensite to austenite).

Let us consider an example: a strip that is flat in the austenite phase, that is, the “memorized shape” (step 1 in Fig. 1). If a stress is applied below the martensite finish temperature (M_f) and if this stress is higher than the critical stress to detwin martensite, the variant reorientation occurs, and the strip is deformed in a plasticlike way (step 2). This means that when the stress is released, almost all of the deformation remains. When the material is heated above A_f (step 3), the material transforms to austenite and recovers its original shape. Repetitive cooling (step 4) does not cause any shape change.

The term “one-way, shape-memory-effect” is often used to address this effect, because it is a one-time occurrence; the material keeps its original austenitic shape upon further cooling cycles below M_f . Because nonoriented martensite is created upon cooling, martensitic structures have the same specific macroscopic volume as the austenitic crystal. A plasticlike deformation of martensite (“detwinning”) is required to observe a shape change while heating up to the austenite. This phenomenon can be well understood using a one-dimensional phenomenological model

Figure 1. An example of the one-way shape-memory effect: step-by-step description and representation in a stress–temperature diagram.

(Fig. 2). This description is considerably simplified, but it conveys some of the fundamental aspects of the shape-memory effect.

Two martensitic variants are symbolically represented by vertical and horizontal rectangles (M1, M2). The material is assumed to be free of any internal stress. When there is no stress (set 1), the martensitic variants are randomly

distributed: each variant has the same probability. When applying a force (set 2), the variants are reoriented to minimize the stress within the structure. Therefore, the distribution between the two variants is modified. When heated because the austenite that is symbolically represented by a square has higher symmetry than martensite, the two martensitic variants are transformed into the same

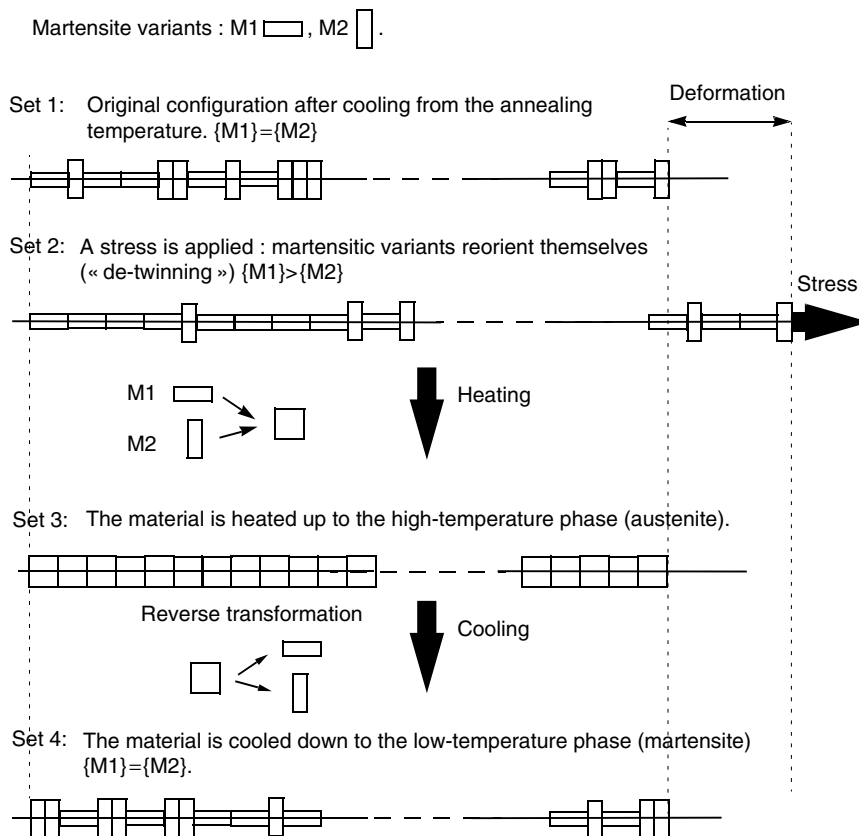

Figure 2. A one-dimensional phenomenological description of the one-way shape-memory effect. The twinned martensitic variant occupies the same specific volume as the austenitic.

“crystallographic” structure, the so-called parent phase: whatever the set of martensite variants is (set 1 or set 2, for instance), the parent shape will be the same. On cooling (set 4), if no stress is applied, the two martensitic variants are equally distributed: the macroscopic shape will remain the same as the austenitic shape. This nonreversibility, from the point of view of change of shape, is the basis for understanding the design of shape-memory actuators. As we see later, all of the design concepts deal with methods for obtaining a reversible effect.

The Superelastic Effect. This occurs when the martensitic transformation is induced by applying a stress at a constant temperature. Figure 3 shows a schematic representation of the superelastic transformation on stress–temperature and stress–strain graphs. The material in its austenitic state is loaded at a constant temperature. The mechanical transformation is purely elastic until the stress reaches a critical level where the transformation starts. At this point, the stress remains constant, and the strain is still increasing. This region, usually called the stress “plateau” extends until the strain has reached typically 8% and even 15% or more for single crystals. When all of the austenite has been transformed into martensite, another elastic domain can be observed that corresponds to the elasticity of the martensite. When unloading, the material displays hysteresis. It is very important to note that the stress level of the plateau is temperature-dependent.

Dissipation Mechanism and Damping

Due to a large density of mobile interfaces between martensitic variants and the austenitic matrix during martensitic transformation, the material displays a very efficient energy dissipation mechanism. Moreover, in martensite, these alloys have very high damping capacity due to internal friction of martensitic variants. Unlike other high-damping metals, the dissipation mechanism in SMAs

does not significantly affect other important mechanical parameters of the material. The high damping capacity of SMA has been successfully used in composite structures that have embedded shape-memory fibers (4) as well as in developing a competition ski (5):

Material Selection (see “Shape Memory Alloy, Types and Functionalities” in this Encyclopedia for an in-depth Description)

Among all of the shape-memory alloys, three main types are commercially available: Ni–Ti–X (where X is an additional component such as Cu, Pd, Hf), Cu–Zn–Al, and Cu–Al–Ni. Ni–Ti alloys are the most interesting for many reasons: they are ductile (about 30 to 40%), biocompatible (binary alloys), and they have high electrical resistivity, which allows efficient actuation by Joule heating.

To appreciate the mechanical properties of Ni–Ti alloys, Table 1 compares Ni–Ti alloys to stainless steels. Ni–Ti alloys have other useful properties such as high wear resistance (6) and good corrosion resistance. Moreover, some Ni–Ti alloys have an additional martensitelike transition: the so-called R-phase transition (1,2). The R-phase transition appears upon cooling before the martensitic transformation under certain conditions of material fabrication and processing. This phase has a narrow hysteresis (nearly 1.5°C) and very good thermal cycling stability. For these reasons, the R-phase has been used in many actuator applications. However, the strain is fairly small (about 1%).

SMA Compared to Other Smart Materials and Bimorph Structures

Criteria for comparison between smart materials obviously depend on the application specifications, functionalities, and technological aspects such as machinability, miniaturization capability and control properties.

Figure 3. Superelastic behavior: representation on stress–temperature (left) and stress–strain graphs (right). The hatched zone represents the superelastic window, that is the temperature window where the material is fully transformed to martensite when loading and where no residual strain due to incomplete transformation is observed when unloading. Datas displayed on the graph are for a binary NiTi and a stainless steel.

Table 1. Mechanical Properties of Ni-Ti Compared to Stainless Steel^a

	Ni-Ti		Typical Data for a Stainless Steel	
Max. reversible elastic deformation	Typ. 8%		0.8%	
Mass density	6450 kg.m ⁻³	12.52 slugs.ft ⁻³	7850 kg.m ⁻³	15.2 slugs.ft ⁻³
Young's modulus (<i>E</i>)	M: 28–41 Gpa A: 83 GPa	M: 4–6 × 10 ³ ksi A: 12 × 10 ³ ksi	190–210 GPa	28–30 10 ³ ksi
Shear modulus (<i>G</i>)	M: 10–15.5 GPa A: 31 GPa	M: 1.5–2.2 × 10 ³ ksi A: 4.5 × 10 ³ ksi	75–80 GPa	11–12 10 ³ ksi
Poisson's ratio (<i>ν</i>)	0.33		0.27–0.30	
Yield stress ^b	A: 195–690 MPa M: 70–140 MPa	A: 28–100 ksi M: 10–20 ksi	400–1600 ^c MPa	60–240 ^c ksi
Ultimate stress	895–1900 MPa	130–275 ksi	700–1900** MPa	100–270** ksi
Coefficient of thermal expansion	A: 11 × 10 ⁻⁶ /°C M: 6.6 × 10 ⁻⁶ /°C	A: 6.11 × 10 ⁻⁶ /°F M: 3.67 × 10 ⁻⁶ /°F	8–10 10 ⁻⁶ /°C	4.5–5.5 10 ⁻⁶ /°F

^aThe data on Ni-Ti, are taken from (2,7). The data for stainless steel are taken from (8). "A" refers to austenite and "M" refers to martensite.

^bThe yield stress for the SMA is not really a yield stress but rather a critical stress to induce martensite when in the austenitic state and a critical stress to reorient martensitic variants when in the martensitic state.

^cThese values apply typically to a spring steel.

However, comparing several physical properties of different smart materials allows a quick assessment of some of the major advantages and drawbacks of shape-memory materials (Table 2). The energy density of SMA is the highest. However, the bandwidth is rather small compared to magnetostrictive and piezoelectric material, for instance. Considering the working mode, SMA can be loaded in bending, torsion, tension, and compression. Unlike bimorph actuators or conducting polymers where the bending response is a consequence of the actuator structure, the stress/strain response will depend on the direction of the applied strain. Piezoelectric and giant magnetostrictive also have different working modes that will correlate with polarization and the applied field. Conducting polymers can achieve higher strain than SMA materials. However, Young's modulus of conducting polymers is rather low compared to SMA.

DESIGNING SMA ACTUATORS: GENERAL PRINCIPLES

Introduction

Now, it is clear that SMAs have some very interesting properties that can be used for actuating. Their unique behavior requires some appropriate design principles based on material properties.

Because the shape-memory effect is a one-time occurrence, it is not sufficient to create a reversible actuator. To bypass this intrinsic property, two main strategies can be pointed out:

- The first is to find a way to make the material reversible by itself without any external "help." This requires thermomechanical treatment or specific manufacturing processes.

Table 2. Comparison Between SMA and Other Smart Materials and Bimorph Actuators

	SMA	Piezoelectric	Giant Magnetostrictive	Conducting Polymers (11)	Bimorph Actuators
Physical phenomenon	Martensitic transformation	Piezoelectricity	Magnetostriction	Electrochemical doping	Differential thermal expansion coefficient
Actuation principle	Thermal	Electrical field	Magnetic field	Voltage	Thermal
Energy density (J m ⁻³)	~10 ⁶ to 10 ⁷	~10 ² (PZT) ~10 ³ (PMN) (9)	~10 ⁴ –10 ⁵ (Terfenol D) (9)	~10 ³	~10 ⁵ (Ni / Si) (10)
Bandwidth (order of magnitude)	Low ^a (10 ² Hz)	High (100 kHz)	High (100 kHz)	High (10 kHz)	Low ^a (10 ² Hz)
Working mode	Bending, torsion, tension, compression	Depends on the electrical field direction	Depends on the magnetic field direction	Electrolyte storage scheme	Bending
Typical strain	1–8% ^b	0.12–0.15%	0.58–0.81%	>10%	~5, 23 10 ⁻⁴ %/C

^aStrongly size and shape dependent.

^bDepends on the lifetime specification. For single crystals, the maximum strain can increase up to 15%.

- The second consists of using an additional element, usually called a biasing element, which will be used as a buffer to provide the required energy to reorient the martensite upon cooling and thus “reset” the actuator.

Another important thing to notice is the complexity of the thermomechanical behavior of these alloys: they have non-linear, dissipative, and temperature-dependent mechanical behavior. Therefore, usual design methods based on linear mechanics of structure, for instance, Castigliano’s theorem and the superposition principle, are valid only in the elastic domain of the mechanical characteristic. Nevertheless, the isothermal behavior can be simulated reasonably accurately by using an elastoplastic model. In addition, several models, which consider thermomechanical coupling, have also been proposed in the literature [see, for instance, (12–14)].

Study of Some Loading Modes

The shape-memory effect can be used in any direction of space. This means that an SMA actuator can work under tensile–compressive stress, bending load, torsion load, or any combined mode. This kind of isotropy greatly enhances the design capabilities of these materials. The trade-off between one loading mode and another can be done, depending on actuator specification such as stroke, force, volume, efficiency, etc.

In the next section, we examine briefly some usual loading modes. A simple way to convey isothermal mechanical behavior is to consider elastoplasticlike behavior, such as that shown in Fig. 4.

This kind of approximation can be used for a superelastic curve as well as a martensitic curve. In the martensitic case, the critical stress will refer to that required to induce a reorientation of martensitic variants, above A_f , and the critical stress will refer to the plateau’s stress.

Tension. This is the simplest loading mode; the material is axially loaded. The normal stress is uniformly distributed within the material. The force is directly

Figure 4. Isothermal elastoplastic model of the SMA mechanical characteristics.

Figure 5. Pure bending loading mode.

proportional to the normal stress. In term of efficiency of energy transformation, this is the optimal mode because all of the material contributes to the transformation. Nonetheless, the motion range is very small.

Bending. Stress distribution in the bending mode is not constant across the material. Figure 5 shows a cantilever subjected to bending deformation. The outer part of the material is in tension and the inner part is in compression. The strain on the neutral fiber is equal to zero, and in a first approximation, the position of the neutral fiber can be mixed with the center of gravity. To characterize the stress distribution, the deformation process during loading can be divided into periods of different deformation mechanisms (8,15) (see Fig. 5). The first period is determined by pure linear-elastic deformation behavior until the stress reaches a critical value corresponding to the beginning of the stress-induced martensitic transformation. The second period is a combination of elastic deformation and ideal-plastic deformation. In a first approximation, the behavior upon loading can be approximated by elastoplasticlike behavior. In this case, the tensile behavior, it is assumed, is the same as compressive behavior. However, Liu et al. (16) showed that this assumption is not true for Ni–Ti alloys: there is no real “plateau” in compression but rather a decrease of the slope of the stress–strain curve. Therefore, Eq. (1) is a rough approximation. The accuracy of this model can be enhanced by adding a strain hardening condition. Let σ_R be the critical stress to induce a reorientation of the martensite, where a cantilever beam of thickness h and width b is considered. Let R be the radius of curvature and z the relative thickness measured from the neutral line which, in a first approximation, can be considered the center of the strip. The strain is a function of z and is equal to z/R . If it is assumed that the cantilever is in the austenitic state, the stress within a section of a cantilever beam can be expressed by

$$\sigma(z) = \begin{cases} E \frac{z}{R} & z \leq z_R \\ \sigma_R & z > z_R \end{cases}$$

where

$$-\frac{h}{2} \leq z \leq \frac{h}{2}, \quad (1)$$

where z_R is the boundary between the elastic and the transformed zones.

Therefore, the bending moment can be written

$$M = \int_A z\sigma(z)dA = \frac{2}{3} \frac{Ebz_R^3}{R} + b\sigma_R \left(\frac{h^2}{4} - z_R^2 \right). \quad (2)$$

The first term of the bending moment expresses the elastic contribution, and the second term denotes the plasticlike mechanical behavior of the transformed region.

Assuming $z_R = \sigma_R R/E$, the bending moment can be written as a function of the radius of curvature:

$$M(R) = \begin{cases} \frac{bh^2}{4} \sigma_R - \frac{b\sigma_R^3 R^2}{3E^2}, & R \leq \frac{Eh}{2\sigma_R} \\ \frac{bh^3}{12} \frac{E}{R}, & R > \frac{Eh}{2\sigma_R} \end{cases}. \quad (3)$$

Torsion. As in bending, the stress distribution is not uniform (see Fig. 6). Consider a wire to which a pure torsion moment is applied: the middle of the wire remains in the elastic region, and the first transformed region is on the edge. Let M_t be the torsional moment, τ the shear stress, G the shear modulus, r the radius along the cross section of the wire, R the wire radius, and θ the twist angle per unit length.

Assuming elastoplastic behavior, the shear stress is

$$\tau = \begin{cases} Gr\theta, & 0 \leq r \leq r_T \\ \tau_R, & r_T < r \leq R \end{cases}, \quad (4)$$

where τ_R is the transition between the elastic region and the transformed region. The torsional moment Γ is:

$$\begin{aligned} \Gamma &= \int_A \tau r dA = 2\pi \int_0^R \tau r^2 dr \\ &= 2\pi \left[\int_0^{r_T} (Gr\theta) r^2 dr + \int_{r_T}^R \tau_R r^2 dr \right]. \end{aligned} \quad (5)$$

Figure 6. Loading mode in pure torsion.

The first integral expresses the elastic contribution, and the second expresses the contribution of the transformed region. Thus, the torsional moment can be written as a function of the twist angle φ :

$$\Gamma(\varphi) = \begin{cases} \frac{\pi r^4}{2} \frac{G\varphi}{L}, & \varphi \leq \frac{\tau_R L}{GR} \\ 2\pi \left(\tau_R \frac{R^3}{3} - \frac{1}{12} \frac{L^3 \tau_R^4}{G^3 \varphi^3} \right), & \varphi > \frac{\tau_R L}{GR}, \end{cases} \quad (6)$$

where L is the length of wire.

Application Example: Equation of a SMA Helical Spring.

Let us consider a spring whose outer radius is ρ , wire radius is R , and has n coils. Considering the expression of torsion from (Eq. 6), the moment becomes

$$\Gamma_t = P \frac{\rho}{2} = \begin{cases} \frac{\pi r^4}{2} \frac{G\varphi}{L}, & \varphi \leq \frac{\tau_R L}{GR} \\ 2\pi \left(\tau_R \frac{R^3}{3} - \frac{1}{12} \frac{L^3 \tau_R^4}{G^3 \varphi^3} \right), & \varphi > \frac{\tau_R L}{GR}. \end{cases} \quad (7)$$

The deflection can be expressed by

$$\delta = \rho L \varphi = 2\pi n \rho^2 \varphi. \quad (8)$$

Substituting Eq. (8) for φ in Eq. (7), we find the equation for an SMA helical spring:

$$P = \begin{cases} \frac{Gr^4}{4n\rho^3} \delta & \delta < \delta_e \\ \frac{2\pi \tau_p r^3}{3\rho} \left[1 - 2 \left(\frac{\pi n \tau_p \rho^2}{G\delta r} \right)^3 \right] & \delta \geq \delta_e, \end{cases}$$

where

$$\delta_e = \frac{\rho \tau_p}{GR}. \quad (9)$$

Tobushi and Tanaka (17) showed that this method provides reasonably accurate results in analyzing a SMA helical spring.

Creating a Reversible Actuator: The External Way

Several studies, for instance, Hirose et al. (18), Waram (1), and Liang and Rogers (13), have been conducted to give basic principles for SMA actuator design. This section gives an overview of these basic design principles.

Constant Force Loading and Transformation under Constraint. The simplest actuator is one working under constant force loading or deadweight (Fig. 7). The stroke is given by the intersection between austenitic and martensitic mechanical characteristics and the straight line corresponding to the force level. If the actuator is mechanically constrained during the transformation to the high-temperature phase, recovery stresses are generated at a constant stress rate (2) until the stress reaches the

Figure 7. Constant force loading of a SMA actuator. A^*f and M^*f are the end-of-transformation temperatures for a given load P .

yield strength of the material. Using the constrained recovery property, one can design a fixture that has a grasping force nearly independent of the tolerances of the grasped object. In addition, the stress is well defined. A detailed and clever presentation of constrained recovery can be found in Duerig and Proft (1).

Figure 8 illustrates this phenomenon: for a stainless steel fixture, the applied force will be variable depending on the stiffness of the fixture and the tolerances of the object. However for SMA fixtures that have at least 1.5% of unresolved recovery, the force remains nearly constant whatever the object's tolerances are.

Spring-Biased Actuator ("Pullback Spring Design"). In this configuration, a passive mechanical element is used to apply a force on the SMA element. This mechanical element or "bias spring" has a known elastic characteristic.

Figure 9 illustrates the principle of this actuator. The SMA element and the bias spring are symbolically represented by two helical springs attached together. The output of the mechanism is symbolically represented by a black rectangle. It is clear that this concept is general and

Figure 8. Illustration of the constant clamping force obtained using the constrained-recovery property of an SMA material.

applies for any kind of SMA design and bias spring characteristics. During the assembly process, the SMA is deformed and prestressed in its martensitic phase (distance OO' in Fig. 9). When the SMA element is heated up to the austenitic temperature, the material tries to recover its original shape and thus generates a recovery force. This force pulls the bias spring which stores some elastic energy. When cooling, the reverse transformation occurs resulting in a change in the mechanical characteristics within the SMA (a decrease in Young's modulus and nucleation of martensitic variants). Thus, the elastic energy stored by the bias spring is released and induces the reorientation of martensitic variants resulting in macroscopic deformation of the SMA element. The two equilibrium points (A and B) can be found by using the corresponding isothermal loading curves of the SMA element.

Antagonistic or "Push-Pull Design". The push-pull actuator consists of two SMA elements that move in opposite directions. A design is shown on the left side of Fig. 10. In this example, it is assumed that the two SMA springs are identical. The motion reference is taken between the two SMA actuators. As for the spring-biased actuator, the structure is prestressed to deform each SMA element in martensite. The principle is to heat up one actuator at a time. The heated element pulls the mobile part in its direction and deforms its counterpart. Inverting the actuation between the heated SMA element and the cool element has the reverse motion. The graph on the right side of Fig. 10 represents the mechanical characteristics of the two actuators: the intersection between the martensitic characteristic of one of the actuators and the austenitic characteristic of the other gives the two extreme positions of the linear stage. Between these two points, different paths are available, depending on heating/cooling strategy. For example, one can choose to supply one actuator at a time or to modulate the power applied to the two actuators at the same time: the dynamic behavior will be different.

Creating a Reversible Actuator: The Internal Way

The Two-Way Shape-Memory Effect (Induced by a Training Process). The "two-way" shape-memory effect (TWSME) (1,2,19), in contrast with the "one-way" shape-memory

Figure 9. Design characteristics of a SMA actuator working against a bias spring. K denotes the stiffness of the bias spring. A_f^* and M_f^* are the end-of-transformation temperatures for a given prestrain length (OO') and stiffness K .

effect, is reversible. This means that the material “memorizes” a shape when cooling, resulting in a spontaneous shape change without any external stress. However, this effect is not intrinsic to the alloy properties: as mentioned by Perkins and Hodgson in (1), this is “learned” behavior. In other words, the material must be subjected to special thermomechanical treatments to exhibit this strange effect. The term “training process” is often used to describe these processes. The TWSME can be explained by the presence of internal stress that results from the training process and creates a given distribution of martensitic variants upon cooling. In the opposite of the one-way effect, the TWSME, preferred oriented martensitic variants are created. The TWSME usually has strain amplitude between 1 and 2%. However, the force generated when heating is much larger than when cooling. This drawback limits the TWSME to specific applications. In the next sections, other methods, that have a reversible effect, are presented. Nevertheless, for better understanding, the term TWSME is reserved throughout this article to the reversible motion induced by training processes.

All-Round Effect [20]. This effect has been observed in Ni-rich Ti–Ni alloys (Ni content > 50.6 at%) (Fig. 11): a flat strip is annealed under constraint into a round shape at a temperature where formation of precipitates is possible (typically above 673 K). After this heat treatment, the specimen has a ring shape in austenite and an

opposite ring shape in martensite so that the inner part of the ring becomes the outer part and vice versa. Kainuma et al. (20) described the mechanism of this phenomenon: oriented precipitates are created within the structure. Under compression, these precipitates have a given orientation, which is perpendicular to the orientation of the precipitates formed in tension. When the specimen is annealed in a round shape, the inner part of the strip is in compression, and the outer part is in tension, resulting in two different groups of oriented precipitates that are perpendicular to each other. When cooling, due to the internal stress induced by precipitates, preferred oriented martensite variants appear, leading to the opposite round shape.

Irradiation. Neutron irradiation can suppress martensitic transformations in Ti–Ni alloys (21). By controlling this effect, one can create a cantilever beam, for example, half of whose thickness is irradiated, and the other half is unaffected. The lattice in the irradiated zone has been altered and does not exhibit any martensitic transformation. Using the irradiated part as the biasing element and the unaffected zone as the actuator allows creating a reversible motion. In a certain way, a bimorphlike structure is created, and the resulting motion is a bending motion (21).

Special Production Methods. Some fabrication processes can create reversible effects in SMA. For instance, melt

Figure 10. Characteristics of an antagonistic design of SMA actuators. A_f^* and M_f^* are the end-of-transformation temperatures for a given prestrain (OO') and mechanical characteristic of an SMA actuator.

Figure 11. Mechanism of the all-round shape-memory effect [after Kainuma et al. (20)].

spinning produces an intrinsic reversible effect under certain conditions (22). Another example is the fabrication process of Ni–Ti shape-memory films developed by Lehnert et al. (23). The method consists of successively depositing pure layers of Ni and Ti ranging from 10 to 20 nm thick. The heat process allows interdiffusion of Ni and Ti and subsequent crystallization. This process leads to an intrinsic two-way effect resulting in a bending motion.

Outlook for Reversible SMA Actuators

SMA actuators can be divided into two categories, depending on the method used to produce the reversible effect (Fig. 12). The first, called *monolithic*, refers to methods for which no external elements are used to produce the reversible effect, and the second, called *multiparts or mechanism*, refers to a reversible effect obtained by adding a second element. The subclass “smart design” denotes the use of design strategies to obtain a reversible motion within a single piece of material. These design methods are presented later.

Thermal Response of SMA Actuators

Time response is the well-known limitation of shape-memory alloys. Because the actuation method is thermal,

only a limited bandwidth can be achieved. However, as the mass decreases, scaling down SMA actuators increases their time response. Table 3 shows the thermal and related properties of Ni–Ti alloy compared to pure copper.

Modeling heat transfer within an SMA can be a tough job if all effects are considered. However, using a few assumptions, the transient response can be evaluated reasonably accurately. One of the basic assumptions is to use the lumped capacitance method. In this method, the solid, it is assumed, is spatially uniform at any instant during the transient process. In other words, the temperature gradient within the solid is negligible, and the thermal equilibrium equation can be written as follows:

$$\rho Vc \frac{dT}{dt} = Q_h - (Q_{\text{conduction}} + Q_{\text{convection}} + Q_{\text{radiation}}), \quad (10)$$

where ρ is the material density, V the volume, c the specific heat, T the temperature, and Q_h denotes the heat source. Considering the usual working temperature of SMA actuators and an application at ground level, the loss by radiation can be neglected ($Q_{\text{radiation}} = 0$). Convection is simply expressed by $hA(T - T_\infty)$, and the conduction heat loss should be evaluated depending on the application. Then, the transient response can be expressed as

$$T(t) = \begin{cases} T_\infty + \frac{Q}{hA} [1 - e^{-t/\tau}] & \text{(heating)} \\ T_\infty + (T_0 - T_\infty)e^{-t/\tau} & \text{(cooling)} \end{cases} \quad (11)$$

where T_∞ is the temperature of the surrounding medium, T_0 the initial temperature, A the area of the material, V the volume, h the convection coefficient, and Q describes the uniform heat medium. The time constant τ is simply $\tau = \rho Vc/hA$, where ρ is the density and c the specific heat. For electrical heating, which is the most common way to provide heat to an SMA actuator, Q is equal to I^2R , where I is the current through the material and R is the electrical resistance.

Using Eq. (11), the heating and cooling time can be expressed by

$$t = \begin{cases} \frac{\rho Vc}{hA} \ln \left(\frac{T - T_\infty}{T_0 - T_\infty} \right) & \text{(cooling)} \\ \frac{\rho Vc}{hA} \ln \left[\frac{(T - T_\infty) - \frac{Q}{hA}}{(T_0 - T_\infty) - \frac{Q}{hA}} \right] & \text{(heating)} \end{cases} \quad (12)$$

However, this simple approach does not consider the release and absorption of internal latent heat due to the phase transformation. Therefore, using Eq. (12), the time response is always underestimated. To include the effect of latent heat, a method used is based on a temperature-dependent specific heat. For instance, Brailovski et al. (24) considered a polynomial approximation of the specific heat during the transformation, where the polynomial's coefficients are determined by using differential scanning calorimeter (DSC) measurements. The delay introduced by the phase transformation is often negligible in heating. It is also interesting to note that the latent heat depends on

Figure 12. SMA reversible actuators: an outlook on the known methods for producing reversible motion.

Table 3. Thermal Properties of SMA vs. Copper at 300 K

	Ti-Ni	Copper (pure)
Density	6450 kg·m ⁻³ (12.52 slugs/ft ³)	8933 kg·m ⁻³ (17.34 slugs/ft ³)
Thermal conductivity	A: 18 W/m K (10.4 BTU/ft h °F) M: 8.6 W/m K (5.0 BTU/ft h °F)	401 W/mK (231.67 BTU /ft h °F)
Specific Heat (c_p)	836 J/kg K (0.20 BTU/lb °F)	385 J/kg K (0.09 BTU/lb °F)

the applied stress and the material. The higher the stress, the smaller the latent heat. Of course, this stress also affects the fatigue performance of the actuator.

Fatigue

An actuator working at a strain level of 8% obviously does not have the same lifetime as an actuator working at a strain level of 2%. Therefore, fatigue specifications contribute to establishing the design parameters of the actuator.

Many parameters make fatigue analysis complex. Alloy composition, loading speed, heat treatment, amount of cold-work, etc. are some of the relevant parameters that need to be considered. A method based on factorial analysis

Table 4. Fatigue Properties as a Function of Strain and Stress^a

Number of Cycles	Typical Strain (%)	Maximum Stress [MPa (ksi)]
1	8	500 (72.57)
100	4	275 (39.91)
10000	2	140 (20.32)
+100000	1	70 (10.16)

^a Ref. 26.

was proposed by Morgan (25) to determine critical parameters involved in fatigue. Moreover, as Van Humbeeck and Stalmans suggested in (2), three different types of fatigue have to be considered:

- failure by fracture due to stress or strain cycling at constant temperature
- changes in physical, mechanical and functional properties, for instance, the two-way, shape-memory effect.
- degradation of the shape-memory effect due to stress, strain, or temperature cycling in the transformation region

Considering all of these aspects, it is difficult to give some general rules. However, some recommendations are made about the maximum strain versus the number of cycles (Table 4).

For binary Ni-Ti, long cycle lifetimes higher than 1,000,000 have been obtained using the R-phase transformation, which, it is known, is very stable (1,2).

SHAPE-MEMORY ALLOYS FOR MICROAPPLICATIONS

Introduction

In the previous sections, some basic design rules were briefly introduced. These rules fit quite well with conventional size actuators such as devices that can be assembled where frictional and adhesive forces do not interfere with the functionalities of the device. What happens if we decrease the size of components? How reliable are the aforementioned design methods?

As Richard Feynman mentioned about miniaturization in his visionary and famous talk "There's Plenty of Room at the Bottom" (27): "*the electrical equipment won't simply be scaled down; it has to be redesigned.*" Let us focus now on the use of shape-memory alloys in microengineering.

Microrobotics and Microdevices

We usually speak of microdevices when the resolution of the motion and the dimensions of the parts are smaller than the precision and dimension usually achievable in a workshop. In a resolution-of-motion versus size-of-components representation, microrobotics is typically located in a region defined by resolutions ranging from 10 microns (about 4×10^{-4} inch) to 1 nanometer (about 4×10^{-8} inch) and dimensions ranging from 10 mm (about 0.4 inch) to 1 micron (about 4×10^{-5} inch). These boundaries are rather a trend than a definition. Figure 13 schematically illustrates this idea and some well-known mechanisms are presented.

Micro-devices, which integrate other functions such as controlling integrated circuits, are usually called "microelectromechanical systems" (MEMS). The MEMS are also often associated with silicon-based technologies and

Figure 13. Micromechanisms: a definition as a function of dimensions and resolution of motion.

Figure 14. An illustration of the scaling effect on cube: ratio between electrostatic force and gravitational force as a function of cube dimension.

processing. However, according to the definition, MEMS should not be restricted to these special processes. Therefore, as a clever definition, the term “microdevices” is used throughout this article, rather than MEMS, to qualify small mechanisms, integrated or not.

Scaling Effect

We have all tried to manipulate small objects in our childhood and found that they stick very well to our fingers! This means that the relevant force is not gravity but rather adhesive forces. For instance, electrostatic or surface tension forces cannot be neglected when considering manipulation on a millimeter scale. This idea is briefly illustrated in Fig. 14 where the ratio between electrostatic force and gravitational force for a small cube is plotted as a function of the cube’s dimensions.

These scaling effects drastically modify our perception of the microworld and a lot of things have to be redesigned to adapt to “this new world.” New actuators and new mechanical components have to be created. SMA is certainly one of the most interesting candidates in this fascinating field of research as actuators and also as high strain flexible structures, as shown later.

SMA as a Smart Material for Microrobotics

The shape-memory effect in combination with an appropriate design or treatment can be used for microactuators as well as for microfastening devices. For instance, super-elasticity can provide an efficient method for enhancing the stroke of flexural hinges. In the previous section, SMA materials were compared to other candidates for small applications. In addition to some of the advantages already described, several interesting properties, relevant to microengineering applications, can be mentioned:

- As mentioned before, SMAs have the highest power/weight ratio among all known actuators in microengineering. Applications that require force production can be very compact.

- SMAs offer solid-state actuation and thus do not produce any dust. They are suitable for clean room conditions.
- The resistivity of the material (similar to stainless steel) is low, which allows efficient Joule heating. Low voltage and simple electronics can be used to power SMA actuators.
- Ni–Ti is compatible with MEMS processes.

However, a few drawbacks need to be considered carefully, such as their thermal activation, which limits the bandwidth. For fast applications, an SMA cannot compete with electrically or magnetically field driven actuators. The actuator efficiency is also very poor (typically a few %), which often excludes SMA microactuators from applications whose power consumption is very low. For example, the power consumption of a watch motor is typically a few picowatts!

Micromachining and Fabrication of SMA Microdevices

Silicon-Based MEMS: Fabrication Processes (28,29). Silicon technologies and related processes were major breakthrough in microelectronics as well as in sensors, actuators, and microsystems. Silicon based processes provide a unique method for large-scale production and miniaturization in the development of microactuators. These production methods are massively parallel and allow batch processing. However, these fabrication processes have a few limitations:

- Silicon microstructuring technologies are planar.
- The technological investment is very high.
- These methods are usually confined to structures of limited aspect ratios.

Ni–Ti and Ni–Ti–X (where X = Cu, Hf, Pd) alloys can be deposited on various substrates such as silicon, silicon dioxide (SiO₂) or titanium. However, the Si substrate is usually avoided because of the possible formation of silicide (SiNi) during crystallization of Ni–Ti thin films. The most

Table 5. HF/HNO₃/H₂O Etching of a Ni-Ti Thin Film Deposited on a Si Substrate^a

HF (46%): HNO ₃ (61%): H ₂ O Etchant Composition	Si Etching Rate ^a (nm/s)	Ni-Ti Etching Rate ^a (nm/s)	Etch Factor
1:1:0	730	180	0.1
1:1:2	1.3	50	0.45
1:1:4	<1.3	30	0.55

^a Ref. 32.^b(1 nm = 4 × 10⁻⁸ in).

common process for producing Ti-Ni thin films is deposition by dc or RF magnetron sputtering. An in-depth description of this process as well as the properties of thin film produced can be found in (29). Other processes such as deposition by flash evaporation (30), laser ablation (31), and multilayer processing (23) can also be used to produce thin films.

Ni-Ti thin films are usually etched by using HF/HNO₃/H₂O solutions. Table 5 shows experimental data obtained by Makino et al. (32). According to their results, a solution of HF:HNO₃:H₂O = 1:1:4 allows selectively etching of a Ni-Ti film deposited on a Si substrate.

Different fabrication methods can be used that depend on the type of actuator. When the actuator is moving freely, an intermediate layer, the so-called sacrificial layer, is required.

Figure 15 presents a method of producing a freely moving micromechanical element represented by a spring (33). In the first step, a polyimide layer is deposited by spin coating and is subsequently cured. The second step is Ni-Ti thin film deposition on the polyimide layer. In the next step, a photoresist thin film is spin coated over the Ni-Ti thin film. Then, the photoresist is baked, patterned, and developed to expose specific portions of the Ni-Ti layer selectively. Then the Ni-Ti film is etched. Finally, the structure is freed through reactive ion etching of the sacrificial polyimide layer.

In another process proposed by Buchaillot et al. (34), the Ni-Ti film is deposited just before removing the sacrificial layer, as is illustrated in Fig. 16 (29). A sacrificial Cr layer is deposited on a SiO₂ substrate. A polyimide layer is spin-coated on the Cr layer. Then, a second Cr layer is deposited on the polyimide. The upper Cr layer is patterned by photolithography and wet etched. The polyimide layer is vertically etched by oxygen plasma using the previously patterned Cr layer as a mask. Then, the Ni-Ti layer whose thickness is less than that of the polyimide layer is deposited. The final step consists of removing the polyimide layer by wet etching (“liftoff”) and releasing the mobile part by wet etching the Cr layer. Because the Ni-Ti layer is never etched, the aspect ratio of the structure is theoretically not limited.

Several applications such as microvalves use membrane actuators or biomorphs of Ni-Ti on SiO₂. This structure can be fabricated by using the process proposed by Wolf et al. (35) (Fig. 17). A Si wafer that has an oxide layer on both sides (SiO₂) is coated by a photoresist and softbacked. The back side photoresist is patterned and results in direct exposure of the Si in defined parts that creates window-like structures. Then, the Si is etched and almost all of the

volume “behind the window” is removed. The front layer is then removed using a buffered oxide etchant. The next step is depositing the Ni-Ti layer. Finally, the rest of the silicon is removed. When bimorphlike structures are desired, the front SiO₂ layer is not removed, and Ni-Ti is deposited directly on it.

Laser Machining. A laser can be used for milling and cutting SMA elements. Nd-Yag lasers are usually used. The sample is fixed on a two-axis linear stage under a fixed focusing objective. A rotational stage is sometimes added for tube cutting. The laser is focused on the sample, and an additional gas flow is usually used to drain off the molten material. The cutting precision depends on the object size and the material. It is possible to cut sheets whose thicknesses range from a few millimeters down to 0.005 m

Figure 15. Thin-film microactuator fabrication process: (a) deposition of the layers, (b) photoresist deposition and patterning, (c) wet etching of SMA layer, and (d) plasma etching of the polyimide layer [after Walker et al. (33)].

(2×10^{-4} in). The spot size varies according to the sample’s thickness. Results for Ni–Ti have shown that the minimum spot size ranges from 0.02 mm (8×10^{-4} in) for 0.01-mm sheet thickness to 0.08 mm (4×10^{-3} in) for 1-mm sheet thickness (0.04 in).

Figure 18 shows part of a microgripper machined by a Nd–Yag slab laser working in the fundamental mode (TEM₀₀). An additional treatment has been used to decrease the edge surface roughness. For small to medium production volume and prototyping, laser cutting is an

Figure 18. A Ni-Ti structure that was laser-cut by a Nd: Yag slab laser.

efficient method for Ni-Ti. However, due to laser heating, a heat-affected zone exists around the cutting edge. The depth of this heat-affected zone is typically of the order of 10 microns (4×10^{-4} inch).

Electrodischarge Machining. Electrodischarge machining (EDM) consists of using sparks created between an electrode and a sample to machine the material. There are two different processes: diesinking EDM and wire-cut EDM. In die-sinking EDM, the required shape is formed negatively in the metal by using a three-dimensional electrode. Various shapes, indentations, and cavities can be created. In the wire-cut process, the required shape is cut by guiding the wire along the given stretch.

Figure 19 shows a microsurgical tool in which a groove about 40 microns (1.57×10^{-3} inch) wide and about 200 microns (7.9×10^{-3} inch) deep has been machined by using a micro-EDM (36). The groove is 7 millimeters (0.27 inch) long. EDM is the most efficient method for creating structures of high aspect ratios that have low surface roughness. EDM is usually used for micromachining of elastic structures of high aspect ratio.

Recent Developments in Microrobotics and Microdevices: The State of the Art

In this section, some recent applications are presented. This discussion is not extensive but gives some general

Figure 19. A Ni-Ti micro-surgical tool: the groove was machined by electrodischarge machining. The groove is 40 microns wide (0.0015 inch) by about 200 microns deep (0.0078 inch) (36).

trends in the field of microengineering. Electronic connectors and other small fasteners are not mentioned in this section. The reader interested may consult the applications section of this encyclopedia or (1,2) for a more detailed description.

Active Catheter and Snakelike Robotic Systems. One of the first microrobotic applications was a prototype of an active miniature endoscope for a gastrointestinal intervention system (18). This endoscope was designed to pass smoothly through the sigmoid colon, which has a very small radius of curvature. The outside diameter was about 13 mm (0.51 in). As one can easily imagine, the heat dissipation of active surgery instruments is a critical issue. To address this problem, authors have proposed a cooling water tube going through the structure. As a result of this pioneering research, many active endoscopes for gastrointestinal surgery have been developed worldwide, for example, by Reynaerts et al. (37). All of these projects are minirobotic rather than microrobotic. Outside diameters range from 8 mm (0.31 in) to 15 mm (0.59 in). In the 1990s, smaller active endoscopes and active catheters were proposed in Japan. Fukuda et al. (38) designed an active catheter whose diameter ranged from about 1.33 mm (0.052 in) to 2 mm (0.079 in). The catheter has also been tested *in vivo*.

A very impressive five-degrees-of-freedom tube-type micromanipulator was recently introduced by Olympus Optical Company in Japan (39). This manipulator, shown in Fig. 20, is dedicated to inspection and maintenance in narrow spaces and for medical applications. The diameter is one mm (0.04 in), which makes this snakelike robot one of the thinnest in the world. The active parts consist of SMA strips working in bending modes. The strips have a two-way reversible effect and are heated by thermal conduction. A “multifunction integrated film” (MIF) is attached to the SMA strip. This circuit combines a heating function and a strain sensor by using a strain gauge measurement principle. The integrated circuit is constructed by successive sputtering of Ti and Pt on a polyimide layer. The authors developed a position controller based on strain sensing feedback, which gives positional accuracy of less than ± 0.25 mm (0.04 in). In another version, tactile sensors have been added that give reflex functions to the catheter, and

when the tube touches something, it automatically bends in the opposite direction.

Mini- to Microgrippers. At the end of the 1980s Ikuta (40) proposed a miniature gripper suitable for clean room conditions. The device consists of two bronze fingers that have two SMA coil springs attached to each finger. The coil springs are mounted opposite one another in an antagonistic or “push-pull” actuating arrangement. These springs were made from a thin film sputter-deposited on a glass substrate. The alloy showed an R-phase transformation around 320 K. The electrical resistivity change was used as an internal variable for monitoring the transformation. In this design, Ikuta proposed a controller scheme that combined a resistance and positional feedback where the positional feedback is given by a photosensor.

In another realization, Hesselbach et al. (41) in Germany developed a compliant microgripper.

In one version (Fig. 21), the compliant structure with flexural hinges is machined by electric discharge machining (EDM) from a superelastic material. Thus, the gripper uses SMA materials for two purposes: for actuation and for the guiding mechanism. The compliant mechanism uses a four-bar linkage that has a transmission ratio of -1 between the input and the output of the mechanism. If the

Figure 21. The microgripper developed by Hesselbach et al. (41). (a) Overall view of the microgripper (5 mm = 0.2 in); (b) design and mechanical equivalent of the flexible structure.

Figure 22. The Lawrence Livermore National Laboratory's microgripper (200 microns = 0.008 inch) (42).

input is one jaw and the output is the other jaw, a movement of the input jaw induces exactly the opposite movement of the output jaw. Hence, the jaws center every grasped object, regardless of the different stiffness of the flexural hinges or disturbance forces. An SMA actuator that has a strip shape deforms the compliant structure. The reversible motion is obtained by using the elasticity of the compliant structure, which acts as a bias spring. A resistance feedback is used to control the position of the finger. The authors have reported a lifetime of more than 450,000 gripping cycles and a close/open time of 0.5 s.

In microrobotics, Lee et al. (42) realized one of the smallest SMA microgrippers (Fig. 22). This gripper's dimensions are $1 \times 0.2 \times 0.38 \text{ mm}^3$ ($0.04 \times 0.008 \times 0.015 \text{ in}$). The design principle is a kind of "bimorph" of SMA/Si materials. The Si layer acts as a bias spring. The mechanism consists of two identical jaws actuated by Ni–Ti–Cu. The thin films are deposited on both external sides of the gripping jaws. The jaws are made of silicon and were shaped by a

combination of precision sawing and bulk micromachining of silicon. The upper part of the gripper is bonded to the lower part by selective eutectic bonding. The silicon gripper cantilevers act as bias springs. When heated, the Ti–Ni–Cu films bend the silicon cantilever, and when cooled, the cantilever deflects back and stretches the shape-memory film. A pushing pad is designed to assist in releasing the gripped object by pushing forward as the gripper is opened. An IC fabricated thin-film resistor heater pad applies heat to the microgripper. Experimental results have shown a gripper opening to 110 microns ($4.3 \times 10^{-3} \text{ inch}$), when fully actuated, and an estimated gripping force of 13 mN. The time response was estimated at 0.5 second.

A microgripper (43) for micro endoscopic (i.e., an endoscope whose diameter is about 1 mm (0.04 inch)) assembly is presented in more detail in the next paragraph.

Linear Actuator and Other Small Actuators. Grant and Hayward (44) proposed a high-speed linear actuator consisting of several thin Ni–Ti fibers woven in a counterrotating helical pattern around supporting disks (Fig. 23). The volume required by the actuator is a 17-mm diameter cylinder $\times 30 \text{ mm}$ ($0.67 \text{ in} \times 1.18 \text{ inch}$) long that belongs to the category of "minirobotics" rather than "microrobotics." Preloaded springs separate the disks, which keep the fibers under tension when unheated. When heated, the fibers shrink and pull the disks, together. The weave pattern of the fibers accomplishes displacement amplification. A rotary actuator has been developed using two of these linear actuators mounted opposite each other. In this configuration, a time response of less than 100 ms was obtained. However, due to the large amount of fibers in parallel, this woven design requires a high level of electrical current (typically 4–8 A).

Using Si-based processes, Buchailot et al. (34) developed an XY linear stage made of Ni–Ti thin films. This linear stage consists of four leaf springs operating in the same plane as the substrate. Each actuator has two parallel leaf springs and is initially stretched during mounting to induce a martensitic reorientation.

Figure 23. The "woven structure" developed by Grant and Hayward (44).

Figure 24. The microvalve developed by Johnson et al. (47,48).

Actuators are mechanically connected to each other and are designed to avoid any coupling between degrees of freedom. Therefore, the basic actuating principle is an antagonistic design, where each actuator deforms its counterpart. The whole structure is a few millimeters square (0.04 inch^2).

Many other reversible actuators have been proposed in the literature. Among these designs, Kuribayashi et al. (45) in 1993 proposed a millimeter-sized robotic arm. The all-round effect (see earlier) was used to produce a reversible effect in a Ni-Ti alloy beam. Three of these microcantilevers were combined to realize a SCARA-type microrobot that has three degrees of freedom. Later, Kuribayashi and Fujii developed a microcantilever made of a SMA thin film prestressed by a polyimide layer (46). The polyimide layer provides reverse motion when cooling.

Fluidic Applications. The pioneers of this field of research were Busch and Johnson (47). In 1989, they patented a micro valve, that uses a SMA thin film that has been processed by MEMS technologies. The valve shown in Fig. 24, consists of a silicon orifice die, an actuator die that has a poppet controlled by a Ni-Ti shape-memory alloy microribbon, and a bias spring. An electrical current heats the actuator (the Ni-Ti microribbon). When no electric current passes through the actuator, the bias spring pushes the poppet against the orifice and closes the valve. When an electric current is applied, the Ni-Ti actuator contracts and lifts the poppet from the orifice, opening the valve. The whole device is less than one-half square centimeter (0.2 in^2). The displacement of the poppet is more than 100 microns (0.004 inch) and produces a force of one-half newton. In a rough approximation, flow through the valve is proportional to the current applied to the actuator. The current and an appropriate feedback may be used to control the flow (48).

In another realization, Kohl et al. (49) designed microvalves by integrating SMA bending actuators fabricated from laser-cut, cold-rolled Ni-Ti sheets (Fig. 25).

Figure 25. The microvalve developed at the Forschung Zentrum in Karlsruhe (49).

The valve consists mainly of a PMMA housing that has an integrated valve seat, a polyimide membrane, a polyimide spacer, and a SMA microdevice. The SMA microactuator is used for deflection control of the membrane, which opens or closes an opening in the valve seat. The actuator is made of “stress-optimized” cantilever elements whose actuation direction is perpendicular to the plane of the substrate.

A CONCEPT OF SMART SMA MICRODEVICES

Basic Idea

Active mechanical systems generally consist of a force generator, a coupling device, a transmission system, a guiding system, and an output element. The basic idea is to integrate all of these elements and functions within one single piece of material to form “a smart SMA microdevice.” This concept is well adapted to microrobotics because a monolithic device does not require any assembly and is free of wear, friction, and dust. Nevertheless, to be reversible, a monolithic design requires that one region of the material act as a biasing spring. Thus, several methods have been developed to address this issue (50,51).

Figure 26. The EPFL's microgripper for submillimeter lens manipulation (43,50).

The Two-Way Shape-Memory Effect (TWSME) Applied to Small Devices

As presented before, thermomechanical treatment of a material can introduce internal stress. This stress will generate preferentially oriented martensitic variants when cooling. Using an appropriate design, the TWSME can also be used to create reversible motion within a device that has a more complex shape than wires, strips, or springs.

The TWSME microgripper shown in Fig. 26 was designed and successfully introduced in a production line of microendoscopes (43). The design consists of crablike tweezers about 1 mm^2 (0.04 inch^2), and the gripper has a moving arm that clamps object against a fixed part. Additional fixtures have been added for visual measurements during calibration and a force limitation in case of mechanical shock to the fixed part.

The material is a Ni-Ti-Cu sheet 0.15 mm (0.006 in) thick. The training process is explained in Fig. 27:

1. The bulk material is annealed at 515°C for 15 min. The microgripper shape is then laser-cut from the sheet. At this point, the gripper does not have any reversible motion: the austenitic shape is the cut shape.
2. The microgripper is fixed on a heat source (thick resistive film, SMD-resistor, thermoelectric devices).

Figure 27. The training process applied to the microgripper (thermal cycles under constraint).

Then, the training process is applied to the device. Different training methods have been reported in the literature (1,2). In this special case, the best method for achieving gripper specifications is to apply thermal cycling under constraint. To perform this task, a shaft is used to deform the gripper up to 4 to 5%. The maximum motion range is reached after 50 cycles. After training cycles, the austenitic shape is not exactly the same as the cut shape. Residual plastic deformation resulting from the training process is observed and has to be considered while designing the gripper.

3. During cooling, the gripper opens. When heating, the gripper recovers its parent shape (high-temperature shape) and closes its jaw. For a hinge thickness of $70 \mu\text{m}$ ($2.7 \times 10^{-3} \text{ in}$), a range of motion of $150 \mu\text{m}$ ($6 \times 10^{-3} \text{ inch}$) was obtained, and a grasping force of 16 mN was measured. If this force is compared with the weight of the gripper itself, the gripper's force/weight ratio is 1000, and if only the active part of the gripper is considered in the gripper weight estimate, this ratio increases to 30,000! However, the force when cooling is about four times lower (approximately 4 mN). This is a limitation of the TWSME: the force induced when cooling is lower than the recovery force generated upon heating. Nevertheless, a gripper needs forces when closing to grasp an object but does not need force when opening. Fatigue experiments consisting of grasping and releasing cycles showed that motion loss saturates after 100,000 cycles. After 200,000 cycles, the motion loss is 10%, and the loss after 1,000,000 cycles is estimated at the same level.

Local Heating of the Material ("Martensite" Spring-Biased Design)

To create a reversible effect, active and passive parts are needed simultaneously within the material. One solution consists of controlling the heating process through the

Figure 28. Optical switch using the local heating design principle. (1) actuating part, (2) bias spring, (3) shutter, and (4,5) fixture and connection pads (scale 1 mm = 0.04 in).

structure. By carefully designing the electrical path, for example, part of the material can be in the austenitic state, and the remainder is in the martensitic state. The elasticity of the martensitic region can be used as a bias spring. The optical switch shown in Fig. 28 illustrates this idea.

The device was machined from a $20\ \mu\text{m}$ thick (7.9×10^{-4} inch) Ni–Ti–Cu foil. The motion can be compared to that of a semaphore. During assembly, the structure is prestressed by pulling the fixed part (#5, see Fig. 28). Then, parts #4 and #5 are fixed and separated from each other (dashed line). When a current passes between the two pads (#4 and #5), the part that has the thinnest section (#1) is heated up to the transformation temperature, recovers its original shape, and pulls down the shutter (#3). When cooling down, the bias spring—the part that has the largest section (#2)—pulls back on the structure causing reverse motion. In this design, the shutter range of motion is $190\ \mu\text{m}$ (7.5×10^{-3} in). The time response when heating is less than 50 ms, and the power consumption is typically 5 mW.

Antagonistic or “Push-Pull” Design

The working principle is the same as described before, except that the two SMA actuators are part of the same piece of material. By designing an appropriate electrical path, one zone of the material is heated at a time. Depending on which zone is heated, the device will move in one direction or the opposite. The main difference from the previous case is that the reverse motion is due to alternative heating of actuating zones.

An illustration of this principle is shown in Fig. 29. This device is a linear actuator that has one degree of freedom. During assembly, the two leaf springs (#2, #2*) are prestressed and fixed on the contact pads (#3, #3*). When a current passes through one of the contacts (#3, #3*) and the main body (#5), the corresponding spring is heated up

to the transformation temperature and pulls the mobile part (#4) in its direction. When the springs are mounted opposite each other, two-way motion is obtained. To obtain precise motion in only one direction, a guiding system (#1) has been added to compensate for machining and assembly errors. The schematic of the mechanical equivalent system is shown in Fig. 29. It consists of two serial four-link structures. One four-link structure guides the motion in one direction, but this guiding is not purely rectilinear, rather it is motion that has a high radius of curvature. Adding a second four-link structure in series compensates for undesired motion in the perpendicular direction. This linear actuator illustrates very well how smart a monolithic design can be: this design is a complete linear stage that includes actuators and guiding elements within one single piece of material.

Figure 29. A one-degree-of-freedom linear stage. The mechanical equivalent of guidance is explained.

Figure 30. Mechanical behavior before and after annealing a cold-worked sheet having a superelastic behavior at room temperature.

Local Annealing

Basic Principle. During the fabrication of SMA devices, annealing is required to obtain a martensitic transformation within the material. In a sputter-deposited thin film, the material is amorphous after deposition. Annealing is required to crystallize the material. In a cold-rolled sheet, the forming process introduces a large number of dislocations which prevent martensitic transformation. In that case, annealing induces recovery and recrystallization of the material. Typical annealing temperatures range from 400 to 900°C.

The basic idea of local annealing is to limit annealing to selected zones of the material. Martensitic transformation occurs only in annealed zones. In other words, some parts are active, and others are passive.

Figure 30 shows a tensile test on a cold-worked sheet of Ni-Ti before and after annealing (the material is in the austenitic state). The superelastic characteristic can be seen only after annealing. In the framework of a monolithic design, the annealed zone can be used for actuating purposes, and the nonannealed zone can be used as a biasing element for a reversible effect. Two methods can be used for annealing small devices locally (51). The first is direct Joule heating of the material, and the second uses a laser to heat the structure.

Local Annealing by Joule Heating. Direct Joule heating actuates most SMA actuators and devices. It can also be used to heat up the material to the annealing temperature. Kuribayashi et al. (52) used annealing by Joule heating a microactuator consisting of a cantilever working in the bending mode.

An example of a structure locally “Joule annealed” is shown in Fig. 31. The device is a linear actuator that has four leaf springs (51). These are the fabrication steps:

1. The structure is cut out by laser from an “as-received” unannealed Ni-Ti-Cu sheet.

Figure 31. A one-degree-of-freedom linear stage, locally annealed by using an electrical current.

2. An electrical current is passed through the left springs causing the temperature to rise to the annealing temperature (about 500°C). The right springs remain at room temperature. An infrared camera measures the temperature during annealing.
3. Once annealing is over, the springs are prestressed along the axis and are fixed.

Because of this local annealing, one part of the material is passive, and the other is active. The passive part is used as a spring, and the active part is the actuator. The mechanical behavior of this structure is exactly the same as the spring-biased multipart mechanism presented in the previous section.

“Joule annealing” can be a low-cost and efficient method of producing smart SMA microdevices. However, a few limitations exist:

- This method can be applied only to devices that contain loops for an electrical path.
- The cross section along the electrical path has to be carefully designed with respect to temperature distribution during heating. The thinnest section will be the hottest and will be annealed first.
- Because the power dissipated in the structure is directly proportional to the resistance and thus to the cross section, the local temperature and the annealing conditions will depend strongly on machining tolerances.

Laser Annealing of SMA (the LASMA Process). A laser beam is used for local heating. The laser is focused on the point where annealing is desired. In contrast to Joule annealing, laser annealing of SMA (LASMA) can be applied to all kinds of designs (51,55). This method has been successfully used on various types and shapes of SMA microdevices. It can easily be applied to thin films, cold-rolled sheets, cold-drawn wires, or other materials that have been work-hardened.

Figure 32 shows some microstructures in a laser-annealed thin film. The material’s microstructure was observed at several distances from where the laser was focused. Near a distance of about 800 μm (3.15×10^{-2} in), the transition from crystallized region to the amorphous zone can be observed. The circularly shaped bubbles are grains growing in the amorphous matrix.

Figure 32. Microstructures along the irradiated zone—observation by transmission electron microscopy.

Two Examples of Laser-Annealed Devices (51,55). The first example is a microcantilever moving up and down, which is shown in Fig. 33.

The structure is machined from a sputtered-deposited Ni–Ti thin film. The LASMA process is used to crystallize the material locally. We have observed that after annealing, the locally affected zone of the material is expanded. This means that a prestrain can be introduced during the process. Therefore, an active structure can be created without

Figure 33. Locally annealed microcantilever: realization and design.

any mechanical interaction. The annealing process is monitored by the resistivity change.

When a current passes through the structure, the annealed cantilever transforms into austenite and pulls the structure downward. Reversible motion is obtained by using the elasticity of the unaffected zone. This example demonstrates that successful reversible motion can be introduced in the device without any mechanical interaction. Moreover, this effect is not limited to bending motion.

Another example of an application is shown in Fig. 34. This device is a microgripper for lens manipulation. The structure is cut out from a cold-worked Ni–Ti sheet. The laser is used to anneal the outer part of the gripper's joint. The inside part is not annealed and is the function of the bias spring. The prestrain is realized by deforming the gripper's unannealed zone well above its plastic limit. When heating the whole structure, only the annealed region will try to recover its original shape. Upon cooling, the inner element, the unannealed portion, will push back the structure and open the gripper. Using the LASMA process, an active element and a bias spring have been introduced in one single piece of cold-worked material. Due to these properties, the LASMA process is a key technology for developing smaller highly integrated microdevices.

Flexible Structures

Flexural designs are a well-established technology in precision engineering (53,54). Their monolithic structure offers many advantages such as freedom from wear, no assembly, and smooth displacements that are contamination-free. However, one of their disadvantages is that flexures are restricted to small displacements for a given size and stiffness in the drive direction. Moreover, like every spring mechanism, the force increases linearly with the displacement. Considering these two limitations, SMA flexures can improve these aspects significantly. The large deformation available enhances the output stroke for a reasonable volume. Moreover, due to their “plateau,” the force will saturate and if the structure is prestrained, a low stiffness linear guiding system can be imagined (55).

Smart Monolithic SMA Microdevices: An Outlook for Design Methods

Table 6 is a summary of some methods for smart design (50). The local hardening mentioned in this table is the exact reverse effect of the LASMA process. Instead of local annealing, the basic idea is to harden or amorphize the material locally. In the design context, one could say that the LASMA process introduces an active region within a passive structure, whereas local hardening introduces a passive element within an active structure.

FUTURE TRENDS

As previously mentioned, scaling down things leads to new design approaches. This rule applies to shape-memory alloy microdevices. Successful breakthroughs have been

Figure 34. Locally annealed microgripper. (a) Design principle; (b) the microgripper and a cylindrical lens on a match head.

made in this field of research, but there is still a further need to understand the behavior of small devices on the microscale. It is well known that the mechanical behavior of a thin film of a few microns is not the same as the behavior of a sheet that is a few hundred microns thick. As W. Nix mentioned (56), thin film materials are, for instance, much stronger than their bulk counterparts. This may be due to the fine grain sizes commonly found in thin films, but single crystal thin films are also much stronger than bulk materials. Many issues remain unresolved or little addressed for SMA thin films:

- How thin can a functional SMA thin film be? In other words, where is the size limit of the shape-memory effect?
- If a micron-size structure is built, how smooth will the motion be? Will we observe a discontinuous effect?
- How does the scaling law apply to fatigue properties?

Magnetostriction is the spontaneous deformation of a material caused by a change in its state of magnetization. Some materials have both a martensitic transformation and a Curie temperature (ferromagnetic martensites). Depending on which phase has larger saturation

magnetization, a field applied either above or below the martensitic transformation temperature will induce a transformation between austenite and martensite. If the temperature is below the martensitic transformation, the martensitic variants can be redistributed by a magnetic field (57). These materials might be a solution to bypass the main drawback of nonmagnetic SMAs, their response time. Considerable effort is still needed to introduce this material in applications.

The design of a controller for a SMA actuator was not discussed in this article. Nevertheless, a lot of work has been done within the robotics community. Most of them have proposed PID controllers or close cousins (40). Many control schemes use electrical resistance as the sensing variable in the feedback loop, as proposed by Hirose et al. (18). Other methods have been proposed by Gorbet (58) who studied control using a Preisach representation and by Grant and Hayward (44) who designed a variable structure control that consists of switching between a set of output signals in response to an input signal. However, all of the proposed methods have been applied only to simple SMA actuator design consisting of a wire, strip, or spring working against a bias spring. For instance, there still is further room for controlling very complex designs, such as antagonistic designs.

Table 6. A Summary of Design Methods for Smart Monolithic Designs^a

Design Methods	Material State	Prestressed	Advantages	Limitations
TWSME	Annealed	No	Actuation methods, low volume required	Low force in one direction, training process
Local heating	Annealed	Yes	No local treatment, simple method.	Low stiffness of martensite, special heating path
“Push-pull”	Annealed	Yes	High range of motion	Volume required
Local hardening ^b	Annealed	No	Different mechanical hardening	Miniaturization
LASMA	Amorph. Work-Hardened	No Yes	Highly integrated design, different annealing conditions	Managing the annealing process

^aRef. 50.

^bLocal hardening is the exact reverse effect of LASMA applied to a cold-rolled sheet.

CONCLUSION

Robotics gathers skills from mechanical, control, and computer engineering. In addition to these fields, microrobotics needs skills from materials sciences and physics. As you come closer to the atomic scale, interaction between the parts of a mechanism requires a more detailed analysis of the physical phenomena involved in the scaling effect. Microrobotics will never be a simple clone of robotic on a smaller scale. Scaling down things leads to a new field of research where our perception of physical interaction has to be modified. New actuators and sensors have to be invented. In this research trend, shape-memory alloys are one of the most interesting candidates for miniaturization. Due to their unique properties, SMA offers a powerful and a flexible solution in many fields of microrobotics. Smart monolithic SMA devices offer a unique approach to further miniaturization and will contribute to exploring the "bottom" scale using powerful robots and tools.

INTRODUCTION

Background

Microtubes are very small diameter tubes (in the nanometer and micron range) that have very high aspect ratios and can be made from practically any material in any combination of cross-sectional and axial shape desired. In smart structures, these microscopic tubes can function as sensors and actuators, as well as components of fluidic logic systems. In many technological fields, including smart structures, microtube technology enables fabricating components and devices that have, to date, been impossible to produce, offers a lower cost route for fabricating some current products, and provides the opportunity to miniaturize numerous components and devices that are currently in existence.

In recent years, there has been tremendous interest in miniaturization due to the high payoff involved. The most graphic example that can be cited occurred in the electronics industry, which only 50 years ago relied exclusively on the vacuum tube for numerous functions. The advent of the transistor in 1947 and its gradual replacement of the vacuum tube started a revolution in miniaturization that was inconceivable at the time of its invention and is not fully recognized even many years later.

Miniaturization resulted in the possibility for billions of transistors to occupy the volume of a vacuum tube or the first transistor, and it was not the only consequence. The

subsequent spin-off developments in allied areas, such as integrated circuits and the microprocessor, have spawned entirely new fields of technology. It is quite likely that other areas are now poised for revolutionary developments that parallel those that have occurred in the electronics industry since the advent of the first transistor.

These areas include microelectromechanical systems (MEMS) and closely related fields, such as microfluidics and micro-optical systems. Currently, these technologies involve micromachining on a silicon chip to produce numerous types of devices, such as sensors, detectors, gears, engines, actuators, valves, pumps, motors, and mirrors on a micron scale. The first commercial product to arise from MEMS was the accelerometer that was manufactured as a sensor for air-bag actuation. On the market today are also microfluidic devices, mechanical resonators, biosensors for glucose, and disposable blood pressure sensors that are inserted into the body.

The vast majority of microsystems are made almost exclusively on planar surfaces using technology developed to fabricate electronic integrated circuits. The fabrication of these devices takes place on a silicon wafer, and the device is formed layer-by-layer using standard clean-room techniques that include electron beams or photolithography, thin-film deposition, and wet or dry etching (both isotropic and anisotropic). Three variations of this conventional electronic chip technology can be used, for example, to make three-dimensional structures that have high aspect ratios and suspended beams. These include the LIGA (lithographie, galvanofornung, abfornung) process (1,2), the Hexsil process (3), and the SCREAM (single-crystal reactive etching and metallization) process (4). The technique most employed, the LIGA process, which was developed specifically for MEMS-type applications, can construct and metallize high-aspect-ratio microfeatures. This is done by applying and exposing a very thick X-ray sensitive photoresist layer to synchrotron radiation. Features up to 600 microns high that have aspect ratios of 300 to 1 can be fabricated by this technique to make truly three-dimensional objects. The Hexsil process uses a mold that has a sacrificial layer of silicon dioxide to form polysilicon structures that are released by removing the silicon dioxide film. A third approach is the SCREAM bulk micromachining process that can fabricate high-aspect-ratio single-crystal silicon suspended microstructures from a silicon wafer using anisotropic reactive ion etching. Note, however, that like the conventional technique used to make electronic circuits, all of these variations use a layered approach that starts on a flat surface.

In addition, there are some disadvantages of the conventional electronic chip fabrication technique and its modifications, even though there have been numerous and very innovative successes using these silicon wafer-based technologies. This is due to the fact that these technologies require building up many layers of different materials as well as surface and bulk micromachining which leads to some very difficult material science problems that have to be solved. These include differential etching and laying down one material without damaging any previous layer. In addition, there are the problems of interconnecting layers in a chip that have different functions. An example of this is a microfluidic device in which there are both fluidic

INTRODUCTION

Background

Microtubes are very small diameter tubes (in the nanometer and micron range) that have very high aspect ratios and can be made from practically any material in any combination of cross-sectional and axial shape desired. In smart structures, these microscopic tubes can function as sensors and actuators, as well as components of fluidic logic systems. In many technological fields, including smart structures, microtube technology enables fabricating components and devices that have, to date, been impossible to produce, offers a lower cost route for fabricating some current products, and provides the opportunity to miniaturize numerous components and devices that are currently in existence.

In recent years, there has been tremendous interest in miniaturization due to the high payoff involved. The most graphic example that can be cited occurred in the electronics industry, which only 50 years ago relied exclusively on the vacuum tube for numerous functions. The advent of the transistor in 1947 and its gradual replacement of the vacuum tube started a revolution in miniaturization that was inconceivable at the time of its invention and is not fully recognized even many years later.

Miniaturization resulted in the possibility for billions of transistors to occupy the volume of a vacuum tube or the first transistor, and it was not the only consequence. The

subsequent spin-off developments in allied areas, such as integrated circuits and the microprocessor, have spawned entirely new fields of technology. It is quite likely that other areas are now poised for revolutionary developments that parallel those that have occurred in the electronics industry since the advent of the first transistor.

These areas include microelectromechanical systems (MEMS) and closely related fields, such as microfluidics and micro-optical systems. Currently, these technologies involve micromachining on a silicon chip to produce numerous types of devices, such as sensors, detectors, gears, engines, actuators, valves, pumps, motors, and mirrors on a micron scale. The first commercial product to arise from MEMS was the accelerometer that was manufactured as a sensor for air-bag actuation. On the market today are also microfluidic devices, mechanical resonators, biosensors for glucose, and disposable blood pressure sensors that are inserted into the body.

The vast majority of microsystems are made almost exclusively on planar surfaces using technology developed to fabricate electronic integrated circuits. The fabrication of these devices takes place on a silicon wafer, and the device is formed layer-by-layer using standard clean-room techniques that include electron beams or photolithography, thin-film deposition, and wet or dry etching (both isotropic and anisotropic). Three variations of this conventional electronic chip technology can be used, for example, to make three-dimensional structures that have high aspect ratios and suspended beams. These include the LIGA (lithographie, galvanofornung, abfornung) process (1,2), the Hexsil process (3), and the SCREAM (single-crystal reactive etching and metallization) process (4). The technique most employed, the LIGA process, which was developed specifically for MEMS-type applications, can construct and metallize high-aspect-ratio microfeatures. This is done by applying and exposing a very thick X-ray sensitive photoresist layer to synchrotron radiation. Features up to 600 microns high that have aspect ratios of 300 to 1 can be fabricated by this technique to make truly three-dimensional objects. The Hexsil process uses a mold that has a sacrificial layer of silicon dioxide to form polysilicon structures that are released by removing the silicon dioxide film. A third approach is the SCREAM bulk micromachining process that can fabricate high-aspect-ratio single-crystal silicon suspended microstructures from a silicon wafer using anisotropic reactive ion etching. Note, however, that like the conventional technique used to make electronic circuits, all of these variations use a layered approach that starts on a flat surface.

In addition, there are some disadvantages of the conventional electronic chip fabrication technique and its modifications, even though there have been numerous and very innovative successes using these silicon wafer-based technologies. This is due to the fact that these technologies require building up many layers of different materials as well as surface and bulk micromachining which leads to some very difficult material science problems that have to be solved. These include differential etching and laying down one material without damaging any previous layer. In addition, there are the problems of interconnecting layers in a chip that have different functions. An example of this is a microfluidic device in which there are both fluidic

and electronic functions. Clearly, there are numerous materials issues central to this technology.

Other technologies are available that, like conventional lithography, can construct or replicate microscopic features on a flat surface. These approaches include imprint lithography that involves compression molding (5), lasers (6–8), ion beams (9) and electron beam (10) micro-machining, soft lithography (11), writing features into the surface using an atomic force microscope (12,13), and very limited application of deposition using a scanning tunneling microscope (14,15). The majority of these technologies are not discussed in detail because there is not a close link to microtube technology.

In addition to the processing problems mentioned before, there are other limitations inherent in conventional lithographic techniques that are based on planar silicon. For example, in some applications such as those that involve surface tension in fluidics, it is important to have a circular cross section. However, it is impossible to make a perfectly round tube or channel on a chip by conventional technology. Instead, channels on the wafer surface are made by etching a trench and then covering the trench by using a plate (16,17). This process can produce only angled channels such as those that have a square, rectangular, or triangular cross section. Because of the limitations already mentioned, we heartily agree with Wise and Najafi in their review of microfabrication technology (18) when they stated, “The planar nature of silicon technology is a major limitation for many future systems, including microvalves and pumps.”

In the literature, there are at least two technologies in addition to microtubes that remove microfabrication from the flatland of the wafer. One uses “soft lithography,” and the other uses laser-assisted chemical vapor deposition (LCVD). “Soft lithography,” conceived and developed by Whitesides’ outstanding group at Harvard, encompasses a series of very novel related technologies that include microcontact printing, micromolding, and micromolding in capillaries (11). These technologies can fabricate structures from several different materials on flat and curved surfaces. By example, structures can be fabricated using microcontact printing by first making a stamp that contains the desired features. This stamp, which is usually made from poly(dimethylsiloxane) (PDMS) has raised features placed on the surface by photolithographic techniques. The raised features are “inked” with an alkanethiol and then brought into contact with a gold-coated surface, for example, by rolling the curved surface over the stamp. The gold is then etched where there is no self-assembled monolayer of alkanethiolate. Features as small as 200 nm can be formed by this technique. However, the microstructures produced by this technique are the same as those produced by standard techniques, except that the starting surface need not be flat. By using these techniques, submicron features can be fabricated on flat or curved substrates made of materials, such as metals (19), polymers (20), and carbon (21). In addition, these technologies can be used to make truly three-dimensional free-standing objects (22,23).

Another step away from the standard planar silicon technology is the LCVD process (24,25) which can “write in space” to produce three-dimensional microsystems. In

this process, two intersecting laser beams are focused in a very small volume in a low-pressure chamber. The surface of the substrate on which deposition is to occur is brought to the focal point of the lasers. The power to the lasers is adjusted so that deposition from the gas phase occurs only at the intersection of the beams. As deposition occurs on the substrate surface, it is pulled away from the focal point. Under computer control, the substrate can be manipulated so that complex, free-standing, three-dimensional microstructures can be fabricated.

In addition to LCVD and soft lithography, only microtube technology offers the possibility of truly three-dimensional nonplanar microsystems. However, in contrast to these two technologies, microtube technology also offers the ability to make microdevices from practically any material because the technology is not limited by electrodeposition or the availability of CVD precursor materials. In addition, in contrast to these other technologies, microtube technology provides the opportunity to make tubing and also to make it in a variety of cross-sectional and axial shapes that can be used to miniaturize systems, connect components, and fabricate components or systems that are not currently possible to produce.

Microscopic and Nanoscopic Tubes and Tubules

Commercially, tubing is extruded, drawn, pultruded, or rolled and welded which limits the types of materials that can be used for ultrasmall tubes as well as their ultimate internal diameters. In addition, it is not currently possible to control the wall thickness, internal diameter, or the surface roughness of the inner wall of these tubes to a fraction of a micron by these techniques. Using conventional techniques, ceramic tubes are currently available only as small as 1 mm i.d. Copper tubing can be obtained as small as 0.05 mm i.d., polyimide tubing is fabricated as small as 50 μm i.d., and quartz tubing is drawn down as small as 2 μm i.d. This means that quartz is the only tubing commercially available that is less than 10 μm i.d. This quartz tubing is used principally for chromatography.

There are, however, other sources of small tubing that are presently at various stages of research and development. For some time, several groups have been using lipids as templates (26–28) to fabricate submicron diameter tubing. These tubes are made by using electroless deposition to metallize a tubular lipid structure formed from a Langmuir–Blodgett film. Lipid templated tubes are very uniform in diameter, which is fixed at $\sim 0.5 \mu\text{m}$ by the lipid structure. Lengths to 100 μm have been obtained by this technique which is extremely expensive due to the cost of the raw materials.

Other groups are making submicron diameter tubules using a membrane-based synthetic approach. This method involves depositing the desired tubule material within the cylindrical pores of a nanoporous membrane. Commercial “track-etch” polymeric membranes and anodic aluminum oxide films have been used as the porous substrate. Aluminum oxide, which is electrochemically etched, has been the preferred substrate because pores of uniform diameter can be made from 5–1000 nm. Martin (29–31) polymerized electrically conductive polymers from the liquid phase and electrochemically deposited metal in the

pore structure of the membrane. Kyotani et al. (32,33) deposited pyrolytic carbon inside the pores of the same type of alumina substrate. In each case, after the inside walls of the porous membrane are covered to the desired thickness, the porous membrane is dissolved leaving the tubules. A variation of this technique, used by Hoyer (34,35) to form semiconductor (CdS , TiO_2 , and WO_3) nanotubes, includes an additional step. Instead of coating the pore wall directly to form the tubule, he fills the pore with a sacrificial material, solvates the membrane, and then coats the sacrificial material with the material for the nanotube wall. The sacrificial material is finally removed to form the nanotube. As in the lipid process, all of the tubules formed by this process in a single membrane are uniform in diameter, length, and thickness. But in contrast to the lipid process, the diameter of the tubules can be varied by the extent of oxidation of the aluminum substrate. Although diameters can be varied in this process, it should be clear that these tubules are limited in length to the thickness of the porous membrane. In addition, the wall thickness is also limited in that the sum of the inside tubule diameter and two times the wall thickness is equal to the starting pore diameter.

Using a sol-gel method, tubules can be made in about the same diameter range as in the membrane approach. By hydrolyzing tetraethylorthosilicate at room temperature in a mixture of ethanol, ammonia, water and tartaric acid, Nakamura and Matsui (36) made silica tubes that had both square and round interiors. The tubules produced by this technique were up to $300\ \mu\text{m}$ long, and the i.d. of the tubes ranged from 0.02 to $0.8\ \mu\text{m}$. By introducing minute bubbles into the sol, hollow TiO_2 fibers that have internal diameters up to $100\ \mu\text{m}$ have also been made (37) by using the sol-gel approach.

On an even smaller scale, nanotubes are fabricated using a number of very different techniques. The most well-known tube in this category is the carbon "buckytube" that is a cousin of the C_{60} buckyball (38–42). Since carbon nanotubes were first observed as a by-product in C_{60} production, the method of C_{60} formation using an arc-discharge plasma was modified to enhance nanotube production. The process produces tubules whose i.d. is in the range of 1–30 nm. These tubules are also limited in length to about 20 microns. Similar nanotubes of BN (43), B_3C , and BC_2N (44) have been made by a very similar arc-discharge process. In addition, nanotubes of other compositions (45,46) have been prepared using carbon nanotubes as a substrate for conversion or deposition.

An alternative technique for manufacturing carbon tubes that have nanometer diameters has been known to the carbon community for decades from the work of Bacon, Baker, and others (47–50). The process produces a hollow catalytic carbon fiber by pyrolyzing a hydrocarbon gas over a catalyst particle. The fibers, which vary in diameter from 1 nm to $0.1\ \mu\text{m}$ have lengths up to centimeters, can be grown either hollow or has an amorphous center that can be removed by catalytic oxidation after a fiber is formed.

Other nanoscale tubules whose diameters are slightly larger and smaller than buckytubes have been made from bacteria and components of cytoskeletons and by direct chemical syntheses. Chow and others (51) isolated and

purified nanoscale protein tubules called rhabidosomes from the bacterium *Aquaspirillum itersonii*. After the rhabidosomes are metallized by electroless deposition and the bacteria are removed, metal tubules approximately 17 nm in diameter and 400 nm long are produced. Using a similar metallization technique, metal tubes have been fabricated (52) whose inner diameters are 25 nm by using biological microtubules as templates. These microtubules, which are protein filaments of 25 nm o.d. and whose lengths are measured in microns, are components of the cytoskeletons of eukaryotic cells. In contrast to tubules produced from biological templates, the tubules produced by direct chemical synthesis involve using the technique of molecular self-assembly. Some of the nanotubules that fall into this category are made from cyclic peptides (53), cyclodextrins (54), and bolaamphiphiles (55). Cyclic peptide nanotubules have an 0.8 nm i.d. and can be made several microns in length. Other self-assembled nanotubules that range from 0.45 to 0.85 nm i.d. have been synthesized from cyclodextrins (54,56) in lengths in the tens of nanometers.

Although it is clear that individual nanotubules are currently useful for certain applications, such as encapsulation, reinforcement, or as scanning probe microscope tips (57), it is not obvious how individual nanotubules can be observed and economically manipulated for use in devices other than by using a scanning probe microscope (58). Until this problem is solved, the future of individual nanotubes in devices is uncertain. However, this problem can be circumvented if the nanotubules are part of a larger body such as in an array.

If oriented groups or arrays of submicron to micron diameter tubes or channels perpendicular to the surface of the wafer or device are desired, there are at least four means available to make them. Using the technique described before for making anodic porous alumina, a two step replication process (59) can be used to fabricate a highly ordered honeycomb nanohole array from gold or platinum. The metal hole array is from 1–3 micron thick and has holes 70 nanometers in diameter. For smaller tubes or channels, a technique (60) has recently been developed to draw down bundles of quartz tubes to form an array. This process produces a hexagonal array of glass tubes each as small as 33 nm in diameter. This translates to a density of 3×10^{10} channels per square centimeter. Even smaller regular arrays of channels can be synthesized by a liquid crystal template mechanism (61,62). In this process, aluminum silicate gels are calcined in the presence of surfactants to produce channels 2–10 nm in diameters. Finally, channels of ~ 4 nm in cross section can be produced (63) perpendicularly to the surface of an amorphous silica film by forming hematite crystals in a Fe–Si–O film and then etching away the hematite crystals.

Finally, several technologies exist to make channels or layers of channels of desired orientation in solid objects. These technologies are another spin-off of the photolithographic process used for integrated circuits. On a two-dimensional plane, channels that range in size from tens to hundreds of microns in width and depth have been fabricated (16,17) on the surface of silicon wafers by standard microphotolithographic techniques. Forming of microscopic channels and holes in other materials originated

in the rocket propulsion community in 1964. Work at Aerojet Inc. (64) produced metallic injectors and cooling channels in metallic parts using a process that included photolithographic etching of thin metallic platelets and stacking the platelets followed by diffusion bonding of the platelets to form a solid metallic object that has micron-sized channels. The group at Aerojet has recently modified its technique to use silicon nitride. Variations on this technique include electrochemical micromachining and sheet architecture technology.

Electrochemical micromachining (65,66) avoids generating toxic waste from acid etching by making the thin metal part covered with exposed photoresist the anode in an electrochemical cell where a nontoxic salt solution is the electrolyte. Sheet architecture technology (67) developed at Pacific Northwest National laboratory is used to fabricate numerous microscopic chemical and thermal systems, such as reactors, heat pumps, heat exchangers, and heat absorbers. These devices may consist of a single photolithographically etched or laser-machined laminate that has a cover bonded to seal the channels, as described before, or may consist of multiple layers of plastic or metal laminates bonded together.

It is quite apparent from this brief and incomplete review, that a number of very novel and innovative approaches have been used to make microsystems as well as tubes and channels whose diameters are in the range of nanometers to microns. In the next section, the basics of microtube technology which complements these other technologies are discussed.

AFRL MICROTUBE TECHNOLOGY

Properties and Production of Microtubes

Except for self-assembled tubules, the microtube technology developed at the Propulsion Directorate of the Air Force Research Laboratory (AFRL) can produce tubes in the size range of those made by all of the other techniques cited. In contrast to tubing currently on the market and the submicron laboratory scale tubing mentioned before, microtubes can be made from practically any material (including smart materials) and will have precisely controlled composition, diameter, and wall thickness in a great range of lengths. In addition, this technology can produce tubes in a great diversity of axial and cross-sectional geometries. For most materials, there is no upper diameter limit, and for practically any material, internal diameters greater than 5 μm are possible. In addition, for materials that can survive temperatures higher than 400°C, tubes can be made as small as 5 nanometers by using the same process.

To date, tubes have been made from metals (copper, nickel, aluminum, gold, platinum, and silver), ceramics (silicon carbide, carbon, silicon nitride, alumina, zirconia, and sapphire), glasses (silica), polymers (Teflon), alloys (stainless steel), and layered combinations (carbon/nickel and silver/sapphire) in sizes from 0.5–410 μm . Like many of the techniques described before, microtube technology employs a fugitive process that uses a sacrificial mandrel, which in this case is a fiber. High-quality coating

techniques very faithfully replicate the surface of the fiber on the inner wall of the coating after the fiber is removed. By a proper choice of fiber, coating, deposition method, and mandrel removal method, tubes of practically any composition can be fabricated. Obviously, a great deal of material science is involved in making precision tubes of high quality. Some scanning electron microscope (SEM) micrographs of a group of tubes are shown in Fig. 1.

Cross-sectional shapes and wall thickness can be very accurately controlled to a fraction of a micron, which is not possible by using any of the approaches cited before. Numerous cross-sectional shapes have already been made, and some of them are shown in Fig. 2. These micrographs should be sufficient to demonstrate that practically any cross-sectional shape imagined can be fabricated. As seen in Fig. 2, the wall thickness of the tubes can be held very uniform around the tube. It is also possible to control the wall thickness accurately along the length of the individual tubes and among the tubes in a batch or a continuous process. It can be seen in Fig. 2 that the walls can be made nonporous. It will be shown later that the microstructure of the walls and extent of porosity that the walls contain can also be controlled. In addition to the possibility of cross-sectional tube shapes, using a fugitive process also allows fabricating tubes that have practically any axial geometry, as is shown later.

The maximum length in which these tubes can be made has yet to be determined because it depends on many variables, such as the type of tube material, the composition of the sacrificial tube-forming material, and the degree of porosity in the wall. It is possible that there is no limitation in length for a tube that has a porous wall. For nonporous wall tubing, the maximum length would probably be in the meter range because there is a direct relationship between the tube i.d. and the maximum possible length. However, for most applications conceived to date, the length need only be of the order of a few centimeters. Based on a quick calculation, it is apparent that even "short" tubes have a tremendous aspect ratio. For instance, a 10- μm i.d. tube 25 cm long has an aspect ratio of 2500.

Using microtube technology, there is no upper limitation in wall thickness for most materials. To date, free-standing tubes have been made whose wall thickness range from 0.01–800 μm (Fig. 3a). Most of the microtubes tested to date have demonstrated surprising mechanical strength. In fact, preliminary studies of both copper and silver tubes whose wall thickness is in the micron range have shown that microtubes can have up to two times the tensile strength of an annealed wire of the same material of the same cross-sectional area. Besides precise control of the tube wall thickness and composition, the interior surface of these tube walls can have practically any desired texture or degree of roughness. In addition, the walls can range from nonporous to extremely porous, as seen in Fig. 4, and the interior or exterior surfaces of these tubes can be coated by one or more layers of other materials (Fig. 5).

In addition to free-standing microtubes, solid monolithic structures that have microchannels can be fabricated by making the tube walls so thick that the spaces between the tubes are filled (Fig. 6). The microchannels can be randomly oriented, or they can have a predetermined orientation.

Figure 1. Examples of microtubes: (a) 10- μm silicon carbide tubes; (b) 410- μm nickel tubes; (c) 26- μm silicon nitride tube; and (d) 0.6- μm quartz tube.

Any desired orientation or configuration of microtubes can be obtained by a fixturing process. Alternatively, composite materials can be made by using a material different from the tube wall as a “matrix” that fills in the space among the tubes. The microtubes imbedded in these monolithic structures form oriented microchannels that, like free-standing tubes, can contain solids, liquids, and gases, and as act as waveguides for all types of electromagnetic energy.

Microtube Applications

Discrete thinner walled microtubes are useful in areas as diverse as spill cleanup, encapsulation of medicine or explosives, insulation that is usable across a very wide range of temperature, and as lightweight structural reinforcement similar to that found in bone or wood. The cross-sectional shape of these reinforcing tubes can be tailored to optimize mechanical or other properties. In addition, thinner walled tubes are useful as bending or extension actuators when fabricated from smart materials. Thicker walled tubes (Fig. 3b: nickel and SS) that are just as easily fabricated are needed in other applications, such

as calibrated leaks and applications that involve internal or external pressure on the tube wall.

The ability to coat the interior or exterior surface of these tubes with a layer or numerous layers of other materials enlarges the uses of the microtubes and also allows fabricating certain devices. For example, applying oxidation or corrosion protection layers on a structural or specialty tube material will greatly enlarge its uses. A catalyst can be coated on the inner and/or outer tube surface to enhance chemical reactions. The catalytic activity of the tube can also be enhanced by increasing the porosity in the wall, as shown before in Fig. 4. Multiple alternating conductive and insulating layers on a tube can provide a multiple-path microcoaxial conductor or a high-density microcapacitor.

As stated before, the interior surface of these tube walls can have practically any desired texture or degree of roughness. This control is highly advantageous and allows using microtubes in many diverse applications. For example, optical waveguides require very smooth walls, whereas catalytic reactors would benefit from rough walls. (Because of the fabrication technique, the roughness of the tube wall interior can be quantified to a fraction of a micron by using scanning probe microscopy techniques on the mandrel.)

Figure 2. Tubes larger than $1\ \mu\text{m}$ i.d. can be made in any cross-sectional shape such as (a) $17\text{-}\mu\text{m}$ star, (b) $9 \times 34\text{-}\mu\text{m}$ oval, (c) $59\text{-}\mu\text{m}$ smile, and (d) a $45\text{-}\mu\text{m}$ trilobal shape.

Figure 3. Tubes can be structurally sound and have (a) very thin walls or (b) thick walls.

Figure 4. Microtube that has a porous tube wall.

Microtubes can be made straight or curved (Fig. 7), or they can be coiled (Fig. 8). Coiled tubes whose coils are as small as $20\ \mu\text{m}$ can be used, for example, as flexible connectors or solenoid coils. For the latter application, the coils could be of metal or of a high temperature superconductor where liquid nitrogen flows through the

Figure 5. (a) Sapphire tube that has a silver liner. (b) Nickel tube that has a silver liner.

Figure 6. Solid nickel structure that has oriented microchannels.

tube. Another application for coils is for force or pressure measurement. No longer are we limited to quartz microsprings. Using microtube technology, the diameter and wall thickness of the tube, the diameter of the coil, the tube material, and the coil spacing can be very precisely

Figure 7. Examples of curved silver tubes: (a) single tube; (b) multiple tubes.

Figure 8. (a) Section of “large” coiled tube. (b) Open end of coiled tube.

controlled to give whatever spring constant is needed for the specific application. In addition, these microcoils can be made from a variety of smart materials and used as actuators or sensors. For example, the length of a spring made from Nitinol[®] can easily be changed by applying heat. It is also possible to wrap one or more coiled spring tubes around a core tube (Fig. 9). Applications for this kind of device range from a counterflow heat exchanger to a screwdrive for micromachines. (For the screw application, the wrapped coil cross section could be made rectangular.)

Like coiled spring tubes, bellows can be used as microinterconnects, sensors, and actuators and can be made in practically any shape imaginable. Figure 10a shows a bellows that has a circular cross section, and the bellows in Fig. 10b has a square cross section and aligned bellows segments. The bellows in Fig. 10c is square and has a twist. A slightly more complex bellows shown in Fig. 10d is a tapered-square camera bellows that has a sunshade to demonstrate the unique capability of this technology. It demonstrates the ability to control cross section and axial shape and to decrease and increase the cross-sectional

Figure 9. A coiled tube wrapped around a tube or fiber that can be used as a heat exchanger or as a microscopic screwdrive.

dimension in the same device. Bellows fabricated by microtube technology can have a variety of shaped ends for connections to systems for use, for example, as finned heat exchangers, hydraulic couplings for gas and liquid, or static mixers for multiple fluids. The bellows in Fig. 10e has a thicker transitional region and a dovetail on the end for connection to a device machined on a silicon wafer. The female dovetail to mate with this bellows is a commercially available trench design (68) on a silicon wafer that provides a way to attach the bellows to the wafer, which can be pressurized by using proper sealing. (No other technology available can join a fluidic coupling to a wafer for pressurization to relatively high pressures.)

If one end of the bellows is sealed, an entirely new group of applications becomes possible. For example, if a bellows end is sealed, the bellows can be extended hydraulically or pneumatically. In this configuration, a bellows could be used as a positive displacement pump, a valve actuator, or for micromanipulation. As a manipulator, a single bellows could be used for linear motion, three bellows could be orthogonally placed for 3-D motion, or three bellows could be attached at several places externally along their axes (Fig. 11) and differentially pressurized to produce a bending motion. This bending motion would produce a microfinger, and several of these fingers would make up a hand. The large forces and displacements possible by using this technique far surpass those currently possible by electrostatic or piezoelectric means and fulfill the need expressed by Wise and Najafi (18) when they stated that “In the area of micro-actuators, we badly need drive mechanisms capable of producing high force and high displacement simultaneously.”

For most applications, it is necessary to interface microtubes and the macroworld. This is possible in a number of ways. For example, a tapering process can be used in which the diameter is gradually decreased to micron dimensions. Alternatively, the tubes and the macroworld can be interfaced by telescoping or numerous types of manifolding schemes (Fig. 12). An example of a thin-walled 5- μm i.d. tube telescoped to a 250- μm o.d. tube is shown in Fig. 13. A tube of this type could be used as a micropitot tube and, of course, could be made more robust by thickening the walls.

Figure 10. (a) A conventional round bellows. (b) A straight bellows that has a square cross section (c) A square bellows that has a twist. (d) A tapered square camera bellows that has a sun shade to demonstrate the versatility of the technique. (e) A round bellows that has a dovetail connector.

Although microtube technology has unique capabilities, it should be obvious that no single technology can fill all of the requirements imposed by diverse applications. Thus, microtube technology cannot easily compete with other technologies in certain applications. One of these involves gas and liquid separation such as in chromatography. For example, quartz tubing that can be extruded and drawn

in very long lengths is inexpensive and available in micron dimensions. However, note that even in areas such as separation, there are niches for microtubes that involve the composition of the tube material, the cross-sectional shape, or the inner wall coating. For example, Fig. 14 shows microtubes manifolded to a tubular frame for a specific gas separation that requires microtubes

Figure 11. Microtube bellows finger: (a) unpressurized; (b) pressurized.

of a specific composition, precise diameter, and wall thickness.

Currently, these tubes have been made by a batch process in the laboratory, but the technique is equally suited to a continuous process which would be more efficient and also much easier in some cases. Obviously, a continuous process would reduce costs. For most materials, costs are already rather low because, unlike some other processes, expensive tooling is not required. For many materials such as quartz, aluminum, and copper, the anticipated cost is

~\$0.01/cm for thin-walled tubes. For precious metals such as gold or platinum, the cost would be significantly higher due to the cost of raw materials.

Microtubes have almost universal application in areas as diverse as optics, electronics, medical technology, and microelectromechanical devices. Specific applications for microtubes are as diverse as chromatography, encapsulation, cross- and counterflow heat exchange, injectors, micropipettes, dies, composite reinforcement, detectors, micropore filters, hollow insulation, displays, sensors,

optical waveguides, flow control, pinpoint lubrication, microsponges, heat pipes, microprobes, and plumbing for micromotors and refrigerators. The technology works equally well for high- and low-temperature materials and appears feasible for all applications that have been conceived to date. As can be seen, there are numerous types of devices that have become possible as a result of microtube technology. One category of devices that is highlighted is that based on surface tension and wettability.

MICROTUBE DEVICES BASED ON SURFACE TENSION AND WETTABILITY

Now, there is great interest in developing microfluidic systems to decrease the size of current devices, increase their speed and efficiency, and decrease their cost because microfluidic systems have the potential, for example, for drastically decreasing the cost of certain health tests, allowing implantable drug delivery systems, and very significantly reducing the time needed to complete the Humane Genome Project. Microtube technology based on surface tension and wettability is unique in its capabilities and is truly an enabling technology in the microfluidic field.

Figure 14. Microtubes are manifolded to a tubular frame for gas separation.

As miniaturization of mechanical, electrical, and fluidic systems occurs, the role of physical and chemical effects and parameters has to be reappraised. Some effects, such as those due to gravity or ambient atmospheric pressure, are relegated to minor roles or can even be disregarded entirely as miniaturization progresses. Meanwhile, other effects become elevated in importance or, in some cases, actually become the dominating variables. This “downsizing reappraisal” is vital to successful miniaturization. In a very real manner of speaking, new worlds are entered into in which design considerations and forces that are normally negligible in real-world applications become essential to successful use and application of miniaturized technology.

Surface tension and wettability are closely related phenomena that are greatly elevated in importance as miniaturization proceeds. Surface tension involves only the strength of attraction of droplet molecules for one another (cohesive forces), but wettability also includes the strength of attraction of droplet molecules to molecules of the wall material (adhesive forces). It is important to realize that surface tension and wettability are usually not comparable in effect to normal physical forces at macroscopic levels. For example, surface tension is usually ignored when determining fluid flow through a pump or tube. Its effect is many orders of magnitude smaller than pressure drop caused by viscosity because the difference in pressure ΔP between the inside of a droplet and the outside is given by the Young and Laplace equation of capillary pressure (69,70):

$$\Delta P = 2\gamma/r. \quad (1)$$

In this equal-radii form of the capillary pressure law used for a spherical droplet, γ is surface tension and r is droplet radius. The pressure inside the droplet can be thought of as caused by a surface “skin,” similar to a balloon that holds air in. Instead of a thin membrane of rubber as in the case of balloons, however, confining forces in surface tension are caused by the affinity of molecules of droplet material for one another. Because molecules are missing a

binding partner looking outward on the surface of a drop, they pull on their nearest neighbors.

Normally, droplet dimensions in most macroscopic applications are measured in thousands of microns. Therefore, pressure differences due to surface tension are inconsequential and typically measure far less than atmospheric pressure. For comparison, pressure drops resulting from viscous flow are typically of the order of magnitude of tens of atmospheres. When r is of the order of microns, however, pressure differences due to surface tension become enormous and frequently surpass tens of atmospheres. This is precisely the reason that fine aerosol droplets are so difficult to form. However, the formation of tiny droplets is not specifically the focus of discussion here, but rather their behavior in miniature voids, such as cavities, capillaries, and channels that are shaped so that they partially confine the droplet. The position of droplets within such microvoids is governed by the surface tension of the droplet fluid, the wettability of the fluid with respect to microvoid walls contacted during displacement, the geometric configuration of the walls that confine the fluid droplets, and any pressure external to the droplet. Microdevices fabricated from these microvoids can be made to operate when wettabilities are greater than or less than 90° , but not exactly 90° . They can operate using either nonwetting or wetting fluids. The difference between wetting and nonwetting fluids in capillaries can be explained by using Fig. 15.

In Fig. 15a, a nonwetting fluid droplet is forced into a single microtube. An insertion pressure has to push the nonwetting droplet inside the microtube because of the repulsion between the droplet and the walls. Once it is inside, however, no further pressure is necessary. In fact, any pressure simply moves the nonwetting droplet along the microtube at a velocity determined by the applied pressure and the frictional forces between the droplet and the microtube wall. Note that the nonwetting droplet becomes elongated when it is constrained in the capillary and has a convex-shaped interface along the axis of the capillary. In addition, it can be seen that the radius of the nonwetting droplet is now greater than the radius of the microdevice tube and that the contact angle θ with the capillary surface is between 90° and 180° , which is the contact angle for a totally nonwetting droplet. In contrast, the situation is very different if the fluid totally wets the microtube surface, as seen

in Fig. 15b. In this case, the fluid is sucked into the microtube, and fluid flow is governed only by frictional forces. This is the situation in normal macroscopic applications. For wetting fluids, the ends of the droplets are concave because the walls of the microdevice are wet by the droplet and attract the droplet molecules. The contact angle for wetting fluids is between 0 and 90° , 0° indicates a totally wetting fluid. In this article, the term nonwetting refers to a contact angle greater than 90° , and the term wetting means a contact angle less than 90° .

The behavior of a microtube device that employs nonwetting droplets is easily understood if one compares it to the mercury intrusion method (71–73) of measuring the pore-size distribution within porous solids. This technique is based on the understanding that the pressure needed to force a nonwetting fluid into a capillary or a pore in a solid is given by the relationship proposed by Washburn (71):

$$P = 2\gamma \cos \theta / r \quad (2)$$

where θ is the contact angle of the fluid with the material under test, P is the external pressure applied to the nonwetting fluid, and r is the radius of the capillary or pore which, act is assumed for simplicity, is spherical and has a constant diameter. This equation is valid for any fluid in contact with a capillary or porous solid whose contact angle is greater than 90° . Once the external applied pressure exceeds that needed to insert the nonwetting fluid into a constant-diameter capillary or pore, the nonwetting fluid flows into that particular diameter capillary or pore until it fills it. Then, the volume of the intruded fluid is a direct measure of that particular capillary's or pore's void volume. If a smaller capillary or pore branches off the larger diameter void, it remains unfilled until the insertion pressure is raised sufficiently high that Eq. (2) is again satisfied, and the process repeats itself.

In contrast to the mercury intrusion method of determining pore volume, instead of determining the pore volume, the emphasis in devices based on microtube technology is placed on the movement and the position of the droplet in the confining voids. These droplets can be wetting or nonwetting. As will be apparent later, a myriad of smart microdevices are based on surface tension and wettability.

Because these microdevices have no moving mechanical parts, they are very reliable, can be used in both static and dynamic applications, and are very rugged. They can experience pressures or forces far beyond their normal operating range and still return to their original accuracy and precision. In addition, unlike technology built up on a silicon wafer, these microdevices can be made from practically any material. Thus, high-temperature microdevices can be fabricated by properly choosing the device and droplet material.

Devices That Use the Interaction of Nonwetting Droplets and Gases and Wetting Fluids

This group of devices uses the surface properties of materials, primarily surface tension and wettability, as the principal means of actuating and controlling motion by and

Figure 15. Behavior of fluid droplets in capillaries: (a) nonwetting droplet; (b) wetting droplet.

Figure 16. Nonwetting droplet inserted into a microtube under pressure. (a) Constant diameter tube. (b) Tube that has a transition to a smaller diameter.

within microtube devices. These devices, which have no moving mechanical parts, can perform mechanical tasks whose scale of motion is measured in microns.

These devices, similar to other microdevices based on surface tension and wettability, are composed of various sizes of nonwetting droplets inserted into microscopic voids of various shapes and sizes. These voids can be in the form of cavities, capillaries, and channels that are shaped so that they partially confine the droplet. Gas or wetting fluid is placed in the microcavities along with the nonwetting fluid. During operation, the nonwetting droplets move in response to fluid or gas pressure or vice versa. Specifically, these nonwetting droplets may translate within a void of the microtube device that is filled with the gas or wetting fluid, translate from one void space to another, or rotate in a fixed position. Microtube devices of this type can stop fluid flow or act as a check valve, a flow restricter, a flow regulator, or a gate, for example. The minimum dimension of the voids in these devices typically ranges from about 20 nm to about 1000 μm .

In Fig. 16a, a non-wetting fluid droplet is forced through a single microtube. An initial insertion pressure has to push the nonwetting droplet inside the microtube. If the diameter of the microtube in Fig. 16a decreases at a certain point to form a telescoping microtube (Fig. 16b), a considerably higher pressure must be applied by a gas or wetting fluid to squeeze the nonwetting drop into the smaller section of the microtube. In contrast, if a wetting fluid is employed instead of a gas, as before, it is also sucked into the smaller diameter section, completely filling all the available space in the microcavity. By inserting an appropriately sized nonwetting droplet into a tapered microtube or a microtube that has a transition to a smaller dimension that is filled by a second fluid that wets the tube walls, all flow of the wetting fluid can be stopped by applying a pressure that forces the nonwetting droplet to block the

Figure 17. Microtube check valve: (a) flow possible through bypass tubes; (b) flow is blocked.

entrance to the smaller section of the cavity. This is the situation in Fig. 16b where the nonwetting droplet has been forced to the intersection of the larger and smaller microtube sections by the flowing gas or wetting fluid. Figure 17a,b illustrates an extension of this concept. By adding additional small-diameter bypass-flow paths to one end of a doubly constricted tube, flow is possible only in the direction of the end that has the added flow paths attached to the cavity. Of course, these bypass tubes must be properly sized to prevent nonwetting droplets from squeezing into them. This microtube device in Fig. 17 acts as a check valve and has no solid moving parts. This cannot be achieved at the macroscopic level because forces that arise from surface tensions of fluids are too small due to the much larger geometries employed.

Figures 18 and 19 are further extensions of this same concept. In Fig. 18, bypass tubes are left off the microtube check valve and convert it to either a microtube flow limiter (Fig. 18) or a microtube flow restricter (Fig. 19). In Fig. 18, because the nonwetting droplet and the larger tube wall form a seal, the only wetting fluid flow that can occur in either direction when the nonwetting droplet travels back and forth is equal to the volume of the larger tube section minus the volume of the nonwetting droplet. In Fig. 19, the diameter of the nonwetting droplet is now smaller than the diameter of the larger microtube section but larger than

Figure 18. Microtube flow limiter.

Figure 19. Microtube flow restricter.

the diameter of the smaller microtube. Thus, flow can take place around the nonwetting droplet. However, fluid flow is not merely restricted, but is entirely stopped if there is enough flow to push the drop to one end that blocks the smaller tube.

Figure 20 illustrates a microtube pressure/flow regulator. In this device, bypass tubes have openings or are open along their entire lengths to a conically shaped transitional region placed between the larger and smaller diameter tubes. Furthermore, the lengths of the joined bypass tubes (now better described as bypass channels) up to the conical transitional region can be varied. Increased pressure or flow forces the nonwetting droplet farther into the conical transitional region and exposes more flow channel openings to wetting fluid. The result is increased flow of the gas or wetting fluid as a function of pressure. By suitably sizing the nonwetting droplet, properly orienting the device, correctly shaping the transitional cone, and precisely positioning bypass channels, this device can also function as a microtube pressure-relief valve; no flow occurs until some predetermined pressure is exceeded. Then, flow takes place as long as pressure is maintained. Note that only two bypass flow channels are shown in Fig. 20. This was done to simplify the drawing. Any convenient number, one or more, of channels can be employed. Finally, by making bypass-flow channels vary in cross-sectional area, uniformly increasing or decreasing flow can be produced as a function of pressure.

In addition to a check valve, it is possible to use nonwetting fluids to make a positive closure valve that has zero dead space to control a gas or wetting fluid. Figure 21a,b

Figure 20. Microtube flow or pressure regulator.

Figure 21. Positive closure microtube valve that has zero dead space: (a) top view; (b) side view.

illustrates a microvalve composed of a fill tube joined to an end bulb, where two microchannels are attached to the fill tube. In this example, the nonwetting droplet controls the flow of a wetting fluid or gas through a microchannel whose thickness is less than that of the fill tube. In this microvalve, an inlet fluid flows through an inlet duct and then into one of the microchannels. If the fill tube is not blocked by the nonwetting droplet, the inlet fluid traverses the unblocked fill tube at the point where both microchannels attach to it. Then, the fluid exits the microvalve through an outlet duct as outlet fluid. In Figure 21a,b, the nonwetting

Figure 22. Microfluidic logic circuit that acts as comparator: (a) output; (b) no output.

droplet is activated by a heater and only partially fills the fill tube. Obviously, many other forms of activation are possible, and it is possible to assemble these microvalves in parallel to control large flows of liquids or gases.

A final category of microfluidic devices in which one fluid controls another can be understood by the more complex examples given in Fig. 22. These figures present microtube devices that use surface tension and wettability in fluidic logic circuits that are fully digital, not analog. The device in Fig. 22 functions as a comparator; there is an output only if the inputs are equal. Thus, if pressure is applied to either branch A or B, the gate (nonwetting droplet 2) closes, as in Fig. 22b, and no flow occurs (and no pressure is transmitted) between branches C and D. If equal pressure is applied to A and B or no pressure is applied to A and B, the gate remains open as in Fig. 22a, and flow occurs (and pressure is transmitted) between C and D. Nonwetting droplet 1 is returned to the center position whenever pressure is removed because surface tension always minimizes droplet surface area and a sphere has the lowest surface area per unit volume of any object. Only at the center position can it be a sphere, and unless placed under unbalanced force by pressure from A or B, it remains at

the center. Numerous other types of logic circuits, such as OR, NOR, AND, and NAND gates, can also be fabricated in this manner. By combining a number of these logic components in a suitable arrangement, digital operations can be performed identically to those of electrical devices. Instead of electricity being on or off in a circuit, pressure is applied or not applied, and fluid flow does or does not occur.

Microdevices Based on the Positions and Shapes of Nonwetting Droplets

In this group of microdevices, the basic principle of operation is the movement or shape change of nonwetting droplets in tubes, channels, or voids that have at least one microscopic dimension. This movement or shape change results from external or internal stimuli. The change in droplet shape depends on the cavity shape and always minimizes the surface free energy of the droplet. The cavity that constrains the droplet in these devices can be sealed or can have one or more openings. The shape of this cavity determines the reaction of the droplet to a stimulus, as well as the use of the microdevice, and the output that can be obtained from it. Uses for these microdevices are as diverse as sensors, detectors, shutters, and valves.

As just stated, microtube sensors based on surface tension and wettability are one type of device in this group. Some of these sensors respond to one or more external stimuli such as pressure, temperature, and gravity or acceleration by changes in the displacement or shape of liquid interfaces contained within microtubes and/or microchannels that have either fixed or variable axial geometries and circular or noncircular cross-sectional profiles. Other sensors respond to internal stimuli, such as a change in surface tension of the liquid droplet or a change in the wettability of the microdevice's internal walls. Some of these sensors can quantify the displacement or change in shape of the constrained droplet that results from external or internal forces acting on it.

An example of one of the simplest microdevices in this group of devices is a microtube pressure sensor (Fig. 23) that uses a nonwetting fluid in the form of a droplet. Figure 23a illustrates the position of the droplet when the entrance pressure P_{ent} is equal to the device pressure P_{dev} . Figure 23b illustrates the position of the droplet when the entrance pressure is greater than the device pressure P_{dev} , and Fig. 23c illustrates the position of the droplet when there is a much higher entrance pressure. This sensor demonstrates the reaction of such a device to an outside stimulus which in this case is an increase in externally applied pressure P_{ent} . As can easily be seen, the shape of the nonwetting droplet changes in reaction to increases in the applied external pressure P_{ent} . More precisely, increasing the external pressure P_{ent} , that acts through an entrance microtube squeezes the droplet into ever smaller diameter locations within a microcavity, which results in displacing the nonwetting interface toward the smaller diameter end of the device. For this type of sensor, this microcavity may be tear shaped, circular, or have practically any shape, as long as there is a change in at least one dimension and this dimension is from 0.003–1000 μm . For simplicity, the pressure on the smaller side of the microdevice P_{dev} , which

Figure 23. Microtube pressure sensor based on surface tension and wettability.

opposes the external pressure P_{ent} , is set at zero in this figure. P_{dev} is most easily thought of as a residual gas pressure left over inside the device from the actual fabrication process. It does not have to be zero, as shown later. The only requirement for this type of sensor is that P_{dev} be less than P_{ent} and that both pressures be smaller than the bursting strength of the walls of the microtube pressure sensor. It should be apparent from Fig. 23 that an overpressure of the device will push the droplet further into the device tube than designed for, but when the pressure is released, the droplet will return to its equilibrium position. As long as the walls of the device have not been damaged and maintain their original shape, the sensitivity and accuracy of this device and the others that are described following will be unaffected by overpressure.

The reaction of the droplet to external pressure is easily calculable from surface tension theory (the change in radius of the smaller end of the droplet is inversely proportional to applied the external pressure), but the actual decrease in radius and resulting displacement of the nonwetting interface can be understood only intuitively or observed visually by microscope, as presented in Fig. 23. Figure 24 illustrates a modification of this microtube pressure sensor based on surface tension/wettability which enables nonvisual determination of the displaced interface. This nonvisual response to the reaction (movement or shape change) of the droplet interface caused by a stimulus can take many forms. One of these is a change in electrical resistance. A center contact, which has a measurable electrical resistance, is inserted through the microtube device and establishes electrical contact with the nonwetting droplet. This center contact can be a wire, tube,

Figure 24. Microtube pressure sensor that has a resistance wire continuous readout.

tape, or any other elongated geometry desired. A second or side contact is likewise placed in a position to make electrical contact with the conductive droplet, but not make direct contact with the center contact. These two contacts are then connected to an apparatus that measures resistance. If the nonwetting droplet material composition has been selected so that it is electrically conductive as well as nonwetting, any displacement of the nonwetting interface that reduces the length of the center contact not touching the droplet thereby results in reducing the center contact's resistance measured by the resistance measuring apparatus. To maximize this effect, the center contact should have a very high resistance per unit length compared to the side contact, the actual droplet itself, and compared to the remainder of the circuit that connects both contacts to the resistance measuring apparatus.

As stated previously, the opposing pressure P_{dev} need not be zero. It has been set at zero thus far for simplicity. For this type of sensor, it merely needs to be less than the externally applied pressure P_{ent} ; otherwise, the nonwetting droplet could be expelled from the microtube pressure sensor.

Note here that the devices shown schematically can measure a variety of external or internal stimuli. The pressure sensor in Fig. 24, for example, could also measure acceleration and oscillation along the device axis as well as rotation and temperature, which affect both the thermal expansion and the surface tension of the droplet. If another center contact is also placed in the device on the end opposite the present center contact, the device can measure acceleration in two directions. In addition, it should be apparent that to measure parameters such as temperature, rotation, acceleration, or oscillation, it is not even necessary for the entrance tube and the device tube to be open to the atmosphere. Thus, to measure these external stimuli or some internal stimulus, a totally sealed cavity would function as well as the open pressure sensor in Fig. 24.

For simplicity, only pressure sensors are shown schematically, and it should be understood that the devices work equally well in reaction to many other stimuli. A partial list that includes vibration, acceleration, rotation, temperature, electromagnetic fields, and ionizing radiation demonstrates the broad scope of this sensor technology.

When a wetting droplet is employed in place of a nonwetting droplet, instead of needing P_{ent} to reach some value given by Eq. (2) to force the droplet into the microtube, it goes in automatically. This behavior is often referred to as "wicking." In contrast to the nonwetting droplet, no pressure is needed to get the drop into the tube. The fact that wetting droplets behave similarly to nonwetting droplets in

Figure 25. Microtube pressure sensor that has a “Yes-No” straight port.

some respects means that microdevice sensors can employ either wetting or nonwetting fluids as the droplet material and still serve the same function. For microtube pressure sensors, this would require switching the side of the droplet that actually “feels” the applied pressure. Microdevices that sense other stimuli would also need similar kinds of modification. These would be specific for the actual sensing application.

Figure 25a,b illustrates the relationship between the radius of curvature of the small end of the drop and the various pressures involved for a microtube pressure sensor that has a digital type of response; this will hereafter be referred to as a “Yes-No” response. In Fig. 25a, the applied pressure P_{ent} is not sufficient, compared to P_{dev} , to force the nonwetting droplet into the straight port. Therefore, the continuity apparatus registers an open circuit, or “No” response. In Fig. 25b, the applied pressure P_{ent} is sufficient to force entry of the nonwetting droplet into the straight port. Once the droplet has entered the straight port, it completely fills it, and the continuity apparatus registers a closed circuit, or “Yes” response. As mentioned previously, this same kind of “Yes-No” response can be duplicated by using wetting fluids. However, because a wetting fluid would spontaneously wick into the smaller diameter tube, the only difference would be that now an applied pressure of sufficient magnitude would need to be directed to P_{dev} to expel the wetting droplet from that same straight tube. Therefore, for a wetting fluid, the continuity apparatus would work in reverse to the “Yes-No” response for a nonwetting droplet. In this case, P_{dev} must be greater than P_{ent} , and therefore, an open circuit signifies “Yes,” and a closed circuit signifies “No.” However, because a wetting droplet adheres to the microdevice walls, including the straight port, fluid remaining on these surfaces might compromise the accuracy of the continuity apparatus. Therefore, it is preferable to use nonwetting droplets in this kind of sensor. This same logic applies to most microdevices based on surface tension and wettability, and so in the discussion that follows, only nonwetting behavior is illustrated.

There are obviously many other means for measuring displacement of a nonwetting droplet. Other basic electrical parameters that can be employed are capacitance

and inductance. Note here that for all of the aforementioned techniques for measuring displacement of a nonwetting droplet by using electrical means, the electrical properties of the nonwetting droplet must, of course, be suitable for the measurement technique employed. For some applications, the resistance of the nonwetting droplet must be sufficiently low to permit measuring the resistivity of the center contact accurately enough for the application, at hand. For other applications, the conductivity must be high enough to enable measuring capacitance accurately. For certain applications, permeability must be sufficiently different between the nonwetting droplet and its surrounding medium in the microdevice to allow measuring inductance accurately enough to satisfy the demands of the desired application. These electrical property requirements are most likely to be different, depending on the measuring technique employed and the particular application being developed. Note that it is also possible to combine two or more readout techniques in a single device.

For either multirange or redundancy-driven applications, a great deal of variation is possible. These variations are in the form of identical or different devices, cavity, and/or channel or tube configurations, as well as identical or different types of readouts. Many different types of device channel or tube configurations are possible that will give either linear or nonlinear responses, as well as analog or digital responses to the stimuli being sensed. For example, a gradual taper would produce a linear response, whereas a very rapid taper would give a nonlinear response. In another example, a device such as that shown in Fig. 25 could be modified with a tapered section to follow the constant dimension tube. This would result in a digital response followed by an analog response. In addition to these differences in individual sensors, multiple sensors could all be used together simultaneously or switched on or off as needed.

As mentioned previously, the presence or absence of nonwetting material in a straight tube (Fig. 25) enables the pressure sensor or other microdevice that derives its capabilities from surface properties of materials to function in a digital or a “Yes-No” mode of response. Figure 26 illustrates another very simple kind of “Yes-No” readout response for a pressure sensor that does not have a straight tube. Now, the center contact in Fig. 24 has been truncated, so that it does not make contact with the nonwetting droplet for low values of the pressure difference between P_{ent} and P_{dev} . This lack of contact, or gap, is shown in Fig. 26. The truncated center contact makes contact only with the nonwetting droplet once a predetermined

Figure 26. Microtube pressure sensor that has a “Yes-No” central contact.

Figure 27. Microtube pressure sensor that has a variable “Yes-No” central contact.

pressure difference exists (P_{ent} greater than P_{dev}). Once this occurs, the continuity meter signals that contact has been made, and the desired “Yes-No” readout response is provided. Once sufficient pressure difference has been established, the truncated center contact can then function as a center resistance contact, center contact, some other kind of readout implement, or some combination thereof. The truncated center contact should not move relative to the microdevice walls in this simple form of “Yes-No” readout microdevice. It should be apparent that devices of this type that have a truncated center contact can also serve as an electrical switch, based on surface tension and wettability, that can be made to operate independently of gravity, can be impervious to radiation, and can be activated by numerous stimuli.

A more sophisticated “Yes-No” readout microdevice pressure sensor is illustrated in Fig. 27. Now the truncated center contact is attached to a positioner, which, in turn, is attached to a positioner holder, which is itself held firmly in place relative to the actual microdevice walls. In Fig. 27, the positioner holder is shown attached to the microdevice walls. The positioner is any type of device that can move the truncated center contact relative to the microdevice walls in a predetermined fashion. Examples of such positioning devices are numerous. They can be the type where the operator sets the gap and thereby controls the device’s sensitivity, such as a pressurized microbellows and a piezoelectric crystal. Alternatively, the positioning device can be the type that is influenced by its environment, such as those made from photostrictive, chemostriptive, electrostrictive, or magnetostrictive materials, which change length due to light, a chemical environment, or an electric or magnetic field. In these types of “smart” materials, the positioner can be controlled in real time by its environment, and thus the device can respond to two stimuli simultaneously. Moreover, using any such positioning devices, the gap can be changed by a feedback circuit. By altering the size of the gap either before or during actual operation of the microdevice, the amount of pressure difference needed between P_{ent} and P_{dev} to establish contact and thereby evoke the “Yes-No” readout response or continuity, as measured by the continuity apparatus, can be changed. Thus, the sensitivity of this device can be changed by an operator, by its environment, or by a feedback circuit. As before, once continuity has been established for the simple “Yes-No” readout response microdevice of Fig. 27, the truncated center contact

Figure 28. Microtube pressure sensor that has an interferometer readout.

can be used for other kinds of readout purposes. For example, the continuity apparatus can be modified to function as the resistance measuring apparatus shown in Fig. 24. If this is done, both digital and analog readout responses can be garnered from the same sensor. More than one center contact of different lengths and/or more than one side contact can also be employed in Fig. 27, thereby providing multiple digital responses from one device.

Note that the sensing techniques mentioned thus far have all been relatively simple and have employed principles of physics that are intuitively easy to understand: changes in resistance, capacitance, or inductance. Another simple technique for detecting the position of a droplet interface is using an electromagnetic beam impinging on a detector that is blocked by the advancing surface of the droplet. This type of arrangement can basically give only a “Yes”-“No” response. Two other techniques that can also be employed to monitor displacement of the nonwetting droplet interface are optical interference and electron tunneling. These techniques are capable of much higher levels of resolution of the nonwetting droplets’ displacement, which results in greater levels of sensitivity.

Figure 28 illustrates the readout technique that employs optical interference. The only additional requirement that must be imposed to use this technique is that the nonwetting droplet must reflect at least some of the electromagnetic radiation input through the fiber-optics input/output cable back through the same cable. If these conditions are met, an interference pattern can then be generated between the incoming and outgoing rays of radiation that can be detected by a suitable apparatus located at the opposite end of the fiber-optics input/output cable. This interference pattern will be highly dependent on the position of the internal interface of the nonwetting droplet, as well as on the wavelength of radiation employed. Therefore, it is an extremely accurate technique for monitoring any displacement of that interface.

Figure 29 illustrates the readout technique for electron tunneling. There are two primary differences between this readout technique and the previous readout technique that employs a truncated center contact, as illustrated in Fig. 27. In this apparatus, the truncated center contact is replaced by a very sharp needle-shaped electrode. In addition, the continuity apparatus is replaced by a much more sensitive electron tunneling current detector that can measure the tiny electrical currents generated when the needle-shaped electrode moves very close to the internal interface and creates gaps of the order of atomic dimensions. As in optical interference, tunneling current measurements are many times more sensitive to

Figure 29. Microtube pressure sensor that has a tunneling current readout.

displacements of the internal interface than simpler readout techniques discussed initially. Obviously, any other detecting technique used in scanning probe microscopy, such as atomic force, magnetic force, or capacitance, can be used in place of the needle-shaped electrode and the current-detection circuit. In addition, the sensitivity of these devices, as in the device in Fig. 27, can be changed by varying the gap between the tip and the droplet.

At this point, it is well worth mentioning again that the movement of a droplet in a microscopic tube, channel, or void and the process of remote measurement of displacements of the internal interface itself is of critical significance to the devices shown, not the actual kind of remote measurement technique employed. Whatever technique is employed affects only the accuracy of the remote readout. Thus, regardless of the measurement technique, displacements of the internal interface in reaction to external stimulus will be the same and will depend only on the surface tension and wettability of the sensor components and on sensor geometry.

Until now, it has been tacitly assumed that motion of the internal interface during any remote readout of its displacement is negligible. This is not necessarily so. Any measurement of the position of the internal interface will take some finite amount of time. If there is motion of the internal interface during this finite measurement time, the position of the internal interface will be some sort of average readout. If this is acceptable to the designer of the microdevice, all is well. If it is not, either the method of remote readout or the level of precision of the analytical instruments employed must be changed to increase the speed of readout to the degree required. Once this has been done, microdevices based on surface tension and wettability that have remote readout capabilities can function either as static or dynamic analytical detectors or sensors.

Until now, it has also been assumed that the shaped or tapered microtubes or microchannels within which droplets move or flow under the influence of surface tension and wettability and some external forcing agent such as pressure or acceleration, had circular cross sections. This does not have to be so. Figure 30a, b illustrates flow of an elongated nonwetting mercury droplet constrained on

Figure 30. Nonwetting droplet in square channel: (a) side view; (b) end view.

four sides by walls that form a square cross section. For mercury and other high contact angle liquids whose contact angles are greater than 135° , there will always be open corners in a channel that has right-angle corners. These corners remain unfilled because infinite internal pressure would be required in these high contact angle liquids, the result of setting r equal to zero in the relationship given in Eq. (2), to fill in all corners completely. This can never be true for two reasons. First, there is no such entity as infinitely high pressure. Second, in Fig. 30a,b, bypass flow of externally applied pressure P_{ent} will occur through all open corners, thereby reducing the actual pressure applied to the nonwetting droplet. An analogous situation occurs when a child shoots an irregularly shaped pea through a circular straw. Even though gaps equivalent to the open corners in Fig. 30a,b exist around the pea, the child can still expel the pea from the straw simply by blowing hard enough, thereby producing a sufficiently effective pressure on the pea to accomplish the purpose. This is exactly the situation that exists for flow of nonwetting droplets in noncircular microtubes or microchannels. Therefore, all previous arguments for remote sensing of droplet interfaces in circular cross-sectioned microtubes or microchannels apply equally well to remote sensing of droplet interfaces in microtubes, microchannels, or voids that have any type of noncircular profile. Moreover, noncircular microtubes or microchannels can certainly be used in conjunction with circular microtubes or microchannels in the same microdevice. In fact, there is very good reason to do so. Noncircular microtubes or microchannels can be fabricated relatively easily by using techniques such as photolithography and LIGA on a surface. This is currently done on silicon wafers by a sequence of deposition and/or etching techniques in a number of different ways, two of which will be given. A noncircular channel can be formed, for example, by etching the channel in the surface and then covering the channel by sealing a glass plate over it. Alternatively, for example, the noncircular channel can be formed by etching a channel in the surface and then filling it with

a sacrificial material. Another material is deposited over the filled channel and then the sacrificial material is removed to leave a microchannel. However, no matter how the noncircular channel is formed in the surface, a bypass flow of gases occurs through its open corners, as illustrated in Fig. 30b, if the liquid has a high contact angle. As just mentioned, this makes it difficult to apply pressure accurately and reproducibly to some nonwetting droplets contained within such microtubes or microchannels. This is not true for circular microtubes or microchannels. Thus, the presence of small circular microtubes or microchannels at appropriate positions in any device fabricated from noncircular microtubes or microchannels will allow either gases or wetting fluids to apply hydrostatic pressure to microdevices that contain nonwetting droplets at 100% efficiency. The reverse is also true. A circular cross section in the device will also allow the nonwetting droplet to apply force to the gas or wetting fluid at 100% efficiency. This also means that it is possible to have wetting and nonwetting fluids in the same microdevice. Finally, regardless of the cross-sectional shape of the microtubes, microchannels, or voids, all wetting fluids will have 100% efficiency.

It is extremely important to realize that the previous discussion also illustrates that an elongated non-wetting droplet confined within a microtube or microchannel that has, for the sake of illustration, square walls can serve purposes other than remote sensing. For example, it can be used to act as a shutter in optical applications, where the presence or absence of the droplet controls whether or not light or other electromagnetic radiation is allowed to pass through the square microchannel walls. In this instance, the nonwetting droplets function in much the same fashion as a window blind by controlling whether or not light is let through a window depending on whether or not the blind is up or down. It could also control particle beams in a similar manner.

Figure 31 illustrates a much more familiar looking shutter mechanism that could very easily function identically to traditional mechanical shutters. An end bulb is connected to a fill tube, and both are filled by a nonwetting liquid, which is called the working fluid and is opaque for the particular application. A rectangular void is also connected to the fill tube, but its thickness is less than the diameter of the fill tube. (The thickness of the void in this figure is exaggerated for clarity.) The shutter that has constant void thickness is illustrated in the open configuration in Fig. 31a,b, where the incident radiation or particle beam passes through the shutter, and is closed in Fig. 31c,d where the incident beam or radiation is blocked by the shutter. The void width and void length can be much greater than the void thickness and only one void dimension has to be macroscopic to carry out a shutter's function. This illustrates an extremely important point: although all of the dimensions of a device can be microscopic, only one dimension of a device must be in the range where surface tension and wettability become dominant factors in the device's reaction to internal or external stimuli to consider the device a microdevice. The rectangular shutter of constant void thickness illustrated in Figure 31 must be considered a microdevice because of the microscopic dimensions of its thickness, even though

Figure 31. Macroscopic microtube rectangular shutter: (a) side view of open shutter; (b) top view of open shutter; (c) side view of closed shutter; (d) top view of closed shutter.

it can have very macroscopic dimensions for one or more of its other features. This is true for all microdevices based on surface tension and wettability. In this example, the method of actuation of the rectangular shutter shown in Fig. 31 is derived by an externally generated electrical current input through a heater contained within the working fluid. As the working fluid expands due to this heat input,

any gas bubbles or other gas-filled voids contained within the working fluid become compressed, thereby raising the internal pressure P_{int} within the working fluid. This thrusts the internal interface farther and farther into the rectangular void. At some point, the radius will decrease sufficiently, so that the internal interface will shoot across the void length, providing that the volume of compressed gas-filled voids is much larger than the volume of the shutter. This will close the shutter in the same fashion as the “Yes-No” devices described earlier in Fig. 25. If gas bubbles or other gas-filled voids are not present in the working fluid, then the heat input will not cause a “Yes-No” type of reaction, but rather will enable the shutter to close more gradually. In this way, a partially closed shutter can be maintained by controlling the heat input appropriately. The gradual closing capability can be obtained for a pressure-activated shutter by employing a void thickness that has a decreasing taper. A different tapered end is shown at the end of the rectangular void where the working fluid stops in the closed position. This is to minimize the water hammer effect and does not have to be present for the shutter to work. Of course, external pressure or some other external stimuli as well as an internal stimuli could also be used in place of the heater, and the shutter would still function. If pressure were employed, it would then be a pressure sensor that has some macroscopic dimensions that would be very easy to observe. Filling of the void would signify that a certain pressure had been reached. Obviously, there are numerous other applications of this technology but only two others will be mentioned. One involves using a reflective nonwetting fluid, so that a mirror results when the void space is filled, and the second application encompasses a much larger microscopic void area. If the void space is made as large in area as a window pane, solar energy acting on the reservoir could be used to force liquid into a void of microscopic dimensions in the window pane and thus block sunlight from going through the window if an opaque nonwetting liquid is employed.

The void shown in Fig. 31 has constant thickness and is rectangular. Neither parameter is necessary. Figure 32 illustrates a circular shutter, which has a straight top face and a curved bottom face that make up the void. Now, depending on the amount of expansion of the working fluid caused by electric power supplied to the heater, the shutter can be completely open when all of the working fluid is contained within the outside bulb, completely shut and have no circular gap in the center at all, or anywhere in between, as Fig. 32 illustrates. Certainly, both the top face and bottom face can be curved or straight, and virtually any shutter geometry can be employed. Likewise, actuating techniques other than heat input to the working fluid by an internal heater can be used. External heat input by radiation or conduction or changes in the internal pressure of the working fluid by any other means can be used to achieve the same resulting shutter behavior.

As mentioned earlier, surface tension and wettability govern the position of droplets within microdevices. Thus, in addition to the external stimuli already mentioned, any external stimuli that changes either the surface tension of the droplet or the wettability of the surface can be detected by a suitably designed microdevice sensor. Some, but

Figure 32. Circular shutter or iris: (a) side view; (b) top view.

not all, such stimuli include the following: temperature, magnetic field, electrical field, rotation, radiation, and beams of particles.

Until now, all of the microdevice sensors illustrated have been designed to respond to external stimuli. This is not the only mechanism for displacing microdevice droplets. Any compositional change that occurs within droplets themselves or on the walls of microdevices can also change surface tension or wettability. These changes can be either reversible or irreversible and can be caused by a gas or wetting fluid in the device along with the nonwetting droplet. In addition, the surface tension of the droplet increases as both the temperature and rotation increase. If these or any other internally induced change in a microdevice's surface tension or wettability occurs, it can be detected and monitored remotely using any of the techniques described previously. Obviously, these internally induced changes in a microdevice's surface tension or wettability can also be used to move the droplet(s) to perform work.

In addition, no actual dimensions of either microtubes or microchannels have yet been discussed. Assuming a nonwetting fluid such as mercury, which has a surface tension at room temperature of approximately 470 dynes/cm and a contact angle on glass microdevice walls of roughly 140° , one can calculate the following droplet radii for the indicated internal pressures using Laplace's equation modified to include the effect of wettability (Table 1):

In this section, we have shown that the flow of droplets within microtubes and microchannels that is controlled by surface tension and wettability can be used to sense, qualitatively and quantitatively, any environmental factor that acts on a droplet or affects either its surface tension or

Table 1. Calculation of Droplet Radii

r_{dev} (μm)	P_{int} (lb/in^2)	P_{int} (kPa)
950	0.1	0.69

9.5	10	68.9
0.95	100	689
0.095	1,000	6890
0.003	100,000	689,000

wettability, or both. This sensing can be performed remotely by a variety of techniques. It has also been demonstrated that wetting droplets can sometimes be used with only minor device modifications. Static as well as dynamic remote sensing can be performed, and microtubes or microchannels that have circular or noncircular cross sections and variable axial geometries can be employed either individually or together. The reaction of these devices to any stimuli can be tailored by the device geometry and the method of sensing and result in linear and nonlinear analog output, as well as digital output. The use of this technique in nonsensing applications that perform mechanical functions was also demonstrated. Finally, whenever at least one microdevice dimension lies between $1000 \mu\text{m}$ and $0.003 \mu\text{m}$, it has been shown that it can perform all of the various tasks that have been discussed.

Nonwetting Droplets That Perform Work

The preceding discussion has indicated that the movement of nonwetting droplets within microtubes or microchannels can be used for sensing and controlling fluids. In addition, microscopic nonwetting droplets can be used for mechanical control and manipulation within microdevices, including tasks such as position control, moving objects, deforming objects, pumping fluids, circulating fluids, and controlling their flow. Obviously, complex machines and engines can be produced by properly joining actuator and pumping elements.

An application of a microscopic nonwetting droplet for low friction position control is a microtube liquid bearing shown in Fig. 33. Referring to Fig. 33a, for example, the bearing assembly is a microtube that has one or more circular channels on its circumference that actually join the microtube's interior void space in a narrow ring-shaped opening. A center rod only slightly smaller in diameter than the bearing assembly is supported by nonwetting fluid that fills the circular channels. This fluid cannot leak out around the center rod if the gap is small enough because too much pressure (Table 1) is required to form the droplet of smaller radius that would be able to leak. Therefore, the center rod is free to either rotate or translate axially within the bearing assembly. It is called an external bearing because of this outside configuration. The only restraining forces involved are frictional forces between the center rod and the non-wetting fluid.

Figure 33b illustrates a reciprocal situation called a microtube internal bearing. A straight walled microtube is used. A central rod has at least one groove about the circumference, and the nonwetting fluid fills this groove, which allows both rotational and translational motion.

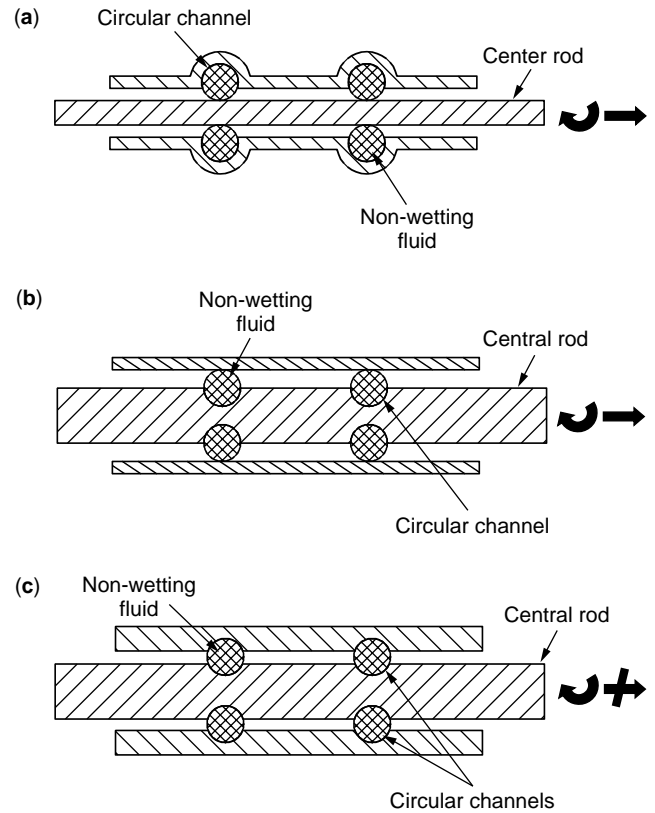

Figure 33. Shaft supported by nonwetting fluidic bearings: (a) rotating and translating outer bearing; (b) rotating and translating inner bearing; (c) inner/outer bearing that rotates but does not translate.

Figure 33c is a mixed combination of internal and external microtube liquid-bearing locations. In this configuration, however, only rotational motion is easily achieved. For translation to occur, shearing of a wetting droplet must take place. Although this is not as difficult as forming a small-radius annular droplet, it still involves generating new droplet surface area and therefore requires more force to produce translation than for either the purely internal or purely external bearings.

Figure 34 illustrates a microtube liquid bearing that will not allow significant translational motion. It is a

Figure 34. Thrust bearing that incorporates four nonwetting fluid bearings.

Figure 35. Piston actuated by nonwetting fluid.

thrust bearing that uses four separate microtube liquid bearings in an external configuration. As before, an internal or mixed configuration is also possible, and additional microtube liquid bearings that use surface tension/wettability effects can be employed.

Figure 35 illustrates how a nonwetting droplet can be employed as an actuator; its motion down a microchannel or microtube is used to move a loosely fitting piston. It is important to note that as long as the droplet does not wet the piston and walls, none of the droplet will squeeze by the piston if the clearance is less than the radius of the nonwetting droplet. The nonwetting droplet is deliberately shown only in part in Fig. 35 to demonstrate that the actual mechanism, external stimuli, or internal stimuli, or wetting fluid, that causes it to push on the piston is unimportant. Its ability to function to transmit force mechanically and thereby perform work is all that matters.

CONCLUSIONS

Microtubes appear to have almost universal application in areas as diverse as optics, electronics, medical technology, and microelectromechanical devices. Specific applications for microtubes are as wide ranging as chromatography, encapsulation, cross- and counterflow heat exchange, injectors, micropipettes, dies, composite reinforcement, detectors, micropore filters, hollow insulation, displays, sensors, optical waveguides, flow control, pinpoint lubrication, microsponges, heat pipes, microprobes, and plumbing for micromotors and refrigerators. The technology works equally well for high- and low-temperature materials and appears feasible for all applications that have been conceived to date.

The advantage of microtube technology is that tubes can be fabricated inexpensively from practically any material in a variety of cross-sectional and axial shapes in very precise diameters, compositions, and wall thicknesses of orders of magnitude smaller than is now possible. In contrast to the other micro- and nanotube technologies currently being developed, microtubes can be made from a greater range of materials in a greater range of lengths and diameters and far greater control over the cross-sectional shape. These tubes will provide the opportunity to miniaturize (even to nanoscale dimensions) numerous products and devices that currently exist, as well as allowing the fabrication of innovative new products that have to date been impossible to produce.

Space only allowed presenting one application of microtube technology to new innovative products in greater detail. This one application comprised those devices that are based on surface tension and wettability. The few devices that were shown as examples demonstrated the breadth of this technology only in one field. The application of microtube technology to other fields is considered equally rich and limited only by a designer's imagination.

ACKNOWLEDGMENTS

The invaluable help provided by Hong Phan in fabrication, Marietta Fernandez in microscopy, and Tom Duffey in artwork is greatly appreciated. Financial support from Dr. Alex Pechenik of the Chemistry and Materials Science Directorate, Air Force Office of Scientific Research was responsible for much of this work.

MOLECULARLY IMPRINTED POLYMERS

BRADLEY R. HART
 KENNETH J. SHEA
 University of California
 Irvine, CA

INTRODUCTION

Molecular imprinting is a process for synthesizing materials that contain highly specific recognition sites for small molecules (scheme 1). The imprinting process consists of a template molecule (*T*) that preorganizes functional, polymerizable monomers (*M*). This template assembly (*TA*) is copolymerized with a large excess of cross-linking monomers to produce an insoluble network material. Extraction of the template molecule leaves behind a region that is complementary in size, shape, and functional group orientation to the template molecule. The resulting polymeric materials are referred to as molecularly imprinted polymers (MIPs):

Scheme 1

Intermolecular forces between the template, functional monomers and polymer matrix determines MIP structure. Pre-organization of the functional monomers has been achieved with covalent (1–4), electrostatic (5,6), and hydrogen bonding interactions (7–9). The most common method of polymer formation employs free radical initiation. These materials are tough, easy to handle, and have been shown to retain their recognition properties for over five years without loss of selectivity or capacity (10,11). As a result, they have advantages over more fragile biological systems for molecular recognition and have been referred to as “plastic antibodies” (12). Under the proper conditions, MIPs have shown the ability to function as selective binding materials (13–15), microreactors (3,16,17), facilitated transport membranes (18,19), and catalysts (20–23). Their utility, coupled with their longevity and robustness, make MIPs candidates for applications in separation science, as industrial catalysis, and for medical diagnostics (24,25).

Molecular imprinting began as an attempt to develop “synthetic antibodies.” Initially referred to as “specific adsorption,” a technique developed by Dickey utilized silica polymers to create synthetic receptors for the dye molecules methyl orange and ethyl orange (26,27). Dickey found that a material prepared using methyl orange was able to re-adsorb that molecule 1.4 times better than ethyl orange, and that the selectivity could be reversed by using ethyl orange during the polymerization. These results were followed by the first imprinted chiral stationary phase (CSP), which was prepared in 1952 by Curti and Columbo. Dickey’s method was used to imprint silicate polymers with *D*-camphorsulfonic acid and enantiomers of mandelic acid (28). Curti and Columbo were able to achieve chromatographic separation of camphorsulfonic acid enantiomers and mandelic acid enantiomers using this process.

The first report of an imprinted organic polymer was made by Wulff in 1972 (29). A *D*-glyceric acid template was covalently bonded to *p*-amino styrene and 2,3-*O*-*p*-vinylphenylboronic ester and was then incorporated into a divinylbenzene polymer (29,30). This important development increased the specificity of interaction between template and functional groups within the polymer and allowed for more controlled design of functionality within the imprinted polymer. Another major contribution to the field of molecular imprinting was made by Mosbach and co-workers in 1984 when they introduced a new

method of forming the pre-polymerization complex based on noncovalent interactions (31). Instead of covalently imprinting target molecules, a template assembly was formed utilizing electrostatic and hydrogen bonding interactions to specifically position functional monomers. Since this time, there has been a tremendous amount of work in the area of molecular imprinting, much of which has been reviewed in the literature (11,32–34,35–38).

POLYMER CHEMISTRY

Organic Materials

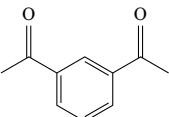

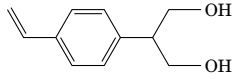

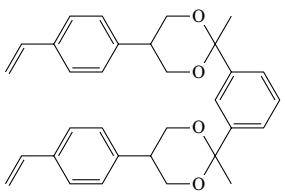

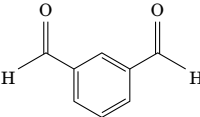

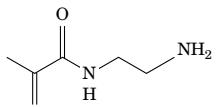

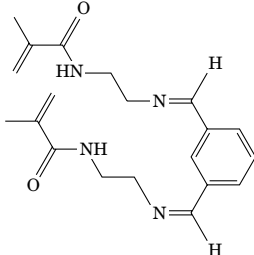

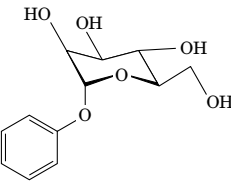

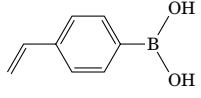

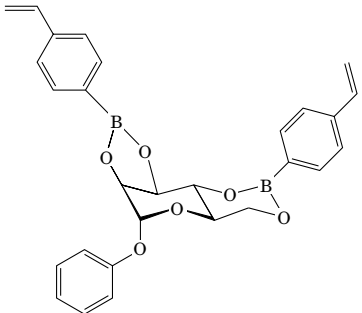

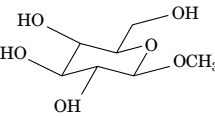

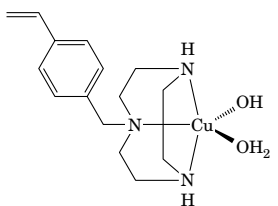

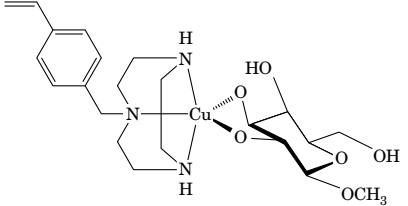

Molecularly imprinted polymers are almost exclusively composed of highly cross-linked organic polymers. These polymers may be prepared using a variety of monomers and polymerization methods. By far, the most common method has been the free radical polymerization of acrylate functionalized monomers. A detailed description of the chemistry of free radical polymerization is available in the literature (39).

Typical formulations consist of equal parts of monomer/template assembly and an inert deluent, referred to as a porogen. The choice of porogen is important since it must solubilize the monomers and, in the event of noncovalent imprinting, must not suppress interactions between the imprinting molecule and the functional monomers. The porogen also serves as an important determinant in the formation of the final polymer morphology.

The resulting network polymers are macroporous in nature. Their macroporosity arises from the phase separation of solid polymer from solvent and unreacted monomer. The timing of the phase separation is dependent on the extent of polymerization and the polymer solubility in the porogen. The phase separated polymer particles aggregate and create a high internal surface area (40,41). This is particularly important since the highly cross-linked networks present a barrier to facile transport of solvent and reagents to the functional sites. The high internal surface area (200–400 m²/g) exposes a large fraction of polymer mass to the external solvent and reagents.

The high percentage of cross-linking monomer (80 to >90 mol %) that is usually employed results in a polymer with a rigid three-dimensional structure. In addition to providing a rigid structure, the cross-linking provides a scaffold for positioning functional groups within voids

enabling recognition of the imprinted molecules. The interaction between the template molecule and the functional monomers can be covalent or noncovalent in nature. The former can consist of any number of interactions including electrostatic, hydrogen bonding, hydrophobic, and π - π interactions.

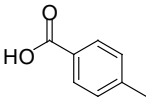

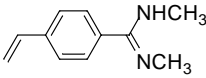

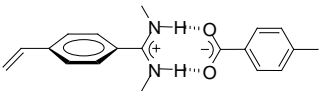

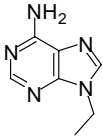

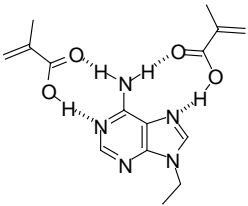

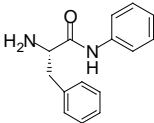

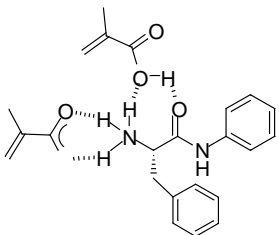

Covalent Imprinting

The covalent method of imprinting requires the synthesis of a polymerizable derivative of the template molecule. Covalent bonds are chosen so as to permit their cleavage following the polymerization. After the cleavage step, the monomers should present functionality that can interact with the imprint molecule either by reforming the covalent

linkage or by noncovalent interactions. Some common covalent bonds used for this purpose are carboxylic (42) and boronic esters (43–45), ketals (13,46), and Schiff bases (2). Also included in this area are metal complexes that bind and orient the template (47–49). Representative examples of covalent template assemblies are given in Table 1.

The covalent method of pre-organization has several advantages over noncovalent methods. Perhaps the most important is that there is no requirement for excess functional monomer. This minimizes the amount of nonspecific bonding that can occur between the analyte and the polymer matrix. A nonspecific interaction in this case is any bonding that occurs other than between the analyte and the defined binding site. In addition, covalent imprinting may produce more “well-defined” binding sites, thus reducing the

Table 2. Representative Examples of Templates, Monomers, and Their Associated Complexes Used for Noncovalent Imprinting

Type of Linkage	Template	Monomer	Complex	Reference
Electrostatic				(51)

distribution of binding sites with varying affinities for the template molecule. Potential disadvantages of this technique include the additional steps required to synthesize the template-monomer complex and for the chemical cleavage of the template from the polymer. If rebinding is to occur by reformation of covalent bonds, the rate of rebinding may be slow and not suitable for certain applications such as separation media for chromatography.

Noncovalent Imprinting

Non-covalent imprinting employs weaker interactions between the template, functional monomers and cross-linking monomers to position the functional groups and define the binding cavity (31,50). The interactions that have been most commonly utilized are hydrogen bonds, electrostatic, π - π , and hydrophobic interactions. Some representative examples of noncovalent template assemblies are given in Table 2.

The noncovalent method has the benefit of being relatively simple to carry out. It requires fewer steps than the covalent approach and is more compatible with automated or combinatorial methods. In addition, the types and number of potential templates is greater than what can be achieved using the covalent approach. This method is limited, however, to templates that can interact somewhat strongly with functional monomers. In addition, an excess of functional monomers is usually required in the polymerization mixture to ensure optimal results. In part because of this requirement, polymers prepared in this manner contain large numbers of functional groups, which

can contribute to nonspecific bonding and in general may provide lower affinity sites than can be achieved with covalently imprinted polymers.

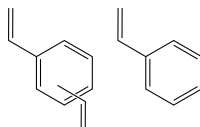

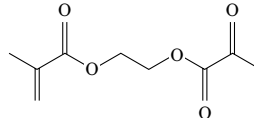

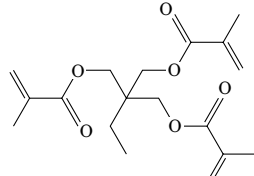

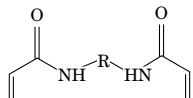

Polymer Networks

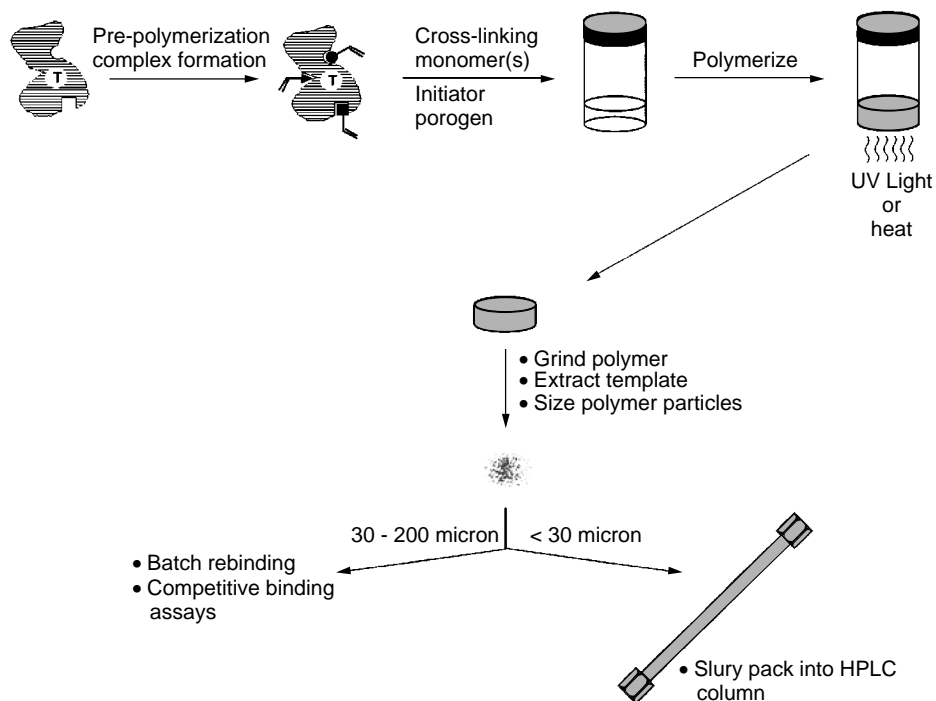

In most imprinting systems the bulk of the polymer is made up of difunctional cross-linking monomers. A wide variety of these have been developed, with the majority being acrylate or styrene based (Table 3). Cross-linking monomers play an important role in determining the bulk properties of the materials. In addition, compatibility between the cross-linking monomers and all other monomers in the formulation must be established.

Preparation and Processing. The initial step in the imprinting protocol is formation of a prepolymerization complex between the molecule to be imprinted and the functional monomers which will provide recognition (Fig. 1). This complex can be formed through either covalent or noncovalent interactions. In both cases, the formation of the complex must be reversible to allow extraction/rebinding of the template molecule. This complex is combined with the cross-linking monomer(s), initiator, and the porogen. Oxygen, which can interfere with free-radical polymerizations, is removed from the formulation either by freeze-pump-thaw methods or by displacing it from the solution by sparging with an inert gas.

Free-radical polymerization of the monomer/porogen mixture is initiated either photochemically or thermally.

Table 3. Representative Polymer Networks Used in Molecular Imprinting

Monomer System	Description	Structure	Reference

**Figure 1.** Schematic representation of the molecular imprinting process.

Scheme 2

Due to the large number of initiators available, the range of conditions in terms of radiation intensity, temperature, and time that is required is large. The choice of conditions and method of initiation is dictated by the sensitivity of the template to temperature and/or photochemical radiation.

The polymer that is produced is often a monolithic solid. For noncovalent imprinting, releasing the template molecule from the polymer is often achieved by extracting the polymer using a solvent such as methanol. In some cases, it is beneficial to use a small quantity of acid to aid in the removal of the template. For covalent imprinting, the conditions for removal of the template are dictated by the requirements for chemical cleavage of the template–monomer bond.

The next step in the processing sequence involves crushing the polymer followed by sizing of the resulting particles. Many of the chromatographic applications of imprinted polymers require the polymer to be ground into small particles (25–150 μm) and sized to a uniform range.

APPLICATIONS

To date, the applications of MIPs have fallen into four areas: (1) separation technology, (2) catalysis (enzyme mimics), (3) recognition elements for sensors, and (4) anti-body and receptor site mimics.

Separation Technology

The use of MIPs as stationary phases for chromatography is the most studied application of this technology. The list of molecules that have been examined includes biomolecules such as amino acids, small peptides, proteins, carbohydrates, nucleotides, nucleotide bases, steroids, and a number of small drug molecules. The majority of separation studies have focused on the preparation of stationary phases for high performance liquid chromatography (HPLC) (59). MIPs have also been used in thin layer chromatography (TLC) (60), capillary electrophoresis (61,62), membranes (18,19) and solid-phase extraction (SPE) (63–65).

Mosbach and coworkers demonstrated direct enantioselective separation of β -blocker (-)-S-timolol (template 1; scheme 2) using a chiral stationary phase (CSP) prepared by molecular imprinting (66).

Macroporous copolymers of EGDMA and MAA, prepared with template 1 as the imprinting molecule, were employed as a chiral stationary phase. Following extraction of the template with acetic acid, the MIP stationary phase was used for separation of racemic (template 1) by HPLC. The imprinted polymer stationary phases

gave baseline separation of racemic timolol with a separation factor (α) of 2.9. The separation factor (α) is a measure of the separation of two peaks in a chromatogram and is given by $\alpha = k_2/k_1$, where k' is equal to the capacity factor of each peak. The capacity factor is a measure of binding strength and is defined as $k' = (t - t_0)/t_0$, where t is the retention time of the solute, and t_0 is the void time. The structurally related racemic derivatives atenolol (template 2) and propanolol (template 3) were *not* separated into their enantiomers, nor were they retained on the column to any substantial degree.

Shea et al. explored the ability of MIPs to separate enantiomers of a series of benzodiazepine molecules (9). Enantiomerically pure benzodiazepine derivatives (molecules 4–8, Scheme 3) were used to imprint EGDMA polymers using MAA as the functional monomer. The resulting materials were ground into particles and analyzed by HPLC.

Scheme 3

Regardless of the benzodiazepine used for the imprinting, enantioselectivity could be achieved for the entire family of benzodiazepines. In each case, the imprinted enantiomer was retained over the nonimprinted isomer ($\alpha > 1$; Table 4). Additionally, the greatest separation for each polymer corresponded to the benzodiazepine which had been imprinted (bold entries). The ability of benzodiazepine MIPs to produce separation for a family of molecules in favor of the absolute configuration of the template is an important result of this study.

Synthetic polymer complements to biologically important nucleosides have been prepared using 9-ethyladenine (9-EA; polymer 9, scheme 4) as the imprinting molecule (15). The molecular basis for the imprinting arises from the fact that adenine and its derivatives are known to form complexes with carboxylic acids. 9-EA was employed as the template; methacrylic acid (MAA; polymer 10) was employed as the functional monomer (scheme 4). The formulation included EGDMA as the cross-linking monomer in chloroform solution. Polymerization was initiated photochemically at 12°C in the presence of AIBN.

Table 4. Benzodiazepine α Values for Retention on MIP Stationary Phases

MIP Template	Benzodiazepine Derivative Injected				
	4-Hydroxybenzyl (7)	Benzyl (6)	Indolyl (8)	Isopropyl (5)	Methyl (4)
(S)-7 4-Hydroxybenzyl	3.8	2.5	1.3	1.6	1.4
(S)-6 Benzyl	2.3	3.0	1.7	1.6	1.7
(S)-8 Indolyl	1.5	1.8	2.3	1.3	1.4
(S)-5 Isopropyl	1.2	1.3	1.3	2.2	1.6
(S)-4 Methyl	1.0	1.1	1.1	1.1	1.3

**Scheme 4**

When used as the stationary phase for HPLC, the 9-EA imprinted column packing was found to have a strong affinity for adenine and its derivatives. The remaining purine and pyrimidine bases elute close to the void volume.

**Scheme 5**

An illustration of the selectivity is given in Fig. 2. An HPLC trace of a sample mixture of adenine (A; template 11), cytosine (C; 12), guanine (G; 13), and thymine (T; 14) reveals C, G, and T elute close to the void volume (~ 2 min at 1 ml/min flow) while adenine elutes in 23 minutes. In contrast, polymers made by replacing 9-EA with benzylamine show no affinity for the nucleoside bases: all elute between 1.6 and 2.0 minutes.

Most studies with imprinted polymer have been carried out using polymer particles either in the batch or chromatographic mode. There have been several reports however of the preparation of imprinted polymers fabricated

Figure 2. HPLC race of a 4.6 mm \times 10 cm column packed with polymer templated with 9-ethyladenine (9-EA). A mixture of adenine (A), thymine (T), guanine (G), and cytosine (C) was injected. Adenine elutes at 23 minutes; all other nucleosides elute close to the void volume (2 min). The mobile phase is MeCN:AcOH:H₂O in the ratio 92.5:5:2.5.

into membranes for the selective transport and separation of molecules. One example involves the preparation of MIPs with 9-ethyladenine (template 9) as the template and methacrylic acid (10) as the polymerizable functional monomer (scheme 4) (18).

The free-standing films of imprinted polymers were obtained by the polymerization of films of a DMF solution of ethylene glycol dimethacrylate and methacrylic acid with 9-ethyladenine (template 9) as the template.

Transport studies were carried out with an H-shaped two-compartment cell. The concentration of substrate in the receiving phase as a function of time was quantified by HPLC. Under steady-state conditions, a linear correlation between amount of substrate transported and time was observed. The transport rates of adenine, thymine,

and cytosine were measured; in all cases it was found that adenine was transported at a higher rate than other nucleic acid bases through membranes imprinted with template 9. Furthermore, the imprinted membranes transported adenosine (15) at a higher rate than guanosine (16) (Fig. 3). In contrast, reference polymer membranes, prepared in the absence of template (9), transported adenine at a comparable rate to those of cytosine and thymine. A reference polymer membrane of the same monomer composition prepared without template 9, on the other hand, transports adenine at rates comparable to those of thymine and cytosine.

Sensors

MIPs have been used as the recognition element in chemical sensing devices. Biosensors utilize a recognition element, such as an antibody or enzyme, in conjunction with a transducer. A chemical signal results from the binding of the analyte to the receptor that is then transformed into an electrical or optical signal that can be monitored. In many cases, the development of recognition elements lags far behind the transduction methods available, such as optical, resistive, surface acoustic wave (SAW) or capacitance measurements. There is considerable potential for new chemical sensing devices if suitable recognition elements were available.

There are several potential advantages that may be gained by utilizing MIPs as the recognition element in place of biological receptors. Since MIPs are synthetic receptors, they have a virtually unlimited pool of analytes. In addition, MIPs are stable to harsh conditions that may not be compatible with biologically based sensors. Furthermore, the ability to incorporate a signaling element, such as a fluorescent probe, in the vicinity of the binding

Figure 3. Plot of the facilitated transport of adenosine from an equimolar methanol/chloroform (6:94 v/v) solution (adenosine = guanosine = 26 μ M). The membrane was imprinted with 9-ethyladenine. The selectivity factor is 3.4.

Table 5. Summary of Sensor Applications Using Molecularly Imprinted Polymers

Class	Typical Analyte	Functional Monomer	Detection Range	Reference
Fluorimetry	Dansyl-L-phenylalanine	MAA, 2VPy	0–30 $\mu\text{g/mL}$	(68)
	cAMP	DMASVBP + HEMA	0.1–100 μM	(69)
Conductometry	Atrazine	DEAEM	0.01–0.5 mg/L	(70)

Luminescence	PMP	Eu(III) + DVMB	0.125–150000 $\mu\text{g/L}$	(49,72)
pH	Glucose	STACNCu	0–25 mM	(48)

site could be utilized in sensor applications. It may also be possible to prepare sensors with an array of polymers imprinted for any number of analyte molecules for fabrication of a single sensor capable of detecting many substances. Some examples of sensor applications using MIPs and their detection ranges are shown in Table 5.

The use of luminescence spectroscopy combined with fiber optics can provide systems for sensor applications. Utilizing molecularly imprinted polymers in combination with these systems can add chemical selectivity to these types of sensors. This technology has been applied to the detection of many types of compounds including nerve agents (49), herbicides (72,73), drugs molecules (70), and biomolecules (68,74).

Mosbach et al. demonstrated the use of a MIP based fiber-optic sensing device for a fluorescence-labeled amino acid (dansyl-L-phenylalanine; template 17, scheme 6) (67). These materials were prepared using MAA and 2-vinyl pyridine as the functional monomers and EGDMA as the cross-linking monomer. A system was devised in which polymer particles were held against the fiber tip using a nylon net (Fig. 4).

In both systems the polymers showed an increased affinity for the imprinted enantiomer. This was demonstrated as an increase in the measured fluorescence in the fiber-optic system. In addition, the ability to follow increases in concentration by monitoring the increases in fluorescence was demonstrated. Binding of the analyte to the polymer

Figure 4. Fiber-optic sensing device configuration. A layer consisting of 2 mg of polymer particles was held below the quartz glass window. The layer was kept in place by a nylon net (20 μm pores) and an O-ring. An optical fiber was connected through the quartz window onto the polymer surface. Part of the total light emitted from the polymer was collected and guided through the fiber bundle to the detector (visible light-sensitive photodiode).

could be followed in real time as the time required to reach a steady-state response was 4 hours. This rebinding time correlates with the equilibration time of this imprinted system.

Scheme 6

Powel et al. prepared imprinted polymers for the detection of cAMP (polymer 18) (68). These polymers are unique in that they contain a fluorescent dye, *trans*-4-[*p*-(*N,N*-dimethylamino)styryl]-*N*-vinylbenzylpyridinium chloride (19, scheme 8), as an integral part of the binding site. The polymer serves as both the recognition element and the transducer for the detection of cAMP. The polymer was prepared by polymerization of trimethylol trimethacrylate (TRIM), 2-hydroxyethyl methacrylate (HEMA; 20), and the fluorescent functional monomer, template 19, in the presence of cAMP. The polymerization was initiated photochemically at room temperature.

Scheme 7

Scheme 8

Possible interactions between the template and the polymer include aryl stacking and electrostatic interactions between 19 and the template. HEMA is able to provide additional sites in the polymer for hydrogen bonding with the template.

The fluorescence of the imprinted polymer was diminished when in the presence of aqueous cAMP. The quenching was found to reach a maximal level between 10 and 100 μ M cAMP. In addition, no quenching was observed in a control polymer prepared without template. Addition of cGMP (**21**) had little effect on the fluorescence of both the imprinted and control polymer.

Catalysis

One of the most challenging applications of molecularly imprinted polymers is the fabrication of designed catalysts and the preparation of artificial enzymes. Because of their ability to prearrange functional groups within the polymer matrix, MIPs lend themselves to this application. Methods for preparing these MIPs include (1) utilizing a template that pre-arranges the catalytic groups within the binding site, this method has been referred to as the "bait-and-switch" method, (2) the use of a transition state analog as the template, (3) the use of coordination compounds to effect the catalytic reaction (32,75).

The use of templated polymers as catalysts for chemical transformations has been demonstrated using the dehydrofluorination of 4-fluoro-4-(*p*-nitrophenyl)butan-2-one (22, scheme 9) (21).

Scheme 9

Scheme 10

The strategy for preparing the MIP catalyst is illustrated in scheme 10 below. The template molecule, benzylmalonic acid (template 23), was used to orient *N*-(2-aminoethyl)-methacrylamide (24) monomers prior to polymerization. The bulk of the polymerization solution consisted of a mixture of EGDMA, methyl methacrylate, monomer 24, and DMF as the porogen.

A survey of the catalytic performance of the templated polymer and that of a control polymer with randomly oriented amino groups indicated that both polymers were found to catalyze the reaction shown in scheme 9; however, the rate of dehydrofluorination by the templated polymer (k_{template}) under pseudo-first-order conditions was 3.2 time greater than k_{control} (Fig. 5).

The imprinted polymer exhibits Michaelis-Menten kinetics in benzene with a K_m of 27 mM and a k_{cat} of $1.1 \times 10^{-2} \text{ min}^{-1}$. In comparison, an antibody designed to catalyze the dehydrofluorination of 22 in water shows a K_m of 0.182 mM and a k_{cat} of 0.192 min^{-1} .

Wulff et al. have reported the preparation of molecularly imprinted polymers which catalyze the hydrolysis shown in scheme 11 (23). The polymers were prepared using a phosphonic acid monoesters 25 as a transition state analog template (scheme 12).

Scheme 11

Scheme 12

Coordination of monoester **25** with two equivalents of amidine **26** provides a polymerizable complex, Eq. (3). The bis(amidinium) complex was polymerized with a large excess of EGDMA in THF.

Removal of the phosphoric acid monoester transition state analogue left a cavity bearing two *N,N'*-diethylamidinium groups (Fig. 6). Hydrolysis of ester **27** by the polymer imprinted with phosphoric acid monoester **25** was accelerated by nearly 100-fold over the reaction of ester **27** with amidine **26** in homogeneous solution. In addition, the catalyzed hydrolysis showed typical Michaelis-Menten kinetics while the homogeneous solution has a linear relationship between reaction rate and concentration. The catalysis could also be inhibited by addition of phosphoric acid monoester **25** which has a higher affinity ($K_i = 0.025$ mM) for the polymer than acid **27**. The activity of these catalysts is only one to two orders of magnitude below that of catalytic antibodies.

Figure 5. Pseudo-first-order plot of the dehydrofluorination of polymer **22** (scheme 9) under conditions of excess substrate to catalyst. The log of the ratio of the initial concentration of substrate **22** (S_0) to that at time t (S_t) is plotted against time. In the presence of pyridine as a scavenger, the catalyst demonstrates seven turnovers after 23 hours. Imprinted polymer catalyst (♦); control polymer (●); homogeneous reaction (2-aminoethyl acetamide) (◇).

Antibody and Receptor Site Mimics

Binding assays are used for the determination of small quantities of compounds in blood serum and other systems and for screening compounds for affinity to a specific receptor. Assays of this type require a receptor, often an antibody that specifically binds the molecule being studied. Antibodies often show extremely good recognition properties for their associated molecule (antigen); however, their use is hampered by their sensitivity to harsh conditions and what can be an involved and costly production process.

Several studies have been performed that utilize imprinted polymers as artificial antibodies for use in binding assays. These studies have been performed using competitive radioligand binding protocols and simple batch binding methods (24,76,77). The advantages of using these

Figure 6. Schematic representation of catalytic cycle for the hydrolysis of ester 27 (scheme 11). A cavity bearing two *N,N'*-diethylamidine groups remains after removal of the template 25 (middle) scheme 10. The alkaline hydrolysis of ester 27 is catalyzed by the polymer that stabilizes the transition state of the reaction (bottom).

Table 6. Cross-reactivity of Xanthine and Uric Acid Derivatives for Binding of ³H-Theophylline and Benzodiazepines for Binding of ³H-Diazepam to Imprinted Polymers

Theophylline Antibodies	Cross-reaction	Diazepam Antibodies	Cross-reaction
<i>Competitive Ligand</i>	(%)	<i>Competitive Ligand</i>	(%)
Theophylline (1,3-dimethylxanthine)	100	Diazepam	100
3-Methylxanthine	7	Alprazolam	40
Xanthine	<1	Desmethyldiazepam	27
Hypoxanthine	<1	Clonazepam	9
7-(β-hydroxyethyl-1,3-dimethylxanthine)	<1	Lorazepam	4
Caffeine (1,3,7-trimethylxanthine)	<1	Chlordiazepoxide	2
Theobromine (3,7-dimethylxanthine)	<1		
Uric acid	<1		
1-Methyluric acid	<1		
1,3-Dimethyluric acid	<1		

materials as the recognition elements in assays include their ease of preparation, the stability of the polymers under harsh conditions such as high temperature, extreme pH, and organic solvents. In addition, the ability to prepare MIPs when a biological receptor is unavailable or difficult to isolate provides further impetus for their use.

The first use of imprinted polymers as the recognition element in a radiolabeled ligand binding assay was demonstrated with assays for Diazepam (28) and Theophylline (29), in human serum (24) (scheme 13). The results of this assay are comparable to established antibody assay protocols for these drugs. The method employed for this study uses inhibition of radiolabeled ligand binding by the serum analyte. The amount of radioligand bound to the polymer is inversely proportional to the analyte concentration in the serum.

**Scheme 13**

Both assays showed linear responses over ranges satisfactory for the therapeutic monitoring of both drugs (14–224 μM for Theophylline and 0.44–28 μM for Diazepam). The cross-reactivity of major metabolites and compounds of similar structure to Theophylline and Diazepam was determined to evaluate the specificity of the synthetic receptors. Theophylline imprinted materials proved to be highly specific with only 3-methylxanthine showing cross-reactivity (Table 6). The Diazepam assay indicated that cross reactivity of the synthetic receptor was

very similar to antibody assays. In this case, several structurally similar benzodiazepines showed some cross-reactivity (Table 6). In fact, both assays displayed very good agreement with the corresponding antibody assays.

CONCLUSIONS

Molecular imprinting is a method with which materials with high affinities for a wide range of organic compounds can be made. Since its inception, the number and types of monomers and templates that have been used successfully has increased dramatically. In addition, our understanding of the mechanisms through which the materials operate is increasing. While there is still enormous room for development, some areas of application have become well developed and commercial applications are on the horizon.

The applications discussed in this article are only a few examples of what has been achieved. Other uses for MIPs are being explored, as well as new ways to develop and optimize their capabilities. The true utility of molecularly imprinted materials is limited only by the ingenuity of those developing them.

NEURAL NETWORKS

JERRY A. DARSEY

University of Arkansas at Little Rock
Little Rock, AR

A SHORT TUTORIAL ON ARTIFICIAL NEURAL NETWORKS

The first part of this article introduces the reader to the fundamentals of artificial neural network (ANN) computing, but it is, in no way, comprehensive. Many books and articles give more detailed knowledge of this subject, and this author strongly recommends that the reader refer to them. Some of the references at the end of this article will be of great value in this regard. In the two succeeding sections, we present examples of the way an artificial network may be used for predictive purposes. It is felt that the most efficient way to familiarize a reader with the power and beauty of artificial neural networks is through presentation of examples.

The next section concerns the use of an ANN for extrapolating heat capacity data of polymers to a temperature range where measurements are difficult. It is an example of using ANN to predict parameters outside the range of data on which it was originally trained. This section shows that predictions can be made accurately, even outside the training range of the data.

The final section illustrates the “power” of ANN in correlating vast amounts of input parameters with output parameters oriented to physical properties. The basic principles used in this section can generally be applied to a wide range of problems in material sciences for a large number of chemical and physical systems.

INTRODUCTION

The volume of information that is available for any given physical or chemical system is becoming increasingly unmanageable. We are literally in danger of being “swamped” by this profusion of available data. It is now very common that a system we are interested in studying may have a terabyte of information associated with it, that is, one or more trillion bytes of information that need to be processed. Artificial intelligence is one of the only techniques by which we have any chance of sorting through this voluminous amount of data and extracting meaningful information about the system under study, and an artificial neural network is one of the more powerful techniques of artificial intelligence.

So what exactly is an artificial neural network (ANN)? It can be defined as “a massively parallel distributed processor that has a natural propensity for storing experiential knowledge and making it available for use” (1). Figure 1 shows a typical fully connected, three-layered ANN. These networks were first developed as computer

models derived primarily from an attempt to model the human brain (2). However, it was not until the 1980s that interest in them was renewed (3). Of the various types of networks researched, probably the most widely used is called the backpropagation network. A backpropagation neural network is constructed from a simple totally connected set of neurons. Neurons are the basic element of neural networks. Each neuron’s purpose is to accumulate the sums of weighted inputs and then transfer its result of summation to the next level of neurons through an activation function. Figure 2 shows an example of a typical neuron. The most common activation function applied is commonly referred to as the sigmoid function, defined as

$$f(x) = \frac{1}{1 + \exp(-ax)}, \quad (1)$$

where a is the slope of the sigmoid function. Other activation functions sometimes used are the hyperbolic tangent and a scaled arctangent function. In theory, any bounded, differentiable nonpolynomial function can be used as a transfer function. The important feature of these functions, however, is their nonlinearity. It is actually this nonlinearity of these functions that gives rise to the “learning” capabilities of artificial neural networks. For information on other transfer functions which have been suggested, see (4) and references within.

Each neuron of each layer is connected in the forward direction, that is, from the input layer to the output layer. However, when the results of propagating the input data of a network are compared to the data provided in the output nodes, an error is calculated between the output data and the numbers calculated for each cycle. When this error is higher than a given limit, the weights between the input layer and the hidden layer and between the hidden layer and the output layer are modified, and the cycle is repeated. This feature of propagating the error backward through the network is responsible for calling the network a backpropagation neural network.

Neural networks are not programmed in the conventional sense. These networks use a large amount of data as examples and work by trial and error. This trial-and-error phase is called training. Before starting the training process, all of the weights between the various nodes are set to a small random number. Next, each training pattern is presented to the input nodes. The input from each input node is then multiplied by the appropriate weight, and the resulting number is distributed to the appropriate hidden node in the hidden layer. One number from each input node will be distributed to each hidden node, that is, for a six-input-node network such as shown in Fig. 1, each hidden node receives six weighted numbers, all of which are summed. The summed value of each node in the hidden layer is then transformed by an activation function and passed on for processing by the output layer of nodes. The nodes in the output layer process numbers that it receives

Figure 1. Typical architecture of an artificial neural network.

similarly to the numbers received by the middle or hidden layer of nodes. The processed numbers in the output layer are compared to the numbers submitted to the network for training (the answers), and an error is calculated. If the error calculated is greater than some convergence limit, the weights are changed in a prescribed manner, and the entire procedure is repeated until the error is below the set limit.

In a feed-forward network, the processing elements (PEs) are interconnected through unidirectional information channels or connections. A typical processing element is shown in Fig. 2. The output y is given by the nonlinear transformation,

$$y = f \left[\sum_{ij} w_i x_i - \theta \right], \quad (2)$$

where θ is a node bias and w_i are the connection weights. Various types of threshold functions are used in networks; the most common is the sigmoidal function shown in Eq. (1). This satisfies the nonlinear differential equation 3,

$$\frac{df}{dz} = \beta f(1 - f). \quad (3)$$

Thus, the relationship between two sets of information can be approximated, in general, by any degree of nonlinearity. The key to developing a neural network to model this

Figure 2. A typical processing element of a neural network.

relationship is to train the network by using as many examples as possible. An artificial neural network should not simply memorize patterns but should generate an implicit functional relationship between “input-output” data. This unique property of neural networks has been exploited in this article.

Most neural networks use the training of a three-layer, feed-forward, and fully connected network incorporating the backpropagation algorithm first developed by Rumelhart and McClelland (7). In experiments using three- and four-layer perceptrons, there were indications that a three-layer perceptron was more than adequate for interpolative problems. This also indicated that the mapping interfaces were fairly regular. The backpropagation network algorithm was an iterative gradient technique that minimizes the global error between the actual output and the network output. The algorithm required a continuously differentiable nonlinear function, such as the sigmoidal function [see Eq. (1)]. The “error function” δ_j^p in the computation of connection weights between hidden layers is given by Eq. (4):

$$\delta_j^p = x_j^p(1 - x_j^p)(t_j - x_j^p) \quad (4)$$

Note that δ_j^p at lower level p is a function of δ_j^{p+1} corresponding to the error in layer $p + 1$. Because of this property, the algorithm is called the backpropagation network. t_j is the target value of the j th output node. The output of node j in layer p is given by

$$x_j^p = \left[1 + \exp \left(- \sum_i w_{ij} x_i^{p-1} + \theta_j^p \right) \right]^{-1}. \quad (5)$$

The iterative procedure continues until the global error is less than a set tolerance. The evolution of the correction weights w_{ij} during training or their pattern for a trained network is not studied in this article. This is a very important aspect of quantifying network performance. For more detail, see (8–10) and references therein.

SELECTING INPUT DATA

The most effective input data for training an ANN are those data that span the space from which predictions are to be made. These are not the only data, however, that can be used. An ANN also work for prediction outside the data space. However, it usually requires much more data for this purpose. For example, if one wishes to predict the molecular weight of a group of molecules based on one or more of the physical properties of these molecules such as boiling point or density, then the values used as inputs should be only for molecules whose molecular weights are between the highest and lowest molecular weights to be predicted. Let us say that you have molecules whose molecular weights are between 50 and 250 U. You should train only on the physical properties corresponding to molecules whose masses are between 50 to 250 U. If you train on properties of molecules corresponding to this range of molecular weights and then try to predict the molecular weight of a

molecule of a mass of, say, 350 or 400 U from its corresponding physical properties, your prediction will probably not be very accurate. To make this prediction, you need to have some examples of data of physical properties from molecules whose masses are between 350 or 400 U. However, this is not the whole story. It is possible to predict outside the range of values to some extent. It all depends on how much data is available and how much of a "connection" exists between the input data and output values. If the data are sufficient for the neural network to make a strong connection, then it can predict outside the training range. If the connection is weak, then the prediction will not be good.

PREPARATION OF DATA

Now that you have selected your training set of data, you need to process your data into a format compatible with your neural network program. Many programs available handle this function automatically, but there will be times when you may need or want to process the data yourself. As previously discussed, there are several transformative functions that are applied in ANNs. The most common transfer function is the sigmoid function shown in Eq. (1). This function requires that all of the input data be in the range of zero to one. For practical reasons, most data is scaled between 0.1 and 0.9. An example of an equation for scaling data is given by

$$x'_i = [a(x_i - x_{\min}) / (x_{\max} - x_{\min})] + b \quad (6)$$

where x'_i is the scaled input data, x_i is the original input data, x_{\min} is the minimum value of the input data, x_{\max} is the maximum value of the input data, and a and b are constants allowing fixed limits of the scaled data. For example, if $a = 0.90$ and $b = 0.05$, the scaled values of the input data will range from 0.05 to 0.95.

NUMBER OF NEURONS IN HIDDEN LAYER(S)

There are probably as many ways of selecting the number of nodes in a hidden layer as there are people who use ANNs. No hard-and-fast rules can be used to choose either the number of hidden layers or the number of nodes in the hidden layer or layers. For almost all purposes, one hidden layer should be sufficient. Jack Aurada however has pointed out in his book, *Introduction to Artificial Neural Systems*, that there sometimes can be advantages of a two hidden layer architecture from the viewpoint of efficiency (11). The convergence in the error "with two hidden layers yielded superior results" compared to a similar network that had only one hidden layer and the same total number of hidden nodes (11). Several authors have proposed a rule of thumb for selecting the number of hidden nodes in a three-layer system (12,13). However, probably, the procedure that is most commonly used is either a bottom-up or a top-down trial-and-error procedure (14). The top-down approach starts with too many neurons and removes neurons until the network can no longer converge in a reasonable time. The bottom-up approach starts with too few neurons

and add neurons as necessary until the network converges in a reasonable time. Most of the time, it is a compromise between the time it takes to converge and the number of neurons in the hidden layer. The one condition you must avoid is not to have too many neurons in the hidden layer. This could lead the network to "memorize" the results of the learning process and not generalize. This is sometimes called overfitting.

How do you know how many nodes to start with in the hidden layer? Some authors propose some type of empirical rule. For example, Eberhart and Dobbins found that a reasonable number of nodes in the hidden layer at starting in a three-layer network is the square root of the number of input plus output nodes, plus a few (15). Leigh uses a procedure that "dictates that the number of hidden nodes in one hidden layer network should not exceed 30% of the size of the input layer (16). Another empirical rule proposed by Weiss and Kulikowski uses the procedure that "a network should average at least ten samples per weight in the network" (17).

SUPERVISED VERSUS UNSUPERVISED NEURAL NETWORKS

So far, we have discussed only supervised ANNs. To summarize, these networks "learn" to make associations between input data and output parameters (e.g., physical properties, desired characteristic) through training. This training is performed by presenting numerous examples to the network, and the ANN makes numerous adjustments of its weight space until a given set of input data can elicit a correct output within some predetermined error limit.

There is another major type of ANN called an unsupervised ANN. An unsupervised ANN, sometimes called a self-organized ANN, perform its function by doing a multidimensional clustering of the input data. What typically happens is that the input data is presented to the network and the network adjusts its internal parameters so that similar inputs produce similar outputs. In essence, different clusterings of data inputs are mapped into different "regions" of a multidimensional space that allow quick and easy analysis of very large and seemingly unrelated amounts of data. Some of the more notable supervised networks are based on adaptive resonance theory. Examples of programs based on this theory are ART1, ART2, AR2, Fuzzy ART, etc. Other programs based on the unsupervised model are Hopfield nets, bidirectional associative memory, Kohonen self-organizing maps, fuzzy associative memory, and many others. For additional details on unsupervised ANNs, see (18) and references therein. For a list of some additional programs that use supervised or unsupervised algorithm, see Table 1 of (19).

ARTIFICIAL NEURAL NETWORK EXTRAPOLATIONS OF HEAT CAPACITIES OF POLYMERIC MATERIALS TO VERY LOW TEMPERATURES

As a first example of applying an ANN to materials, we present the use of neural network computing to predict the temperature dependence of heat capacities C_p , in the

Table 1. Polymers Used in Training Heat Capacities to Very Low Temperatures

Nylon 6,6	Poly(ethylene terephthalate)
Poly(oxymethylene)	Poly(<i>p</i> -methacryloyloxybenzoic acid)
Poly(propylene)	Poly(<i>p</i> -hydroxybenzoic acid)
Poly(ϵ -caprolactone)	Poly(vinyl alcohol)
Poly(chlorotrifluoroethylene)	Poly(<i>p</i> -phenylene)
Poly(vinyl benzoate)	Poly(oxy-1,4-phenylene)
Poly(oxyoctamethylene)	Poly(tetrafluoroethylene)
Poly(methyl methacrylate)	

temperature range 10–100 K of a series of 15 polymeric materials and relate these values to the temperature dependence of C_p in the temperature range 100–360 K (20). In this way, newly measured values of the heat capacity C_p in the higher temperature range (100–360 K) can be extrapolated to the low-temperature domain where measurements are difficult. Note that this is a different use of an artificial neural network because we are predicting values of a physical property outside the range of values in which the training occurred. Remember, this is an example of an application of artificial neural networks. For more details on the results of the work being presented, the reader should refer to (21).

Introduction

The field of thermal analysis of polymers has greatly enlarged in about the last 20 years since the introduction of simple and comparatively inexpensive instrumentation. The measurement of the heat capacities of polymers is fundamental to understanding the theory of glass transition temperatures, for example, because the measure of the heat absorbed provides a direct measure of the increase in the molecular motion of molecules. This knowledge can be used to help polymer scientists understand a wide range of properties of these systems in response to temperature and temperature changes. These could include, but are not limited to, polymerization, degradation, and other chemical changes associated with temperature.

Application of Neural Network Computing to the Extrapolation of Heat Capacities

Figure 3 shows the three-layered backpropagation network used in this specific project. The input layer consist of 25 neurons, a middle or “hidden” layer of 15 neurons, and an output layer with 10 neurons; the network has been trained using the backpropagation learning algorithm (22).

As we stated in the previous section, a set of correct input/output pairs, which we call examples, was presented to the ANN considered in this work and the internal weights were adjusted to represent these examples best through the backpropagation learning algorithm. The name backpropagation is due to the procedure for updating the weights during training in which the network corrects its internal parameters by starting with the output values and propagating backward through the hidden layer to the input layer.

**Figure 3.** Neural net work used in predicting heat capacities of polymers.

Each neuron of an ANN constitutes a processing element (PE), and it is connected through various weights to other PEs. The processing element sums the product of each input, and the connection weights form the previous layer of PEs and then filter it by a nonlinear function, usually called the activation function. The form of this function is given by Eq. (1).

The weights w_{ij}^p (weighing the signal between the i th PE of layer $p - 1$ and the j th PE of layer p are initialized randomly and then adjusted during training. Training the network means establishing the values of these weights between pairs of processing elements. For a multilayer network, the output layer of the j th PE in layer p is given, in general, by

$$x_j^p = f \left[\sum_i w_{ij}^{p-1} x_i^{p-1} + \theta_j^p \right], \quad (7)$$

where the nonlinear function f has the sigmoidal form of Eq. (1) and θ_j^p is the bias of the j th PE layer of layer p . The connection weights, w_{ij}^p and the biases θ_j^p are initially uniformly distributed in the range $\{-1, +1\}$. They are updated each time an example is presented to the network during training, according to the backpropagation algorithm described in detail in (21,23). Several variations and enhancements of the backpropagation algorithm are aimed at accelerating the learning process and improving its accuracy. In the variant employed at the University of Tennessee and used for this study, the parameter β in Eq. (3) is adjusted during training. Different values for β in the range 0.1 to 0.9 are used; the one that demonstrates the fastest convergence is selected.

During training, the input pattern and a target output pattern are associated. To make the outputs as close as possible to the desired value, we minimize the sum of the squared errors

$$E(w) = 1/2 \sum (t_j - a_j)^2 \quad (8)$$

with respect to the set weights of w , where t_j is the target (i.e., the output part of an example) and a_j is the

actual value of the output layer. The local error at each mode is computed, and the connection weights are adjusted through a gradient descent algorithm to minimize the global error (20). The computational burden in applying multilayered ANNs lies primarily in network training. The weights of the network are fixed after training is completed. These values are then used during "recall" sessions, when an unknown input is presented to the network and it computes the appropriate network.

RESULTS

In our calculations, we trained the network by using input-output pairs for values of C_p versus temperatures from 10–360 K in increments of 10 K for polymers taken from the ATHAS data bank of heat capacities of more than 100 macromolecules (24). The input layer of our network consisted of 25 neurons, a middle layer of 15 neurons, and an output layer of 10 neurons. These heat capacities are based on experimental data, fitted to approximate vibrational frequency spectra. The computed heat capacities are smooth functions of temperature and contain no statistical errors. The input consisted of C_p in the temperature range of 110–360 K; using backpropagation, the output was C_p for $T = 10, 20, \dots, 100$ K. The 15 polymers used in training are given in Table 1. It can be seen that the input data covered a wide variety of polymers.

All calculations were implemented on a VAX 2000 workstation. After the network was trained, five additional polymers were chosen to test the ability of the network to predict the low-temperature C_p from the high-temperature C_p . The polymers chosen for our test cases were PEN [poly(ethylene 2,6-naphthalenedicarboxylate)], PE (polyethylene), PVF [poly(vinyl fluoride)], PS (polystyrene) and nylon 6 [poly(ϵ -caprolactam)]. From Table 2, it can be seen that typical errors ranged from 0.80% to 0.01%, and the average error was 0.34%. Errors were calculated as the difference between the "expected value" and the value calculated by the neural network.

Errors of this order of magnitude are far less than experimental errors that are typically 1–5%; the larger errors occur at lower temperatures where heat capacities are of low magnitude. Knowing this, the heat capacity in the easily accessible temperature range from 100–360 K permits reasonably precise extrapolation to low temperatures. The low-temperature data are needed to evaluate the total heat content of the polymeric materials.

CONCLUSIONS

This example shows the feasibility of using neural networks for extrapolating heat capacities of polymers in the low-temperature region. The exciting possibility of this method is that by "teaching" a neural network a sufficient quantity of known experimental data, an excellent extrapolation to unknown data may be possible. This procedure can also be applied to a wide range of properties of many materials, including but not limited to polymeric materials, as demonstrated in this section. For additional examples

ARTIFICIAL NEURAL NETWORK MODELING OF MONTE CARLO SIMULATED PROPERTIES OF POLYMERS

Our second example looks at a neural network used to learn features of the rotational potential energy surface of a number of polymers and relate those features to conformational properties of the polymers. Specifically, we modeled Monte Carlo simulations of 20 polymers (see Table 3) in which we calculated two statistical properties, the characteristic ratio and the temperature coefficient of the characteristic ratio of each polymer. This particular example is illustrative of any modeling study where one can relate a theoretically calculated parameter or series of parameters and a property of the materials being studied. The reader can find additional examples by this author and others in the references at the end of this article.

INTRODUCTION

Monte Carlo techniques have been used to study chemical systems for many years. It has been a particularly effective technique for studying the statistical properties of polymers. Flory used the Monte Carlo technique in effectively predicting many properties of polymers (25). Coupling neural networks (26–28) with Monte Carlo techniques provides a powerful new tool for predicting the properties of molecules. Accurate knowledge of the rotational potential energy surface is fundamental to the overall accuracy of the predictions from a Monte Carlo study. In this light, we first created 20 rotational potential energy surfaces corresponding to the 20 polymers in this study by using the semiempirical technique MNDO (modified neglect of differential overlap) and then used these energy surfaces corresponding to the 20 polymers in this study to produce 10,000 chains of each polymer, each chain 100 bonds long. From these results, we calculated the mean-square end-to-end distance, the characteristic ratio, and its corresponding temperature coefficient. A neural network was then used to model the results of these Monte Carlo calculations. We found that artificial neural network simulations were highly accurate in predicting the outcome of the Monte Carlo calculations for polymers for which it was not trained. The overall average error for predicting the temperature coefficient was 0.89%.

Previous discussions of using a neural network has focused on predicting heat capacity relationships (28,29) between the potential surface and quantum mechanical eigenvalues (30), molecular dynamic results (31,32), and frequencies computed by normal mode analysis (33).

In this project, we first created 20 rotational potential energy surfaces for 20 different polymers using the semi-quantum mechanical program MNDO (34). Next, we used these surfaces in our Monte Carlo program to calculate various average statistical properties of our 20 polymers. Last, we submitted our 144 potential energy points of each polymer to the 144 input nodes of our network and trained the network to predict the statistical properties that we obtained from our Monte Carlo calculations. Our calculation section provides more detail.

CALCULATIONS

We began our calculations by first optimizing the geometry of each of the 20 polymers using the Gaussian-92 (35) ab initio SCF-MO (self-consistent field molecular orbital) program that has a 4–31G basis set of functions. Of course, we optimized on only a fragment of each polymer, that was small enough so that we could run it on our PC computer but large enough so that end effects were small. We also made sure that the two ends of each fragment of each polymer were identical. The fragments were usually between 8 and 12 main chain bonds long. We also optimized the geometry of each molecule when the main chain was in the plane's zigzag (all main chain dihedrals were 180°) conformation.

Next, we took the optimized geometry of each polymer and calculated 144 rotational potential energy states using

the semi-quantum mechanical program MNDO. This program was run on our (primitive) Zenith 386 PC that has a math coprocessor available from C-graph software, Inc. of Austin, Texas (36). Each of the 144 rotational energy states was produced by rotating most interior dihedral angles by 30 through 360°. It should be emphasized that we were not attempting to produce the most accurate rotational potential energy states. To do so would have required a much more accurate quantum mechanical program such as Gaussian 92 (12) or higher, and would have required several hundred additional CPU hours of computational time, probably using a supercomputer.

Next, we used our rotational potential energy surfaces in Monte Carlo simulations (37) to calculate several average statistical properties for each polymer. The procedure adopted was to produce a Markov chain in which each atom k along the backbone of the chain was added in a configuration dictated by its conditional probability calculated from its corresponding Boltzman factor $\exp[-E_k/(RT)]$, where E_k is the k th rotational potential energy, R is the gas constant, and T is the temperature in degrees K. The properties calculated were the mean-square end-to-end distance from which we calculated the characteristic ratio and the temperature coefficient of the characteristic ratio. We took the last two numbers and used them as the output parameters to train two neural networks. The first network used the 144 rotational potential energy points of each polymer as input and the mean-square end-to-end distance as output (see Fig. 4). The second network was used to train the temperature coefficient of the characteristic ratio. This network used eight input nodes corresponding to four temperatures and four mean-square end-to-end distances, and one output node corresponding to the temperature coefficient of the characteristic ratio (see Fig. 5). For more detail on the way the neural network program worked and how neural networks work in general, see (25–27, 38) and the references therein.

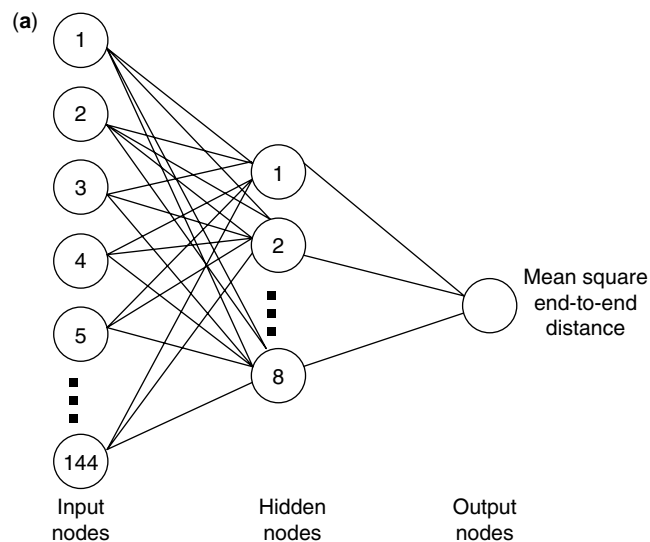

Figure 4. Architecture of neural network for calculating the mean-square end-to-end distance of polymers.

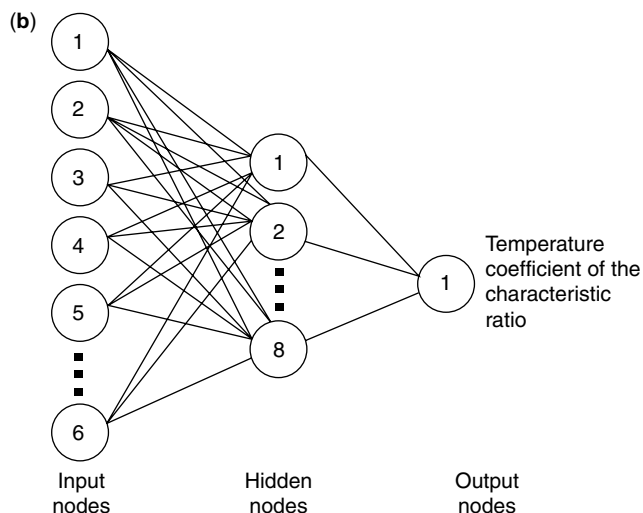

Figure 5. Architecture of neural network for calculating the temperature coefficient of the characteristic ratio.

RESULTS

Table 3 lists the polymers used in this study for training and testing. Note that two of the polymers have two different isomers, I and II. These correspond to rotations about two different consecutive bonds in these two polymers. We calculated a total of 20 polymers, trained on 16, and tested on four. Table 4 presents the results for seven runs in which we randomly chose four polymers from the list of 20 in Table 3 to test our training. Each run represents a different set of four polymers. As can be seen, the relative error ranged from a high of 15.4% to a low of 0.33%, and the overall average error in the prediction of the characteristic ratio (C.R.) was 4.82%. We feel that this error was very acceptable considering that most experimental error for measuring the characteristic ratio is about 5% or higher. It should also be mentioned that no attempt

was made to reproduce the experimental characteristic ratio. The purpose of this work was to determine whether a characteristic ratio could be accurately predicted from a given rotational potential energy surface, whether or not that surface could predict the experimental characteristic ratio and/or temperature coefficient. However, if the rotational potential energy surface was an accurate representation of the molecule, then this procedure should accurately predict the various macromolecular properties. We feel that the results of this study verify this conjecture.

Table 5 lists the characteristic ratios of various polymers calculated at several temperatures. The training and testing of the characteristic ratio (C.R.) for those numbers were generated at 300 K. The C.R. was also calculated at 255, 325, and 450 K. From this data, we calculated the temperature coefficient of the characteristic ratio in Table 6. This number was found by determining $d[\ln(r_{0,n}^2)]/dT$

Table 4. The Predicted Characteristic Ratio (C.R.) for Selected Polymers at 300 K

where n , the number of main chain bonds, was 101 (39). As for the characteristic ratio, there was no attempt to obtain an accurate reproduction of the experimental temperature coefficient by training it on a series of characteristic ratios. As can be seen from Table 6, the predictions were exceptionally good. The errors ranged from 0.02% to 3.27%, and the average error was only 0.89%. Noted that the network was trained on the characteristic ratio, not $\langle r^2 \rangle$ or $\ln \langle r^2 \rangle$. The network was able very quickly to "learn" the correct functional association.

CONCLUSIONS

In this study, we demonstrated the feasibility of using artificial neural network procedures to model macromolecular properties of polymeric systems. Although the results were not perfect, this author feels they are very satisfactory. The maximum error for predicting the characteristic ratio from its corresponding rotational potential energy surface was about 15%, and the overall average error, however, was only 5%. Using more polymers in the training, this error would be reduced. The temperature coefficient, however, was substantially better. Its maximum error was only about 3%, and the average error was less than 1%. It should be reemphasized that we were not attempting to produce the most accurate experimental characteristic ratios or temperature coefficients. To do so would have required producing much more accurate rotational potential energy surfaces for the 20 polymers, and this would have required a much more powerful quantum mechanical program than MNDO and an immense amount of computer time. The major emphasis was to see whether, given a potential energy surface, one can predict the corresponding characteristic ratio and temperature coefficient by using a trained artificial neural network.

The advantage of using neural networks rather than other more traditional techniques is that once you properly train your network, it requires no more than one second or less of computer time to obtain results for other polymers for which the network has not been trained. If the original

choice of polymers was sufficiently diverse and the data set for a trained neural network was sufficiently accurate, predictions of any properties for which you trained should be very good. Therefore, this could reduce or eliminate the costly and time-consuming Monte Carlo simulations (or other simulations such as molecular dynamics) and, therefore, greatly reduce the time and cost of computations.

SUMMARY

We have seen how artificial neural networks provide a very powerful tool to material scientists. The training phase of these networks may be very time-intensive, but the predictive powers are immense. This article only scratches the surface of ANN. There are numerous journal articles as well as books that may be taped to teach the reader more about this technique as well as many other techniques involved in the general field called artificial intelligence. There are also numerous Internet sites where additional information can be obtained. Some of these useful sites where the reader can find additional information on neural networks, as well as on other artificial intelligence procedures, in addition to some free software, are listed here:

INTRODUCTION

Ultrasound is widely used in health care for noninvasive diagnostics and in industry for nondestructive testing. In the human body, it generates visual images from inside the test medium: the fetus, malignant tissue, stones, etc. In industrial applications, besides defect detection, ultrasound is also useful for determining significant material characteristics such as density, thickness, mechanical properties, and level sensing. Knowledge of ultrasonically analyzed information is important for human health as well as for cost-effective production of quality industrial materials.

Ultrasound operates on the same principle as other characterization methods also based on wave-material interactive phenomena, such as optical, X ray, infrared,

Table 1. Categories of Ultrasonic Measurements and Their Applications

Measurement Category	Measured Parameters	Applications
Time domain	Times-of-flight and velocities of longitudinal, shear, and surface waves	Density, thickness, defect detection, elastic and mechanical properties, interface analysis, anisotropy, proximity and dimensional analysis, robotics, remote sensing, etc.
Attenuation domain	Fluctuations in reflected and transmitted signals at a given frequency and beam size	Defect characterization, surface and internal microstructure, interface analysis, etc.
Frequency domain	Frequency dependence of ultrasound attenuation, or ultrasonic spectroscopy	Microstructure, grain size, grain boundary relationships, porosity, surface characterization, phase analysis, etc.
Image domain	Time-of-flight, velocity, and attenuation mapping as functions of discrete point analysis by raster C-scanning or by synthetic aperture techniques	Surface and internal imaging of defects, microstructure, density, velocity, mechanical properties, true 2-D and 3-D imaging.

Raman spectroscopy; nuclear magnetic resonance; and neutron, γ -ray, and mass spectrometry. By propagating a wave in a given medium, useful information about the medium can be generated by analyzing the transmitted or reflected signals. Ultrasound differs from other wave-based methods because it does not require sample preparation, is nonhazardous, and provides the means to determine mechanical properties, microstructure, imaging, and microscopy. Ultrasonic equipment is also portable and cost-effective. Most significantly, ultrasound is applicable to all states of matter, except plasma and vacuum. Furthermore, propagation of ultrasound in a material is not affected by its transparency or opacity. Table 1 provides a comprehensive introduction to ultrasound measurements and to the information revealed either directly or through correlation with measurements.

Since about 1980, both ultrasound and its applications have grown substantially. Uses in industry have gone beyond overt defect detection in metals to include characterization of elastic and mechanical properties; delaminations in multilayered, particulate and fibrous materials; proximity and dimensional analysis; measurements of anisotropy and heterogeneity; surface profiling, chemical corrosion, crystallization and polymerization; liquid and gas flow metering; imaging of surface and internal features of materials; viscosity of liquids; texture and microstructure of granular and cellular materials; applied and residual stresses; high temperature, pressure, and radiation environment applications; and robotics, artificial intelligence. These highly desirable applications have attracted the attention of a wide range of industries: structural and electronic materials and components manufacturers, aircraft and aerospace, chemical and petroleum, plastics and composites, lumber and construction, highways and aircraft landing strips, bridges and railroads, rubber and tire, food, and pharmaceutical products.

In medical diagnostics where the sophistication of ultrasound is more advanced than in industry, it can replace harmful X rays in many critical instances. Ultrasound is useful for visualizing a fetus, measuring the cornea, tissue

characterization, imaging of plaque in arteries and gum disease, brain wave measurements, monitoring of the heart beat, skin and breast cancer detection, blood flow metering, etc.

In 1980, we were content if ultrasound could detect a 1-mm defect and 0.5-mm resolution in a given test material. Today, after much R&D, we have developed short-pulse and high-frequency transducers by using advanced electronics and signal processing to the point that we can measure resolution and detectability in the micrometer range. Obviously, ultrasound has come a long way since the discovery of piezoelectricity by Pierre and Jacques Curie in 1876 (1) and its first application by Richardson in 1913 for sonar (2).

Ultrasound and its applications have grown phenomenally in recent years, but the mode by which it is propagated in a given test medium is severely limited. Due to extremely high attenuation of ultrasound by air, its transmission in a test medium is done by physically contacting (coupling) the transducer to the test medium. Therefore, all conventional ultrasound has the severe limitation of physical contact between the transducer and the test medium by a liquid gel (3). If this contact could be eliminated, then we could diagnose burnt or malignant skin damage without discomfort to the patient. Similarly, a number of industrial materials sensitive to liquid contact could be tested to measure thickness, density, mechanical properties, defect detection, etc. This is significant in ensuring materials quality and process control and for cost-effective production. The development of a noncontact ultrasound (NCU) mode would allow many more useful applications of ultrasound. For example, using NCU, characteristics of materials that are porous and hygroscopic could be determined. Similarly, materials in the early stages of formation (uncured plastics, green ceramics, and powder metals) and those that are continuously rolled on a production line (plastics, rubber, paper, construction, and lumber) could also be tested under manufacturing conditions. NCU could also be applied to medical problems where contact with a patient can be harmful, as in the evaluating wounds and diagnosis of the eye.

However, for NCU to become a reality, we first need transducers and electronic systems sensitive enough to transmit and detect ultrasound without contact with the test medium. And herein lies a big problem. Conventional wisdom stipulates that ultrasound (from ~200 kHz to >5 MHz) cannot be propagated through solids or liquids without physical contact between the transducer and the test medium. Therefore, NCU has been generally considered an impossible dream due to the phenomenal mismatch of acoustic impedance between the coupling air and the test media. This mismatch can run as high as six orders of magnitude when we consider propagation of ultrasound from air to materials such as steels, superhard alloys and dense ceramics, cermets, diamond, and diamond-like materials. To realize the NCU mode, this barrier of acoustic impedance must be broken. And for this to happen, it is imperative that ultrasonic transducers be characterized by phenomenally high sensitivity. Achieving NCU is analogous to “throwing a helium-filled rubber balloon so that it can pierce a stainless steel wall.”

REALITY THAT DEFIES NONCONTACT ULTRASOUND

The exorbitant mismatch between the acoustic impedance of the coupling medium, air, and that of the test material generates enormous resistance to ultrasound propagation in materials. This, in conjunction with the extremely high attenuation of ultrasound (in MHz region) by air, further compounds the problem of the NCU mode. In simple terms, when ultrasound travels from a medium of low acoustic impedance to one of high acoustic impedance, only a fraction of the energy is transmitted in the latter. The fraction of ultrasound transmission and energy transferred at the air-material interface is given by

$$T \text{ (Transmission coefficient in the propagation medium)} = 4Z_1Z_2 / (Z_1 + Z_2)^2 \tag{1}$$

where Z_1 is the acoustic impedance of the ultrasound carrier medium (for example, air for the NCU mode) and Z_2 is the acoustic impedance of the test medium. The transmission coefficient is derived as the ratio of transmitted acoustical energy V (measured in volts) and the input

Figure 1. Interfaces to be crossed by ultrasound (shown by arrow) in the noncontact transmission mode to propagate ultrasound through a test material. Interface “a” corresponds to air–material (from acoustic impedance Z_a to Z_m) transmission. Interface “b” corresponds to material–air (from acoustic impedance Z_m to Z_a) transmission

energy V_0 of a plane wave when refracted at 0° incidence on the interface between the two media:

$$T \propto V^2 / V_0^2 \tag{2}$$

This relationship can also be described by a decibel scale:

$$T = 20 \log V / V_0 \text{ (dB)}, \tag{3}$$

$$\begin{aligned} \text{Energy transferred in the propagative medium} \\ = 20 \log T \text{ (dB)}. \end{aligned} \tag{4}$$

For more details and the significance of plane wave transmission and reflection at a number of interfaces in terms of acoustical pressure and intensity, see (4).

Ultrasound in noncontact transmission must propagate from air into the test material and then again into air so that the transmitted wave can be detected by a receiving transducer (Fig. 1). Therefore, the high energy loss at the air–material interface is doubled by further loss at the material–air interface. Table 2 provides the transmission

Table 2. Transmission Coefficients and Energy Transfer in Selected Materials at Various Interfaces in the Noncontact Mode, per Fig. 1. As a Reference, Similar Data for Water Are Also Shown. Z (air) = 440 Rayl; Z (water); 1.5 Mrayl; 1 Rayl = $\text{kg/m}^2 \text{ s}$.

coefficients and energy losses in selected test materials in the noncontact ultrasound mode calculated by using Eqs. (1) and (4). As a reference, similar losses for water immersion (contact technique) are also provided. The following conclusions can be drawn from the data:

1. Transmission losses decrease as the acoustic impedance of the test material comes within the vicinity of that of the coupling medium, whether it is air or water.
2. Total energy loss at various interfaces in the noncontact transmission mode can run as high as six orders of magnitude compared to similar losses by using water as the coupling medium.

While conducting this exercise, we did not address the issues of the interrogating frequency of the transducer and the frequency dependence of ultrasound attenuation by air. When these factors are combined with the inherent loss of ultrasound energy at various interfaces in the NCU mode, the problem of noncontact transmission in solids is only exacerbated. Relatively speaking, the attenuation of ultrasound in air is intrinsically high compared to that in solids and liquids. And because attenuation in a medium increases as a function of the fourth power of the frequency, transmission of megahertz frequencies in air becomes almost incomprehensible. To overcome these NCU-defying realities, first we need to create ultrasonic transducers that have high sensitivity (or very low insertion loss). Sensitivity is needed to overcome interfacial transmission losses (Table 2) and also to facilitate transducer excitation by relatively low power voltages. This will help avoid unwanted heating of transducers and their subsequent destruction. Once optimum sensitivity is achieved, we can increase the transducer frequency to make it comparable to that used in conventional contact testing. Accomplishing this task has captivated the imagination of materials and transducer researchers.

PURSUIT OF NONCONTACT ULTRASONIC TRANSDUCERS

A few researchers have tried to develop noncontact material characterization by using wave phenomena, which include optics, thermal, infrared, X ray, and nuclear magnetic resonance. In pursuit of bulk ultrasonic wave propagation in 1963, White (5) reported generating elastic waves in solid materials by momentarily heating a material surface. This technique eventually led to the development of the thermographic method which has been used for surface and subsurface imaging of composites, metals, etc. by sensing minute temperature fluctuations as a function of material texture, microstructure, defects, and other variables. This method has been applicable to those materials that can sustain heat or emanate heat during the testing.

Next came laser-induced ultrasound (6) that was used to characterize Rayleigh waves in metals (7) and for subsurface materials evaluation (8). The laser-based method has been applied to those materials that can withstand

Table 3. Transmission Coefficients and Energy Transferred in Air as a Function of the Final Acoustic Impedance Matching Layer on the Piezoelectric Element. As a Reference, Similar Data Are Also Shown Using Water as the Coupling Medium. Z (air): 440 Rayl; Z (water): 1.5 MRayl.

the impact of a high-power laser beam. Laser-based ultrasound has become acceptable for high melting point metals and ceramics. The nondestructiveness of this laser-based ultrasound method is questionable when analyzing heat and shock-sensitive materials, such as polymers, green ceramics and powder metals, pharmaceutical and food products, and tissue. Ultrasound generated by electromagnetic acoustic transducers has been used in the NCU mode for nondestructive testing (9). This method is applicable only to ferromagnetic materials.

The various noncontact analytical methods outlined do provide useful information about the test materials. However, all of them are limited to specific materials and are partially destructive, complex, or expensive. The difficulty of propagating ultrasound in test media by the noncontact mode, as shown in Table 3, presents limited alternatives for achieving this mode in practical terms. These involve the techniques of ultrasound generation based upon true production of ultrasound, so that its propagation in the test medium is not affected by its (medium) exclusive properties.

Researchers and transducer experts have been designing piezoelectric devices by manipulating the acoustic impedance transitional layers in front of the piezoelectric element. In the materials industry, one of the early applications of noncontact ultrasound was testing Styrofoam blocks by using a 25-kHz frequency (10). A precursor to high-frequency, noncontact transducers was the 1982 development of piezoelectric dry coupling longitudinal and shear wave transducers up to 25-MHz frequency. Since 1983, these transducers have been commercially available for characterizing the thickness, velocity, and elastic and mechanical properties of green, porous, and dense materials (11–13). Dry coupling transducers feature a solid compliant and acoustically transparent transitional layer in front of the piezoelectric materials such as lead metaniobates and lead zirconate–lead titanate. These devices, which eliminate the use of a liquid coupling agent, do require contact with the material.

An important by-product of dry coupling devices was the development of air/gas propagation transducers, which use less than a 1-Mrayl acoustic impedance matching layer of a nonrubber material on the piezoelectric material. These

commercially available transducers have been successfully produced in planar and focused beam configurations for transmitting ultrasound in air up to ~ 5 MHz frequency and receiving up to 20 MHz. Air/gas propagation transducers, between 250 kHz to ~ 5 MHz, quickly found applications in aircraft/aerospace industries for imaging and for defect detection in fibrous, low- and high-density polymers, and composites. For such applications, these transducers have been used with high energy or tone burst excitation and high signal amplification systems. However, for applications such as level sensing and surface profiling, the low energy spike or square wave transducer excitation mechanism has been sufficient.

Similar transducers of 1-MHz and 2-MHz frequency were also produced at Stanford University by using silicone rubber as the front acoustic impedance matching layer (14). By using such a transducer at 1 MHz, the distance in air could be measured from 20 to 400 mm at an accuracy of 0.5 mm. Further improvements in transduction efficiency were shown by planting an acoustic impedance matched layer that is composed of tiny glass spheres in the matrix of silicone rubber on piezoelectric elements (15,16). Researchers at Strathclyde University (17) have reported air-coupling transducers based on piezoelectric composites between 250-kHz to 1.5-MHz frequencies. By using tone burst transducer excitation, they have been successful in producing millivolt level transmitted signals through a composite laminated honeycomb structure at 500 kHz.

More recently, piezoelectric transducers featuring perfect acoustic impedance matched layers for optimum transduction in air have been successfully developed from <100 kHz to 5 MHz (18).¹ The sensitivity of these new transducers in air is merely 30 dB lower than their conventional contact counterparts. As a result, ultrasound in the megahertz region can be easily propagated through practically any medium, including even very high acoustic impedance materials such as steel, cermets, and dense ceramics. This advancement, the major focus of this paper, is discussed in detail along with the various medical and industrial applications in the noncontact ultrasound mode.

Air-coupled transducers based upon capacitance (electrostatic) phenomena have also undergone substantial developments in recent years. Researchers at Kingston and Stanford Universities have successfully produced micro-machined capacitance air transducers; the latter claim a high 11-MHz frequency (19,20). These transducers that are characterized by high bandwidths have been used to evaluate composites and other materials. Ultrasound experts at the University of Bordeaux, have reported generating and detecting Lamb waves in the noncontact mode in anisotropic viscoelastic materials by using capacitive transducers (21).

Though much progress has been made in enhancing the transduction efficiency of transducers based on piezoelectric and capacitive phenomena, from a practical standpoint these advancements have by no means reached a saturation point. In the subsequent sections of this article, we describe the successful development of piezoelectric

transducers that are characterized by extraordinarily high sensitivities in the frequency range from 100 kHz to 5 MHz. The evidence of the high sensitivity of these new transducers can be seen from the fact that even very high frequencies such as 2–5 MHz can be propagated through a number of solids in the NCU mode.

PIEZOELECTRIC TRANSDUCERS FOR UNLIMITED NONCONTACT ULTRASONIC TESTING

The efficiency of an ultrasonic transducer depends on the coupling coefficients and other electromechanical properties of the piezoelectric material. It also depends on the mechanism by which ultrasound is transferred from the piezoelectric material to the medium in which ultrasound needs to be propagated. In the noncontact mode, this medium is air. Because the acoustic impedances of piezoelectric materials are several orders of magnitude higher than that of air, it is usually necessary to implant transitional (acoustic impedance matching) layers of various materials in front of it (the piezoelectric material). Ultimately, the characteristics of the final layer determine the transduction efficiency of a transducer device. The significance of the final acoustic impedance matching layer in the noncontact transducers cannot be overemphasized. Because the properties of a given piezoelectric material can be considered constant for a given device, the ultimate transfer of ultrasonic energy in air is entirely controlled by the acoustic characteristics of the final matching layer on the piezoelectric material (Fig. 2). To understand this, we examine the effect of the final acoustic impedance matching layer on the piezoelectric material with respect to transmitting ultrasound from it (piezoelectric element) to air, as per Eqs. (1) and (4). Table 3 shows the transmission coefficients and the transfer of ultrasonic energy in air as well as in water (as a reference) by assuming a number of final acoustic impedance matching materials on the piezoelectric material. The following conclusions can be drawn from the data:

1. The transmission coefficient in air increases as the acoustic impedance of the front layer on the piezoelectric material is reduced.

Figure 2. Schematic of an ultrasonic transducer showing the critical final acoustic impedance matching layer relative to the piezoelectric element and the coupling medium, air.

¹U.S. and international patents pending and in process.

- There is a significantly high transfer of ultrasonic energy in water compared to that in air due to better acoustic impedance matching of the final layer on the piezoelectric element with that of water.

In the light of (14–17) and this author's 1983 design (commercially available as air/gas propagation transducers from Ultrat Laboratories), the best final piezoelectric matching layer for maximum ultrasound transmission in air is composed of soft polymers. The polymer layer in these transducer designs can be porous or nonporous or can have embedded hollow spheres (in the polymer layer). For the sake of simplicity, we will identify all polymer acoustic impedance matched layer transducers as air-coupled (AC) transducers. These transducers yield a -58 to -54 dB transfer of ultrasonic energy in air, which is significant for propagating up to ~ 2 -MHz ultrasound in some solids in the noncontact mode. For example, by using a suitable transducer excitation mechanism and high received signal amplification, ultrasound can be transmitted in low acoustic impedance materials (typically materials that are lower than ~ 3 Mrayl) by using AC transducers. However, ultrasound propagation by such transducers in materials > 3 Mrayl is arduous, if not impossible.

The AC transducers based on polymer matching layer transducers do demonstrate the feasibility of noncontact ultrasound, but they are far from the most efficient. To enhance transduction efficiency in air, this author has been developing and applying a number of low acoustic impedance final matching layer materials since 1978. In 1995, we produced and evaluated (18) a transducer that had compressed fiber as the final matching layer. For the sake of simplicity and comparison, we will identify them as noncontact (NC) transducers. This transducer design exhibited unprecedented and phenomenal transduction in air which was found sufficient for NCU transmission in practically all material types. Perfected in 1997, the NC transducers can increase ultrasonic energy transfer from the transducer to air from -54 dB (AC transducers) to -35 dB; see Table 2 (18). An increment of sensitivity by an order of magnitude is extremely significant and warrants special attention. After initial trials at 200 kHz, 500 kHz, 1 MHz, and 2 MHz, NC transducers have been produced up to ~ 8 MHz. However, from a practical standpoint, it has been shown that they propagate up to 5-MHz ultrasound in nearly all material types in the NCU mode in ambient air. Leaving aside transmission in plastics and composites, the sensitivity of NC transducers is also high enough for transmission in materials that have extremely high acoustic impedance such as steel, dense ceramics, and cermets. In the following sections, we provide detailed observations about NC transducers and their sensitivity compared to AC types.

Transducer Characterization Scheme

NC transducers, like their contact or water-coupled counterparts, can also be characterized in the transmission or in the reflection (pulse-echo) modes. Figure 3 shows the setup for characterizing transducers in the transmission mode which is used to analyze NC and AC transducers. Here, the

Figure 3. Noncontact ultrasonic transducer characterization scheme in transmission mode. Frequency, bandwidth, pulse width, and signal-to-noise ratio are read directly from the oscilloscope. Sensitivity = $20\text{Log}(V_x/V_0)$. V_0 = Excitation in volts. V_x = Received signal amplitude in volts.

transmitting and receiving transducers are aligned and separated by a 10-mm (or more, depending on the transducer frequency) column of ambient air. In this case, the transmitting transducer is excited by a pulse of known voltage, V_0 . The output from the receiving transducer is directly fed into a measurement oscilloscope that has a mechanism to measure the frequency domain characteristics. Frequency and bandwidth are measured directly from the frequency domain envelope, and V_x , the received signal amplitude in volts, and the pulse width are measured from the time domain RF trace. The signal-to-noise-ratio (SNR) is determined by the following relationship when measurements are made without signal averaging. It is understood that while doing so, the instrument and cable noise also factor into the measurement.

$$\text{SNR} = 20 \log V_x/V_n \text{ (dB)}, \quad (5)$$

where V_n is the amplitude of the noise in volts. Sensitivity (insertion loss) is determined by

$$S = 20 \log V_x/V_0 \text{ (dB)}. \quad (6)$$

By using this characterization scheme, several NC transducers were analyzed in ambient air. Figures 4–7 show typical time and frequency domains for 200-kHz, 1.5-MHz, 3.0-MHz, and 5.0-MHz NC transducers and their salient acoustic characteristics.

Sensitivity Comparison of NC and AC Transducers with Conventional Contact Transducers

Because sensitivity is the most critical requirement for NC or AC transducers, it is important to develop some kind of comparison scheme. To this effect we chose conventional contact, water immersion transducers as a reference. A number of NC transducers were characterized for sensitivity in the transmission mode according to Fig. 3. Similar

Figure 4. Time and frequency domain of broadband 200-kHz, 50-mm active area transducers in transmission mode. T-R air separation: 100 mm. Bandwidth center frequency: 200 kHz. Bandwidth at -6 dB: 100 kHz (50%). Pulse width: $<20 \mu\text{s}$. Sensitivity: -46 dB. SNR: 50 dB.

transducers, suitable for conventional contact water immersion operation where acoustic impedance matches that of water, were characterized in water for sensitivity measurements. The setup for such transducer characterization is the same as in Fig. 3, except that in this case the 10-mm air column was replaced by a 10-mm column of water. Sensitivities for both transducer types, calculated according to Eq. (6), are shown in Table 4. From this comparison, it is quite clear that the sensitivity of the new noncontact transducers is approximately 30 dB below their contact counterparts. AC transducers were approximately 50 dB below their conventional contact water immersion counterparts.

Figure 5. Time and frequency domain of broadband 1.5-MHz, 25-mm active area transducers in transmission mode. T-R air separation: 10 mm. Bandwidth center frequency: 1.4 MHz. Bandwidth at -6 dB: 0.92 MHz (65%). Pulse width: $<2 \mu\text{s}$. Sensitivity: -58 dB. SNR: 46 dB.

Figure 6. Time and frequency domain of broadband 3.0 MHz, 12 mm active area transducers in transmission mode. T-R air separation: 10 mm. Bandwidth center frequency: 2.6 MHz. Bandwidth at -6 dB: 2.0 MHz (75%). Pulse width: <700 ns. Sensitivity: -62 dB. SNR: 40 dB.

Application Related Experiments and Sensitivity Comparison

In the previous section, we demonstrated the high sensitivity of new NC and AC transducers by analyzing them according to a transducer characterization scheme and by comparing them to similar observations of conventional contact transducers. Although this comparison provides substantial evidence of the superiority of NC transducers over the AC types, it still does not present a convincing argument. Graphical evidence is needed to prove this point. To this effect, we performed several application-related experiments aimed at propagating ultrasound in an NCU

Figure 7. Time and frequency domain of narrowband 5.0 MHz, 12-mm active area transducers in transmission mode. T-R air separation: 5 mm. Bandwidth center frequency: 4.5 MHz. Bandwidth at -6 dB: 1.5 MHz (33%). Pulse width: <800 ns. Sensitivity: -68 dB. SNR: 40 dB.

5.0	12.5	-68	Below 44

^aSensitivities reported here were obtained by exciting the transmitting transducer using a broadband and 15-ns pulse. Tone burst excitation sensitivities will be 12 dB higher.

^bFor some contact transducers, a -20-dB sensitivity is assumed.

mode through a solid material by using AC and NC transducers. Figures 8 and 9 present observations in support of this. Both observations correspond to NCU transmission through 20-mm thick aluminum by 1-MHz and 20-mm active area diameter transducers in the direct transmission mode. In both cases, transducers are separated from the test material surfaces by an ~5-mm air column. Furthermore, in Figs. 8 and 9, the transmitting transducer was excited by a high-energy 400-volt (into 4Ω input impedance) pulser, and the signal received from the

Figure 8. A 1-MHz noncontact transmitted signal through 20-mm aluminum by using transducers based on a soft, porous, polymer matching layer. Excitation of the transmitting transducer: 400 V into 4-Ω input impedance. Receiving transducer amplification: 64 dB. Transmitting and receiving transducers are 5 mm away from the material surfaces. Under these conditions, the transmitted signal amplitude is 13.1 mV. Compare with Fig. 9.

Figure 9. A 1-MHz noncontact transmitted signal through 20-mm aluminum by using new transducers based on a compressed fiber matching layer. Excitation of the transmitting transducer: 400 V into 4-Ω input impedance. Receiving transducer amplification: 64 dB. Transmitting and receiving transducers are 5 mm away from the material surfaces. Under these conditions, the transmitted signal amplitude is 111.1 mV. Compare with Fig. 8.

receiving transducer was amplified by a 64-dB gain. The key difference is that Fig. 8 was obtained by AC transducers and Fig. 9 by NC transducers. Under these conditions, the amplitude of the transmitted signal through 20-mm aluminum by AC transducers is 13.1 mV, whereas it is 111.1 mV for NC transducers. This clearly establishes the superiority of the new noncontact transducer design over the other air-coupled transducers described in (14–17),

Figure 10. A 1-MHz noncontact transmitted signal through 20-mm aluminum by using new transducers based on compressed fiber matching layer. Excitation of the transmitting transducer: one burst 16-V sine wave. Receiving transducer amplification: 64 dB. Transmitting and receiving transducers are 5 mm away from the material surfaces. Under these conditions, the transmitted signal amplitude is 3.26 mV. No other air-coupled transducer can transmit ultrasound under similar conditions in high acoustic impedance materials by very low level excitation.

Figure 11. Ultrasound transmission through 25-mm carbon steel (Z , 51Mrayl) by using the new noncontact transducers (1-MHz, 20-mm active area diameter) with a single burst of 16-volt sine wave excitation and 64-dB amplification of the received signal by an equivalent transducer. No other air-coupled transducer can transmit ultrasound under similar conditions in high acoustic impedance materials by very low level excitation.

including this author's air/gas propagation transducers that are commercially available from Ultran Laboratories since 1983.

To demonstrate further the exceptionally high sensitivity of NC transducers, we decided to conduct an experiment that would normally be considered impossible! An experiment analogous to that described before was performed, except that in this case the NC transmitter was excited merely by a single burst of a 16-volt sine wave and 64-dB amplification of the received signal. Figure 10 presents the observation from this, showing a 3.26-mV signal transmitted through 20-mm aluminum in the noncontact mode. AC transducers (based on soft polymer matching layers, that is, porous or nonporous or have hollow spheres) were unsuccessful in generating ultrasound transmission through 20-mm aluminum by 16-volt excitation, despite high signal averaging! It is also interesting to note that by low energy excitation, using NC transducers, we propagated megahertz frequencies even in steel, whose acoustic impedance is 51 Mrayl, six orders of magnitude higher than in air! We show an example of this startling conclusion in Fig. 11. It is important to note that the purpose of observations shown in Figs. 8–11 was to demonstrate the high sensitivity of NC transducers relative to any other similar device. The purpose of these experiments is not to recommend or suggest the usage of low-energy transducer excitation for testing materials.

NONCONTACT ULTRASONIC ANALYZER

As is evident from the preceding sections, NC transducers can be used with any suitable commercially available pulser-receiver to transmit and to detect ultrasound through any material. However, our ultimate goal was to generate an NCU mode that would rival the performance

Figure 12. Ultrasonic noncontact analysis system, the NCA 1000, using noncontact transducers and a monitor screen displaying the thickness and velocity through the test material.

of conventional contact or immersion ultrasound. The high transduction of NC transducers is not enough to accomplish this task. For example, we still need to overcome the natural barrier of acoustic impedance mismatch between the coupling air and the test medium. From Table 2, we see that losses due to this mismatch are formidable. To circumvent this and not jeopardize our objective of equating NCU performance with that of conventional contact-based ultrasound, a new mechanism of transducer excitation and signal amplification was needed. Nevertheless, this seemingly impossible task, too, was overcome. In 1997–1998, a novel ultrasonic system was conceived and produced. Identified as the NCA 1000,² this instrument was developed by Leon Vandervalk and Ian Neeson of VN Instruments, Canada. It is based on synthesizing a computer-generated chirp combined with the best attributes of noncontact transducers. Signal processing in the NCA 1000 is done by synthetic aperture imaging techniques. The NCA 1000 is characterized by a dynamic range of >150 dB and a time-of-flight (TOF) measurement accuracy of ± 10 ns in ambient air and better than ± 1 ns in closed conditions. The NCA 1000 (Fig. 12) measures the TOF, thickness, velocity, and integrated response (area underneath transmitted or reflected signals in dB) of materials in the time domain. By using the FFT mechanism of this system, it is also possible to conduct noncontact ultrasonic spectroscopy. Furthermore, by raster scanning the transducers or the test material, we can generate surface or internal images of the test material. Such images can be representative of the material surface roughness, TOF, transmission attenuation, velocity, or thickness.

REFLECTION AND TRANSMISSION IN NONCONTACT MODE

Analogous to conventional contact or immersion ultrasound, ultrasound in the non-contact mode is also reflected and transmitted at various interfaces as well as through a test medium. In this section, we provide examples of

²U.S. patent pending and in process.

Figure 13. Noncontact ultrasound pulse-echo reflection from 9-mm thick silicone rubber. Transducer: 1-MHz, 12.5-mm active area diameter, and 76-mm point focused. Transducer to material distance in air: 40 mm. It is important to note that the material thickness reflection is ~40 dB lower than that of the air-material interface.

various paths of ultrasound reflection and transmission as functions of test material's interfaces and its volume.

Single-Transducer Operation (Pulse-Echo)

By operating one transducer simultaneously as a transmitter and receiver (analogous to the pulse-echo technique), it is very easy to generate reflection from an air-material interface due to the extremely high reflection coefficient at this interface. However, in this mode, it is nearly impossible to produce a far side reflection corresponding to the test material thickness in ambient air. This difficulty stems from several factors, such as the extremely small transmission of ultrasound in the test material, the extremely high beam spread on the surface of the material, and the inherent electrical noise associated with single transducer operation from the initial pulse. To a degree, the adverse effects of these factors can be minimized by a focused transducer, which will reduce the beam spread and focus ultrasound (thus intensify the reflected energy) within the test material. Figure 13 shows pulse-echo reflection signals from a 9 mm thick silicone rubber sample. This observation was generated by using a 1-MHz focused NC transducer. Similar results have also been observed for other plastic materials. However, at this time, we have no concrete proof of generating these observations from high acoustic impedance materials, such as metals and ceramics. Because reflection from an air-material interface is extremely strong in single transducer operation, ultrasonic reflectivity can be used to characterize the surface characteristics of the material. Such applications include surface acoustic impedance, surface roughness, particle size measurement, surface texture and microstructure, distance, proximity, and level sensing, and any other surface conditions that are sensitive to noncontact ultrasound.

Separate Transmitter and Receiver Operation on the Same Side (Pitch-Catch)

By using two noncontact transducers, one a transmitter (T) and the other a receiver (R), on the same side of the test material, (Fig. 14), it is possible to launch and measure the characteristics of longitudinal, shear, and surface waves in practically all types of material. Generation of these waves

Figure 14. Schematic of a setup for same side operation of separate transmitting (T) and receiving (R) transducers, also showing various types of wave propagation in the test material.

is determined by Snell's law,

$$\sin i / \sin r = V_a / V_m, \quad (7)$$

where i is the incident angle in air, r the refraction angle in the test material, V_a is the ultrasound velocity in air, and V_m the velocity in the test material.

By manipulating the incident angle in air, a variety of wave types can be produced in a test material. Figure 15 shows the far side thickness reflection of a longitudinal

Figure 15. Thickness reflection of longitudinal wave propagation in 12-mm thick aluminum per Fig. 14 setup. Distance between the transducers and the material surface: ~15 mm ambient air. Distance between T and R: ~50 mm. Incident angle in air: ~3.0°.

Figure 16. Thickness reflections of longitudinal and shear waves in 32-mm thick transparent polystyrene per Fig. 14 setup. Distance between the transducers and the material surface: ~ 13 mm ambient air. Distance between T and R: ~ 50 mm. Incident angle in air: $\sim 6.0^\circ$.

wave from 12-mm thick aluminum. Figure 16 shows the far side thickness reflection of longitudinal and shear waves from 32 mm thick transparent polystyrene. Figure 17 is a longitudinal wave refracted surface wave in aluminum produced by an incident angle equal to the first critical angle (i.e., total reflection of a longitudinal wave) which is 3.16° for aluminum. Figure 18 shows a shear wave refracted surface wave in aluminum, generated by an incident angle equal to the second critical angle (i.e., total reflection of a shear wave), which is 6.3° for aluminum. It is important to note that while performing these experiments, distances—corresponding to transducers and the test materials and angles of transmitting and receiving transducers—were not measured accurately. The primary function of this exercise is to show the feasibility of various types of bulk and surface wave generation by noncontact ultrasound. Applications of such measurements include NCU evaluation of materials from one side, defect detection, anisotropy measurements, and relationships of ultrasonic velocities to test material elastic and mechanical properties.

Figure 17. Surface wave in aluminum produced by total reflection of longitudinal wave when the incident angle is equal to the first critical angle. Setup for this is shown in Fig. 14. Distance between the transducers and the material surface: ~ 15 mm ambient air. Distance between T and R: ~ 100 mm. Incident angle in air: $\sim 3.2^\circ$.

Figure 18. Surface wave in aluminum produced by total reflection of shear wave when the incident angle is equal to the second critical angle. Setup for this is shown in Fig. 14. Distance between the transducers and the material surface: ~ 15 mm ambient air. Distance between T and R: ~ 100 mm. Incident angle in air: $\sim 6.5^\circ$.

Direct Transmission

When a test material is inserted between two noncontact transducers facing opposite each other in air, then ultrasound is transmitted and reflected from all interfaces corresponding to air and the material. Details of this are shown in Figs. 19 and 20. Direct transmission is relatively the easiest technique in noncontact ultrasound. Therefore, it has been quite extensively studied and developed. Applications of this technique are numerous: thickness and velocity measurements, defect detection, textural and

Figure 19. Propagation of ultrasound in the direct transmission noncontact mode. Here, t_c is the complete time of flight (TOF) corresponding to the propagation of ultrasound in air and the test material, $2t_m$ is the round-trip TOF through the test material thickness, t_1 and t_2 are, respectively, TOFs from transducer T_1 to the top surface of the material, and transducer T_2 to the bottom surface of the material. For the further significance of this, see Fig. 20.

Figure 20. Direct transmission non-contact ultrasound propagation through a test material (7-mm thick cheese) per Fig. 19 setup.

microstructural evaluation, transmission, velocity, thickness, and TOF imaging, detection of the presence or absence of liquids in containers, and many more.

VERY HIGH FREQUENCY NCU PROPAGATION IN MATERIALS

By using NC transducers in ambient air, we have amply demonstrated that frequencies as high as 2 MHz can be easily propagated through a variety of materials, including fibrous and particulate, plastics, ceramics, metals, and composites. However, frequencies even higher than 2 MHz have been successfully investigated for propagation through solids. Figure 21 shows an example of 4-MHz propagation through 4.5-mm thick multilayer graphite fiber-reinforced plastic composite in ambient air. Similar observations have also been made for soft polymers, thin

metals, and fibrous and particulate materials. As expected, the magnitude of transmitted signals through solids increases substantially when examined under high gas pressures. Figure 22 shows the propagation of 4-MHz transmission through 8-mm thick steel under 60 bars nitrogen by using a single transducer in the pulse-echo technique.

NONCONTACT ULTRASONIC MEASUREMENTS

Because ultrasound can be reflected and transmitted through a test material and its surfaces, one can use the respective signals to make significant measurements in the time and frequency domains. Such measurements can be further related to important test material characteristics, such as velocity, thickness, defects, internal and surface texture or microstructure, and other ultrasound-dependent parameters.

Figure 21. Noncontact ultrasound direct transmission through 4.5-mm thick multilayer graphite fiber-reinforced plastic composite at 4 MHz in ambient air per Fig. 19 setup. Transducers are 4-MHz and 12.5-mm active area diameter. Distances from transducers to test materials surfaces are ~3 mm. First peak: directly transmitted signal through air and the test material. Subsequent peaks: test material thickness reflection and its multiples.

Figure 22. Single transducer (pulse-echo) signal through 8-mm thick section of steel at 4 MHz under 60 bar nitrogen pressure. Transducer used is 4-MHz and 12.5-mm active area diameter. Distance from transducer to the surface of test material is ~25 mm. First peak: gas-materials interface. Subsequent peaks: thickness and thickness multiples corresponding to the test material.

Velocity and Thickness Measurements

There are several ways to determine longitudinal wave velocity in test materials by noncontact ultrasound. For example, if multiple reflections corresponding to the thickness of the test material are observed (Fig. 23), then one can measure the TOF, t_m , between the two successive peaks to determine the velocity of a material of known thickness. The TOF measured this way corresponds to the round-trip TOF in the test material. Therefore,

$$V_m = 2d_m/t_m. \quad (8)$$

For example, t_m measured between any two successive peaks from Fig. 23 is $10.4 \mu\text{s}$ for a 13.5-mm thick material (in this case, isotropic graphite); thus, the velocity is 2595 m/s.

It is important to note that the appearance of multiple thickness reflections in the NCU mode depends on the attenuation and acoustic impedance of the test material and the frequency of transducers. For example, the lesser

the attenuation, the lower the acoustic impedance, and at thicknesses greater than one wavelength in the test material, material thickness reflections are observable. On the other hand, when only the transmission signal is observed (i.e., without thickness multiples for attenuative materials), one can determine the TOF of the known thickness of the test material similarly to using contact delay line transducers. In such a case, the solid delay lines on the transducers are replaced by air columns in front of the transmitting and receiving transducers as functions of air distances between the test material surfaces.

As seen in the aforementioned technique, to determine the test material velocity, its thickness must be known. However, in the NCU mode, the thickness of the test material can also be measured. For simultaneous measurements of material thickness and its velocity in the NCU mode, we must examine all paths of ultrasound transmission and reflection to and from the test material. These paths relate to propagation of ultrasound relative to transmitting and receiving transducers “taking to each other” in the air column, ultrasound transmitted through the test

Figure 23. Velocity in material determined by direct transmission NCU propagation in a test material (in this case, 13.5-mm thick isotropic graphite) characterized by multiple thickness reflections. Note that the TOF (round-trip TOF through the material) between any two successive peaks is $10.4 \mu\text{s}$; thus, the velocity in the material is 2595 m/s.

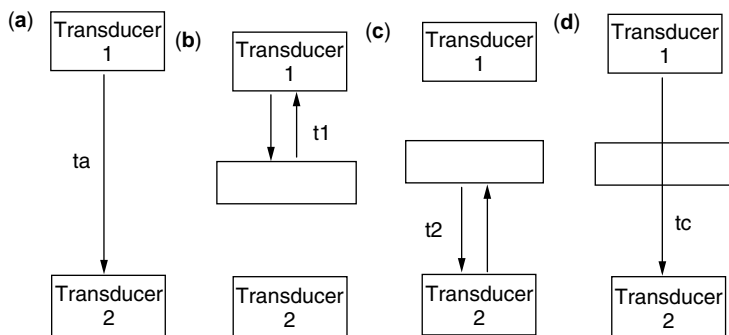

Figure 24. Propagation of ultrasound with respect to a test material in the noncontact transmission mode. The NCA 1000 measures and calculates all times of flight shown in this figure and then displays them on the monitor screen (Fig. 25). See text for details.

material, and ultrasound reflections from the test material surfaces in air. These paths of ultrasound propagation in the NCU transmission mode—needed to determine the test material thickness and velocity—are shown in Fig. 24. The signals generated by these paths of propagation and their significance are as follows:

Path (a) is the transmission from transducer 1 to transducer 2 in air—measures TOF, t_a . If ultrasound is propagated from transducer 2 to transducer 1, the same TOF is measured. Path (b) is the reflection from transducer 1 to the material surface in air—measures TOF, t_1 . Path (c) is the reflection from transducer 2 to the material surface in air—measures TOF, t_2 . Path (d) is the transmission from transducer 1 to transducer 2, and the test material is in between—measures TOF, t_c . If ultrasound is propagated from transducer 2 to transducer 1, the same TOF is measured.

From these times of flight measurements, the test material thickness and its velocity are determined according to the following relationships:

$$V_m = d_m/t_m \quad (9)$$

$$d_m = V_a t_{am} \quad (10)$$

$$t_{am} = t_a - (t_1 + t_2)/2 \quad (11)$$

$$t_m = t_{am} - (t_a - t_c) \quad (12)$$

In these equations, d_m is the test material's thickness, V_m , the velocity of ultrasound in the test material V_a , the velocity of ultrasound in air (determined from a reference material), t_{am} , the time of flight in air corresponding to the test material thickness d_m , and t_m is the time of flight in the test material.

By proper substitutions,

$$d_m = V_a [t_a - (t_1 + t_2)/2] \quad (13)$$

$$V_m = d_m/t_{am} - (t_a - t_c) \quad (14)$$

As an example, Fig. 20 shows actual transmitted and reflected signals when a test material is examined in the noncontact transmission mode. Identification and location of these signals with respect to the test material are shown in Fig. 19. As can be seen from Eqs. (13) and (14), to determine the thickness and velocity according to this scheme, one only needs the measurements of four times of flight (t_a , t_1 , t_2 , t_c) and the velocity of ultrasound in air. These parameters

were measured and calculated by the NCA 1000 computer and are displayed with the velocity and thickness of the test material on the monitor screen (Fig. 25).

Integrated Response, Transmissivity, and Reflectivity Measurements

In the time domain, the NCA 1000 measures and displays the times of flight of the signals and also shows the integrated response (IR) of these signals. IR is a measurement of the area underneath a particular peak in power dB units. Due to the very high, >150-dB, linear dynamic range of the NCA 1000, the IR can be used to measure the amount of ultrasonic energy transmitted (transmissivity) or reflected (reflectivity) from a test material and relate it (IR) to subtle changes in the material. For example,

$$IR_m = IR_c - IR_a, \quad (15)$$

where IR_m is the amount of ultrasonic energy transmitted in the test material, IR_c is the ultrasound transmission through air and the material (between the transmitting and receiving transducers), and IR_a is the amount of ultrasound energy transmitted only through air. IR_c and IR_a are measured directly by the NCA 1000.

If a given test material is homogeneous, then the measurement of IR_m , it has been found, is related to the transmission coefficient [Eq. (1)]. To illustrate this, we evaluated a flat polished specimen of polystyrene. Figure 26 shows the IR_c (−21.72 dB) of the transmitted peak of ultrasound from air into the specimen, and Fig. 27 shows a similar peak, but only through air, corresponding to IR_a (+41.7 dB), thus yielding IR_m −63.42 dB for the specimen. It is important to note that this measurement corresponds very closely to

$$IR_m = 20 \log T, \quad (16)$$

where T , the transmission coefficient, is defined by Eq. (1).

For example, the calculated value for ultrasonic energy transmitted in polystyrene [Eqs. (1) and (4)] is −63.34 dB, which is very close to −63.42 dB determined by measuring integrated response peaks. It should be pointed out that the transmission coefficient is assumed to be independent of ultrasonic attenuation and the thickness of the test medium. In reality, this is not absolutely true. For example, varying thicknesses of polystyrene samples at different frequencies yield different values of T . Though these variations are

Figure 25. The NCA 1000 screen displaying velocity of ultrasound and thickness of a material. The test material is a 22.5-mm porous sintered ceramic.

very small, yet they are measurable. On the other hand, if the transmission coefficient can be measured with a very high degree of certainty and precision, then it should also be possible to measure the absolute density of the test material by first determining the acoustic impedance Z_m of the test material:

$$Z_m = \frac{Z_1}{T} [(2 - T) + 2(1 - T)^{1/2}], \quad (17)$$

$$\rho_m = Z_m / V_m. \quad (18)$$

Measurement of IR_m and solving Eqs. (17) and (18) provide approximate ideas about the acoustic impedance and

Figure 26. Noncontact transmission through a 20-mm thick flat polished polystyrene sample showing the integrated response IR_c of the transmitted peak.

density of the test material. For accurate determination of these characteristics, factors such as ultrasound attenuation (analogous to absorption coefficient in X-ray absorption) and material thickness must also be considered:

$$T = I_2 / I_0 = Z_1 Z_2 / (Z_1 + Z_2)^2 = \exp(-\mu \rho x), \quad (19)$$

where T is the transmission coefficient, I_2 the ultrasound energy transmitted into the material (acoustic impedance

Z_2) from air (acoustic impedance Z_1), I_0 the input ultrasound energy, μ the material ultrasound attenuation coefficient, ρ the material density, and x the material thickness. At this time, the development of these relationships and techniques for measuring T , Z , μ , and ρ by noncontact ultrasound are in progress (21).

Because the measurement of the transmission coefficient still needs to be validated, it is best to refer to IR_m as transmissivity (when propagating ultrasound through the material in the direct transmission mode) or reflectivity (when ultrasound is reflected from the surface of the material). Such measurements are useful in evaluating the test material's internal and surface characteristics, such as defects, texture, microstructure, and roughness.

Noncontact Ultrasonic Spectroscopy

By performing the fast Fourier transformation (FFT) of transmitted or reflected time domain signals, test materials can also be characterized to investigate the frequency dependence of ultrasonic attenuation. Such examinations are important while testing microstructurally complex materials or those for which time domain velocity measurements are not sensitive enough. The first step for

Figure 31. Relationship between density and noncontact velocity in sintered alumina. Transducers: 1 MHz for samples less dense than 3.5 g/cc and 2 MHz for samples denser than 3.5 g/cc.

Figure 32. Comparison of ultrasonically and physically determined density of green alumina.

frequency dependence of ultrasonic characterization is the acquisition of a reference frequency magnitude spectrum of a transmitted signal in air without the test material. The next step is to do the same when the test material is inserted between the transducers. As an example, the FFT magnitude spectra for air and the test material are shown in Fig. 28. To generate the frequency dependence of ultrasonic attenuation, the sample spectrum is subtracted from that of the reference air spectrum (Fig. 29). By performing a similar analysis, the surfaces of materials can also be analyzed in the frequency domain. Frequency-dependent attenuation can be related to the test material's internal and surface characteristics, such as defects, texture, microstructure, and roughness.

APPLICATIONS OF NONCONTACT ULTRASOUND

Noncontact transducers have now been successfully produced in the frequency range of 100 kHz to >5 MHz.

Figure 33. Relationship between velocity and density for isostatically pressed, high-density green alumina. Transducers: 1-MHz, 12.5-mm active area diameter.

Figure 34. Relationship between velocity and density for pressed green tungsten carbide. Transducers: 500-kHz, 12.5-mm active area diameter.

Applications of noncontact transducers greater than 3MHz in ambient air are limited, but transducers between 200 kHz and 3 MHz have been extensively used for several industrial and medical applications (22–29). In this section, we present selected examples of NCU applications for materials testing and other objectives.

Materials Characterization and Defect Detection

Figures 30 and 31, respectively, show the relationships between densities of green and sintered alumina and the noncontact velocities in these materials. Figure 32 shows a correlation between ultrasonically (from reference samples) and physically determined densities of green alumina. The noncontact ultrasonic technique has been successfully applied to characterize density and defects in a variety of green materials such as ceramics tiles, multilayer electronic packages, powder metals, cements, and concrete. Figures 33 and 34, respectively, show the velocity–density relationships for isostatically pressed high-density green alumina and tungsten carbide. Examples of defect detection in green and sintered ceramics are shown in Figs. 35 and 36, and similar observations for aluminum are shown in Fig. 37. Figures 38 and 39, respectively, show trend plots of direct transmission and same side reflection in graphite fiber-reinforced plastic (GFRP) composites bonded to a honeycomb structure. The same side observations (Fig. 39)

correspond to the bond between the GFRP and the honeycomb.

Examples of textural and microstructural analysis by noncontact ultrasonic spectroscopy are shown in Figs. 40 and 41. Figure 40 shows the frequency dependence of ultrasound attenuation by three specimens of extremely porous ceramics (in this case, space shuttle tiles), and Fig. 41 shows similar observations from two samples of packaging foam whose cell dimensions vary. Figure 42 shows very high frequency noncontact transmission spectroscopy of two samples of paper towels. Similar observations have

also been made to detect bubbles and pores in liquids and other materials.

To evaluate surface characteristics by noncontact ultrasonic spectroscopy, several grinding discs of SiC varying in particle size were chosen. These discs were placed at a fixed air distance of 10 mm from a 2-MHz, 12.5-mm active area diameter transducer. Reflection from a polished sample of steel was assumed as a reference signal. Reflected signals from the reference and test materials were analyzed by performing FFT, and the frequency dependence of ultrasound was measured by subtracting the sample FFT spectra from

and food packages has also been determined by this technique. Analogous to green ceramics and like material (Figs. 30, 33, and 34), tablets, capsules, and other powder-based pharmaceutical products have also been characterized as functions of the velocity and frequency dependence of ultrasound attenuation. This method has also been successfully applied to detect the presence or absence of liquids (milk, beverages, chemicals) in cardboard cartons and plastic and metal containers. The feasibility of detecting the absence or presence of foreign and unwanted materials in liquid containers has also been successfully demonstrated.

Medical

One of the first medical applications of NC transducers was evaluating burnt skin and bed sores in burn victims (24). By using 2-MHz transducers and a prototype portable ultrasonic pulser-receiver, many observations were made at various points on a healthy and a burnt human hand at the Burn Center, University of California, Irvine,

Samples in plastic bottles were analyzed in the transmission mode, and transmitting and receiving transducers were separated from the bottles by ~ 15 mm of ambient air.

Figure 52. Noncontact ultrasound image cross section of healthy (left) and burnt (right) human hands. Note the damaged region between the epidermis and capillary bed in the burnt hand. The transducer used for this analysis was a noncontact 2-MHz in the reflection (pulse-echo) mode. These images were generated by Joie P. Jones, University of California, Irvine, and his Burn Center team.

under the direction of Joie P. Jones. The NC transducer was used in the reflection (pulse-echo) mode. The collected data were processed to create internal images of two skin conditions (Fig. 52). Detection of damage underneath the burnt skin is evident from the disruption of the interface between the epidermis and the capillary bed. Figure 53 shows the propagation of noncontact ultrasound through a human heel paving the way for bone disease (osteoporosis) diagnostics without any contact with the patient.

Very High Frequency Noncontact Ultrasonic Antennas

Because the sensitivity of NC transducers is very high, it is also possible to use them in a passive mode as “listeners” for very high frequencies. To demonstrate this, we conducted an experiment using the setup shown in Fig. 54. Here, the source of high frequency is 25-mm thick carbon steel, generated by a transducer (in contact with steel) that has a bandwidth at -6 dB from 800 kHz to 8 MHz. This transducer was excited by a single burst of a 16-volt sine wave. A noncontact transducer, nominally 3.5 MHz and 12.5-mm active area diameter, was placed 3 mm from

Figure 53. Noncontact ultrasound transmission through a human heel using 250-kHz (top) and 500-kHz (bottom) frequency transducers. The first peak corresponds to ultrasound transmission through air, skin, tissue, and heel bone. Other peaks are not identified.

the material surface in ambient air. The ultrasound received by this transducer was amplified by a 64-dB gain. Figure 55 shows the time and frequency domain of the ultrasound detected (heard) by the NC transducer. By sweeping the frequency across a wide range, the frequency-dependent response from the source (vibrating system) can be investigated and related to its characteristics or condition. In this mode, we successfully interrogated frequencies

Figure 54. Experimental setup for passive operation of noncontact transducer.

Figure 55. Time and frequency domains of ultrasound detected by noncontact transducer, per Fig. 54 setup.

as high as 7 MHz in ambient air. This opens the door to noncontact acoustic emission, acoustoultrasonics, and any other situation where detection of high frequency ultrasound is desired. Applications of the passive use of NC transducers are dynamics of vibration, materials cutting, testing of railroad, highways, bridges, runways, etc.

Other Noncontact Ultrasound Applications

Besides the applications of NCU described here, this mode can also be used for level detection; dimensional and proximity analysis; high temperature material evaluation; analysis of liquid-sensitive and hazardous material, and analysis of gases and liquids. Finally, it suffices to say that if ultrasound can be propagated through a medium or reflected from an interface, then much information about the medium and the interface can be obtained.

CONCLUSIONS

In this paper, we outlined the significance of ultrasound for nondestructive characterization of materials and for non-invasive diagnostic applications in the medical field. We have also shown the feasibility of noncontact ultrasonic measurements in the time, frequency, and image domains, analogous to other wave-based methods.

Underscoring the significance of the noncontact ultrasound mode, we presented a detailed discussion about the difficulty of achieving this mode. We have also shown that this work ultimately resulted in very high transduction noncontact transducers, thus making the noncontact ultrasound mode a reality. Applications of these transducers in industry and the medical field have been described by using documentary evidence.

We also provided an introduction to a novel ultrasonic noncontact analyzer and its applications for characterizing industrial and biomedical materials and products.

We believe that the noncontact ultrasound mode is among the most significant developments for characterizing and analyzing all states of matter. Though we have

provided selected examples of its applications, there is no doubt that the users of this technology will further enhance its use in materials quality, process control, and health care in our increasingly complex world. This advancement in the field of ultrasound and materials characterization has opened much needed and unprecedented opportunities in research and education.

ACKNOWLEDGEMENTS

The author gratefully acknowledges the assistance of M. Langron, Ultrason Laboratories, in producing the transducers used for this paper. The enthusiastic support and valuable suggestions of E. Blomme, Katholieke Hogeschool, Belgium and M. Landa, Academy of Sciences, Czech Republic, are acknowledged in kind. The work presented in this article was supported by the continuing efforts of SecondWave and Ultrason Laboratories for the advancement of industry and medical science through innovative developments in ultrasound.

INTRODUCTION

Paints are used everywhere in an industrialized society (1,2). The most important functions of paints are protection and decoration of a substrate. Paints can protect substrates against corrosion, oxidative aging, weathering, and mechanical damage and can also provide pleasant color contrasts or a lustrous appearance, hide imperfections in the substrate such as knots in wood, or enhance the beauty of the substrate by using a wood grain. In other words, paints can add to the useful life of materials and also to their attractiveness (1).

Smart paints are an innovative type of paint that has a sensor function as well as the protective and decorative functions of conventional paints. Smart paints can detect abnormal vibration of a structural material by monitoring the natural frequencies and mode shapes of the material. They can also detect damage generated in the material by monitoring the acoustic emission (AE) wave traveling from the damage location to the material surface. Vibration and AE can be monitored in real time, thus enabling health monitoring of the material even during operation.

Smart paints are used in large-scale structures such as vehicles operated at high speeds, civil infrastructures of huge mass and volume, and special facilities that contain large amounts of petroleum, nuclear fuel, and explosive substances. An accident in these facilities can be catastrophic because an enormous amount of energy stored in the form of kinetic, potential, or internal energy is released suddenly by the accident. Smart paints can possibly prevent such a disaster by warning of abnormal vibration and damage generated in a structural material. Hence, one reference goes so far as to say "Brush with disaster—Smart paint warns of impending doom" (3).

The frequency of health monitoring needed for structural materials increases steadily as age increases because the corrosion of steel and concrete progresses gradually during the service period of several decades. Smart paints can be applied to a structural material at any time before and after the construction of the structure, thus making health monitoring quite, easy even for a structure already in active service. Smart paints can make a significant contribution to increasing the service life of a structure, and consequently to saving natural resources.

*Deceased

BASIC CONCEPTS OF SMART PAINTS

The frequency range covered by vibrational measurements is the low-frequency range below ~ 20 kHz (4), whereas that covered in AE wave monitoring is the ultrasonic frequency range above ~ 20 kHz (5). Therefore, if the sensitivity of a smart paint is high enough in both frequency ranges, the paint can be used as a vibrational and AE sensor integrated into a structural material. Such a sensor function of a smart paint is analogous to the action of a sponge that discharges and soaks up water in response to the application and release of external pressure (6). In this analogy, a smart paint is a sponge that repeats the cycle of releasing and drawing an electrical charge at the natural frequency of a structural material or at a frequency of the AE wave traveling through the material.

A smart paint is applied directly to the surface of a structural material when the material is a conductor like metal or carbon fiber composite. In this case, the conducting material can be used as a bottom electrode for the smart paint. When the structural material is an insulator like concrete or ceramic, on the other hand, an electroconductive paint is first applied to the material surface, thus forming a thin conducting layer as a bottom electrode. Then, the smart paint is applied to the surface of the bottom electrode. Whether the structural material is conducting or insulating, an electroconductive paint is applied to the surface of the smart paint film, thus forming a thin conducting layer as a top electrode. Then, a high voltage is applied to the smart paint film using the top and bottom electrodes, thus making the film piezoelectrically active. This poling procedure is usually performed in air at room temperature.

Smart paints are piezoelectric composites that consist of piezoceramic and polymer phases (see Characterization of Piezoelectric Ceramic Materials; Piezoelectricity in Polymers). Thus, smart paints and piezoelectric composites have essentially the same nature with respect to many factors such as the ceramic/polymer composition, the method of preparation, the poling procedure, and the mechanical, electrical, and piezoelectric properties. An essential difference exists in that a piezoelectric composite is used as a discrete point sensor or actuator, but a smart paint is used as a continuously distributed sensor that can cover a large surface area of a structural material.

PIEZOELECTRIC COMPOSITES

Piezoceramics such as barium titanate (BaTiO_3) and lead zirconate titanate (PZT) are typical piezoelectric materials that have excellent properties such as a high electromechanical coupling coefficient and a moderate dielectric constant (7,8). Piezoceramics, however, have the problem that the high density inherent in ceramics makes the specific acoustic impedance much higher than that of water or human tissue, thus causing impedance mismatch (7). Brittleness common to all ceramics is

another drawback of piezoceramics. Piezoelectric polymers such as poly(vinylidene fluoride) (PVDF), on the other hand, do not have the problems of brittleness and impedance mismatch, and furthermore have the excellent property that they can be formed into thin, broad films. However, the electromechanical coupling coefficients and the dielectric constants of piezoelectric polymers are much lower than those of piezoceramics (8).

A solution to these problems is the previously mentioned piezoelectric composites that consist of piezoceramic and polymer phases. The polymer phase in the composites increases the composite toughness and also decreases the composite density and dielectric constant, thus solving the problems of piezoceramics and piezoelectric polymers simultaneously (9–11). The electrical and mechanical properties of piezoelectric composites are determined primarily by the fraction of the piezoceramic and polymer phases and by the properties of these constituent materials (12–14). Composite properties are affected also by the connectivity pattern of the piezoceramic and polymer phases (15–20).

COMPOSITION OF SMART PAINTS

The smart paints reported so far are piezoelectric composites made up of piezoceramic particles dispersed in a polymer matrix. The polymer matrix need not be piezoelectrically active, and hence popular polymers such as alkyd, acrylic, and epoxy resins can be used as the matrix resin. The preparation of smart paints and the application procedures are essentially the same as those of conventional paints, except for poling for a dried film of smart paint. As a result, most of the fundamental characteristics and functions of conventional paints are imparted to smart paints, thus enabling smart paints to have protective, decorative, and sensor functions simultaneously.

Smart paints can form continuous paint films covering a large surface area of a structural material. Because of the electrically insulating nature of the paint film, however, the electrical charge actually detected is only that generated in a region that has an electrode on the surface of the paint film. Therefore, if a set of separate electrodes is formed on the paint film surface, the electrical charge generated in each region can be detected and analyzed separately. This feature of smart paints enables the application of the paints as a vibrational modal sensor that can determine the natural frequencies and mode shapes of a structural material (21,22). Furthermore, this feature enables another application of smart paints as an AE sensor that can determine the damage location in a structural material quite easily without using the conventional technique based on the arrival time difference of an AE wave (5).

Paints in general can be applied to all kinds of materials such as metals, composites, concrete, and ceramics; the material surface can be flat, curved, or even irregularly shaped. Furthermore, paints can be applied and reapplied at any time, when necessary. Final dry films of paints are generally light, flexible, and tough. These excellent properties of paint in general are imparted to smart paints as well, thus giving the smart paints further useful features

as vibrational and AE sensors integrated into a structural material.

FORMATION OF SMART PAINT FILMS

Paint Preparation, Application, and Curing

Paints in general are made up of three components: pigment, binder, and volatile liquid (1,2). The volatile liquid is a solvent or a nonsolvent that provides a practical viscosity for packaging and application and does not normally become part of the dried paint film. The binder is a film-forming substance which is mostly a polymeric material such as alkyd, acrylic, or epoxy resin. The binder is used as a solution in a solvent or as a dispersion of fine particles in a nonsolvent. Such a solution or dispersion is called a vehicle. Paint pigments are finely divided, insoluble, solid particles such as titanium dioxide (TiO_2), zinc oxide (ZnO), and calcium carbonate (CaCO_3). The pigment particles are dispersed stably in the paint vehicle before application and the pigment particles are distributed uniformly throughout the binder resin in the dried paint film. The decorative functions of a paint are due, for the most part, to the pigment.

The basic components of smart paints are essentially the same as those of conventional paints, except that piezoceramics such as PZT and BaTiO_3 are used as pigments in smart paints. The piezoceramics used in the smart paints so far are PZT (23–30) and lead titanate (PbTiO_3) (23), and the binders used are acrylic resin (23), polyurethane (23), and epoxy resin (25–29). Smart paints made up of these components are prepared by essentially the same procedure as used for conventional paints. Smart paints are applied by using familiar coating tools such as brushes, rollers, or spray guns. Smart paints are also cured in the usual way in air at ambient temperature or at elevated temperatures.

Electrode Formation and Poling

A simple method for forming an electrode on the surface of a paint film is to apply an electroconductive paint by using a coating tool such as a brush or roller. A more elaborate method is to deposit a vapor of gold or aluminum onto the paint film surface (30). A screen mask technique is also effective for this purpose, especially when the electrode pattern is complicated. The main advantage of this technique is that leads as well as electrodes can be printed on the paint film surface, as shown in Fig. 1. This technique, however, has the disadvantage that it cannot be used for large structures such as airplanes, trains, or bridges.

For such large structures, an ordinary coating method by brush, roller, etc. may be the most practical for forming an electrode on the paint film surface. As a lead for the electrode, on the other hand, a thin electrical wire or tape $\sim 50 \mu\text{m}$ thick or so may be the most practical choice for a large structure because such a thin wire or tape is comparable in thickness to a paint film and hence, can be buried in the paint film or under a topcoat. Note that when smart paints are put into practical use, the electrodes and leads are covered by a topcoat, thus making the appearance exactly the same as that of conventional paints.

Figure 1. Electrodes and leads printed on a PZT/epoxy paint film formed on one surface of an aluminum beam. The left end of the beam where the leads come together is wrapped in an electrically insulating material. The aluminum beam is clamped at this section for vibrational measurements.

Piezoelectric composites are usually poled in an oil bath at elevated temperatures because poling at a higher temperature achieves saturation poling in a lower poling field. For smart paints, on the other hand, poling is done in air at room temperature because even room temperature poling can achieve high enough piezoelectric activity for the paint application to serve as vibrational and AE sensors integrated into a structural material (25–29).

EVALUATION OF SMART PAINT FILMS

The sensor function of smart paints relies heavily on the piezoelectric activity of the poled paint film. Usually, the activity is expressed in terms of a piezoelectric constant which is the ratio of the charge developed per unit surface area or the voltage developed per unit film thickness to the stress or strain applied externally. The charge-to-stress, voltage-to-stress, charge-to-strain, and voltage-to-strain ratios are the piezoelectric constants d , g , e , and h , respectively (7).

Piezoelectric materials are inherently anisotropic, and hence two subscripts are attached to the piezoelectric constant to describe the anisotropic properties. The first subscript is used to indicate the direction of the charge or voltage development, and this is always the film thickness direction for a piezoelectric film such as PVDF or a smart paint film. The second subscript is used to indicate the direction of the stress or strain applied externally, and this direction is any of the 1, 2, and 3 axes of the film which correspond to the length, width, and thickness directions, respectively (7).

Sensitivity as a Vibrational Sensor

When a structural material is deformed, strain is developed in all directions of the material, including the direction tangent to the material surface. This is also true when the structural material is vibrating. For a smart paint used as a vibrational sensor, therefore, one of the most important sensitivities to be evaluated is the piezoelectric constant e_{31} because this constant is the ratio of the charge per unit surface area to the strain in the direction tangent to the paint film surface.

The e_{31} constant is evaluated from vibrational measurement on a cantilever beam like that shown in Fig. 1. A typical example of the measurement is shown in Fig. 2

Figure 2. Frequency spectra of output signals from a PZT/epoxy paint film formed on one surface of an aluminum beam and from a strain gauge bonded to the opposite surface of the beam.

for a paint film which has the PZT/epoxy composition of 53/47 by volume and is formed on the surface of an aluminum beam 3.0 mm thick, 30 mm wide, and 460 mm long (350 mm long as a cantilever beam) (27). This example is for a 109- μm thick paint film cured at room temperature and poled at 240 kV/cm for 5 min. The spectrum shape obtained from the paint film is similar to that obtained from a strain gauge which is bonded to the opposite surface of the beam to monitor the strain developed in the direction of the cantilever length. Then, the e_{31} constant is evaluated from the charge-to-strain ratio at a natural frequency of 18 or 112 Hz.

The e_{31} constant thus evaluated depends on many factors such as the poling field, the film thickness, the cure temperature, and the PZT/epoxy composition (26,27). A typical example of the poling-field and film-thickness dependence is shown in Fig. 3 for paint films cured at room temperature that have the PZT/epoxy composition of 53/47 by volume (27). The e_{31} constant increases steadily as the poling field increases for all of the paint films shown here, and saturation poling is not achieved, even at a high poling field of ~ 150 kV/cm. The e_{31} constant obtained at a particular poling field, say, 100 kV/cm, increases as film thickness increases from 33 to 152 μm , thus exhibiting a clear film-thickness dependence. This point is further described later.

Figure 3. Plots of the piezoelectric constant e_{31} vs. the poling field for PZT/epoxy paint films cured at room temperature and evaluated as a vibrational sensor.

Sensitivity as an Acoustic Emission Sensor

In many cases, eventual failure of a structural material occurs after a certain amount of damage accumulates within the material. The generation of such damage is almost always accompanied by the emission of an AE wave, and hence the damage generated and accumulated can be detected by monitoring the AE wave (5). The AE wave is emitted in all directions, and consequently, an AE wave that arrives at the material surface and enters the smart paint film on the material surface always exists. Furthermore, an AE wave that enters the paint film nearly perpendicularly always exists. Such an AE wave develops strain in the paint film in the direction normal to the film surface because the AE wave is a compression wave in which particle motion is in the same direction as the propagation of the wave. For a smart paint used as an AE sensor, therefore, the sensitivity to be evaluated is the piezoelectric constant h_{33} because the h_{33} constant refers to the ratio of the voltage per unit film thickness to the strain in the direction normal to the paint film surface.

For a conventional AE sensor, the sensitivity s is usually given by $s = V/v_0$, where V is the output voltage of the sensor and v_0 is the velocity amplitude of AE waves (31). The strain amplitude of AE waves ε_0 is given by $\varepsilon_0 = v_0/v$, where v is the phase velocity of AE waves. Combining these equations with $h_{33} = (V/d)/\varepsilon_0$ leads to $s = h_{33}d/v$, where d is the film thickness. This equation indicates that the paint film sensitivity as an AE sensor s is independent of the frequency of AE waves and that the sensitivity increases linearly as film thickness increases. This equation also indicates that the h_{33} constant is calculated from $h_{33} = sv/d$.

The paint film sensitivity as an AE sensor is evaluated from measurement using an ultrasonic transducer to produce AE waves and a laser Doppler vibrometer to monitor the velocity amplitude of the AE waves (28). A typical example of the measurement is shown in Fig. 4 for a paint film that has the PZT/epoxy composition of 53/47 by volume and is formed on the surface of square aluminum plate

Figure 4. Frequency spectra of output signals from a PZT/epoxy paint film formed on one surface of an aluminum plate and from a laser Doppler vibrometer that monitors the velocity amplitude of AE waves.

0.2 mm thick that has 50 mm sides. This example is for a 152- μm thick paint film cured at room temperature and poled at 184 kV/cm for 5 min. The spectral shape obtained from the paint film is similar to that obtained from the laser vibrometer in the frequency range above ~ 0.3 MHz. Such a similarity of spectral shapes reflects a nearly flat frequency response of the paint film to AE waves. Then, the paint film sensitivity as an AE sensor is evaluated from the average ratio of the output voltage of the paint film to the velocity amplitude of AE waves in the frequency range 0.3–1.0 MHz.

The paint film sensitivity thus evaluated, s can be converted into the h_{33} constant by using the relationship $h_{33} = sv/d$, where v is the phase velocity of AE waves in the PZT/epoxy paint film. The h_{33} constant calculated by using an assumed value of $v = 2850$ m/s (6) is plotted in Fig. 5 as a function of film thickness for paint films cured at room-temperature that have the PZT/epoxy composition of 53/47

Figure 5. Plots of the piezoelectric constant h_{33} at 50 (○), 100 (●), 150 (△), and 250 kV/cm (▲) vs. film thickness for PZT/epoxy paint films cured at room temperature and evaluated as an acoustic emission sensor.

by volume (28). It is seen that the h_{33} constant obtained at a poling field of 50, 100, 150, or 250 kV/cm increases steadily as film thickness increases, thus exhibiting a clear film-thickness dependence. Such a film-thickness dependence is also observed for the e_{31} constant shown in Fig. 3.

FACTORS DETERMINING POLING BEHAVIOR OF SMART PAINT FILMS

The poling behavior of a PZT/epoxy paint film depends on the film thickness, as shown in Figs. 3 and 5. Furthermore, the poling behavior also depends on the cure temperature and the PZT/epoxy composition (26–29). Such complicated poling behavior is virtually determined by the electric field that acts on the PZT particles dispersed in the epoxy matrix. The most important factors that determine the electric field and, consequently, the poling behavior of the paint film are the electrical conductivities of the PZT particles and the epoxy matrix, the connectivity pattern of the PZT phase, and the space charge accumulated at the PZT/epoxy interface.

Electrical Conductivities of Constituent Materials

It is now well established that in poling a composite specimen made of piezoceramic particles dispersed in a polymer matrix, the electric field that acts on the ceramic particles is very low compared with that applied externally to the composite specimen (14,32). This occurs because the electrical conductivity of polymeric materials in general is much lower than that of ceramic materials, and hence the polymer matrix in the composite specimen bears almost all of the externally applied electric field at the expense of the electric field that acts on the ceramic particles. As a result, the piezoelectric activity of the ceramic/polymer composite specimen is very low, compared with a pure piezoceramic specimen poled in the same electric field. This idea explains why saturation poling is not achieved, even in a high poling field of ~ 150 kV/cm, as seen in Fig. 3. Saturation poling for a pure PZT ceramic specimen, on the other hand is achieved in a low poling field of ~ 10 kV/cm (12).

A promising solution to this problem is to increase the electrical conductivity of the polymer matrix up to that of the ceramic particles, so that the electric field distribution becomes uniform throughout the composite specimen. This can be achieved by adding a small amount of a semiconductor filler such as carbon, germanium, or silicon to the composite specimen (32). This can also be achieved by poling at a high temperature where the electrical conductivity of the polymer matrix becomes equal to that of the ceramic particles (33).

Connectivity Pattern of Ceramic Phase

Figure 6 is a scanning electron microscopy (SEM) picture that shows the internal microstructure of a paint film that has the PZT/epoxy composition of 53/47 by volume (27). It is seen that the size of PZT particles ranges from ~ 0.5 to ~ 1.5 μm , and that a substantial fraction of the PZT particles are in contact with each other, so that the PZT phase

Figure 6. SEM picture of a paint film that has the PZT/epoxy composition of 53/47 by volume. This example is a 49- μm thick paint film cured at 150°C.

is practically self-connected in three dimensions. The self-connectivity of the PZT phase is one of the most important factors that determines the poling behavior of a PZT/epoxy paint film. In fact, the paint film is hardly poled when the PZT volume fraction is decreased to such a level that the PZT particles are isolated from one another by the continuous phase of the epoxy matrix (26).

Figures 3 and 5 show that the poling behavior of a PZT/epoxy paint film depends on the film thickness even when the PZT volume fraction remains constant at 53%. A SEM picture like that shown in Fig. 6, however, detects no observable difference in the PZT phase connectivity for paint films that have different thicknesses. The difference in the PZT phase connectivity is reflected much more explicitly in the current–voltage characteristic of the paint film rather than in the SEM picture, as described here.

Space Charge at the Ceramic/Polymer Interface

The current–voltage characteristic of a PZT/epoxy paint film shows that the conduction is ohmic in a low electric field, whereas in a high electric field, the space-charge-limited (SCL) conduction predominates over ohmic conduction (28). Furthermore, the current–voltage characteristic shows that the critical electric field at which the ohmic-to-SCL transition takes place decreases as the film thickness decreases. The result is that conduction during the poling process is mostly SCL for a thin film, whereas conduction is mostly ohmic for a thick film.

The SCL conduction becomes predominant when a space charge of electrons is injected into the PZT/epoxy paint film during the poling process. The space charge has a tendency to build up preferentially at the interface between the PZT and epoxy phases in the paint film (28). The space charge decreases the electric field acting on the PZT phase, and hence decreases the piezoelectric activity of the paint film obtained in a given poling field. This effect of the space charge becomes significant, particularly for a thin film, because SCL conduction becomes more

predominant as the film thickness decreases. Therefore, the film-thickness dependence of the piezoelectric constant shown in Figs. 3 and 5 is ascribed to the space charge of electrons injected into the paint film during the poling process.

The fact that the current-voltage characteristic of a PZT/epoxy paint film depends on the film thickness is closely related to the drying rate of the wet paint film. In fact, it is well known that the thickness of a wet paint film has a significant influence on the rate of solvent evaporation and, consequently, on film formation during curing (3). Thus, it is quite possible that the degree of self-connectivity of the PZT phase depends on the thickness of the dried paint film. Therefore, the drying rate of the wet paint film is another important factor that determines the poling behavior of a PZT/epoxy paint film.

TECHNIQUES FOR APPLYING SMART PAINT FILMS

Techniques for applying smart paint films as vibrational and AE sensors are essentially the same as those for a PZT ceramic or PVDF film bonded to the surface of a structural material. Theories, models, methods, and systems constructed for use of the PZT and PVDF sensors (21,22,34) can also be applied to smart paint films used as vibrational and AE sensors integrated into a structural material.

Vibrational Modal Sensor

One example of an application of smart paints is a vibrational modal sensor integrated into a structural material. As noted before, the sensitivity of the paint film used for this purpose is the e_{31} constant which is the ratio of the charge per unit surface area to the strain in the direction tangent to the paint film surface. Figure 7 shows a result of vibrational modal testing of a cantilever beam like that shown in Fig. 1 by using a PZT/epoxy paint film

Figure 7. Modal strain shapes of a cantilever aluminum beam for the first (\circ), second (\bullet), and third modes (\square) determined by a PZT/epoxy paint film formed on the beam surface.

that has an e_{31} constant of 9.0×10^{-3} (C/m²)/(m/m) (26). A set of vibrational measurements is carried out for all of the electrodes formed on the paint film surface: an identical excitatory force is applied at a fixed point on the cantilever beam. Then, the output charge of the paint film at each electrode is converted into the strain using the e_{31} constant and is plotted against the distance from the clamped end of the beam to the center of each electrode. The modal strain shapes thus obtained are shown in Fig. 7 for the first three modes at 18, 112, and 315 Hz.

It is worth noting that the modal strain shapes shown in Fig. 7 can be converted into modal displacement shapes by $d^2\phi/dx^2 = -\varepsilon/\eta$, where ϕ is the transverse displacement of a uniform cantilever beam, x is the longitudinal coordinate of the beam, ε is the longitudinal strain in the beam surface, and η is the half-thickness of the beam (35). Modal displacement shapes determined by this equation are identical to those determined by a laser Doppler vibrometer that measures the transverse movement of the beam surface (26). Thus, smart paints offer an interesting and promising alternative to conventional sensors such as accelerometers and laser vibrometers (1).

FUTURE DIRECTIONS

Smart Paints

The highest sensitivity of smart paint films achieved so far is $e_{31} = \sim 40 \times 10^{-3}$ (C/m²)/(m/m) as a vibrational sensor and $h_{33} = \sim 100 \times 10^6$ (V/m)/(m/m) as an AE sensor, as shown in Figs. 3 and 5. For commercially available PVDF films, the sensitivity is $e_{31} = \sim 66 \times 10^{-3}$ (C/m²)/(m/m), $e_{32} = \sim 6.8 \times 10^{-3}$ (C/m²)/(m/m), and $h_{33} = \sim 50 \times 10^6$ (V/m)/(m/m), determined in essentially the same way described before for smart paint films. This indicates that the sensitivity of smart paint films is comparable to that of PVDF films. So far as sensitivity is concerned, therefore, smart paints have already reached a level suitable for practical use.

For smart paints to be put into practical use, however, the paints must meet performance requirements such as exterior durability and sensitivity stability. Exterior durability is the paint films resistance to environmental factors such as uv radiation, heat, moisture, oxygen, and ozone (2). These environmental factors can cause mechanical degradation of paint films, thus leading to the failure of the protective and decorative functions of smart paints. These environmental factors may also cause electrical degradation of paint films, thus leading to the failure of the sensor function of smart paints. Considering that smart paints are truly appreciated when used in severe and isolated environments, the evaluation of exterior durability and sensitivity stability is absolutely necessary for the paints to be put into practical use.

Smarter Paints

According to a concept of intelligent materials in Japan, the intelligence in materials is classified into three categories; intelligence from the human standpoint, intelligence inherent in materials, and intelligence at the most

primitive levels in materials (36). The intelligence from the human standpoint is a relative concept based on the value of a material and its utility in relation to all aspects of society such as economy, conservation of resources, intensiveness of information, human friendliness, reliability, harmony with the environment, and optimum life span.

Water-borne piezoelectric paints are smarter paints from the standpoint of harmony with environment (37). A paint that can spontaneously become a piezoelectric film after the usual drying process will also be a smarter paint from the standpoint of human friendliness. In fact, poling a paint film at a high voltage is dangerous work and should be avoided if possible. A feasibility study of a poling-free piezoelectric paint shows that a paint made of PVDF particles and epoxy resin does not need poling for the final dry film to be piezoelectrically active (38). At the present stage, however, the piezoelectric activity is not enough for practical use of the paint film. Studies are currently under way to increase the piezoelectric activity of the paint film.

From the standpoint of intensiveness of information, a smarter paint of the future will have a sensor function for material conditions such as vibration and damage generation and also for atmospheric variables such as temperature, pressure, moisture, and wind velocity. Such a paint resembles human skin in that the skin has a sensor function for the external stimuli imposed on the human body and also for the surrounding conditions such as temperature, humidity, wind, and rain. The ultimate goal of smart paints, therefore, should be to mimic the human skin as closely as possible.

PEST CONTROL APPLICATIONS

SHERRY DRAISEY
Good Vibrations Engineering, Ltd
Nobleton, Ontario, Canada

INTRODUCTION

The smart aspects of the piezoceramic ultrasonic application being used for pest control are just beginning to evolve. Pest control, using ultrasonics, is based on developing a pressure environment which is extremely unpleasant or deadly to the pests in question. The feedback aspect of smart structure applications involves three types of sensing:

- motion sensors (designed to power up the ultrasonic device when large pest groups have been detected)
- pressure sensors (these are used in fluid media to sense if pressure levels have risen enough to generate structural instability)
- sound sensors (for antinoise generation to stop the sound from being externally transmitted) that coordinate the antinoise generation

Airborne or land pests, such as some insects, spiders, rodents, and small cats and dogs are driven away by the unpleasant sound created by the noise generated by the ceramic elements. For fluid-borne pests, the ceramic is driven to create a pressure field that includes cavitation. The release of energy from the collapse of cavitating bubbles provides the source deadly to small microorganisms.

Table 1 lists the types of pests that have been effectively deterred by ultrasonic measures. The table lists the frequency range that has been successful for these pests, as well as the approximate coverage (or flow rate) across which they are effective. The coverage is directly related to the system size and power.

The Environmental Protection Agency (EPA) has suggested that pest control devices have a deterrent effect of >60% to be considered viable.

SOUND AS A PEST DETERRENT

The control of airborne and land pests is based on generating high-frequency noise. This is done to disturb and confuse the species, making the environment generally unpleasant. The sound levels are in the range of 90+ dB at 1 meter from the source.

The concept behind ultrasonic pest control is to alter the behavior patterns of the pests to the extent that they are forced to leave the area. Some devices have been designed for operation within buildings, others for outdoors. Versions of the devices target specific pest groups (mice), and more sophisticated versions have settings that allow selecting particular pest groups.

The power supplies for the designs varies from plug-in wall units (110 or 220/240 V) to battery operated systems.

Motion sensors are used for detecting larger size pests. This reduces power consumption and eliminates unnecessary noise pollution.

Test Results

The test data presented here were provided by the Weitech company, a manufacturer of a variety of ultrasonic deterring devices designed to produce ultrasonic sound in air.

Mosquitoes. At least one company's test results of the high-frequency ultrasonic deterrent effect on mosquitoes has suggested that it does not meet the EPA suggested deterrent level.

Small Rodents. The available test results (1) for small rodents depend on the particular rodent. Two types of rodents are considered. For each test set, there were six rodents in the sample—three males and three females. They were housed in two adjoining chambers, one exposed to the ultrasonic sound (~90 dB), the other at much lower noise levels (30 to 35 dB or lower).

Two parameters are used to evaluate the influence of the ultrasound—food consumption (measurement of the daily food consumption in the treated and untreated chambers) and activity (animal track evidence in the treated and untreated chambers). Before the introduction of ultrasonic treatment, healthy mice that had good hearing (hearing test—Preyer's reflex, a reaction to loud noise) are housed in the two chambers, and their activity and food consumption levels are measured.

The effect of the ultrasonic deterrent on the Norway rat (*Rattus norvegicus*) is more pronounced than on wild house mice (*Mus musculus*). The average weight of the Norway rats in the test was 237 grams (8.4 oz). The average weight of the wild house mice was 17 grams (0.6 oz). The results are shown in Figs. 1 and 2 as an index (the ratio of the treated measurements to the total measurements). Food consumption influence is shown in black bars, and tracking activity is shown in gray.

Table 1. Pests Effectively Controlled by Ultrasonic Devices

Pest	Frequency Range	Coverage (varies with power consumption)
Dogs, cats, skunks	14–25 kHz	278.8 m ² (4000 ft ²)
Mice	26–50 kHz	46.4 sq m ² (500 ft ²)
Moths	40 kHz	5.7 m ³ (200 ft ³)
Rodents, spiders, some insects	26–42 kHz	74.3 m ² (800 ft ²)
Microorganisms	23 kHz	273.6 liters/h (60 imp. gal/h)

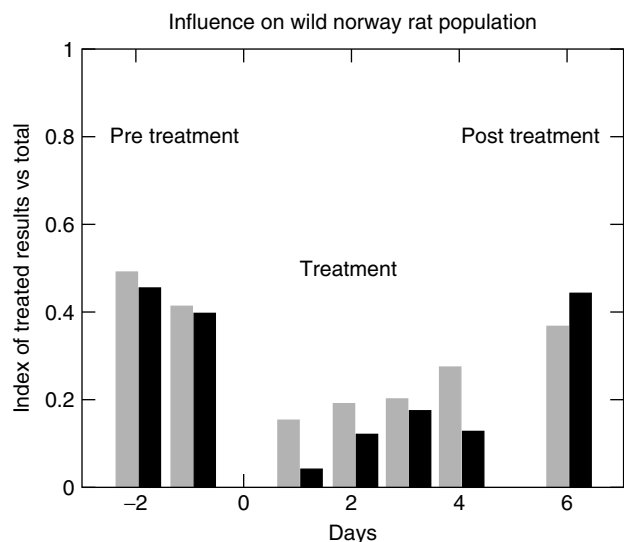

Figure 1. The influence of ultrasonic noise on the Norway rat population.

Figure 1 shows the effect of treatment on the Norway rat. Figure 2 shows the effect of the treatment on wild house mice. The influence on both populations is most significant for food consumption. The tracking activity of the wild house mice is not heavily influenced by the ultrasonic effect.

The rodents' hearing was checked before and after the testing. Only rodents that had good hearing were selected for the study. It has been postulated that the rodents might eventually become accustomed to the noise, but this was not the case. There were instances where rodents were not influenced, but this was due to hearing loss.

The sound patterns (frequency and amplitude) of four of the pace electronic pest repeller units were measured.

Figure 2. The influence of ultrasonic treatment on the wild house mice population.

The primary source of total sound output was at 40 kHz and above. The sound output dropped slightly at 31.5 kHz. Sound output below 20 kHz was negligible.

CAVITATION AS A DESTRUCTOR

Piezoceramic elements are commonly used to induce cavitation in fluids in biological applications for scaling instruments, but killing microorganisms is normally done by high-temperature sterilization. The erosive effect of cavitation is what is useful in removing a variety of type of scales. Cavitation is caused when the localized pressure drops below the fluid vapor pressure. This results in cavitating bubbles.

The collapse of cavitating bubbles is accompanied by a rapid release of energy. It is the collapse of the cavitating bubbles that is used to destroy microorganisms. It is not clear whether the microorganism population is immediately killed by the bubble collapse, or if the population is just weakened enough to limit its viability.

The generation of cavitation is limited to areas fairly close to the pressure/sound source. Cavitation can be applied to a large volume of fluid either by moving the source through the fluid or by moving the fluid past the source. The application described here moves the fluid past the source by pumping the volume through tubing to ensure fairly even exposure of the liquid to the pressure field. This does not sterilize the fluid, but it does eliminate a significant portion of the microorganism population.

The biological test results available indicate that cavitation does significantly reduce the population in both water and diesel fuel, but the effect varies for the types of microorganisms tested. The population reduction is of the order of 50%.

It is expected that piezoceramically induced cavitation could be used to reduce zebra mussel population in nuclear reactor water intake tubes by interfering with the zebra mussels during an early stage of their development, such as the larval stage.

The specific engineering design that follows was based on controlling microbial growth in military marine diesel tanks. These populations are currently controlled by "good housekeeping" of ships' tanks and by using environmentally harmful biocides. If an ultrasonic cavitation system were to be installed on a ship, it would be necessary to include an antinoise system to cancel the ultrasonic sound that creates the cavitation. This would be needed to minimize the likelihood that the vessel would be detected by unfriendly ships.

Engineering Application/Design

The cavitation of a fluid is induced when local pressure drops below its vapor pressure. It involves the release of relatively small amounts of energy (compared to boiling), so that though there is a temperature change in the fluid; it is small (of the order of 1–2°C, depending on exposure time and volume).

One of the well-known side effects of cavitation is its erosive effects on materials. This presents a practical problem

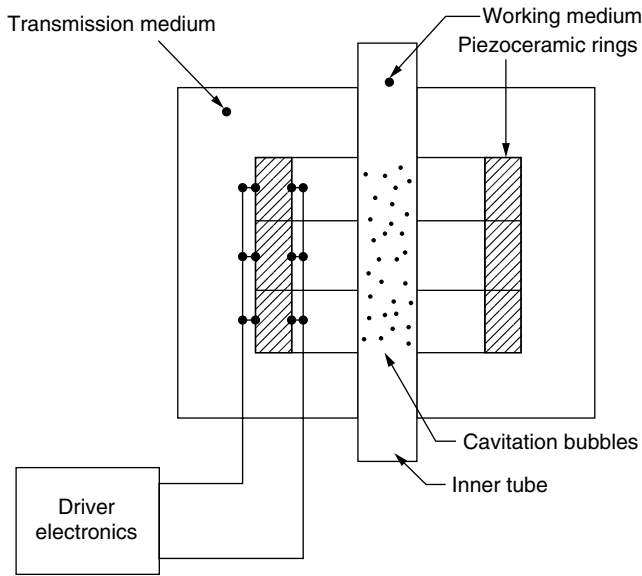

Figure 3. Schematic of cavitation concept.

in trying to use cavitation. The components used to cause the cavitation need special consideration to survive the erosive environment.

A general requirement for pest control is that it is needed for large volumes. Cavitation is a fairly local effect. To apply it to a large liquid volume, the fluid must be brought into a fairly local range. One way of achieving this is a flow-through system. The liquid is pumped through tubes that are exposed to the cavitating field. Such an arrangement could involve expenditures of significant amounts of power.

A flow-through configuration was studied analytically to achieve maximum fluid cavitation at minimum power consumption. The particular system modeled was based on a two-fluid system to avoid the electrode erosion that would be induced by cavitation. Figure 3 shows the conceptual arrangement. The fluid immediately adjacent to the electrodes is pressurized to eliminate cavitation. This fluid is used to transmit energy through a thin-walled pipe (stainless steel) into the fluid that contains the microorganism. The analytical model of the system was a piezodynamic field modeled by using finite elements. It is based on a finite element formulation of the piezoceramic elements, the physical piping structure, a liquid transmission medium, and the sound pressure field experienced by the microorganism-borne fluid (either water or diesel fuel).

The model was then test verified before applying it to a specific design.

Finite Element Formulation. The finite element method is an analytic technique for solving general field problems. It offers a number of advantages over competing methods. It can handle arbitrary geometries and both static and dynamic problems. It uses matrix numerical methods for which very efficient and general algorithms have been developed.

The special purpose FE formulation developed to handle both the fluid characteristics and the electrical input (as well as the normal structural characteristics) was based on the principles of the FE method in (2). The code modeled the structural behavior of the elements that represent the piezoelectric components, as outlined in (2, p. 22). The piezoelectric behavior was included using the approach of (3, p. 86). The fluid areas of the model were analyzed using the approach described in (2, p. 540).

The degrees of freedom of the model are the group of

- nodal displacements of the solid components,
- nodal pressures of the fluid components,
- nodal electrical potentials of the piezoelectric components, and
- the junction voltages of an external electrical circuit connected to the piezoelectric components (this latter capability was not used, though it is included for possible future use).

Then, the defining equations of the finite element approach used are

$$[A_2] \left\{ \frac{d^2 w}{dt^2} \right\} + [A_1] \left\{ \frac{dw}{dt} \right\} + [A_0] \{w\} + [A_{-1}] \int \{w\} dt + [A_{-2}] \iint \{w\} dt \cdot dt = \{b\}, \quad (1)$$

where

$$[A_2] = \begin{bmatrix} M & 0 & 0 & 0 \\ S & G & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}, \quad [A_1] = \begin{bmatrix} c & 0 & 0 & 0 \\ 0 & f & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix},$$

$$[A_0] = \begin{bmatrix} K & \frac{1}{\rho} S^T & E & 0 \\ 0 & H & 0 & 0 \\ E^T & 0 & -\epsilon \nabla^2 & 0 \\ 0 & 0 & 0 & C \end{bmatrix},$$

$$[A_{-1}] = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & R \end{bmatrix}, \quad [A_{-2}] = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & I \end{bmatrix},$$

$$\{b\} = \begin{Bmatrix} F \\ 0 \\ Q \\ Q_N \end{Bmatrix}, \quad \{w\} = \begin{Bmatrix} U \\ P \\ \Phi \\ v \end{Bmatrix}.$$

In these equations,

$$M = \int [N_s]^T \rho_s [N_s] dV_s$$

$$S = \int_S [N_f]^T \rho_f [N_s] dS_{sf}$$

$$G = \int [N_f] \frac{1}{a^2} [N_f] dV_f$$

$$c = \int [N_s]^T \mu_s [N_s] dV_s$$

$$f = \int [N_f]^T \mu_f [N_f] dV_f$$

$$K = \int [B]^T [D] [B] dV_p$$

$$E = \int [B_e]^T [\epsilon] [B_e] dV_p$$

$$H = \int [\nabla N_f]^T [\nabla N_f] dV_f$$

I = external circuit inductance

C = external circuit capacitance

R = external circuit resistance

U = solid element nodal displacements

P = fluid element nodal pressures

V = external circuit voltages

F = externally imposed force on solid element nodes

Q = externally imposed charges on piezoelectric elements

Q_N = externally imposed charges on external circuit

ϕ = piezoelectric element nodal potentials

a = speed of sound in fluid

where

$[N_s]$ = shape function matrix for solid elements

$[N_f]$ = shape function matrix for fluid elements

$[B]$ = shape function derivatives giving strain in solid elements

$[B_e]$ = derivatives of potential shape function in piezoelectric elements

ρ = mass density (subscript s for solid, f for fluid)

μ = damping (subscript s for solid, f for fluid).

The model assumed axisymmetry which was implemented as described in (2, p. 119). The elements describe the cross section of the complete unit from the centerline out, that is, that section which is rotated about the axis of symmetry to sweep out the 3-D geometry of the unit. The elements used were eight-node, isoparametric quadrilaterals, using quadratic shape functions for all fields (2-D solid displacements, fluid pressures, and electrical fields). Third-order Gaussian numerical integration was used for all element integrals. The integrals across volume are done by the usual finite element approach of integrating

across each element independently, followed by assembling the resulting equations into matrix form, as described in (2, p. 9).

Damping was included in the model by adding material damping to the fluid regions, as described in the preceding equations. Based on experimental measurements, enough damping was included to give a resonant amplification (Q factor) of 5 to 8. Two extreme conditions were used. In the first, damping was distributed across both the transmission and working media. In the second, damping was concentrated in the working medium. The first case corresponds most closely to low excitation levels, whereas the second should more closely match high excitations when cavitation is occurring. Then, the energy dissipation will be concentrated in the working medium because of the cavitation.

The model is linear. This is expected to give good results up to the point at which cavitation begins. Beyond that point, the response of the system is no longer linear because the fluid behaves effectively less stiff on the negative side of the pressure wave than on the positive side due to the formation of cavitating bubbles. In principle, this effect could be modeled using the nonlinear approaches described in (2, p. 450). This simplification was accepted because the objective was to compare alternative designs, rather than to analyze the behavior in absolute terms. It is assumed that systems that give a greater linear response will also give a greater nonlinear response. This may not be true in unusual cases, and it may not represent the effect of changes in the spatial distribution of the acoustic field in all cases (it would be expected that the "softening" nonlinearity which will occur here would tend to make the energy distribution more uniform in the system, compared to the linear case).

Figure 4 shows typical results from the model. These show the pressure distribution across the fluid cross section for 100 volt peak-peak excitation of the piezo rings for various excitation frequencies. It can be seen that the energy in the working medium in all cases is concentrated at the center. At low frequencies, only a single pressure peak occurs. At higher frequencies, when the wavelength of the sound waves in the fluid becomes comparable to the dimensions of the device, two and then three pressure peaks

Figure 4. Finite element predictions of cavitating field.

Table 2. Finite Element Model Parameters

Parameter	Material	Dimensions
Inner tubing	Stainless steel tube ($E = 30E6$ psi)	1.5 in outer diameter 0.012 in wall thickness
Piezoceramic rings (stack of four)	PZT4	2 in diameter 0.125 in wall thickness 0.5 in height
Transmission fluid	SAE 10W30 motor oil	Density, speed of sound
Working fluid	Water or diesel fuel	Density, speed of sound

occur axially along the centerline. These observations are consistent with qualitative results. These results were obtained by suspending an aluminum foil strip in the cavitating field. Because it is known that cavitation erodes aluminum, the distribution and degree of perforation provide an indication of the cavitating intensity.

The specific parameters of the model are listed in Table 2.

Test Verification of Analytical Model. Modeling a combined electrical/piezoelectric/structural/fluid system is complex. A number of approximations and simplifications were made. For this reason, some model correlation was done in advance of prototype development (experimental data taken from breadboard unit). The FE model was done for a four-ring prototype. The experimental testing was done on a three-ring arrangement.

There were two type of measurements made for the correlation exercise, the current–voltage relationship and sound pressure measurements. The predicted and measured current versus voltage relationship for the system is shown in Figure 5. Measured values are shown at 22.7 kHz

**Figure 5.** Measured and predicted current vs voltage.

which gives the peak piezo current. Model values are shown for both this frequency and for 26.5 kHz, which is the frequency at which the model shows peak current. It can be seen that the measured values at low voltages are about 60% of the modeled values. This is mainly due to the four rings in the model versus three in the breadboard. The sound pressure field was measured using the Specialty Engineering Associates needle hydrophone, Model SPRH-2-0500.

Figure 6 shows the response of the hydrophone at two different excitatory voltage levels, as captured on a digital storage oscilloscope. Note that the two cases were at slightly different frequencies. These frequencies correspond to the peak responses at each excitatory level. That they are different indicates nonlinearity in the model. It can be seen that the hydrophone response waveform is unsymmetrical and has pressure spikes on the positive voltage (low pressure) side. This is an indication of cavitation. It is more prominent at the higher excitatory voltage.

The model predicts that the peak pressure in the unit should be 1 kPa per volt of excitation. The transducer output should be 0.25 mV per volt of excitation. The results in Fig. 6 show a 20-mV peak-to-peak response at 130-V peak-to-peak excitation in (a) and 65 mV response at 240 V excitation, or 0.16 mV/V and 0.27 mV/V, respectively. This agreement is reasonable given the uncertainty of the hydrophone (it was being used somewhat out of its design frequency range). The model predicts that the pressure should lead the voltage by 10 to 20°, and it can be seen that this is reasonable, though the experimental measurements do not really allow testing this.

Figure 7 shows the pressure distribution measured along the centerline of the device for low voltage excitation (where the nonlinearity of the system does not confuse the results), and Fig. 8 shows the pressure distribution measured across the centerline at the midheight of the piezo rings. The hydrophone readings in these figures have been converted to acoustic pressures. The model predictions are also shown. It can be seen that the model and measured values show the same trends and the differences are 1–3 dB.

Design Studies

Outer Diameter of Transmission Medium. A design was studied to optimize the outer diameter of the transmission medium on the sound intensity in the working medium.

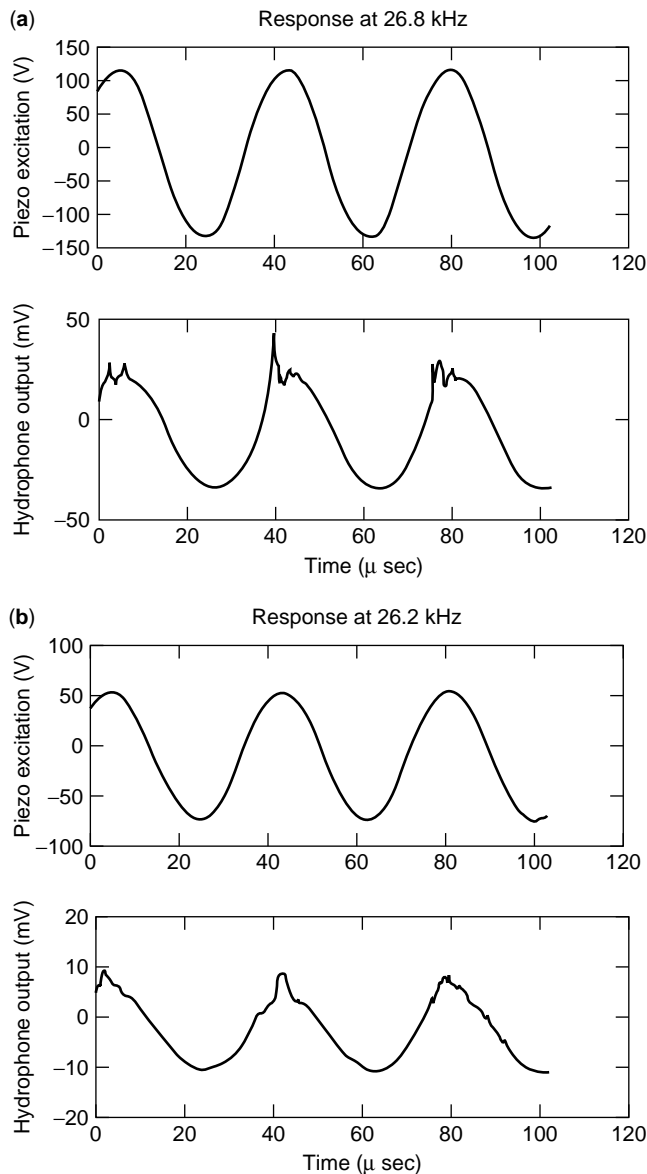

Figure 6. Hydrophone response at (a) 130 V p-p excitation; (b) 240 V p-p excitation.

The integral of acoustic pressure across the volume of the working medium was used as a performance indicator.

Two extremes of damping models were used—damping concentrated in the working medium and damping distributed over both working and transmission media. Figure 9 shows the results for both cases (as the integral of pressure vs. the outer diameter, (OD) of the transmission medium). It can be seen that when damping is concentrated in the working medium, the optimum occurs at an OD of 113 mm because the spacing between the outside of the piezo ring and the OD of the transmission medium is about one-half an acoustic wavelength. Such a condition would be expected to result in translating the high acoustic impedance condition at the rigid outer wall to a low acoustic impedance at the ring [see (8), p. 18 for an example]. This low acoustic impedance of the transmission medium

Figure 7. Acoustic pressure distribution along centerline.

at the ring is mismatched to that of the ring so that the coupling between the ring and transmission medium is poor at the outside of the ring. Little energy is launched outward from the ring, leaving more to be launched inward to the working medium.

The figure also shows that when damping is distributed across both transmission and working media, the optimum occurs at a lower OD. This may be due to the fact that when damping is included in the transmission medium, the increase in transmission medium volume, which occurs as its OD is increased, results in more energy losses in the system, thus biasing the optimum to a smaller diameter.

Figure 8. Acoustic pressure distribution across diameter at ring midheight.

Figure 9. $\int_0^{F_f} Power_{Acoustic} vs \phi$.

Electronics Concept. Three electronics concepts were considered, and two were experimentally evaluated:

- a function generator to produce a sinusoidal (or other) waveform and a power amplifier to generate a final high-power output signal to be sent through a transformer to the piezo elements in the mechanical module
- a high-power oscillator
- a switching power supply

The first approach was used in prototype testing and development. It was not continued in the higher power, high flow-rate evaluation unit because the readily available

power amplifiers are limited in power (so would have to be ganged to drive the larger system) and the class A amplifier action used is relatively inefficient, making cooling of the electronics an issue.

The high-power oscillator was not developed because of concerns of achieving high power without instability problems.

The switching power supply was used for designing the evaluation unit. It is in line with current methods of driving high-power motors using pulse-width modulation (PWM). Digital circuitry is used to generate square waveforms. These may be duty-cycle modulated and are used to switch power MOSFET transistors on and off rapidly so that the average voltage presented to the equipment as a result of the variable duty-cycle appears sinusoidal. Such an approach is efficient because the transistors are always completely on or completely off (except during short switching transients), and they dissipate little power in either of these states. In our case, the output frequencies are too high for true PWM, but square waves can be generated at these frequencies and filtered to eliminate higher harmonics.

Figure 10 shows an electronic filtering concept evaluated by analysis. A high voltage supply that has positive and negative polarity and a 33% duty cycle is switched on and off. The fundamental frequency of the source is 25 kHz. This is followed by a three-pole low-pass filter that has a cutoff at 62.5 kHz. The output from this filter feeds a tuned circuit that represents the piezo rings (21.2-nF capacitance and a 100-ohm resistor to simulate a system Q of 3) in series with an inductance chosen to tune the circuit to the 25 kHz fundamental. This makes the driven system of this tuned circuit appear resistive at the fundamental frequency and so matches the low-pass filter's output impedance expectation. Note that no transformer is shown, though by adding a transformer between the filter and the piezo, lower voltages would exist in the left-hand

Figure 10. Electronics concept.

Figure 11. Frequency response function of electronics concept.

side of the circuit which would probably ease component choice.

Figure 11 shows the calculated frequency response function. It also shows the spectral content of the voltage out of the switched power supply and into the piezo. The output from the switched power supply it is assumed, is both positive and negative in the 33% duty cycle and has switching transients 25% as long as the on-time, that is, $1.67 \mu\text{s}$. Summing all power above the fundamental to 250 kHz gives a total harmonic distortion figure of 71% for the switched power supply output that has this waveform, but only 4% for the voltage across the piezo.

A breadboard of this system was built and tested. It was felt that the advantages of the switching amplifier concept outweighed its disadvantages for a production application. A commercial supplier (Instruments Inc. of San Diego CA) was found.

Implementation Issues. The thin walled stainless steel tube that contains fluid-borne microorganisms was designed to be as thin as possible to maximum the pressure transmitted through to the fluid. The thickness is limited by the pressure in the transmission medium. The thin walled tube is fairly close to buckling under the pressure of the transmission medium.

In the prototype system, there was no pressure sensor to ensure that the pressure of the transmission medium was maintained between 30–100 psi. The small temperature change ($1\text{--}2^\circ\text{C}$) that results from the excitation of the system causes the pressure to vary. The temperature change is kept to this low level by pumping the working fluid continuously past the transmission medium. During

biological evaluation of the prototype system, the pressure did drift above 100 psi. After completing of prototype testing, the system was dismantled, and it was discovered that the tubing had buckled.

The evaluation unit which was built as a follow-on to the prototype includes both a temperature and pressure sensor as part of the design. This ensures that the system will shut down before the critical pressure is exceeded. In an early version of the evaluative design (which contained 16 piezo rings, rather than the original four), the stainless steel tubing did buckle because the unsupported length of the tubing had more than doubled. Modifications of the tubing boundary conditions were made to ensure that buckling did not occur but at the same time maintained as thin a profile as possible to maximize the energy transfer to the microorganism-borne fluid.

Another significant issue that arose during early testing of the evaluative system relates to the importance of tolerancing the rings themselves. After short runs of the 16-ring stack system, failures in the rings occurred. They were failing mechanically—breaking into two pieces. The initiation of the crack seemed to be associated with a burn mark on the ring. It was postulated that the set of rings being used was not sufficiently well toleranced for roundness. The system was rebuilt using rings of improved tolerance (proved by Sensor Technologies of Collingwood, Ontario). There have been no ring failures since the system was rebuilt.

The original electronic drive for the system was based on square wave input switching. When this was implemented, switching noise was feeding back to the input, causing noise spikes that were outside the acceptable range of the microprocessor. To eliminate this problem, the signal generator was rebuilt to use sine wave excitation.

Figure 12 shows a drawing of the cavitation portion of the system. The elements of the figure are as listed in Table 3.

Effectiveness of Cavitation in Destroying Microorganisms

The effectiveness of using a cavitation field to destroy microorganisms was measured for two types of fluid hosts (water and diesel fuel) (9) and three types of microorganisms:

- *Serratia marcescens*
- *Pseudomonas aeruginosa*
- *Saccharomyces cerevisiae* (yeast)

The fitted results are shown in Fig. 13, plotted as a function of exposure time to the cavitation field. Regression analysis was used to fit the data to the following equation:

$$\log\left(\frac{\text{Irradiated}}{\text{Control}}\right) = (\text{Slope} \times \text{Time}) + \text{const.} \quad (2)$$

These test results were for microorganisms exposed to cavitation while the working medium was moving (being pumped) through the cavitation field. Earlier test results were performed while the medium was static during

Figure 12. Cavitation unit—16 ring.

exposure to the cavitation field. The cavitation effect was more pronounced on the moving population than on the static population. It was hypothesized that the motion ensured improved distribution of the microorganisms in the cavitation field.

There were two different strains of *Pseudomonas aeruginosa* used in the study. Tests in water were done using ATCC 10145. A strain of *Pseudomonas aeruginosa* was isolated from a sample of marine diesel fuel. This strain would not survive at elevated temperatures (37°C) where the ATCC 10145 thrived.

 Pseuds in water - - - Pseud in diesel - - - Pseud 'isolate' in diesel

Figure 13. Biological test results.

The results were based on a flow-through testing system that involved recirculating the population to obtain the required exposure time. Figure 14 shows a schematic of the experimental facility. The contaminated working fluid was recirculated during testing. This eliminated the need for disposal of large volumes of contaminated fluid. The recirculating effect underestimates the effectiveness of the method because the population is being gradually reduced for each pass through the cavitation field.

It had been postulated that the pumping action itself might influence the microorganism population, but that effect was studied and found insignificant on either the *Serratia marcescens* or the *Pseudomonas aeruginosa*. There did seem to be a small effect on the yeast results.

An attempt was made to predict the kill efficiency of a single pass of the population through the cavitation field. Kill efficiency *e* is the ratio of microorganisms per unit volume of fluid killed in one pass to microorganisms present in an untreated unit volume of fluid.

Figure 14. Schematic of flow-through experimental facility.

NOTATION

- C_0 = initial concentration (microorganism's/litre)
 C_n = concentration after n passes through cavitation field
 e = kill efficiency
 n = number of times sample passed through cavitation field
 V = volume of cavitation field
 X = holding tank volume

$$\frac{C_n}{C_0} = \left[\frac{X - e \times V}{X} \right]^n \quad (3)$$

When this equation is applied to the yeast test data obtained, the resulting kill efficiency is 0.49. When it is applied to the test results for *Pseudomonas aeruginosa* in diesel fuel, the resulting kill efficiency is 0.45. These results were based on an exposure time of 3.15 seconds in the cavitation field.

PHOTOCROMIC AND PHOTO-THERMO-REFRACTIVE GLASSES

L.B. GLEBOV
 University of Central Florida
 Orlando, FL

INTRODUCTION

Inorganic glasses are the main transparent material, which people have long used for observation (windows in buildings, windshields in cars, eyeglasses, prisms and lenses in optical instruments), light delivery (light bulbs, projectors, lasers, optical fibers), and fine arts (crockery, bijouterie, jewelry). The ability of glasses to change coloration after exposure to sunshine was well known since the last century. A new era in glass application was started

in 1949 by S.D. Stookey's publication (12) in which recording a permanent photographic image in silicate glass was described. This two-step process of exposure to UV radiation and thermal development that resulted in a crystalline phase precipitation in the exposed areas was similar to the classical photographic process. As a result of intensive research during a long period of time, a great number of different photosensitive glasses were developed, which have found very wide application in different branches of industry and personal use. When exposed to optical radiation, these glasses (and glass ceramics) change their optical properties (absorption, refraction, or scattering) instantly or after thermal development, permanently or transiently. Among the great variety of photosensitive glasses, we emphasize only the two most widely used types.

The largest commercial application was obtained for so-called "photochromic glasses," which exhibit reversible coloration after exposure to UV or visible light and can vary their absorption depending on the illumination level. Glasses that contained small concentrations of microcrystals of silver and copper halides, proposed by Armistead and Stookey in 1965 became the most widely used for reversible coloration (13). A peculiarity of these materials is that they are produced by glassmaking technology whereas the photochromic processes occur in microcrystals distributed in the glass matrix. Several hundred original papers were dedicated to different aspects of heterogeneous photochromic glasses in those years. The vast bibliography and detailed descriptions of these heterogeneous photochromic glasses were collected in books (3,4), and therefore we will not include a list of original publications in this article.

Another type of photosensitive glass, which is beginning its application in optics and photonics right now, is "photo-thermorefractive (PTR)" glass. If this glass is exposed to UV radiation followed by heat treatment, it varies in refractive index. A phase hologram in the volume of this glass was recorded in 1990 by Glebov and coauthors (5). The feature of this process is that homogeneous glass is exposed to light and a microcrystalline phase is produced in the volume of the glass matrix by a thermodevelopment process. No books have been written on this subject. The main results concerning phase hologram recording in glasses can be found in a few original papers (5–7) and a survey (8). Similar processes of photoionization followed by thermoinduced crystallization were studied for single- and full-color photography in polychromatic glasses, as described in (1, 9–12). Thus, these references can also be used for learning the basic physical phenomena that result from irradiation and development of PTR glasses. Some basic data concerning intrinsic absorption, electronic excitation, and nonlinear photoionization in multicomponent glasses can be found in (13,14).

PHYSICAL PRINCIPLES OF PHOTOSENSITIVITY IN GLASSES

Photosensitivity is the variation in glass properties from exposure to optical radiation. Photoinduced processes can be caused by the absorption of light and consequent

Figure 1. Absorption spectra of $25\text{Na}_2\text{O}-75\text{SiO}_2$ glass. 1: intrinsic absorption; 2 and 3: extrinsic absorption of 0.1 wt.% of Fe^{3+} and Fe^{2+} , respectively; and 4: color center generation spectrum (arbitrary units).

excitation of electrons from ground to upper levels by which these electrons can be delivered to other places (we will not consider heating and posterior melting or ablation). Absorption spectra of solids may be conventionally divided into three groups. Absorption due to electron transitions in defect-free substances of stoichiometric composition is called “intrinsic,” “basic,” or “fundamental” absorption. The absorption in atoms or molecules that are present as small additives is called “extrinsic,” or “dopant,” or “impurity” absorption. The absorption by defects in the host substance created by chemical or physical effects is called “induced,” or “additional,” or “defect” absorption.

The absorption spectra of widespread alkali silicate glass, which is the basis of the majority of technical glasses, are presented in Fig. 1. Intrinsic absorption (curve 1) is in the range of 210 nm (6 eV) and exhibits an exponential dependence of the absorption coefficient on photon energy (or wave number). This absorption is caused by basic structural units of silicate glass (Si–O–Na), which are called L centers. An example of extrinsic absorption in $25\text{Na}_2\text{O}-75\text{SiO}_2$ glass is shown by curves 2 and 3 for ferric (Fe^{3+}) and ferrous (Fe^{2+}) ions, which determine the actual absorption of commercial silicate glasses in the near IR, visible, and near UV spectral regions. Induced absorption produced by UV and γ radiation (Fig. 2) is caused by ionization in the glass matrix and further trapping of electrons and holes at different glass matrix defects. The presence of different dopants and impurities results additional induced absorption bands. Extrinsic absorption can be caused by additional ions distributed in the glass matrix and also by bigger units, for example, microcrystals. The absorption spectra of borosilicate glass doped with copper and chlorine, which has undergone heat treatment, are shown in Fig. 3. Instead of absorption of copper ions in the glass in the far UV region, a narrow absorption peak near 380 nm (3.25 eV) is seen in these spectra, which corresponds to excitons in CuCl crystals precipitated in the glass matrix as the result of heat treatment. Induced absorption can

Figure 2. Induced absorption spectra of $25\text{Na}_2\text{O}-75\text{SiO}_2$ glass. 1: exposure to UV at 77 K; 2: γ irradiation at 300 K. Arrows show the positions of the absorption bands of electron (E) and hole (H) color centers.

also be produced by relatively big particles. Photoinduced precipitation of microcrystals of such metals as gold, silver, and copper causes additional absorption, usually called colloidal coloration.

Glass exposure to radiation whose photon energy is more than the intrinsic absorption edge (curve 1 in Fig. 1) causes photoionization in the glass matrix followed by the generation of both electron and hole color centers. The dependence of the induced absorption on the photon energy (or wavelength) is called the color center generation spectrum or the spectrum of photosensitivity (curve 4 in Fig. 1). Photoionization in the glass matrix (generation of both electron and hole centers) is impossible if the photon energy of the exciting radiation is less than a bandgap, which is determined by the position of the intrinsic absorption (curve 1 in Fig. 1). In other words, the long wavelength

edge of the color center generation spectrum (curve 4 in Fig. 1) coincides with the intrinsic absorption edge (curve 1 in Fig. 1).

The photosensitivity spectrum can be shifted to the long wavelength side if the glass is doped with some ions in a lower valence state, and the dopant's excited level is placed above the threshold of the charge carrier's mobility. In this case, a mobile electron can be trapped either by defect at an intrinsic electron center formation or by another dopant, that is, to recharge the activators. The depth of the dopant ground level in $\text{Na}_2\text{O}-3\text{SiO}_2$ glass is 5.2 eV for Fe^{2+} , 5.0 eV for Tb^{3+} , and 3.6 eV for Ce^{3+} . Comparison of these values with curve 3 in Fig. 1 shows that the ionization threshold of Fe^{2+} corresponds to the long wavelength edge of the absorption band whose maximum is at 6.5 eV (191 nm). Excitation using smaller photon energy causes tunnel ionization whose efficiency is about one to two orders of magnitude less than that of over-barrier ionization. The thresholds of tunnel ionization of dopants in $\text{Na}_2\text{O}-3\text{SiO}_2$ glass are 3.5 eV for Fe^{2+} , 3.1 eV for Tb^{3+} , and 3.1 eV for Ce^{3+} . Referring Fig. 1, one can see that the tunnel ionization of Fe^{2+} is obtained at an excitation of the long wavelength bands whose peaks are at 5.1 and 4.4 eV (243 and 282 nm) up to 3.5 eV (350 nm). Unlike intrinsic ionization that inevitably produces electron and hole centers, the only hole center generated from the excitation of dopant absorption bands is the same (but oxidized) dopant ion. All newly created centers are electron centers (either intrinsic or extrinsic).

The other way to shift photosensitivity to the long wavelength side is to use nonlinear ionization produced by powerful optical irradiation. In silicate glass exposed to pulsed radiation whose photon energy is more than half of the bandgap ($h\nu > 3$ eV, $\lambda < 400$ nm) and whose irradiance is more than 1 MW/cm^2 , both electron and hole color centers appear as a result of two-photon ionization in the glass matrix. The final concentration of color centers is determined by equilibrium between two-photon generation and single-photon bleaching of color centers.

INDUCED COLORATION OF REVERSIBLE PHOTOCROMIC GLASSES

Generally, the term photochromism may be treated as any variation of color induced by optical radiation, but usually people use a narrower definition, which excludes irreversible color changes. So, photochromism is a reversible variation in color (i.e., of the absorption spectrum or spectrum of attenuation) of a material under optical radiation that relaxes when exposure stops. Naturally, when experimental conditions are changed, for example, a temperature change, the magnitude of the photochromic effect can vary (even to complete disappearance). Therefore, we shall call a photochromic material one that, under specified operating conditions, becomes colored by optical radiation and restores its transparency after radiation ceases.

Relaxation of induced absorption after illumination ceases is usually caused by thermal fading of color centers, which are not stable at a given temperature. This is the most important feature of photochromic materials

because reversibility of the photochromic effect means the absence of any stable induced centers generated by illumination. A great number of electron and hole color centers in silicate glasses produced by UV radiation (Fig. 2) leads to fatigue because of the progressive accumulation of stable color centers. This is the reason that these glasses are not used as photochromic materials, although photochromism was discovered in cerium-doped, reduced silicate glasses. Glasses doped with microcrystals of silver and copper halides (Fig. 3) show complete reversibility of coloration at room temperature and therefore have the widest commercial application.

The main feature of photochromic glasses, variable optical density both observed during exposure and upon its cessation, has to be taken into account to determine characteristics such as integral and spectral sensitivity, darkening degree and rate, thermal fading, and optical bleaching rates. Let us define the main concepts required for photochromic material characterization. Light absorption (or, more exactly, light attenuation or losses, that is the sum of absorption and scattering) is characterized by the transmittance, $\tau = I_{tr}/I_0$ (where I_{tr} and I_0 are the intensities of transmitted and incident light, respectively), or the optical density, $D = -\log_{10} \tau$. The optical density of a sample before irradiation (original absorption, clear glass) is D_0 (Fig. 4). The optical density of the sample at the moment exposure ceases (induced absorption, dark glass) is D_{exp} . The optical density in t seconds of the thermal fading process (induced absorption, partially relaxed glass) is D_t . The spectral dependences of τ_0 and D_0 are the transmission or absorption spectra of clear glass. The spectral dependences of τ_{exp} and D_{exp} are the transmission or absorption spectra of dark glass. Glass has a gray color if the absorption (transmission) spectrum is flat in the visible region. A brown color means that the absorption in the blue region is greater than that in the red region.

The dependences of D_{exp} and D_t on the time of illumination or aging are the kinetics of coloration and relaxation, respectively (Fig. 4). D_{exp} increases when the exposure time increases and comes to the equilibrium level D_e

Figure 4. Kinetics of photochromic glass darkening under illumination and fading in the aging process. D_0 , D_{exp} , and D_t are the optical densities of clear, dark, and relaxed glass, respectively.

when the rate of color center generation is equal to the rate of thermal fading. The criterion of relaxation characterizes the degree of thermal fading in a certain time after illumination ceases:

$$K_{\text{rel}} = \frac{D_{\text{exp}} - D_t}{D_{\text{exp}} - D_0} \quad (1)$$

The value of that time interval should be selected on the basis of the practical applications of a photochromic glass. Thus, for photochromic lenses used as sunglasses, a time interval of 180 s is recommended. From Eq. (12), it is obvious that, if a glass has faded completely in that time, $K_{\text{rel}} = 1$. Contrariwise, if the induced absorption has not reduced at all in that time, $K_{\text{rel}} = 0$. Now, there are photochromic glasses whose K_{rel} vary in the entire range from zero to about one. K_{rel} for a particular glass can be changed by temperature variation.

An important parameter is the spectral sensitivity of a photochromic material, the dependence of the saturated photoinduced optical density (D_e) on the photon energy of the exciting radiation. This dependence is called the color center generation spectrum. The absorption edge of photochromic glass determines the position of the color center generation spectrum because photosensitive crystals absorb exactly in that region (compare curves 1 and 2 in Fig. 5). The short wavelength edge of the color center generation spectrum is connected with the decrease of the thickness of the layer containing color centers, that is due to the increase of the glass absorption coefficient. The long wavelength edge is caused by a decrease in the absorption and in the efficiency of photosensitive center ionization. These photosensitive centers are usually copper centers in silver halide crystals or excitons in a crystalline phase of copper chloride. Owing to that, the position of the maximum in the color center formation spectrum does not coincide with that of any maximum in the photochromic glass absorption spectrum. Moreover, its position is determined by the spectral shape of the photochromic glass absorption edge,

Figure 5. Spectra of glass doped with AgCl(Br). Absorption of original glass (12) and color centers (3), color center generation (13) and bleaching (4) efficiency. Sample thickness 5 mm.

is a function of the sample thickness, and drifts to the short wavelength side as the thickness decreases. The absorption spectrum of an exposed glass doped with AgCl microcrystals is presented in Fig. 5, curve 3. This absorption represents a wide band in the visible spectral range. The spectral shape of this band is usually ascribed to precipitation of colloidal silver particles on the surface of halide microcrystals. Curve 4 in Fig. 5 shows that excitation of the absorption band of color centers destroys these centers and causes optical bleaching. Thus, optical bleaching by visible light is a process additional to thermal fading, which accelerates the relaxation of darkened silver halide photochromic glass.

The photosensitivity of photochromic glasses doped with CuCl can be shifted from the UV region to the long wavelength side. Virgin photochromic glass is photosensitive only to UV irradiation and cannot be darkened by visible light. Excitation of glasses doped with CuCl that are exposed to UV radiation does not produce optical bleaching, as shown in Fig. 5 (curve 4) for silver halide glasses. On the contrary, initial additional absorption (induced by UV radiation) can be intensified by additional exposure to visible and even IR radiation having photon energy much below the ionization threshold of copper centers. Note that the power density of long wavelength irradiation must be high enough to produce this intensification. It is shown in Fig. 6 that the spectra of additional absorption produced in this glass after irradiation at various wavelengths are the same. Consequently, this long wavelength sensitivity results from generating new color centers by exciting the same color centers. Therefore this process is called “cooperative breeding of color centers.”

The mechanism of two-photon cooperative breeding is as follows. Initial exposure to UV radiation causes ionization

Figure 6. Spectra of induced absorption in copper halide photochromic glass (thickness 5 mm) after exposure to radiation at different wavelengths: (12) 440 nm (2.78 eV), (13) 633 nm (1.96 eV), and (3) 1060 nm (1.17 eV).

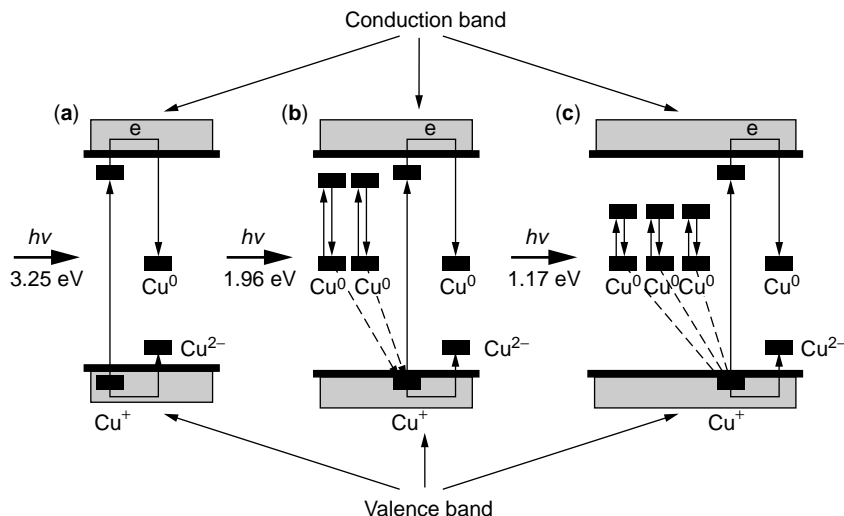

Figure 7. Energy diagram of the first stage of photochromic glass coloration at (a) short wavelength coloration, (b) two-photon cooperative breeding, and (c) three-photon cooperative breeding.

of a photosensitive center (Cu^+) and generates electrons and hole centers (Cu^{2+}). Then released electrons produce color centers by reducing copper (Cu^+) or silver (Ag^+) ions. The initial concentration of color centers (Fig. 7a) is determined by the number of UV-ionized photosensitive centers. This concentration can be rather small and even invisible to the naked eye. Linear absorption of two photons of visible light by two color centers causes a transition of these centers to excited states (Fig. 7b). Further, these centers simultaneously transfer the accumulated energy to the photosensitive centers (Cu^+) and return to their ground states. An excited photosensitive center releases an electron and converts to its ionized state in the same manner as after linear excitation, as illustrated in Fig. 7a. The released electron is trapped by an acceptor, converts to a reduced state (Cu^0), and this is a first stage in generating a new color center. Thus, the number of color centers increases after each cycle. This means that induced absorption increases in the process of exciting previously induced color centers without altering the spectrum of the induced absorption. The efficiency of this nonlinear process is proportional to the squared intensity of the exciting long wavelength radiation.

The coloration caused by exposure to pulsed IR radiation can be explained similarly to the three-photon cooperative breeding of color centers (Fig. 7c). The latter process obeys the cubical dependence of efficiency on the intensity of the exciting radiation. There are several important features of cooperative breeding of color centers. The first is a very high level of additional absorption because photosensitivity in this case is not connected with the sharp absorption edge of glass (Fig. 5) and a thick slab can be homogeneously colored. The second is the opportunity of localizing colored spots in arbitrary places of the bulk glass. The spots are produced by focusing the exciting beam because photosensitivity is proportional to the squared or cubical intensity of the exciting radiation and therefore, is concentrated near the focal plane. The third is an opportunity to store a latent image produced by UV radiation that can be revealed by photodevelopment.

HETEROGENEOUS PHOTOCROMIC GLASSES

Photochromic glasses co-doped with silver and copper halides are heterogeneous materials. They represent two-phase systems that consist of a vitreous host and dispersed photosensitive microcrystals. This is important because microcrystals show a reversible photochromic effect without fatigue. However, in a two-phase system, light attenuation is caused by absorption of each phase and also by scattering produced by the difference between the refractive indexes of the crystalline and vitreous components. Therefore, the parameters of the crystalline phase should be chosen to prevent strong scattering. The size of the particle of most photosensitive microcrystals, whose refractive index is about 2, should be no more than 10–20 nm to keep scattering below the level of acceptability for optical applications.

The main approach to producing dispersed microcrystals in a vitreous host is crystalline phase growth as a result of host glass heat treatment at temperatures from 500–700°C, depending on host composition. These temperatures correspond to a viscosity range from 10^{10} – 10^{13} poise. To secure crystalline phase precipitation, special requirements are applied to the host glass. First, this glass should be an oversaturated solution of the photosensitive phase (silver and copper halides) that allows effective diffusion of these components in the temperature range mentioned. Second, the solubility of the photosensitive components must drop quickly when cooling to allow the homogeneous glass to melt at high temperature and the crystalline phase to precipitate in the secondary heat treatment process. The last is usually connected with phase separation (immiscibility) and altered coordination of different components in the host glass.

The best glass, which satisfies the requirements mentioned before, is alkaline borosilicate glass. This glass matrix is the basis for almost all commercial photochromic glasses manufactured by a number of companies in different countries. Halides (Cl, Br, I) of silver and copper are photosensitive components, which are added to the batch.

Cations such as Mg, Ca, Ba, Zn, Cd, Al, and Pb, or anions such as P and S are used by different companies as additions to modify technical and end use properties. These compositional changes lead to variations in photosensitivity, the criterion of relaxation, and induced absorption spectra. Photochromic glasses can be divided into two large groups: silver halide glasses that have small concentrations of copper, which usually exhibit faster relaxation and lower sensitivity and copper halide glasses that have small concentration of silver, which exhibit slower relaxation and higher sensitivity. In silver halide glasses, small additions of copper are a sensitizer.

The traditional schedule for photosensitive phase creation, "bottom-to-top," consists of four stages: melting, rough annealing and cooling to room temperature, additional heat treatment (roasting), and final annealing. Final annealing is necessary for stress relaxation because crystalline phase precipitation occurs at temperatures above the glass transition temperature. The other method of sensitization is "top-to-bottom," which is used for mass production because of heat energy saving. In the latter, the glass casting cools down to roasting temperature but not to room temperature. It requires the other schedule (time and temperature) because the most effective growth of nucleation centers occurs at temperatures below the roasting temperature.

OPTICAL WAVEGUIDES IN PHOTOCHROMIC GLASSES

The largest commercial application of photochromic glasses is for sunglasses. Tens of millions of photochromic lenses are produced worldwide each year for this purpose. However, the alkaline borosilicate origin of photochromic glasses allows some other applications in modern optics and photonics. It is well known that these glasses are suitable for ion exchange and, consequently, planar and channel waveguides can be created on this glass. Besides that, the mildly sloping dependence of photochromic glass viscosity on temperature allows creating of optical fibers. The optical properties of photochromic waveguides compared with bulk photochromic glasses are unusual because of structural transformations in the ion-exchanged layers or in the drawn fibers and the peculiarities of light propagation in waveguides. An important feature of ion-exchanged glass is incompleteness of structural relaxation. The exchange of ions that have different radii creates stresses in glass. These stresses produce strong differences between the refractive indexes of waveguide modes that are orthogonally polarized (birefringence). Compression of silver halide photochromic glass after substituting Na^+ by K^+ at temperatures below the glass transition temperature reaches 1 GPa and produces birefringence up to 20% of the total refractive index variation, as shown in Fig. 8.

Exposure of waveguides in photochromic glasses to UV radiation produces reversible coloration. This means that ion-exchange treatment does not destroy the photosensitive crystalline phase and this technology is available for photosensitive waveguide fabrication. However, parameters of coloration and relaxation of photochromic waveguides are different compared to bulk glass. For silver

Figure 8. Refractive index profiles of photochromic glass after $\text{Na}_{\text{glass}}\text{-K}_{\text{melt}}$ ion exchange. TE or TM polarizations mean electric or magnetic field oriented along the surface, respectively.

halide glasses, the criterion of relaxation in waveguides is more than that in bulk glass. This means that relaxation in waveguides occurs faster. For copper halide glasses, relaxation in the waveguide was not detected, which means that the coloration of these waveguides is stable. There is a difference in photosensitivity between different waveguide modes. Modes with low numbers propagate near the surface and have lower sensitivity than modes that have a large number and propagate in deep layers. This difference is caused by copper (which is a sensitizer) depletion in the surface layer as result of copper exchange for potassium or other ions. This phenomenon can be used for mode selection.

The other feature of photochromic waveguides is anisotropy of photosensitivity and induced coloration. This phenomenon is connected with ion-exchange stresses. Dichroism (the difference between induced absorption for orthogonal polarizations) is proportional to birefringence in a waveguide. It is important to note that photosensitive microcrystals are plastic or melted at the temperatures of ion exchange. Therefore, dichroism is determined by stresses and also by orientation of liquid drops of the photosensitive phase caused by ion-exchange stresses.

The discrete structure of light propagation in photosensitive planar waveguides gives one more opportunity for multiplexing by mode selection. If a mode in such a waveguide (Mode #1 in Fig. 9) is excited by actinic radiation, the waveguide becomes colored. The spatial profile of induced absorption is determined by the spatial profile of the exciting modes intensity. As a result, a sort of distributed absorbing mask will be formed in the waveguide whose absorption profile is similar to that of the intensity distribution of actinic radiation in the waveguide. Consequently, losses for mode #1 increase after excitation of this mode by actinic radiation. The attenuation of other modes is determined by overlapping of their fields by the distributed mask, that is, by the field of the mode that induced this absorption. Because field profiles for the modes that have different numbers essentially differ from each other

Figure 9. Sketch of a waveguide mode selector. The darkened profile corresponds to the exposed mode, which produces a similar profile of photoinduced absorption and prevents propagation of this mode.

(Fig. 9), the losses for different modes should be significantly different. An example of a mode spectrum of a planar waveguide excited by actinic radiation in the TE_0 mode is shown in Fig. 10. A mode selection of about 10 dB/cm can be reached without special effort in planar waveguides on commercial photochromic glasses. The problem of mask bleaching can be solved by using probe radiation at longer wavelengths, where bleaching is not effective, or using, as described earlier, cooperating breeding of color centers for writing by high-power radiation.

Optical fibers were drawn from photochromic glasses. It was found that thermal treatment of these fibers produces photochromic properties. Fiber plates were made from photochromic glass as a core and a transparent optical glass as a cladding, or vice versa. High contrast was obtained in this fiber element compared to bulk photochromic glass plate. This feature of photochromic fiber plate is determined by gradual leakage of actinic radiation from transparent glass to photochromic glass. This effect increases the length of the interaction of actinic radiation with photochromic glass and, consequently, increases dramatically the induced absorption and possible contrast of a photochromic attenuator.

Figure 10. Effect of exposure to powerful excitation of the fundamental mode (shown by arrow) on the dependence of photochromic waveguide transmission on the angle of incidence onto the input coupler prism (spectrum of waveguide modes). Solid lines before exposure, dashed lines after exposure.

INDUCED REFRACTION THROUGH IRREVERSIBLE PHOTOINDUCED CRYSTALLIZATION

It is clear that photochromic glasses can be used for recording information. Actually some photos and holograms were recorded in these glasses but no great success was obtained because of small contrast in photography and small diffraction efficiency in holography. For highly efficient holography, it is necessary to produce variation in the refractive index but not in the absorption coefficient. The refractive index in glasses, where color centers are induced by radiation, can vary for very small values, less than 10^{-6} . This is not enough for efficient diffraction. Recent discovery of a strong photoinduced refractive index variation in Ge-doped silica opened a new very promising approach for efficient Bragg grating recording in optical fibers. Another approach, which allows an increase of sensitivity of several orders of magnitude compared to Ge-doped silica and avoids interaction between writing and diffracted beams, is based on a two-step process of exposure and development in multicomponent silicate glasses doped with fluorine, silver, and cerium.

Phase volume holograms of high diffraction efficiency were produced in lithium aluminum silicate and sodium zinc aluminum silicate glasses doped with silver and cerium by exposure to UV radiation followed by thermal treatment. Diffraction was caused by a difference in refractive indexes in exposed (enriched by microcrystals) and unexposed (original glass) areas. This phenomenon is called the "photo-thermorefractive" process. Glasses that possess these properties are called "photo-thermorefractive" (PTR) glasses. This two-step process (exposure and thermal development that leads to crystallization) was used earlier to record a translucent image in glass due to light scattering caused by a difference between the refractive indexes of the precipitated crystalline phase and the glass matrix. Later, colored images were recorded in similar glasses by photothermal precipitation of a number of complex crystals of different compositions, sizes, and shapes.

The sequence of processes, which occurs in these glasses and produces coloration, follows (Fig. 11). The first step is exposure of the glass to UV radiation, which ionizes a cerium ion. The electrons released from cerium are then trapped by a silver ion. As a result, silver is converted from a positive ion to a neutral atom. This second stage corresponds to latent image formation, and no significant changes in optical properties of glass occur, except light coloration in near UV and blue regions.

The next step in the process is obtained by thermal development at elevated temperatures. The high diffusion coefficient of silver atoms in silicate glasses leads to the creation of tiny silver crystals at temperatures from 450–500°C. A number of silver clusters arise in exposed regions of the glass after aging at these elevated temperatures. This is the third stage of the process. Further, these silver particles serve as the nucleation centers for sodium and fluorine ion precipitation. Cubic sodium fluoride crystal growth occurs at temperatures from 500–550°C because the PTR glass composition is an oversaturated solution of these components. This is the last step, which finishes the photo-thermorefractive process. Further heat treatment

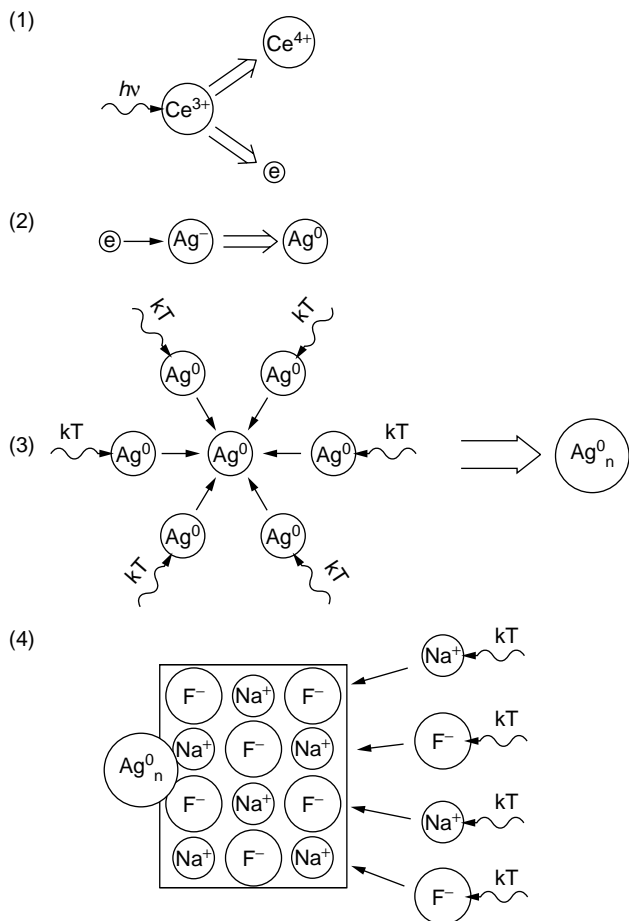

Figure 11. Stages of the photo-thermorefractive process.

leads to the growth of elongated pyramidal complex Na, Ag-F, Br crystals on the surface of cubic NaF crystals. This mixture of crystals can produce an opal coloration in large crystal sizes or a yellow coloration caused by colloidal silver precipitated on the interfaces of dielectric crystals. A second exposure to UV followed by a second heat treatment produces a different coloration because of metallic silver reduction on the surfaces of the dielectric pyramids. The final resulting coloration depends on the size and aspect ratio of these silver particles. These two last steps are used for photography because strong scattering does not allow using them in holography.

A refractive index decrease of about 5×10^{-4} occurs in the areas of glasses exposed to nitrogen laser radiation at 337 nm. The refractive index of NaF in the red spectral region is $n_{NaF} = 1.32$ compared to the refractive index of PTR glass $n_{PTR} = 1.49$. The small value of the refractive index change is due to the small volume fraction of the precipitated crystalline phase, which produces no scattering in the exposed volume. However, it is sufficient to result in highly efficient Bragg grating recording in samples more than several hundreds of microns thick. This photo-thermoinduced refraction is stable up to 400°C. The photosensitivity is in the range of several tens of mJ/cm^2 at wavelengths in the absorption band region of Ce^{3+} , which has a maximum

near 300 nm and a long wavelength tail up to 400 nm. This means that several commercial lasers such as N_2 , Ar, and He-Cd, can be used for recording. Once developed, holograms in PTR glass are not destroyed by further exposure to visible or UV radiation.

PHOTO-THERMOREFRACTIVE GLASS

The composition (mol. %) of PTR glass which was used for hologram recording is $15Na_2O-5ZnO-4Al_2O_3-70SiO_2-5NaF-1KBr-0.01Ag_2O-0.01CeO_2$. Absorption spectra of PTR glasses are presented in Fig. 12. Figure 12a shows the UV part of the absorption spectrum. One can see the wide absorption band of Ce^{3+} that has a maximum at 305 nm. The short wavelength absorption in the region $\lambda < 270$ nm is due to several components, such as Ce^{4+} , Ag^+ , Br^- , and Fe^{3+} . The short wavelength edge, at which writing radiation is attenuated by two times in the recording medium (optical density about 0.3), is placed at 330 nm for a 1-cm thick plate and at 265 nm for a 1-mm thick plate. The range of photosensitivity of this glass is from 280–360 nm.

Absorption of PTR glass is less than 0.01 cm^{-1} in the visible and near IR regions, which is close to the limit of measurements, and therefore it is not shown in Fig. 12. One can see in Fig. 12b that detectable absorption occurs at wavelengths higher than 2700 nm. Absorption in this spectral region is usually ascribed to different vibrations of hydroxyl groups in the glass network and reaches several cm^{-1} in regular silicate glasses. Hydroxyl absorption in fluorine-containing PTR glass is lower compared to similar fluorine-free silicate glass. This phenomenon is caused by high volatilization of HF molecules, which can result from the interaction of fluorine and hydrogen in the glass melting process. This decrease of IR absorption in PTR glass results in an opportunity for PTR use in the middle IR region up to 4300 nm for 1-mm thick specimens.

Additional absorption of PTR glass under UV exposure that is used in hologram recording in this glass is shown in Fig. 12c, curve 1. Detectable photoinduced absorption is seen only in the UV region. Even at the recording wavelength, this absorption is less than 0.1 cm^{-1} and cannot impact the recording process significantly. The small tail of the induced absorption spectrum in the blue region can be distinguished by the naked eye as a slight yellow coloration of the exposed area. Thermodevelopment causes colloidal silver and sodium fluoride precipitation in the glass matrix. Fluoride crystals are colorless and can result in scattering if the size of the crystals is too large (more than 100 nm). A shoulder near 450 nm in the additional absorption spectrum after thermal treatment in Fig. 12c (curve 2) is ascribed to silver particles in glass matrix. One can see that the visible additional absorption does not exceed 0.3 cm^{-1} and 0.03 cm^{-1} in the blue and red regions, respectively. This means that losses in this region do not exceed a few percent for a 1-mm thick plate. Additional absorption in the whole IR region is not detectable and therefore is not shown in Fig. 12c. Consequently, this glass can be used successfully at all wavelengths important for lasers and optical communication in the visible and near IR regions.

Figure 12. Absorption spectra of PTR glass: (a) and (b) original glass in the UV and IR spectral regions, (c) induced absorption after exposure to 325 nm for 400 mJ/cm² (12) and consequent thermal development for 1 hour at 520°C (13). Arrow shows the position of the wavelength of the writing He–Cd laser.

Optical microscopy of exposed and developed samples used for induced absorption measurements has shown optical inhomogeneities in the exposed region. The structure of these inhomogeneities appears as a series of parallel, continuous, aligned filaments whose widths are tens of microns oriented in the direction of light propagation in the glass sample. These microscopic features are caused by structures whose different refractive indexes arise in glass

processing (phase structures). It is proved that these phase patterns are not an intrinsic feature of PTR glass but are caused by various defects of the sample bulk and surfaces. Some additional patterns were found in micrographs; they are combinations of different rings and fringes. It was found that they are recordings of the interference patterns produced by matching propagating beams to beams consequently reflected from the back and front surfaces of different elements in the optical setup. Diffraction of the exciting beam on different apertures produces systems of straight or curved fringes that have variable periods dependent on the shape and position of the aperture. It is necessary to make special adjustments to eliminate these interference and diffraction patterns in the plane of the recording to avoid these parasitic structures. Therefore, the homogeneity of the photosensitive medium (including surface and volume defects) and the writing beam (including interference and diffraction patterns of low visibility) must be tested to avoid undesirable losses.

The pattern of probe radiation transmitted through exposed area consists of the zero and first orders of diffraction but exhibit some rings. The diameters and positions of these rings on the screen depend on the incident angle of the probe beam and on the feature of the writing pattern. The origin of these rings follows. Each medium causes scattering of propagating light. Therefore, even for single beams propagating in a photosensitive medium, one can observe an interference pattern produced by matching the original and scattered beams. In this case, the probe beam used for hologram reading should be scattered twice. The first time is regular scattering by the medium. The second time is scattering produced by a hologram of scattered light recorded together with the main hologram. This hologram can be completely reconstructed only by the reading beam of the same wavelength and direction as the writing beam. When the wavelengths or the directions of the writing and reading beams are different, the whole hologram of scattered light cannot be read out because its wavefronts are not planar. At each angle of incidence, the reading beam can read only that part of the hologram, for which Bragg conditions are satisfied. Because the angular diagram of scattering has cylindrical symmetry, this part should be a ring. All phase defects mentioned (filaments, fringes, and rings) appear in all materials but they are visible well in PTR glass because of the high homogeneity and transparency of this material.

BRAGG GRATINGS IN PTR GLASS

The dependence of the absolute diffraction efficiency of Bragg gratings recorded in PTR glasses in the thermal treatment period is shown in Fig. 13. The specimen exposed for 400 mJ/cm² has undergone consecutive thermal treatments for 10–15 minutes each at 520°C and in intervals between, was cooled down to room temperature for diffractive efficiency measurements. The absolute diffraction efficiency is

$$\eta_A = \frac{I_1}{(1 - \rho)^2 I_L}, \quad (2)$$

Figure 13. Effect of the period of thermal treatment on the absolute diffraction efficiency of a Bragg grating in PTR glass. Exposure 400 mJ/cm^2 at 325 nm , spatial frequency 600 mm^{-1} . Development at 520°C . Specimen thickness 1.42 mm .

where I_L and I_1 are the intensities of the incident and diffracted beams, respectively. The reflection coefficient (ρ) is calculated by the Fresnel formula $\rho = (n - 1/n + 1)^2$.

The dependence of diffraction efficiency versus development time has an inflection point at the beginning of the process and is saturated at the 85% level after long heat treatment. Note that this multiple heat treatment is not the same as a regular development for one or several hours because this procedure includes multiple heating and cooling. However, the curve in Fig. 13 shows a tendency for the diffraction efficiency to approach a high value after some exposure at elevated temperature.

The growth of diffraction efficiency in increasing periods of thermal development is obviously caused by refractive index changes that result from crystalline phase precipitation. Figure 14 shows the dependence of the refractive index on the thermal treatment period. This photothermoinduced refractive index was calculated from

Figure 14. Effect of the period of thermal treatment on the induced refractive index. Exposure 400 mJ/cm^2 at 325 nm , spatial frequency 600 mm^{-1} . Development at 520°C . Specimen thickness 1.42 mm .

Kogelnik's equation:

$$\delta n = \frac{\lambda \cos \Theta \arcsin(\sqrt{\eta_R})}{\pi d}, \quad (3)$$

where λ is the wavelength of the reading beam, Θ is the Bragg angle, and d is the thickness of the specimen. The linear dependence of induced refractive index on the thermal treatment period is present in Fig. 14. The function $\delta n(t)$ shows no inflection point compared to $DE(t)$ (Fig. 13). The linear dependence of $\delta n(t)$ up to the value of 0.00015 allows writing high efficiency holograms in glass plates more than several hundreds of microns thick. The optical quality of inorganic glass allows using plates up to several centimeters thick. The saturation of the diffraction efficiency in Fig. 13 corresponds to the refractive index saturation at about 0.00017 in Fig. 14. No oscillations of diffraction efficiency were recorded in this experiment in long development periods up to 13 hours. This means that no significant result exceeding π for the induced phase was obtained and, consequently, no additional refractive index growth occurred.

The effect of the spatial frequency of the interference pattern on the diffraction efficiency of the grating in PTR glasses is shown in Fig. 15. This was measured in a thin sample of 1.65 mm in a transmittance configuration when writing (325 nm) and reading (633 nm) beams were directed from the same side of the glass plate. This configuration allows spatial frequency variations below 2500 mm^{-1} . Exposure or development of gratings was not optimized for different spatial frequencies. No significant dependence of diffraction efficiency on special frequency can be observed in the region from $300\text{--}2500 \text{ mm}^{-1}$ in Fig. 15. The absence of a drop in the frequency response at low frequencies is a feature of the PTR process, which requires transport of species in the glass matrix to build single crystals (tens of nanometers) and does not require transport of species between exposed and unexposed areas, as is necessary in photorefractive crystals. The

Figure 15. Dependence of the absolute diffraction efficiency on the spatial frequency of the grating. Exposure 600 mJ/cm^2 at 325 nm , development 90 min . at 520°C . Specimen thickness 1.65 mm .

Figure 16. Maximum absolute diffraction efficiencies of Bragg gratings in PTR glasses for different exposures to the radiation of a He-Cd laser at 325 nm.

absence of a drop at high spatial frequencies means that no fringe smearing occurs in the developed interferogram and, consequently, no detectable diffusion of components at distances comparable with the half-period of the gratings studied (up to 200 nm) occurs in PTR glass during thermal processing. These data show that diffusion of glass components in the development process cannot affect the saturation in Fig. 14, which was observed for gratings that have a spatial period of 1600 nm. The lack of drop in the amplitude-frequency response at low frequencies (Fig. 15) is an advantage of PTR glasses compared to photorefractive crystals; this results in a distinct opportunity to design holographic optical elements that have very small diffraction angles.

An interesting consequence of the low level of induced losses (Fig. 12c, curve 2) is the rather low sensitivity of PTR-grating diffraction efficiency on exposure because underexposure can be compensated for by overdevelopment, and vice versa. Figure 16 illustrates this feature of PTR glass. In this figure, the best diffraction efficiencies for specimens of different thickness from different melts, which had undergone different development procedures, are plotted versus exposure to the radiation of a He-Cd laser. A high absolute diffraction efficiency of 80% and more is observed in Fig. 16 for exposures that ranged between 50 mJ/cm² and 5 J/cm².

SUMMARY

Photochromic glasses that have completely reversible coloration are made of borosilicate glasses doped with microcrystals of copper and silver halides. These glasses are sensitive to near UV radiation. Photosensitivity can be extended to visible and near IR regions by cooperative breeding of color centers. Induced coloration is a wide band that covers the whole visible region. Photocontrolled waveguides can be fabricated in photochromic glasses. These waveguides can serve as attenuators and mode selectors. Photo-thermorefractive glasses that have irreversible

photoinduced refraction are aluminosilicate glasses doped with silver, cerium, and fluorine. These glasses are sensitive to near UV radiation. Their photosensitivity is comparable with the best organic and inorganic materials, it allows wide variations of exposure because of image amplification in the thermal development process, and it has high diffraction efficiency and high transparency from the UV to the IR region.

PIEZOELECTRICITY IN POLYMERS

ALEKSANDRA VINOGRADOV
Montana State University
Bozeman, MT

INTRODUCTION

The diverse group of “smart” piezoelectric materials is distinguished by their ability to react actively to changing stimuli as a result of converting mechanical to electrical energy and vice versa. Synthetic piezoelectric polymers, an integral part of the “smart” materials group, exhibit a type of behavior that is often compared with biological reactions involving transformations of the sensed information into the desired response. Due to such

special qualities, piezoelectric polymers have been increasingly used in a rapidly expanding range of applications. At present, these materials continue to offer unprecedented design opportunities, leading to the belief that the industry is on the verge of major technological breakthroughs.

PIEZOELECTRICITY: AN OVERVIEW

Piezoelectricity is a material property that is observed as an electric charge or voltage produced by applied mechanical forces or, conversely, as mechanical deformation that is caused by an applied electric field. These piezoelectric effects have been defined, respectively, as “direct” and “converse.” The latter classification provides a convenient basis for reference purposes, although it is clear that both phenomena have the same physical origin.

Rapid progress in piezoelectric investigations was made at the beginning of the twentieth century after Pierre and Jacques Curie discovered the direct piezoelectric effect in tourmaline crystals in 1880. Subsequently, piezoelectric effects were observed and studied in other crystals, such as quartz, zinblende and Rochelle salt, providing enhanced understanding of the piezoelectric phenomenon and leading to new discoveries of piezoelectric effects in a variety of materials. In the 1940s, research efforts were particularly focused on the piezoelectric response of ferroelectric polycrystalline ceramics, including lead zirconate titanate (PZT), lithium niobate, and barium titanate. For several decades, and, increasingly, toward the mid-1960s, piezoelectricity was investigated as a common property of biopolymers, including natural biological materials that form the structures of plants, animals, and humans. Since 1969, when the strong piezoelectric effect in polyvinylidene fluoride (PVDF) was first discovered by Kawai, attention has been attracted to the piezoelectric properties of synthetic polymers. At present, the traditional group of smart materials involving piezoelectric crystals, ceramics, and polymers is expanding as a new generation of laminated composites that have embedded piezoelectric elements has recently emerged. The history of scientific developments in the dynamic and growing field of smart materials has been reviewed in (1–3).

In phenomenological terms, piezoelectricity is described as coupling between a quasi-static electric field and dynamic mechanical motion. Typically, the direct and converse piezoelectric effects have been treated as reversible. Respectively, the constitutive equations of linear piezoelectricity are based on the principle of energy conservation. The piezoelectric constitutive law can be presented in several alternative forms. One of the formulations is given by

$$\begin{aligned} [\varepsilon] &= [\mathbf{C}][\sigma] + [\mathbf{d}]^T[E], \\ [D] &= [\mathbf{d}][\sigma] + [\mathbf{e}][E], \end{aligned} \quad (1)$$

where $[\sigma]$ and $[\varepsilon]$ denote, respectively, stress and strain tensors that satisfy the condition of symmetry, that is, $\sigma_{ij} = \sigma_{ji}$, and $\varepsilon_{kl} = \varepsilon_{lk}$ ($i \neq j$, $k \neq l$); $[D]$ and $[E]$ denote, respectively, the electric flux density and the electric field;

$[\mathbf{C}]$ is the elastic compliance matrix whose components satisfy the condition $c_{ijkl} = c_{ijlk} = c_{jikl} = c_{klij}$; $[\mathbf{d}]$ is the matrix of piezoelectric coefficients $d_{ijk} = d_{ikj}$; $[\mathbf{d}]^T$ is the transpose of $[\mathbf{d}]$; and $[\mathbf{e}]$ represents the dielectric permittivity matrix whose components $e_{ij} = e_{ji}$ ($i \neq j$, $k \neq l$), $i, j, k, l = 1, 2, 3$. Other forms of the linear piezoelectric constitutive equations are given in (4).

In the general case of fully populated matrices $[\mathbf{C}]$, $[\mathbf{d}]$, and $[\mathbf{e}]$, the electromechanical properties of an anisotropic piezoelectric continuum are defined by 21 independent elastic constants, 18 piezoelectric coefficients, and 6 dielectric constants. However, the actual number of parameters required to characterize the properties of various piezoelectric materials is less than the total of 45. The structure and content of the matrices $[\mathbf{C}]$, $[\mathbf{d}]$, and $[\mathbf{e}]$ depend on the type of material microstructure. The anisotropic properties of piezoelectric crystals and, respectively, the composition of the matrices $[\mathbf{C}]$, $[\mathbf{d}]$, and $[\mathbf{e}]$ are determined by the type of symmetry in the crystal lattice. Because only those crystals that possess no center of symmetry on the atomic scale tend to exhibit piezoelectric effects, only 20 out of 32 crystallographic classes of crystals are piezoelectric. Specific characteristics of various groups of piezoelectric crystals and ceramics, their classification, and properties have been considered in (1,4,5). The material properties of piezoelectric polymers are discussed in detail in the following sections.

It is important to note that the theory of linear piezoelectricity is based on the assumptions of infinitesimal deformations, linear stress–strain relations, and stationary electric fields with respect to an inertial reference frame. Attempts have been made to develop more general nonlinear piezoelectric material models that take into account the effects of higher order electromechanical couplings, such as electrostriction, nonlinear strain-displacement relations, and the material response to large driving voltages. Research efforts in this regard have been reviewed (4,6). A systematic account of anelastic properties of piezoelectric polymers has been given in (7).

SYNTHETIC PIEZOELECTRIC POLYMERS

The diverse group of piezoelectric materials includes a variety of synthetic polymers such as polypropylene, polystyrene, and poly(methyl methacrylate); semicrystalline polyamides such as nylon-11; and amorphous polymers such as vinyl acetate. However, piezoelectric effects in these materials are relatively weak, often unstable, and are considered of limited practical significance. Strong piezoelectricity has been observed only in the synthetic polymer poly(vinylidene fluoride) (PVDF or PVF₂) and PVDF copolymers.

Poly(vinylidene fluoride) is a semicrystalline polymer whose typical crystallinity is approximately 50%. The amorphous phase of the polymer has the properties of a supercooled liquid. The glass transition temperature of the polymer is about -50°C . The molecular structure of poly(vinylidene fluoride) consists of the repeated monomer unit $-\text{CF}_2-\text{CH}_2-$. The atoms are covalently bonded, forming long molecular chains. Because the hydrogen atoms are

positively charged and the fluoride atoms are negatively charged with respect to the carbon atoms, PVDF is inherently polar. However, the net polar moment of the material in its original state is zero due to the random orientation of the individual crystallites.

Permanent dipole polarization of PVDF is obtained through a technological process that involves stretching and polarizing extruded thin sheets of the polymer. Stretching aligns molecular chains in the stretch direction. An applied electric field of up to 100 kV/mm at an elevated, typically, 103°C temperature causes permanent polarization that is maintained after the material cools to room temperature. Sessler (8) provides an overview of polymer polarization methods. In general, it has been observed that polarization in PVDF depends on a number of factors, including polarizing temperature, polarizing time, polarizing process, electrode conditions, and the morphology of the material.

Typically, PVDF is produced in thin films whose thicknesses range from 9 to 800 μm (10^{-6} m). A thin layer of nickel, silver, or copper is deposited on both film surfaces to provide electrical conductivity when an electric field is applied, or to allow measuring the charge induced by mechanical deformation.

ELECTROMECHANICAL PROPERTIES OF PVDF

Since the discovery of piezoelectric effects in PVDF (9), the properties of this material have been studied by many investigators. Research accomplishments in this subject area have been reviewed in (8,10,11).

Typically, the piezoelectric properties of PVDF are determined within the framework of linear piezoelectric theory. An expanded form of the constitutive law defined by Eqs. (1) is formulated for piezoelectric polymers as

$$\begin{bmatrix} \varepsilon_{11} \\ \varepsilon_{22} \\ \varepsilon_{33} \\ \varepsilon_{23} \\ \varepsilon_{31} \\ \varepsilon_{12} \end{bmatrix} = \begin{bmatrix} c_{11} & c_{12} & c_{13} & 0 & 0 & 0 \\ c_{12} & c_{22} & c_{23} & 0 & 0 & 0 \\ c_{13} & c_{23} & c_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & c_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & c_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & c_{66} \end{bmatrix} \begin{bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \\ \sigma_{23} \\ \sigma_{31} \\ \sigma_{12} \end{bmatrix} + \begin{bmatrix} 0 & 0 & d_{31} \\ 0 & 0 & d_{32} \\ 0 & 0 & d_{33} \\ 0 & d_{24} & 0 \\ d_{15} & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} E_1 \\ E_2 \\ E_3 \end{bmatrix} \quad (2)$$

$$\begin{bmatrix} D_1 \\ D_2 \\ D_3 \end{bmatrix} = \begin{bmatrix} 0 & 0 & 0 & 0 & d_{15} & 0 \\ 0 & 0 & 0 & d_{24} & 0 & 0 \\ d_{31} & d_{32} & d_{33} & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \\ \sigma_{23} \\ \sigma_{31} \\ \sigma_{12} \end{bmatrix} + \begin{bmatrix} e_{11} & 0 & 0 \\ 0 & e_{22} & 0 \\ 0 & 0 & e_{33} \end{bmatrix} \begin{bmatrix} E_1 \\ E_2 \\ E_3 \end{bmatrix}$$

Figure 1. Dependence of the coefficient d_{31} of PVDF on polarization time t_p (12).

The latter equations are formulated in an orthogonal coordinate system 1-2-3, so that axes 1 and 2 are considered in the plane of a PVDF film, whereas axis 3 is normal to the film surface. Axes 1 and 2 are, respectively, parallel and normal to the orientation of the polymer's aligned molecular chains.

According to Eqs. (2), coupling of the electromechanical material properties of PVDF is characterized by five piezoelectric coefficients contained in the matrix $[d]$. The most important coefficients that determine the magnitude of piezoelectric effects are the coefficients d_{3j} , ($j = 1, 2, 3$). Sometimes, the hydrostatic coefficient, $d_h = d_{31} + d_{32} + d_{33}$ that determines the electric charge generated by hydrostatic pressure is used to represent the degree of piezoelectric effects in a material.

The values of the piezoelectric coefficients of PVDF depend on the polarization conditions in terms of the polarization time t_p , polarization temperature T_p , and polarizing field strength E_p (12). In particular, the dependence of the coefficient d_{31} on t_p , T_p , and E_p for a PVDF thin film stretched at a 4:1 ratio, is illustrated in Figs. 1–3.

Figure 2. Dependence of coefficient d_{31} of PVDF on polarization temperature T_p (12).

Figure 3. Dependence of coefficient d_{31} of PVDF on polarizing field strength E_p (12).

A number of experimental techniques have been developed to determine the values of the piezoelectric coefficients of PVDF. In particular, the response of 20- μm thick PVDF films has been studied under the conditions of superimposed static and sinusoidal loads (13). The electric charge resulting from the mechanical loading has been measured for various values of the static load and at various temperatures; the amplitude (0.15 N) and frequency (15 Hz) of the dynamic load remained unchanged. It has been determined that the piezoelectric coefficient d_{31} of PVDF strongly depends on temperature, particularly, in the range from -40 to -50°C , close to the glass transition temperature T_g . A similar dependence of coefficient d_{31} on temperature has been observed in (14).

The electromechanical response of PVDF as a function of temperature has been studied in (15) using the piezoelectric resonance method. By applying an alternating stress in the material directions 1, 2, and 3 and using polarization measurements along axis 3, it has been determined that $d_{31}, d_{32} > 0$, and $d_{33} < 0$. In addition, it has been observed that the piezoelectric coefficients of PVDF tend to increase with temperature, as illustrated in Fig. 4.

Figure 4. Piezoelectric coefficients d_{31} , d_{32} , and d_{33} of PVDF as functions of temperature (15).

Figure 5. Electromechanical coupling factors k_{31} , k_{32} , and k_{33} of PVDF as functions of temperature (15).

The piezoelectric properties of PVDF have been also characterized in terms of electromechanical coupling factors k_{31} , k_{32} , and k_{33} . These coefficients represent the ratios between the dissipated and input energies in the respective material directions. It has been determined (15) that the electromechanical coupling factor k_{31} of PVDF tends to increase with temperature, whereas k_{32} and k_{33} remain temperature insensitive. These results are illustrated in Fig. 5.

The shear piezoelectric properties of uniaxially oriented PVDF films have been studied in (16). It has been observed that polarization of PVDF samples is linearly proportional to applied shear stresses. It has been determined that the values of the piezoelectric coefficients d_{15} and d_{24} range from -13 pC/N^{-1} to -27 pC/N^{-1} and from -23 pC/N^{-1} to -38 pC/N^{-1} , respectively.

The mechanical properties of PVDF have been defined by the constitutive equations of linear elasticity in the form of a generalized Hooke's law. For orthotropic materials, the coefficients of the compliance matrix $[C]$ in Eqs. (2) can be represented such that

$$\begin{aligned} c_{11} &= 1/Y_1, c_{22} = 1/Y_2, c_{33} = 1/Y_3, c_{44} = 1/2G_{23}, \\ c_{55} &= 1/2G_{31}, c_{66} = 1/2G_{12} \\ c_{12} &= -\nu_{12}/Y_1 = -\nu_{21}/Y_2, c_{13} = -\nu_{13}/Y_1 = -\nu_{31}/Y_3, \text{ and} \\ c_{23} &= -\nu_{23}/Y_2 = \nu_{32}/Y_3 \end{aligned} \quad (3)$$

where Y_1 , Y_2 , and Y_3 are the elastic moduli in directions 1, 2, and 3, respectively; G_{12} , G_{31} , and G_{23} denote the shear moduli; and ν_{12} , ν_{23} , and ν_{31} are Poisson ratios whose first index indicates the direction of contraction or expansion and the second indicates the direction of force action. Note that due to the symmetry of the compliance matrix $[C]$, the mechanical properties of PVDF thin films are characterized by nine independent elastic constants.

The elastic response of PVDF has been studied in (14,15,17–21). It has been observed that the experimental values of the elastic moduli Y_1 and Y_2 have been consistently very close. This result has been often interpreted

Figure 6. Stress–strain response of PVDF (direction 1) (20).

as evidence that the mechanical properties of PVDF are isotropic. However, it has been demonstrated in (18–20) that PVDF thin films exhibit significantly different responses, depending on the orientation of the aligned molecular chains. In the latter studies, 28- μm PVDF samples were tested under displacement controlled experimental conditions at a strain rate of 1.27 cm/min. The respective stress–strain diagrams for both in-plane material directions of PVDF are given in Figs. 6 and 7.

It is clear that the mechanical properties of PVDF thin films strongly depend on the orientation of the polymer's molecular chains aligned in the stretch direction. The diagram in Fig. 6 demonstrates that the stress–strain response of the material in the direction of the aligned molecular chains (direction 1) is characterized by a continuous increase of stresses that culminates in sudden failure. This type of response is typical for brittle materials. In

contrast, the stress–strain diagram in Fig. 7 for the material direction normal to the alignment of molecular chains (direction 2) is characteristic of ductile material behavior that involves an increase in stresses up to a certain maximum value and a following sharp decrease of load-carrying capacity.

Besides the observed differences in the stress–strain behavior, the ultimate stresses $(\sigma_u)_i$ and ultimate strains $(\varepsilon_u)_i$ ($i = 1, 2$) in the respective in-plane material directions of PVDF have considerably different values: $(\sigma_u)_1 = 3.5 \times 10^8$ Pa, and $(\sigma_u)_2 = 5 \times 10^7$ Pa.

The Poisson ratio for uniaxially stretched PVDF films has been measured experimentally in (21). Material samples were subjected to uniaxial tension in the direction of the aligned molecular chains. The values of the Poisson ratios ν_{31} and ν_{21} were obtained by measuring the respective deformations in the thickness and width directions of

Figure 7. Stress–strain response of PVDF (direction 2) (20).

Figure 8. Elastic compliances of PVDF as functions of temperature (15).

the samples. It has been determined that $\nu_{21} \sim 0.1$ and $\nu_{31} \sim 0.8$. It is important to note that the value of ν_{31} exceeds 0.5, the theoretical maximum possible value of the Poisson ratio for isotropic elastic materials. This result indicates that PVDF thin films are highly anisotropic.

Experimental studies (14,15,22–24) indicate that the elastic properties of PVDF are temperature-dependent. In particular, according to the results reported in (15), the elastic compliances of PVDF increase with temperature. The yield stress and yield strain of PVDF are also temperature-dependent (22). These results are illustrated in Figs. 8, 9, and 10.

Due to the fact that the electromechanical response of PVDF depends on a number of factors, including polarization conditions, stress/strain rates, temperature, and hydrostatic pressure, the reported data for the values of the piezoelectric and elastic constants of the polymer appear to involve certain inconsistencies. Nevertheless, it is possible to identify the typical values of the electromechanical characteristics of PVDF such as summarized in Table 1.

Figure 9. Temperature dependence of the true yield stress of PVDF (22).

Figure 10. Temperature dependence of the true yield strain of PVDF (22).

NONLINEAR AND TIME-DEPENDENT EFFECTS

The constitutive law of linear piezoelectricity in the form of Eqs. (1) tends to neglect energy dissipation, time-dependent effects, and various nonlinearities in the electromechanical response of piezoelectric materials. However, there is consistent experimental evidence that these assumptions have certain limitations. It has been observed that, in general, all piezoelectric materials exhibit nonlinear effects, as well as dielectric and mechanical energy losses, although to different degrees. Thus, energy losses in piezoelectric crystals and ceramics are negligible (26,27), whereas in piezoelectric polymers such effects are of practical significance (28).

One study demonstrates strong nonlinear dependence of the transverse piezoelectric response of PVDF on the applied stress (29). It has been observed that the piezoelectric coefficient d_{32} of 22- μm uniaxially oriented PVDF films becomes negative under large stresses. This effect appeared reversible upon unloading but tended to repeat itself in subsequent loading–unloading cycles.

Under cyclic conditions, piezoelectric polymers exhibit energy losses observed from hysteresis loops formed by the electric displacement D as a function of electric field E (10, 30–34). Furukawa et al. (30) subjected 20- μm thick PVDF films to high sinusoidal electric fields whose amplitudes ranged from 40 to 120 MV/m in the frequency range of 10^{-4} – 10^{-2} Hz at temperatures between -100 and 100°C . These experiments demonstrated a strong dependence of D on temperature and on the amplitude and frequency of the electric field. At sufficiently high electric fields, D – E hysteresis loops have been observed, even in the temperature range below the glass transition temperature of the polymer. The D – E response of PVDF samples at different temperatures is illustrated in Fig. 11.

D – E hysteresis loops similar to those shown in Fig. 11 have been obtained for PVDF copolymers, vinylidene fluoride-trifluoroethylene (VDF-TrFE), and vinylidene fluoride-tetrafluoroethylene (VDF-TFE) (35–37). Similarly, the piezoelectric coefficients of PVDF and its copolymers have demonstrated hysteresis under variable electric fields (38–41).

Table 1. Electromechanical Characteristics of PVDF

Property	Value
Range of film thicknesses	9–800 μm (10^{-6} m)
Mass density, ρ	1.78×10^3 kg/m ³
Water absorption	0.02%
Operating temperature range	-40 to 80°C
Glass transition temperature, T_g	-60 to -20°C
Melting temperature, T_m	170–178°C
Maximum operating voltage	30 V/ μm (750 V/mil)
Breakdown voltage	100 V/ μm (2000 V/mil)
Capacitance	380 pF/cm ² for 28- μm films at 1 kHz
Piezoelectric coefficients	$d_{31} = 21.4 \times 10^{-12}$ C/N; $d_{32} = 2.3 \times 10^{-12}$ C/N; $d_{33} = -31 \times 10^{-12}$ C/N; $d_{24} = -35 \times 10^{-12}$ C/N; $d_{15} = -27 \times 10^{-12}$ C/N
Electromechanical coupling factors	$k_{31} = 12\%$; $k_{32} = 3\%$; $k_{33} = 19\%$ at 1 kHz
Permittivity	$(106\text{--}113) \times 10^{12}$ F/m
Relative permittivity	12–13
Young's moduli	$Y_1 = 2.56 \times 10^9$ Pa; $Y_2 = 2.6 \times 10^9$ Pa
Yield stress	$(\sigma_y)_1 = 4.5 \times 10^7$ Pa; $(\sigma_y)_2 = 3.9 \times 10^7$ Pa
Yield strain	$(\epsilon_y)_1 = 1.8\%$; $(\epsilon_y)_2 = 1.4\%$;
Ultimate stress	$(\sigma_u)_1 = 3.5 \times 10^8$ Pa; $(\sigma_u)_2 = 5 \times 10^7$ Pa
Ultimate strain	$(\epsilon_u)_1 = 16.9\%$; $(\epsilon_u)_2 = 2.5\%$
Dielectric loss factor	0.015–0.25
Mechanical loss tangent	0.10

One of the most obvious indicators of the time-dependent behavior of piezoelectric polymers is their tendency to undergo piezoelectric, dielectric, and mechanical relaxation. As an example, relaxation of the piezoelectric coefficient d_{31} of PVDF thin films stretched at a 5:1 ratio and polarized for 2 hours at a polarization temperature $T_p = 85^\circ\text{C}$ and electric field $E_p = 50$ MV/m is illustrated in Fig. 12.

The relaxation properties of PVDF attracted attention in the early 1960s (42), and since that time, the relaxation phenomenon in piezoelectric polymers has been studied extensively (43–47). Typically, piezoelectric, dielectric, and mechanical relaxation of piezoelectric polymers is characterized by the complex coefficients

$$d_{ijk} = d_{ijk}' - id_{ijk}'',$$

$$e_{ij} = e_{ij}' - ie_{ij}'',$$

**Figure 11.** D - E hysteresis loops of PVDF at various temperatures (30).

and

$$c_{ijkl} = c_{ijkl}' - ic_{ijkl}'', \quad (4)$$

that determine energy losses in terms of the respective loss tangents such as

$$(\tan \delta_{ijkl})_m = c_{ijkl}''/c_{ijkl}',$$

$$(\tan \delta_{ijk})_p = d_{ijk}''/d_{ijk}',$$

and

$$(\tan \delta_{ij})_d = e_{ij}''/e_{ij}'. \quad (5)$$

The experimental values of the dielectric complex coefficients for PVDF and P(VDF-TrFE) are summarized in (43). In general, it has been observed that the dielectric complex coefficients of PVDF and its copolymers depend nonlinearly on temperature and frequency (45–47). The dielectric loss tangent for PVDF films is reportedly in the

**Figure 12.** Piezoelectric coefficient d_{31} of PVDF film (12).

range of 0.015 to 0.25, depending on the experimental conditions (25,42,44).

Time-dependent mechanical properties of PVDF have been studied in (18–20) based on a series of quasi-static creep tests and dynamic mechanical tests of 28- μm thick, commercially produced PVDF thin films. In the experiments, PVDF samples were tested in two in-plane material directions, parallel (direction 1) and perpendicular (direction 2) to the polymer's aligned molecular chains. Creep experiments were performed at 10 different stress levels under sustained loading conditions at room temperature. Strain measurements were taken by a linear variable differential transformer (LVDT).

The time-dependent response of PVDF thin films has been described by the constitutive equations of linear viscoelasticity in either of two alternative forms (48,49):

$$\varepsilon(t) = \sigma(0)C_i(t) + \int_0^t C_i(t-\tau) \frac{d\sigma}{d\tau} d\tau, \quad (6)$$

$$\sigma(t) = \varepsilon(0)Y_i(t) + \int_0^t Y_i(t-\tau) \frac{d\varepsilon}{d\tau} d\tau, \quad i = 1, 2, \quad (7)$$

where the functions $C_i(t)$ and $Y_i(t)$ ($i = 1, 2$) denote, respectively, the creep compliances and relaxation moduli of the polymer in both material directions.

The creep compliances of PVDF were determined by using the method of dynamic mechanical testing and analysis (DMTA), commonly employed for testing and characterizing polymers and polymer matrix composites (50).

The dynamic experimental program described in (18–20) was implemented by subjecting PVDF samples to sustained tensile stresses at several levels below σ_{Y_i} ($i = 1, 2$) that had a superimposed sinusoidal strain $\varepsilon = \varepsilon^\circ \sin(\omega t)$. The response of the material was measured in terms of the respective stress $\sigma = \sigma^\circ \sin(\omega t + \delta)$, and the phase angle δ represented the loss of mechanical energy. Dynamic tests were performed in each material direction for 20 different values of frequency in the range from 1 to 50 Hz at ambient temperature. The viscoelastic properties of the polymer in both directions were characterized in terms of the respective storage and loss moduli, Y'_i and Y''_i , and storage and loss compliances, C'_i and C''_i ($i = 1, 2$).

The experimental frequency range was expanded on the basis of the temperature-frequency correspondence principle that provides a correlation between the viscoelastic material characteristics at a base temperature T_0 and the respective material characteristics at a different temperature T , such that

$$Y'(\omega, T_0) = Y'(\omega a_T, T_0), \quad (8)$$

where a_T denotes the shift factor (48).

The shift factor a_T for PVDF thin films was determined by repeating the entire set of dynamic experiments at 13 different temperature levels in the range from 25.5 to 81°C for the material direction 1 and at 10 different temperature levels in the range from 24.4 to 81.1°C for the material direction 2. On this basis, the loss and storage relaxation moduli and the loss and storage creep compliances of PVDF were determined. As an example, the storage moduli

Figure 13. Storage modulus of PVDF (direction 1) (18).

Figure 14. Storage modulus of PVDF (direction 2) (18).

of PVDF as functions of frequency and temperature are shown in Figs. 13 and 14 in directions 1 and 2, respectively.

Using the approximate inverse Fourier transformation method (48), the creep compliances $C_i(t)$ ($i = 1, 2$) of PVDF were obtained numerically. An analytical approximation of $C_i(t)$ ($i = 1, 2$) was obtained as a power law

$$C_i(t) = a_i + b_i t^{\alpha_i}, \quad i = 1, 2, \quad (9)$$

where the coefficients a_i , b_i , and α_i were determined for the material direction 1 as

$$a_1 = 3.206 \times 10^{-10}, b_1 = 5.018 \times 10^{-11}, \alpha_1 = 0.107, \quad (10)$$

within the range $(0.0032 < t < 1.91 \times 10^6)$ s. and, for the material direction 2, as

$$a_2 = 3.514 \times 10^{-10}, b_2 = 0.111 \times 10^{-11}, \alpha_2 = 0.085, \quad (11)$$

within the range $(0.0032 < t < 4.001 \times 10^4)$ s. The respective relaxation functions of PVDF were obtained (51), as illustrated in Figs. 15 and 16.

It is important to note that, the time-dependent mechanical response of PVDF films is independent of stress only

Figure 15. Relaxation function of PVDF (direction 1) (51).

Figure 16. Relaxation function of PVDF (direction 2) (51).

at stress levels below 57% of the yield stress $(\sigma_Y)_1$ in the material direction 1 and below 76% of $(\sigma_Y)_2$ in the material direction 2 (18). Beyond these limits, the creep and relaxation behavior of PVDF is nonlinear.

It is important to note that, as determined by Holloway (18), the time-dependent mechanical response of PVDF films is stress independent only at the stress levels below 57% of the yield stress $(\sigma_Y)_1$ in the material direction 1 and below 76% of $(\sigma_Y)_2$ in the material direction 2. Beyond these limits, the creep and relaxation behavior of PVDF is nonlinear.

It has been shown (52) that the mechanical and dielectric relaxation responses of piezoelectric solids are interrelated. The same molecular relaxation mechanisms that give rise to mechanical relaxation also give rise to dielectric relaxation. It has been suggested (53) that the inherent coupling between the time-dependent electrical and mechanical properties of piezoelectric materials can be described by the constitutive equations in a form similar to the constitutive law of linear viscoelasticity:

$$\varepsilon_{ij} = \int_0^t C_{ijkl}(t-\tau) \frac{d\sigma_{kl}}{d\tau} d\tau + \int_0^t d_{kij}(t-\tau) \frac{dE_k}{d\tau} d\tau, \quad (12)$$

$$D_i(t) = \int_0^t d_{ijk}(t-\tau) \frac{d\sigma_{jk}}{d\tau} d\tau + \int_0^t e_{ij}(t-\tau) \frac{dE_j}{d\tau} d\tau. \quad (13)$$

Combined nonlinear and time-dependent effects in the behavior of piezoelectric polymers were studied in (54), based on measurements of the stress relaxation modulus of uniaxially stretched 30- μm thick PVDF films in the temperature range from 30 to 100°C. It was observed that, for temperatures below 40°C, the behavior of PVDF samples in the draw direction followed the typical relaxation pattern. However, at elevated temperatures ranging from 50 to 100°C, PVDF samples demonstrated an inverse behavior, an increase of the relaxation modulus after a certain period of continuous decrease. For example, at 100°C, the relaxation modulus of PVDF decreased for about 1 min, reached a minimum, and, subsequently, increased from about 1.14 GPa to 2.97 GPa during a period of 36 hours. This behavior of PVDF, identified as “inverse stress relaxation,” was accompanied by a gradual decay of the piezoelectric properties of the material.

To date, significant progress has been made in the development of various constitutive models of nonlinear piezoelectricity (7,55–57). However, many aspects of experimentally observed nonlinear and time-dependent phenomena that characterize the behavior of piezoelectric polymers still remain unexplained.

APPLICATIONS

Piezoelectric polymers have been increasingly integrated in structural design as active elements that can sense and respond intelligently to external stimuli. On this basis, a new generation of so-called “smart structures” or “smart material systems” has emerged that can detect changes in loading or environmental conditions, decide rationally on a set of respective actions, and carry out these actions in a controlled manner. A broad range of applications using such functions include active vibration damping, acoustic suppression, damage detection, shape and position control of compliant structures, and self-inspection of structural integrity. Systematic reviews (3,25,58,59) provide a consistent account of modern technological developments in the field of smart material systems.

Material selection in designing smart material systems involves considerations of such factors as the maximum achievable strain, stiffness, spatial resolution, frequency bandwidth, and temperature sensitivity. Traditionally, piezoelectric ceramics such as lead zirconate titanate (PZT) and barium titanate (BaTiO_3) have played a leading role in many applications due to their dielectric strength and stable electromechanical properties at high temperatures up to 400°C. However, the potentials of piezoelectric ceramics are limited because these materials are brittle, somewhat heavy, and are difficult to scale to larger applications. In this regard, piezoelectric polymers offer definite advantages because they are light, flexible, easy to shape, and can be bonded to almost any surface. The attractive properties of PVDF and PVDF copolymers include stable response characteristics in a wide frequency range up to 10^9 Hz, low acoustic impedance; a high degree of resistance to impact, and resistance to moisture absorption, intense ultraviolet, and nuclear radiation. However, the effectiveness of piezoelectric polymers tends to decrease in

low-frequency applications, and their use is limited to a temperature range not exceeding 100°C.

The key factor that defines the application range of piezoelectric polymers is their use in the design of transducers, sensors, and actuators. An impressive array of PVDF applications in transducers, including loudspeakers, optical scanners, light deflectors, and variable aperture diaphragms, modulators for fiber optics, pyroelectric detectors, and capacitors has been delineated in (60). PVDF based transducers are particularly effective in high-frequency applications such as acoustics, ultrasonics, and nondestructive material evaluation (61). Examples of such applications include medical diagnostics (62), marine fouling prevention (63), acoustic microscopy (64), and damage detection in fibrous composite materials (65).

Piezoelectric sensors have been typically used for strain measurements through the readings of voltage, rates of voltage change, or the frequency spectra of the signal generated by the sensor. Various commercial applications of piezoelectric film sensors include contact switches, musical instruments, and vibrational sensing devices (66). Because they react to temperature changes, PVDF-based motion sensors are widely used in energy management systems to control room lights, appliance displays, and HVAC equipment (67). PVDF thin films have recently been employed in more advanced sensing technologies, for example, tactile sensors that recognize objects with a high degree of precision and also temperature and pressure sensors that can replicate the functions of human skin (68).

At present, a number of PVDF-based discrete piezoelectric actuators have been developed for different modes of operation. Traditionally, bending mode actuators have been designed in the form of bimorph beams consisting of two piezoelectric layers of opposite polarity bonded together. When an electric field is applied, one of the layers expands while another contracts, producing bending deformation. As shown by Wang and Cross (69), piezoelectric bimorph actuators in the form of cantilever beams can generate considerable tip displacements, although they tend to produce low forces. Thicker films and multilayer designs can expand the range of forces produced but reduce the respective displacements. A three-layer piezoelectric actuator with hysteresis has been analyzed and tested in (70).

The effectiveness of bimorph piezoelectric actuators has been enhanced by shaping them into a curvilinear configuration. As an example, a semicircular bimorph C-block actuator was proposed in (71) and analyzed in (72). Similarly to the beam bending actuator, the C-block design uses the response of two bonded piezoelectric layers actuated by equal and opposite electric fields. As shown in (72), the C-block actuator produces an increased stroke or force output, especially when combined in series or in parallel, to form larger actuator architectures.

Concurrently, a double curvature piezoelectric actuator for vibration control in microgravity environments has been proposed in (73,74). This low force PVDF actuator uses the bimorph design concept and can be produced in a variety of sizes, depending on the performance requirements. The efficiency of the actuator can be enhanced by introducing multilayer configurations and by creating more complex architectures, as in the C-block design.

The bimorph configuration involving PVDF thin films has been effectively incorporated (75,76) into the design of flexible mirror systems to control their shape and, consequently, provide the required precision of the optical surface. A similar concept was implemented (77) in designing large-scale deployable membrane mirrors for space exploration telescopes.

In general, integration of the electromechanical properties of piezoelectric polymers into structural design provides the capability of controlling the mechanical characteristics of structures in terms of stiffness or damping, or modifying the structural response in terms of position or velocity. This type of built-in structural intelligence has been particularly effective in applications involving vibration control and damping enhancement of flexible structural elements.

Piezoelectricity has played a major role in the development of various "passive" and "active" vibration control strategies. Passive damping involves converting mechanical strain energy into electrical energy, which is subsequently dissipated by a simple resistive element. Active vibrational control is achieved through interactive functions of three main components: a sensor that identifies the present state of the structure, a cognitive interpretation and decision system that controls and optimizes, and an actuator that modifies the response of the structure. Active control of sound radiation is based on a conceptually analogous approach.

Typically, piezoelectric sensors and actuators used in vibration control applications are either bonded to the surface or embedded within the structure as a patch, a continuous single layer, or multiple material layers. Spatial arrangements of segmented piezoelectric elements can be optimized to achieve the desired effects.

The response of intelligent structures that have integrated piezoelectric sensors and actuators has been studied extensively. In particular, the effectiveness of passive piezoelectric damping has been examined in (78). Various problems of active and passive vibration control of smart beams using bonded and embedded piezoelectric sensors and actuators have been investigated in (79–85). The linear vibration theory of piezoelectric plates has been developed in (86). An exact solution has been derived for piezothermoelastic orthotropic flat panels subjected to external pressure, and thermal and electrostatic excitations (87). The vibration response of simply supported elastic rectangular plates excited by two-dimensional patch actuators bonded to the plate surface has been investigated in (88). Active vibration control of plates using patches composed of a viscoelastic damping layer sandwiched between two piezoelectric layers has been studied in (89). A similar approach was adopted in (90) to control the vibrations of cylindrical shells actively. The potentials of vibrational control of cylindrical shells using curved piezoelectric actuators have been studied in (91). The problem of active noise control of an elastic panel harmonically excited by multiple piezoelectric actuators has been analyzed in (92).

As an integral part of these efforts, a number of studies specifically focused on using piezoelectric polymers for active vibration and noise control of structural components. Thus, the problem of vibration control of beams

using distributed PVDF sensors has been examined in (93,94). The performance of shaped PVDF modal sensors employed to control specific vibrational modes of rectangular plates under steady-state harmonic excitations has been studied in (95). The results obtained demonstrated the high effectiveness of PVDF sensors in active vibration control applications in both a resonant and off-resonant range of frequencies. A similar conclusion was reached (96) based on a study of shaped PVDF sensors for active structural acoustic control of rectangular plates. One theoretical and experimental investigation (97) concerns the performance of distributed PVDF sensors and actuators that can distinguish between bending and torsional vibration modes of rectangular plates. The results of the study indicate that PVDF thin films can be effectively used in microactuator devices as well as in modal control applications of larger continuous structures. Studies (98) demonstrated the effectiveness of distributed piezopolymer actuators for active control of sound fields radiated from composite structures in acoustic control applications. Similarly, the high effectiveness of PVDF-based distributed sensors and actuators used for active vibration control of flexible manipulators was observed (99).

Piezoelectric polymers represent a group of primary candidates for shape and positional control of flexible structures in weight-sensitive applications. Examples of such applications are smart skin for airborne structures (100) and highly compliant smart material systems for space applications (101). The latter comprise a diverse range of ultra-lightweight structures such as solar sails, deployable membrane mirrors, atmospheric balloons, antennae, and reflectors. By incorporating the capabilities of piezoelectric polymers in structural design, it is possible to enhance the performance of such structures by actively controlling their shape and stability.

At present, a large class of smart composite structures has been developed that combines the traditional advantages of laminated composites and the adaptive capabilities of piezoelectric materials. These structures offer numerous technological benefits. However, they exhibit complex electromechanical behavior that depends on a combination of many factors, such as the individual properties of active and passive constituents, specific material lay-ups, interfacial conditions, and the effects of damage evolution processes. These and other related issues have attracted considerable research interest.

Various theories and analyses of laminated composite structures that have integrated self-sensing, control, and diagnostic functions have been developed. In particular, the coupled mechanical, electrical, and thermal response of piezoelectric composite beams has been analyzed in (102). The development of the general theory of piezoelectric composite plates involves the efforts of many (103–109). The response of curvilinear piezoelectric composite structures has been analyzed in (110–113).

A general finite element formulation for analyzing distributed thermopiezoelectric sensors and actuators as elements of intelligent structures has been proposed in (114). A nonlinear three-dimensional constitutive theory of anisotropic piezoelectro-thermoviscoelasticity for

nonhomogeneous layered media has been developed in (115).

An innovative technique for damage diagnostics of laminated composites by an integrated sensor-actuator system in the form of a thin flexible Stanford Multi-Actuator-Receiver Transduction (SMART) layer embedded within laminated structures has been described in (116). Applications of the method involve identifying the location and force of the unknown external impact, estimating the extent of the impact damage, and monitoring the cure conditions of composites.

Advanced technological developments in intelligent material systems consistently stimulate the search for smart materials that have novel or improved characteristics. Currently, attention is focused on the effectiveness of composite materials that combine the superior piezoelectric properties of ceramics and the compliance and flexibility of various polymers. Piezoelectric composites of this type are typically produced by integrating ceramic fibers or particles of lead zirconate titanate (PZT) or calcium modified lead titanate (PbTiO_3) within a polymer matrix. Fibrous composites have been referred to as 1–3 composites because the fibers have unidirectional orientation, whereas the particulate composites, known as 0–3 composites, are isotropic. Fibrous piezoelectric composites usually have better piezoelectric properties; however, their fabrication processes are complex. Particulate composites can be produced as thin films and have the advantage of being less expensive. The performance and properties of 1–3 and 0–3 piezoelectric ceramic/polymer composites have been investigated in (117–120). In general, potential applications of active polymeric composite materials (APCM) have been discussed in (121).

CONCLUDING REMARKS

At present, the field of intelligent material systems is expanding at an unprecedented rate. The guiding principles behind this progress are structural efficiency, functionality, precision, and durability. Superior adaptive capabilities and other attractive qualities of piezoelectric polymers determine their increasingly leading role in the design of intelligent structures whose applications range from aerospace, construction and transportation to physics and life sciences.

It is clear that effective implementation of piezoelectric polymer systems directly depends on the degree to which their behavior and properties are understood. To date, despite considerable progress, material characterization of piezoelectric polymer films is far from complete. Challenges arise due to the sensitivity of the polymers to variations in fabrication and temperature conditions, time-dependent effects, and material nonlinearities. The matter is complicated by the technological necessity of providing electrical conductivity by depositing metallic surface layers. Effectively, piezoelectric polymers represent a composite material, whose response depends strongly on the thickness and properties of the individual constituents. Due to these factors, stable experimental conditions and highly precise measurements are required to characterize

the properties of piezoelectric polymers accurately in the practical range of their operating conditions.

In the immediate future, continuing progress in the field of smart materials will depend on the intensity of research efforts directed toward the development of piezoelectric polymer systems that have enhanced adaptive capabilities, formulation of advanced theoretical models, and implementation of innovative testing methodologies. On this basis, the unprecedented opportunities offered by the new generation of intelligent materials will continue to stimulate further technological progress and, ultimately, contribute to the betterment of humanity.

Scheme 2

Electropolymerization is a convenient method for preparing insoluble conjugated polymers such as PPV because it yields thin films directly on an electrode surface. Such a film may then be directly used in an application that requires a conducting contact, such as electroluminescence. Several methods have been reported for the electrochemical preparation of PPV films. Electrochemical reduction of 4–6, it has been shown, yields PPV films on metal and indium tin oxide (ITO) electrodes (18–20). Another direct route to thin films is chemical vapor deposition (CVD) from precursors such as 7 or 8 (21,22).

Ring-opening metathesis polymerization (ROMP) has been used to prepare unsubstituted PPV via a soluble precursor. Substituted paracyclophan-1-ene 9 (23) and norbornadiene derivatives 10 (24) have been used as monomers, where $\text{Mo}(\text{NAr})(\text{CHCMe}_2\text{Ph})[\text{OCMe}(\text{CF}_3)_2]_2$ ($\text{Ar} = 2,6\text{-diisopropylphenyl}$) was used as the catalyst in the polymerization (Scheme 3). This route proceeds via a living polymerization and consequently yields a relatively narrow molecular weight distribution.

Scheme 3

Substituted PPV

To increase the solubility and processibility of PPV in the conjugated form, substituents such as alkoxy or phenyl groups have been added to the backbone structure. In addition to enhancing the solubility, these substituents also change the electronic properties of the polymer via both inductive and conjugative effects. An additional benefit of soluble derivatives of PPV is that techniques for polymer characterization that require soluble material may be used and provide direct information about molecular weights and higher order structure.

Sulfonium Precursor Route. The Wessling route has also been used to produce soluble derivatives from monomers that contain solubilizing substituents on the phenyl ring. For example, dialkoxy substituted monomers yield 11 which is soluble in organic solvents such as chloroform and chlorobenzene (25), as well as poly[2-((2-ethylhexyl)oxy-5-methoxy-*p*-phenylene)vinylene] (MEH-PPV) (12) (Scheme 4) (26). The branched side chains in MEH-PPV improve the solubility of this derivative versus unbranched analogs, and this polymer is one of the most popular for electroluminescent applications.

Scheme 4

Other Routes. Substituted PPV derivatives have also been prepared by several other routes. When the resulting polymers are soluble, these methods are often successful in preparing high molecular weight material. The Gilch route has been used to prepare phenyl substituted polymers (13) (Scheme 5) (27), and the McMurry coupling has been used to yield a dihexyl substituted polymer (14) that is soluble in a range of organic solvents (Scheme 6) (28).

Scheme 5

Scheme 6

Copolymers

A number of studies have focused on the preparation of copolymers that contain fully conjugated backbones, as well as those that contain both conjugated and nonconjugated blocks. This work has been motivated by the desire to prepare materials whose range of electronic properties can easily be tuned by variations in the proportion and nature of the monomers used in the copolymer synthesis. In addition, local variations in the $\pi-\pi^*$ energy gap can be introduced in this way which, it has been shown, result in dramatic improvements in the performance of these copolymers in electroluminescent devices.

The sulfonium precursor route has been used to prepare copolymers by using various proportions of different monomers in the synthesis. This method has yielded both partially conjugated (15) and fully conjugated polymers (16) (Scheme 7) (29,30), as well as copolymers that contain other aromatic groups in the backbone in addition to phenylenevinylene moieties such as in copolymer 17 (31).

The Wittig reaction has also been successfully used to prepare soluble copolymers using substituents such as alkoxy groups on the backbone (18) (32), as well as CF_3 substituted copolymers that contain flexible, nonconjugated spacers (19) (33). Heck chemistry has been applied to prepare copolymers such as 20 (34).

Composites and Blends

The mechanical and optoelectronic properties of PPV and its derivatives may be optimized for specific applications by using polymer blends and composite materials. Blends of MEH-PPV and polyethylene have been used to enhance the degree significantly to which the conjugated polymer chains are aligned by stretching (35). The density of entanglements in gels of polyethylene is much lower than in spin-cast polymer solutions, and this effect remains after removing the solvent. This allows tensile drawing of such blends to large draw ratios (>200), which causes the conjugated polymers to align to a degree normally expected in single crystals. Charge transport through blends can also be controlled by using a host polymer that has specific properties. Blue emitters have been prepared from blends of poly(*p*-phenylphenylenevinylene) (PPPV) in poly(9-vinylcarbazole) (PVK), a hole-transporting polymer (36). In addition to enhancing the processibility of PPPV, PVK blue-shifts the electroluminescence, enhances hole-transport, and increases the probability of radiative recombination due to the dilution effect.

Composites of PPV and silica (SiO_2) and vanadium oxide (V_2O_5) have been prepared for use in nonlinear optical applications (37–39). These composites are prepared via sol-gel processing methods, and allow combining the superior nonlinear optical properties of the conjugated polymers with the very low optical losses found in inorganic glasses. Composite films of insulating SiO_2 , TiO_2 , and Al_2O_3 nanoparticles and MEH-PPV were prepared and result in more efficient charge injection and transport in electroluminescent devices formed from them, as well as enhanced emission intensities (40,41). Photovoltaic and time-resolved microwave conductivity measurements were also used to study nanocrystalline TiO_2 /PPV composites; these studies show that excitons generated in the polymer are

Scheme 7

dissociated at the polymer/TiO₂ interface and the electrons are transferred to the nanocrystals (42).

Composites of PPV in films of the polyelectrolyte Nafion have been synthesized by electrostatically binding the dicationic monomer 1 to the film, followed by treatment with base and thermal conversion (43). Ordered nanocomposites of PPV have been synthesized from mixtures of polymerizable lyotropic liquid crystals using PPV precursors (44). Photopolymerization of the host results in a hexagonal architecture, from which thin films and fibers can be fabricated. A significant enhancement in the photoluminescence of the composite relative to PPV was found.

PROPERTIES

Absorption and Emission

Films of PPV show three absorption bands whose maxima are at 6.12, 5.06, and 3.09 eV (45). The two higher energy bands are attributed to localized molecular states, whereas the lower energy band is due to a delocalized electronic excitation. The emission spectrum of PPV upon excitation at 355 nm is resolved into three lines whose spacing of 0.16 eV is due to vibronic coupling (46). Migration of the excited state to the longest conjugation length segments in the polymer appears to occur before radiative decay because smearing out of the vibrational fine structure is expected if emission from a distribution of sites within the polymer occurs. The photoluminescent efficiency varies between 5 and 25%, depending on the synthetic route used and the conversion conditions (47).

Two descriptions of the excited state have been applied to organic semiconductors, the exciton and the band model. The appropriate model depends on the extent of coupling between sites; strong coupling yields uncorrelated electrons and holes, and weak coupling favors correlated electron-hole pairs (excitons). Time-resolved fluorescence and polarized fluorescence experiments suggest that the

exciton model is appropriate in PPV (48). Rothberg and co-workers examined the relative effects of interchain versus intrachain excitations in MEH-PPV by comparing excited state lifetimes and quantum yields in films to those of dilute solutions (49). They observed significantly lower quantum yields for emission in films and attributed this to the formation of nonemissive interchain excitons, that are not formed in dilute solution. They also concluded that film morphology can play a significant role in the photophysical behavior of PPV (50). The presence of trace oxygen in the conversion of precursor polymer to PPV reduces the photoluminescence of the resulting material (51). It was shown that this is correlated with the formation of carbonyl groups in the polymer backbone and can be prevented by carrying out the conversion in a reducing atmosphere.

Photoconductivity

Photoconductivity in PPV was first measured three decades ago (52). A later study revealed low dark conductivities for PPV films ($<10^{-15}$ S/cm) but significant photoconductivity upon irradiation at 440 nm. Significant conductivity was also found upon irradiation of the film in the near-infrared region, despite insignificant optical absorption in this region. This was attributed to a charge-transfer mechanism that involves trace oxygen (53). Oriented PPV films showed enhancements in photoconductivity in light polarized parallel to the direction in which the films were stretched (54). Transient photoconductivity measurements have also been used to address the question of the nature of the charge carriers in MEH-PPV films. The exciton model predicts strong dependence of photoconductivity on temperature, and this is observed for films thicker than 120 nm. In thinner samples, both steady-state and fast time-resolved photoconductivity measurements demonstrate that photoconductivity is independent of temperature. These results are inconsistent with the exciton model (55).

Doping and Electrical Conductivity

Pristine PPV films are insulators at room temperature; however, exposure to oxygen causes an increase in conductivity to 10^{-11} S/cm, an effect attributed to reversible doping where the oxygen acts as an electron acceptor (56). Irreversible doping of PPV films with strong oxidants such as FeCl_3 or H_2SO_4 produces black films whose conductivities are very high relative to the pristine material (57). Films doped with sulfuric acid showed conductivities of $\sim 10^4$ S/cm that were only weakly temperature dependent, indicating metallic behavior. The conductivity of films doped with FeCl_3 was slightly lower (10^3 S/cm) and decreased with temperature. The doped films are stable in oxygen but are moisture sensitive. Copolymers of PPV derivatives that contain electron-donating groups, such as poly(1,4-phenylenevinylene-*co*-2,3,5,6-tetramethoxy-1,4-phenylenevinylene) (21), can also be doped with weaker oxidants such as I_2 to give materials whose conductivities are as high as 7×10^{-2} S/cm (58).

Microstructure and Liquid Crystallinity

The degree of structural order in PPV films depends greatly on the method of preparation. The degree of broadening in electron diffraction patterns has been used to assess the extent of ordering in different PPV samples (59). High-resolution transmission electron microscopy revealed, crystalline regions of approximately 7 nm in oriented PPV films, and these crystallites are retained upon doping the films with H_2SO_4 (60). Substituents also affect the structural order of PPV derivatives. Methoxy substituents allow chains to interlock and

form a more ordered three-dimensional structure, whereas methyl groups distort the backbone due to repulsive interactions between the backbone and side groups, resulting in a more disordered material (61). X-ray diffraction studies on MEH-PPV films cast from different solvents have shown that the chain orientation is anisotropic and the aromatic rings are oriented predominantly parallel to the film plane (62). The crystallinity of films cast from THF is highest, and the crystalline domains are largest compared to films prepared from other solvents.

Liquid crystallinity has been observed in derivatives of PPV that bear mesogenic substituents, as well as in copolymers that contain phenylenevinylene segments in the main chain. Copolymers in which some of the phenyl rings have alkoxy side chains (20) exhibit a nematic liquid crystalline phase which has been characterized by polarized microscopy and differential scanning calorimetry (34). The temperature range between the melting point and the nematic–isotropic phase transition, it was found, depends on the length of the alkoxy group. A PPV derivative (22) that bears the well-known cyanobiphenyl mesogen as a side chain has both nematic and smectic mesophases (63). This polymer was oriented by rubbing a film with a Teflon stick, and a significant degree of orientation was observed by polarized UV/visible and IR spectroscopies. Several examples of main-chain liquid crystalline polymers that contain phenylenevinylene moieties bridged by saturated linkers are known. The thermotropic polymer 23 was prepared by using a Wittig procedure, and it was found that it melts anisotropically (64). A related main-chain polymer (24) has a mesophase that exists between 218 and 275°C (65).

Nonlinear Optical Properties

For many optical signal processing applications, it is desirable for materials to have large optical nonlinearities and fast response times. For example, third-order nonlinear optical (NLO) properties result in laser pulse induced refractive index changes that occur on the femtosecond timescale. These changes could be exploited in fast optical switches. Conjugated polymers are expected

to be good candidates for such applications due to the delocalization of charge in the polymer backbone (66).

PPV has many of the characteristics desired in a NLO material, including good transparency, high π -electron density, and optical quality films that may be oriented and ordered. PPV has a third-order nonlinear optical susceptibility ($\chi^{(3)}$) of 7.8×10^{-12} esu (67), whereas $\chi^{(3)}$ for a substituted derivative, poly(2,5-dimethoxy-*p*-phenylenevinylene), is 5.4×10^{-11} esu at $1.85 \mu\text{m}$ (68). The higher value for the dimethoxy-substituted derivative may be due to more extended conjugation in this material. An alternative strategy which has been investigated is to introduce a NLO-active moiety pendent to a PPV backbone. For example, Disperse Red 1 has been tethered in this way (25), and the resulting polymer has a $\chi^{(3)}$ value of 2.5×10^{-12} esu (69).

APPLICATIONS

Photovoltaics

Heterojunctions between conjugated polymers and films of electron acceptors behave as rectifying p-n junctions and may be used in photovoltaic devices. Such junctions have been prepared by vacuum evaporation of n-type buckminsterfullerene (C_{60}) onto spin-cast films of p-type MEH-PPV on ITO-glass substrates (Fig. 1) (70). These devices behave as rectifiers in the dark and pass a photocurrent when

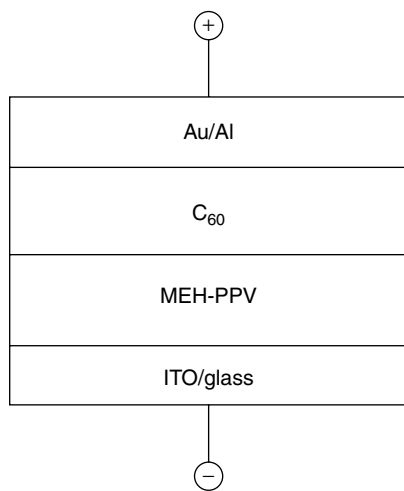

Figure 1. Schematic of a MEH-PPV photovoltaic cell.

illuminated by visible light. The open circuit voltage (V_{oc}) saturates at 0.53 V and has a fill factor of 0.48 and a power conversion efficiency of 0.04%. The Cambridge group also reported photovoltaic devices in which a heterojunction between bis(phenethylimido)perylene and PPV is sandwiched between ITO and Al. These devices had a somewhat greater fill factor (0.6), and V_{oc} approached 1 V; the quantum yield was 6% (electrons per incident photon) (71). A related approach involves using a blend of MEH-PPV and bis(phenethylimido)perylene that gives a fill factor of 0.27 at an open circuit voltage of 0.58 V; however, improvements in these devices are limited by the poor solubility of the bis(phenethylimido)perylene (72).

Photovoltaic cells have also been constructed from light-emitting electrochemical cells (LECs; see later) (73). In these devices, a phase-separated blend of MEH-PPV and cyano-PPV is used along with a solid electrolyte that consists of a mixture of polyethylene oxide (PEO) and LiCF_3SO_3 . Sandwich photovoltaic cells using Al and ITO as the electrode contacts were doped using a prebias of 3 V and resulted in a V_{oc} of 1.0 V and a power conversion efficiency of 0.1%, assuming a fill factor of 0.25. The built-in potential is determined by the chemical potential difference between the p-doped and n-doped layers, rather than the work function of the electrodes; thus, air-stable electrodes can be used in these cells.

Optical Memory

Data have been permanently stored in films of PPV derivatives by irradiating films of the sulfonium precursor polymers using either a Xe arc lamp or Ar ion laser (488 nm) (74). Subsequently heating the films resulted in the formation of colored, conjugated films only in regions that were not irradiated. Photochemical scission of the polymer chains leaves a water-soluble residue which is readily removed by rinsing the heat-treated films in water. This process may also be used for lithographic patterning of PPV films onto substrates.

Light-Emitting Devices

In the late 1980s, Tang and VanSlyke reported electroluminescent devices that used thin films of 8-hydroxyquinoline aluminum (Alq_3), as the emitting material (75). They distinguished these devices from those based on conventional inorganic semiconductors by calling them "organic," despite the fact that the emissive compound is actually an inorganic coordination complex. The devices consisted of a layer of a hole-transporting aromatic amine on an ITO electrode, 600 Å of the luminescent Alq_3 , and a Mg/Ag electrode. The devices behaved like rectifiers and emitted light whose peak intensity at 550 nm had a forward bias of as little as 2.5 V. In a subsequent publication, Tang and VanSlyke showed that doping the Alq_3 layer with other highly fluorescent molecules, such as coumarin 540, increases the electroluminescent efficiency and allows tuning the color from blue-green to orange-red (76).

In 1990, the discovery that PPV could be used as the emitter in an electroluminescent device was reported by Friend and co-workers at the Cavendish Laboratory in

Cambridge (2). The devices consisted of a PPV film, prepared by using the sulfonium precursor route, sandwiched between an indium tin oxide (ITO) and an Al electrode; green-yellow light was emitted under a forward bias of 14 V and the quantum efficiency was up to 0.05%. Shortly after this initial publication, Braun and Heeger demonstrated that MEH-PPV could also be used to fabricate EL devices in which the polymer was directly cast from solution in the conjugated form. They used both indium and calcium cathodes and observed visible light at 4 V forward bias using a calcium cathode whose efficiency was 1%.

Device Operation. Single-layer devices consist of an electroluminescent layer sandwiched between an electron-injecting cathode (usually a low work-function material such as Ca or Al) and a hole-injecting anode (most commonly the transparent conductor indium tin oxide (ITO) on glass).

The operation of the device under forward bias may be understood by using a simple band diagram (Fig. 2a). The anode and cathode materials are chosen to provide low

barriers to electron and hole injection by matching the valence and conduction band energies of the polymer to the electrode work functions. A disadvantage of the single-layer device configuration is that charge recombination often occurs close to the cathode because most EL polymers are better hole conductors than they are electron conductors. The metal electrodes can quench excitons in close proximity, thus reducing EL efficiency.

An approach that has been used successfully to move the emitting zone away from the electrodes is constructing two-layer cells in which recombination occurs at the interface between the two organic layers (Fig. 2b). Here, the material in the layer adjacent to the cathode is selected for high electron mobility but hole mobility lower than the EL polymer which is located adjacent to the anode. Thus, electrons and holes are readily injected into the adjacent layers that contact the respective electrodes and accumulate at the interface between the two layers. A number of materials have been exploited for use as the electron transporting layer (ETL), including 2-(4-biphenyl)-5-(4-*tert*-butylphenyl)-1,3,4-oxadiazole (butyl PBD) 26 (77). Two-layer devices constructed from PPV as the emitting layer and butyl PBD dispersed in poly(methylmethacrylate) (PMMA) as the ETL showed a 10-fold improvement in efficiency relative to analogous single-layer devices constructed only from PPV. Polymers that contain oxadiazole moieties pendent from the backbone and in the main chain, have been synthesized and tested as ETLs and also improve external quantum efficiencies in two-layer devices (78). The EL efficiency is temperature independent in these devices, suggesting that charge injection from both electrodes is well balanced.

Hole injection from the anode can be improved by using a hole-transport layer that functions by improving

Figure 2. Band diagram for (a) single-layer and (b) two-layer polymer EL devices.

26

hole injection into the electroluminescent layer and maximizing recombination of injected charges. Optimally, these materials should possess high glass transition temperatures (T_g) and low ionization potentials. A large variety of triaryl amines have been investigated for use as hole-transport materials including *N,N'*-diphenyl-*N,N'*-di-*m*-tolyl-1,1'-biphenyl-4,4'-diamine (TPD) 27 (79), *N,N'*-1-naphthyl-*N,N'*-diphenyl-1,1'-biphenyl-4,4'-diamine (NPD) 28 (80), 1,3,5-tris(2'-anthracyl-4''-methoxyphenylamino)benzene 29 (81), and the atropisomeric *cis*- and *trans*-5,11-dihydro-5,11-di-1-naphthylindolo [3,2-*b*]carbazole 30 (82).

*trans*-30

The brightness of EL polymer devices varies, depending on the device configuration and the polymer used. Uniax Corporation has reported ITO/PANI-CSA/MEH-PPV/Ca (PANI-CSA = polyaniline-camphor sulfonic acid) devices whose brightness is as high as 10,000 cd/m² for bias voltages >5 V, more than twice the brightness of a fluorescent lamp (83). Device brightness can be increased by using short drive pulses, that permit high current operation (84).

Luminous efficiencies as high as 0.8 cd/A can be achieved this way using current densities of 1 kA/cm² in single-layer PPV-based devices. Poly(3,4-ethylenedioxythiophene) (PEDOT) doped with polystyrene sulfonic acid (PSS) has also been investigated as a polymeric anode and it has been shown, results in increases in efficiency, brightness, and lifetime for devices based on MEH-PPV (85). When PPV is thermally converted by using a PEDOT/PSS overlayer, an interface of large surface area results due to interpenetration of the two layers, possibly contributing to the improvement in quantum efficiency measured for these devices (86).

An application for which polymer-based EL devices may be uniquely suited is as flexible emitting materials. Such devices were first reported in 1992 by workers at Uniax, using a thin layer of PANI-CSA on flexible poly(ethylene terephthalate) (PET) as the anode, an MEH-PPV film as the emitter, and vacuum-deposited Ca as the cathode (87). The PANI-CSA film is light green, but the absorption is low in the spectral region where MEH-PPV emits (500–700 nm), so emission is readily observed through the anode.

Doped silicon has also been used as a hole-injecting electrode material (88). Devices consisted of a MEH-PPV film on a thin SiO₂ layer atop a heavily p- or n-doped Si substrate. The top contact was a semitransparent Ca or Au electrode, and light emission was observed through this layer. The insulating SiO₂ layer allows matching the electrode Fermi level to the conduction band of the polymer, thus permitting the devices to operate in reverse bias using

a high work-function cathode such as Au. The Cambridge group also investigated the effect of separating the polymer layer from the Al cathode by a thin SiO₂ layer. This results in an increase in PL quantum efficiency because the emission zone is brought away from the metal interface (89).

31

Circularly polarized electroluminescence (CPEL) has been obtained from a single-layer device in which the emitter is a PPV derivative that has chiral pendent groups (31) (90). The CPEL is due to the inherent chirality of the polymer; polymers that contain racemic side groups did not show any effect, so it is believed that aggregation of the polymer chains in the solid state, enhances the magnitude of the effect.

The external efficiencies of electroluminescent devices based on PPV derivatives are typically between 0.2 and 4% (4), comparable to the efficiencies of inorganic EL devices. In addition to using electron- and hole-transporting layers to enhance efficiencies, other strategies have also been used. Son and co-workers reported polymers in which cis linkages were intentionally introduced into the PPV backbone (91). These defects prevent the polymer chains from packing efficiently in the solid state, thus producing amorphous PPV films. Both single- and two-layer devices prepared from this material had significantly higher efficiencies than comparable devices fabricated from PPV synthesized in the conventional fashion (high trans content). This improvement in efficiency may result from better chain separation in the amorphous material.

Degradation of polymer EL devices that leads to limited lifetimes is a serious problem, particularly for commercial applications that typically demand lifetimes of >10,000 hours. The low work-function metals used as cathode materials (Al, Ca, In) are air and moisture sensitive to varying degrees. Encapsulation to prevent intrusion of air and water is necessary for practical devices. It has also been shown that the polymer layer is susceptible to degradation by singlet oxygen, which can form from oxygen impurities in the film by energy transfer from a nonradiative exciton in the polymer (92). Strict removal of oxygen in the film preparation process thus results in longer device lifetimes. Oxidation of MEH-PPV, it has been shown, results in reduced fluorescence due to the formation of carbonyl groups, along with reduced carrier mobility as a consequence of chain scission. Localized shorts also form in these devices, which are initially isolated by melting of the

cathode; however, eventually these coalesce and cause device failure (93).

Although most studies have been carried out on PPV prepared by solution processing, EL devices have also been made from PPV prepared by chemical vapor deposition (94). The advantage of this approach is that many of the side reactions that typically occur during solution processing are eliminated, and this method is also compatible with existing methods for processing inorganic LEDs. Single-layer devices prepared this way had turn-on voltages as low as 4.5 V and brightness of 20 cd/m³.

32

It has also been demonstrated that modifications of the PPV structure affect the performance of EL devices (95). A PPV copolymer that bears acetate side groups (32) which disrupt the conjugation in the backbone has been used to fabricate encapsulated single-layer devices using Al cathodes and ITO anodes which operated continuously in air for 12,000 hours without degradation. The devices were encapsulated by gluing a glass slide over the top of the device using epoxy resin.

For many display applications, it is useful to pattern the emitting area of a device. Several successful approaches have been developed in this vein, including ink-jet printing and solvent-assisted micromolding. In the ink-jet approach, a conventional printer was modified to spray a solution of PEDOT onto defined areas of an ITO electrode (96). The whole area was then coated by a MEH-PPV film, and a Ca cathode was deposited to complete the device. Emission occurs only in the areas defined by the PEDOT layer due to the enhanced charge injection from this polymer relative to the ITO layer. Typical pixel sizes ranged from 180 to 400 μm, and the density of the dots could be used to control the brightness of emission from a given area. Solvent-assisted micromolding involves using methanol to wet a polydimethylsiloxane mold and allowing a solution of PPV precursor polymer to wick into the recessed regions of the mold (97). The mold is initially prepared by casting and curing a prepolymer against a lithographically prepared relief structure. When the methanol evaporates, the mold is removed, leaving the PPV precursor polymer patterned on the surface. Curing yields PPV, and the devices are completed by depositing Ca or Al. Emitting features as small as 800 nm can be prepared by this method.

Color Range and Tuning. Variations in polymer structure allow tuning the emitted color across the entire visible spectrum. Polymers such as 16 in which the conjugation is broken due to the presence of methoxy groups show blue-shifted electroluminescence relative to unsubstituted PPV and an emission maximum at 508 nm (98). Blue emission was also obtained from a copolymer containing short methoxy-substituted phenylenevinylene segments (33)

(99). Single-layer devices that contain this polymer sandwiched between Al and ITO have a maximum at 465 nm in the EL spectrum. A PPV derivative that has Si groups in the backbone (34) emits blue light in both single and two-layer device configurations (100). Green light was obtained from multilayer devices using poly(2-methyloctylsilyl-1,4-phenylenevinylene) (DMOS-PPV) (35) as the emitter combined with an electron-conducting and hole-blocking layer of either butyl PBD or a polymeric oxadiazole derivative (101). A low-band-gap, cyano-substituted thienylene phenylenevinylene copolymer 36 emits in the near-IR region. The maximum in the EL spectrum is at 740 nm, and emission tails down to 1000 nm (102).

These structures were prepared by alternate absorption of PPV precursor polymer and negatively charged CdSe particles onto an ITO substrate. Electroluminescence in these devices, arises exclusively through charge recombination on the CdSe particles and has a maximum intensity at 650 nm. The PPV, it is believed, acts only to transport charge, thus significantly reducing the turn-on voltage in these devices compared to those using insulating poly(allylaminehydrochloride) as the host.

Polymer-based light-emitting devices in which the emitted color may be tuned by varying the bias voltage have been fabricated. In one approach, the emitting layer consists of a mixture of poly(2,5-dioctyl-*p*-phenylenevinylene)

33

34

35

36

37

Several groups have developed polymer LEDs that emit light across a broad wavelength range, resulting in white light. Photoluminescence from polymer 37 arises from both the pendent diphenylanthracene units and the polymer backbone, thus covering much of the visible spectrum (103). However, electroluminescence from single-layer devices that contain this polymer is significantly red-shifted relative to the photoluminescence that emits green-red light apparently only from the main chain. Another approach that has produced white electroluminescence involves CdSe/PPV multilayer structures (104).

(ROPPV-8) and Alq₃ sandwiched between a Mg:In cathode and an ITO anode (Fig. 3a) (105). The electroluminescence from this device varies from orange to greenish-yellow as the bias voltage is increased from 15 to 22 V. Increasing the voltage increases the proportion of emitted light from the Alq₃. Devices in which ROPP-8 and Alq₃ are in separate layers emit only from the polymer layer, regardless of the applied voltage. Another approach uses a three-layer device, consisting of PPV, perfluoropropylated poly(*p*-phenylene) (F-PPP), and poly(3-dodecylthiophene) (PDT) (Fig. 3b) (106). The F-PPP acts as an

Figure 3. Schematics of tunable color light-emitting devices.

electron-blocking layer and confines emission only to the side of the device to which a negative bias is applied. Thus, green light is emitted when the negative bias is on the PPV side, and red light is emitted when it is applied to the PDT side.

Self-Assembled Devices. Rubner and co-workers at MIT developed a self-assembly approach to constructing PPV-containing heterostructures for use in EL devices (107). The heterostructures are built up by alternately dipping a substrate in solutions of the sulfonium PPV precursor polymer and anionic polyelectrolytes such as the sodium salts of poly(styrenesulfonate) (PSS) or poly(methacrylic acid) (PMA). The layers are then heated to convert the PPV to the fully conjugated form. This method allows very precise control of thickness, as well as manipulation of the nature of the surface (cationic or anionic) in contact with the anode and cathode. Device efficiency is very sensitive to the chemical nature of the interface; the PMA/Al interface consistently yielded efficiencies greater by a factor of 2 than devices that have a PPV/Al interface.

Light-Emitting Electrochemical Cells

Recently, Heeger and co-workers developed light-emitting devices in which a blend of a semiconducting, luminescent polymer and a solid-state electrolyte is used in the emitting layer (108). These devices function as solid-state electrochemical cells, and charge injection results in forming a p-i-n junction through electrochemical doping. Many of the requirements of conventional polymer LEDs, such as a match between the electrode work function and the polymer valence and conduction bands, are circumvented in such light-emitting electrochemical cells (LECs).

Polymer LECs, it has been demonstrated, function in a dynamic-junction mode, in which ions move under the external bias to create the junction. These devices degrade when the drive voltage is beyond the window of electrochemical stability. When polyethylene oxide (PEO) is used

as the ion transport medium, the devices can operate in a frozen-junction mode at 100 K. Response times in this mode are comparable to those of polymer LEDs. An improvement on this approach allows the frozen junction to function at room temperature (109). In these single-layer devices, a PPV derivative such as poly(2-butyl-5-(2-ethyl(hexyl))-1,2-phenylenevinylene) was blended with an electrolyte containing a crown ether and lithium triflate. The devices were activated by applying a small voltage while heating to 60–80°C, creating the p-i-n junction, and functioned at room temperature at a turn-on voltage of 2.1 V and an external EL efficiency of 2–3%.

Stimulated Emission and Lasers

In 1996, Friend and co-workers demonstrated optically driven lasing from thin films of PPV sandwiched between a distributed Bragg reflector and an Ag mirror (110). Excitation was by a Nd:YAG laser, frequency-tripled to 355 nm. Emission occurs in three cavity modes, equally distributed at low excitation energy, but the 545 nm emission dominates at higher excitation energy, indicating that the device is lasing. In the same year, the Santa Barbara group reported laser emission from solutions and films of MEH-PPV and TiO₂ nanocrystals. The nanoparticles multiply scatter photons in the composite material, and the scattering length exceeds the gain length (111). Stimulated emission has also been observed from crystalline films of an oligomer of phenylenevinylene substituted with octyloxy groups (34) (112).

FUTURE CONSIDERATIONS

The last 10 years have seen an explosion of research interest in PPV and its derivatives, driven by the potential of these materials as emitters in EL devices. Companies such as Philips, Uniax (DuPont Displays), Cambridge Display Technology, and Covion are engaged in bringing display applications for low-information content (cell phone and

38

alphanumeric displays) based on organic emitters to market, and in late 1999, Pioneer Electronics had already begun selling a monochrome display for use in vehicles. Applications for higher information content, such as computer and television displays, may be developed in the near future.

Although many of the problems which are of concern in optoelectronic applications of organic materials have been overcome, there are still many challenges ahead in the field. Many of the polymers that have been made recently have not yet been investigated in detail, and more work is needed to optimize them for specific applications. Fundamental questions also remain, such as the exact nature of the charge carriers in PPV films, and further studies of the photophysical behavior of these polymers are required.

Perhaps the most exciting prospect which has arisen from the intense research activity on PPV is the realization that organic materials and polymers can be used in real-world optoelectronic applications. Hopefully, this will stimulate efforts to make and study more novel materials and to find new applications for them. In particular, any integration of conventional and molecular electronics will require many advances. The success of PPV and other organic EL materials has demonstrated that research in this field is a worthwhile enterprise, and the development of entirely new classes of materials that have unknown properties may be on the horizon.

POLY(VINYLLIDENE FLUORIDE) (PVDF) AND ITS COPOLYMERS

Q.M. ZHANG
VIVEK BHARTI
GEORGE KAVARNOS
Pennsylvania State University
University Park, PA

INTRODUCTION

Poly(vinylidene fluoride) (PVDF) and the family of P(VDF-TrFE) [TrFE = trifluoroethylene] copolymers are arguably the best-known examples of a class of high-performance polymers noted for their remarkable piezoelectric and ferroelectric properties (1–4). In 1969, Kawii discovered the exceptional piezoelectric behavior of PVDF, which at that time, was the highest among the known synthetic polymers (5). After more than 30 years of study and development, the piezoelectricity and electromechanical properties of PVDF and its copolymers have been improved markedly. Today this class of polymer still possesses the highest electromechanical responses over a broad temperature range among known synthetic organic materials. Further, when considered along with their easy conformability, flexibility, robustness, and lightness, it is not surprising that electroactive polymers continue to be the focus of interest of the designers of high-performance electromechanical devices (4). When PVDF is stretched and poled in a strong electric field, it exhibits piezoelectricity (3). In its piezoelectric form, PVDF finds use in transducer devices requiring the interconversion of mechanical and electrical energy. Piezoelectric PVDF can be fabricated and used in a variety of sensors and actuators such as artificial muscles and organs, medical imaging, blood-flow monitors, microphones, smart skins, underwater acoustic transducers, seismic monitors, fluid pumps and valves, surface acoustic wave devices, robots, and tactile sensing devices (4–11). P(VDF-TrFE) copolymers display similar and in some cases even superior properties (4,12).

Even before the discovery of the high piezoelectricity in PVDF, the existence of its ferroelectric nature was postulated by Lando et al. based on the crystal unit cell structure. This hypothesis was confirmed about 10 years later (13–17). Many organic substances in fact exhibit a key ferroelectric property that is called polarization hysteresis (18–20). The copolymer of PVDF with TrFE and tetrafluoroethylene (TFE), however, is the only polymeric system that shows both a well-defined polarization hysteresis loop

and a transition to a paraelectric phase with increased temperature.

SYNTHETIC PATHWAYS AND MOLECULAR AND CRYSTAL STRUCTURES

Synthetic Pathways and Morphology

PVDF is synthesized by the successive addition of a vinylidene fluoride monomer units (21).

The reaction can be initiated by a free radical that might be formed by the thermal decomposition of, say, benzoyl peroxide:

The generated free radical then reacts with a vinylidene fluoride molecule in an initiation step:

Thus begins the process of growing a polymer chain, a series of steps called chain propagation:

In this sequence, the CF_2 “head” of the VDF monomer is shown to add to the CH_2 “tail” in a “head-to-tail” addition. Propagation may also, however, involve head-to-head (CF_2 to CF_2), tail-to-tail (CH_2 to CH_2), and tail-to-head (CH_2 to CF_2) addition. Chain termination of the growing polymer chains may occur by the combination of two growing chains or by hydrogen atom abstraction from a good hydrogen donor such as isopropyl alcohol (RH):

The synthesis of PVDF is normally carried out by emulsion polymerization where a dispersing medium such as water dissipates the high heat of the polymerization reaction (21).

The copolymer P(VDF-TrFE) is synthesized in a similar manner by the copolymerization of trifluoroethylene and vinylidene (22). Here the growing chain can add to either monomer, for example

Figure 1. Polymers such as PVDF consist of crystal and amorphous regions. This figure depicts the crystalline regions as stacks of folded lamellae.

The mole ratios of VDF in P(VDF-TrFE) copolymers that display the most striking ferroelectric properties range from about 50 to over 90 mol%. On the basis of these ratios, TrFE is much more likely to be adjacent to VDF than itself in a polymer chain. The relative proportions of the monomers in the copolymers prescribe the ferroelectric properties of the copolymers, as we shall show in later sections. Furthermore, although head-to-tail bonding prevails in the polymer chains, there may be some tail-to-tail bonding ($-\text{CH}_2-\text{CF}_2-\text{CF}_2-\text{CH}_2-$) as well head-to-head ($-\text{CF}_2-\text{CH}_2-\text{CH}_2-\text{CF}_2-$). The percentage of these defects generally is only a few mole% for most PVDF compositions. It is most important to note that the monomer sequences as well as the number of head-to-head or tail-to-tail linkages give rise to defects, which ultimately may influence the material properties of PVDF and P(VDF-TrFE).

PVDF and P(VDF-TrFE) are semicrystalline polymers (24). They are comprised of ordered regions of monomer units (crystallites) surrounded by an amorphous sea of scrambled, spaghettilike chains, as shown in Fig. 1 (1,2). From many SEM studies, it has been estimated that these crystallites have thickness of about 10 to 20 nm along the polymer chain direction and extend to several microns in the other directions (23). The degree of crystallinity as well as the orientation of the crystallites can be controlled by various processing techniques. Before discussing these techniques, we present a survey of the major crystalline forms of PVDF and P(VDF-TrFE).

Molecular Conformations

PVDF and P(VDF-TrFE) are polymorphic in the sense that they may exist in several crystal forms (24). In each form, the chains are packed within crystal lattices in specific conformations. The crystal structures are described by the conformations of the chains (as a series of *trans* (T) or *gauche* (G) linkages), by the orientation of these chain sequences about the chain axis (parallel or antiparallel), and by the relative directions of adjacent chains as up-up (same direction) or down-down (opposite direction). To visualize conformations along a PVDF chain (Fig. 2), a single

Figure 2. Extended chain segments of an all-*trans*, TGT \bar{G} , and TTTGTTT \bar{G} conformations.

carbon-carbon bond within one monomer unit can be projected perpendicular to the plane of the page (Fig. 3). One carbon atom (of an adjacent monomer) and two hydrogen or fluorine atoms are then connected to the front carbon atom by bonds shown as solid lines; likewise, three atoms are connected to the back carbon atoms by bonds shown as dotted lines. If the front carbon atom with its three atoms is rotated together while keeping the back atoms stationary, the steric energy of the structure changes because of repulsions between the atoms on the front and back carbons. The angle of rotation is $\varphi = 0$ when the four carbon atoms in figure all lie in the same plane. In this structure, the substituted atoms are eclipsed and engaged in strong mutual repulsion. As φ is varied to 60° , the repulsions decrease as the atoms on the front and back move away from one

Figure 3. Interactions between fluorine and hydrogen atoms on adjacent carbon atoms in PVDF polymer chains lead to changes in the potential energy as the bond connecting the carbon atoms is rotated.

another. The energy increases again and then decreases as φ reaches 120° . Finally, going to 180° , the energy reaches a minimum value. The structures at $\varphi = 60^\circ$ and 240° are referred to as *gauche* G and \bar{G} conformations. At $\varphi = 180^\circ$, the structure is in a *trans* conformation. The energy of the *trans* conformation is the lowest of all the structures as the substituent atoms are farthest apart. The energies of the two *gauche* conformations are equal and higher than the *trans* structure. When PVDF or P(VDF-TrFE) polymers crystallize during annealing, the chains pack as ordered arrays within distinct crystal structures. The structures and lattice dimensions of these crystal structures are determined by the existence of *trans* and *gauche* conformations, whose energies are governed by the number of fluorine atoms substituted on adjacent carbon atoms in the chain.

Crystal Structures

There are four major crystalline forms of PVDF (24). In form I, which is also known as the β phase, two chains in an all-*trans* planar zigzag conformation are packed into individual orthorhombic unit cells having lattice dimensions of $a = 8.58 \text{ \AA}$, $b = 4.90 \text{ \AA}$, and the chain direction or fiber axis $c = 2.56 \text{ \AA}$ (Fig. 4) (25). The space group symmetry of each unit cell in $Cm2m$. It has been suggested that a more accurate model has CF_2 groups deflected by about 7° in opposite directions in a planar zigzag conformation with a fiber axis of $2c$ or 5.12 \AA (25). It will be noted from Fig. 4 that

Figure 4. Projection of form I (β -phase) of PVDF. The conformation of the packed chains is all-*trans*. The chains are so aligned that the carbon-fluorine dipoles are in the same directions along the *b*-axis. The small and large filled circles represent carbon and fluorine atoms, respectively; the small open circles represent hydrogen atoms.

Figure 5. Projection of form II (α -phase) of PVDF. The conformation of TGT \bar{G} . The chains are packed in an antiparallel in two directions about the chain axis. The small and large filled circles represent carbon and fluorine atoms, respectively; the small open circles represent hydrogen atoms.

in the all-*trans* conformation, the fluorine atoms are positioned on one-side of the unit cell resulting in a net dipole moment. The form I unit cell is quite polar having a net dipole of 2.1 debye. As the structure of the unit cell of the form I crystal satisfies the symmetry requirement of a piezoelectric crystal, meaning that the crystal belongs to a noncentrosymmetric class, this is the form of PVDF that is responsible for its piezoelectric properties.

In form II, or the α -phase, the chain conformations are represented as a sequence of alternating *trans* and *gauche* sequences, or TGT \bar{G} (Fig. 5) (26). Each unit cell containing two chains is orthorhombic with lattice parameters $a = 4.96 \text{ \AA}$, $b = 9.64 \text{ \AA}$, and $c = 4.62 \text{ \AA}$. In the α -phase, adjacent chains are packed such that the dipole moments of the individual carbon-fluorine bonds are aligned perpendicular to the chain direction, canceling one another out. The directions of the chains consist of a statistical average of up-up and up-down orientations. A form IV (δ -phase) has been identified where the chains have the same conformations as in the α form but the carbon-fluorine bonds are aligned in one direction around the chain direction

Figure 6. A projection of form III (γ -phase) of PVDF. The chain conformation is TTTGTTT \bar{G} . The small and large filled circles represent carbon and fluorine atoms, respectively; the small open circles represent hydrogen atoms.

resulting in a net dipole (27), and the crystal lattice parameters are identical to form II. In form III (γ -phase) crystals, the chain conformations are TTTGTTT \bar{G} , and the crystal lattice is monoclinic with lattice parameters $a = 4.96 \text{ \AA}$, $b = 9.67 \text{ \AA}$, $c = 9.20 \text{ \AA}$, and $\beta = 93^\circ$ (28,29). The alignment of the form III chains perpendicular to the chain axis is in one direction, resulting in a polar cell (Fig. 6).

In the P(VDF-TrFE) copolymers, the form I and form II crystal lattices are expanded structures in the directions perpendicular to the molecular chain (Table 1). The expansion of the lattices accommodates the presence of a greater number of substituted fluorine atoms, since fluorine has a van der Waals (vdW) radius of 1.35 \AA , which is to be compared with the vdW radius of hydrogen of 1.2 \AA (31). The interchain spacing from (110,200) reflection in the form I crystal as a function of the VDF content for P(VDF-TrFE) copolymer is presented in Fig. 7 (2,32,33). In the form I

structure of copolymers, it is to be noted that the net dipole of the polar cell is reduced by the opposing orientation of the “third” carbon–fluorine dipole on the TrFE monomer unit.

There have been several studies that have attempted to use molecular modeling to simulate the crystal structures as well as mechanical properties and polarizations of PVDF and P(VDF-TrFE) crystals (34–39). The primary focus of these studies have been on developing algorithms to predict the structures and properties of PVDF and P(VDF-TrFE). For the most part, these simulations have utilized molecular mechanics force fields to calculate the crystal lattice dimensions, polarizations, and compliances, and have yielded values in close agreement with results obtained from X-ray crystallographic studies. For several model structures of P(VDF-TrFE) crystals, the increase in lattice dimensions with an increase in fluorine contents has been correctly predicted (37). For these same structures, the trends in the compliances and piezoelectric constants were calculated as a function of the molecular percentage of VDF and found to follow experimental measurements (38).

PROCESSING AND FABRICATION

There are two distinctly different ordering processes for PVDF and P(VDF-TrFE) polymers: crystalline ordering and dipolar ordering. Both orderings can be influenced to a large extent by sample processing conditions. Furthermore, one can also control the dipolar ordering by introducing defect structures in the crystalline phase. As a consequence, the ferroelectric and electromechanical responses will depend substantially on the sample treatment conditions, such as annealing, quenching, mechanical drawing, irradiation, and doping (24,39). It should be pointed out that because of the slow kinetics of the various polymer transitional processes and the high-energy barrier of the transformation between the different crystalline forms, metastable phases can be formed and be present for long periods of time even though these phases are not the most

thermodynamically favored. This phenomenon leads to the formation of different crystalline phases by making use of different sample processing conditions (24).

The eventual choice of the processing steps has much to do with the design, geometry, and size of the device that is required. In preparing PVDF or P(VDF-TrFE) films or thicker dimensions for certain applications, the synthesized polymer in the form of pellets or powder is heated to produce a melt or is dissolved in an organic solvent (40). For both PVDF and P(VDF-TrFE), these processing procedures will dictate the form that will predominate, which in turn is influenced by the energies of the crystalline forms as well as the energy barriers involved in producing these forms (41). The crystal phase that predominates during processing is also controlled by the number of fluorine atoms in the polymer chains. The increasing number of fluorine atoms enhances unfavorable van der Waals repulsive forces within the chains as well as between adjacent chains. These interactions force the energies of packed α -phase chains with TGT \bar{G} bonding, where repulsions between closely positioned fluorine atoms are enhanced, to increase significantly relative to the β -forms.

This picture helps to explain why melts of P(VDF-TrFE) crystallize directly into the electroactive polar β -phase. Not only are the crystal energies of β -phase P(VDF-TrFE) lowered, but the energy barriers to these states are reduced. In contrast, when PVDF is annealed and slowly cooled from the melt or cast from solutions of an organic solvent such as methyl ethyl ketone (MEK), formation of the α -phase rather than the β -phase is favored. Although the crystal lattice energy of the β -phase unit cell is slightly lower than that of the α -phase cell, molecular dynamical calculations have suggested that formation of the α -phase PVDF is kinetically favored; that is, the barriers for formation of the all-*trans* phase prevent crystallization directly into this phase from the melt. When films of PVDF α -phase are mechanically stretched or drawn, the TGT \bar{G} chains convert into the polar all-*trans* β -phase. This happens to be the basis for the drawing procedure followed in most commercial processes for the preparation of piezoelectric PVDF films. Quenching of melted PVDF under high pressure or casting PVDF from hexamethylphosphoric triamide solutions will also result in the direct formation of polar β -phase PVDF. Form III (γ -phase) PVDF can be produced by casting from dimethylsulfoxide. Polar form II (δ -phase) can be produced by poling α -phase PVDF in strong electric fields.

In the form I β -phase crystallites that predominate after PVDF is stretched or when the P(VDF-TrFE) copolymer is cooled from the melt, there are ferroelectric domains in crystallites that are polar but are nonetheless orientated in all crystallographically allowed directions. Furthermore, these crystallites are randomly oriented within the film. This accounts for the absence of any piezoelectric activity unless the films are poled. To be made piezoelectric, the domains must be oriented in a strong electric field called the “poling field.” Poling can be accomplished by electroding the polymer surfaces with a metal, followed by application of a strong electric field to orient the crystallites. An alternative method of poling is the use of a corona discharge where a corona charge is injected into the polymer from a needle electrode placed a centimeter or two from the

polymer film. In corona poling, no electroding is required as in the case of direct field poling.

Thus, the choice of PVDF or P(VDF-TrFE) for a specific application will in many cases be determined by the size and complexity of the desired device. P(VDF-TrFE) is normally the choice material for thick and unusual shapes in that no stretching is required to convert the polymer into its ferroelectric form prior to the poling step. Casting of polymers dissolved in organic solvents onto substrates can produce films of P(VDF-TrFE) that can be subsequently annealed. P(VDF-TrFE) can also be molded or extruded to produce larger dimensions or unusual shapes. Unlike P(VDF-TrFE) copolymers, which do not have to be mechanically drawn to induce ferroelectric β -phase, PVDF films have to be oriented by stretching in one direction (uniaxial orientation) or in two directions (biaxial orientation). Multilayering of thin polymer films is another technique for fabricating thicker elements. Multilayered and electroded polymer films that are subsequently wired in parallel have been proposed to reduce the electrical requirements for devices such as sonar drivers (7).

POLARIZATION RESPONSES AND PHASE TRANSITIONS

Phase Diagrams: An Overview

With knowledge of the major crystalline phases of PVDF and its copolymers, it is useful to review its phase diagram showing the interconversions between the various crystalline forms where the relative proportions of the monomer units are varied. The phase diagram of PVDF and P(VDF-TrFE) polymers shows a ferroelectric-paraelectric transition that signals a change from a ferroelectric (polar) phase to a paraelectric (nonpolar) phase (Fig. 8). The ferroelectric-paraelectric (F-P) transition temperature increases with vinylidene fluoride mole fraction content. Below the F-P transition, the crystal is best represented as an ordered form I (β) structure with long sequences of all-*trans* bonds. As the temperature of the crystals rises and goes through the F-P transition, an increasing number of *gauche* bonds is introduced into the ordered all-*trans* structure. As a result, the crystal lattice dimensions enlarge, as we have seen above, and the crystal regions tend toward disorder, leading to the formation of the *paraelectric* phase containing a random mixing of TG, $T\bar{G}$, TTTG, and TTT \bar{G} . Eventually, at higher temperatures the paraelectric phase passes through the melt transition.

One should note from Fig. 8 that PVDF and P(VDF-TrFE) copolymers with high VDF concentrations do not appear to possess distinct F-P transitions; rather, it appears that melting takes place before a F-P transition. However, it must be mentioned that even in the ferroelectric phase, conformational defects can be introduced as the temperature of the polymers is raised. These defects are introduced so subtly that they may not be apparent in thermal studies such as differential scanning calorimetry (DSC). Moreover, in P(VDF-TrFE), in addition to a low-temperature (LT) phase, where the chain conformation is predominantly all-*trans*, a cooled (CL) phase has been identified (38). Structural analysis indicated that the most probable structure of the so-called CL phase is a mixture of two disordered

Figure 8. Phase diagram for VDF/TrFE copolymer (x: crystal melting point, o: ferroelectric to paraelectric transition point).

crystalline phases, one trans planar and the other 3/1 helical (frozen-in high-temperature phase) (42–45). Because of this “frozen-in” disorder, copolymers with VDF contents below 50 mol% lose ferroelectricity. Accordingly, there is no clear phase transition signal as shown in the phase diagram.

Polarization Responses and Phase Transitions

In this section, we examine the ferroelectric nature of PVDF and P(VDF-TrFE) in greater detail. As ferroelectric materials, PVDF and its copolymers with TrFE and TFE exhibit well-defined polarization hysteresis loops. Figure 9(a) shows the polarization loop measured on a P(VDF-TrFE) 68/32 mol% copolymer stretched film for which, at low cyclic electric fields (<55 MV/m), the polarization loop is nearly linear with very little hysteresis. At field amplitudes exceeding 55 MV/m, a well-defined polarization loop appears. The coercive field E_c (the field when $P = 0$) and remanent polarization P_r (the polarization when $E = 0$) do not change appreciably with the applied field amplitude. In contrast, unstretched 50/50 mol% copolymer films display very little hysteresis at fields below 25 MV/m. As the field amplitude increases beyond that, the polarization loop gradually expands where both E_c and P_r increase with the applied cyclic field amplitude, as shown in Fig. 9(b). Eventually, when the field amplitude exceeds 100 MV/m, E_c and P_r , which are now saturated, define the maximum coercive field and remanent polarization. Moreover, even at fields far below E_c measured from the saturated loop, polarization often is switchable (2). Such behavior is related to the nucleation process in the polarization switching, which will be discussed below (46,47). Because of the semicrystalline nature of the polymer, the magnitudes of P_r and E_c are particularly sensitive to sample preparation conditions. For instance, Fig. 10 illustrates that both crystallinity and remanent polarization for stretched 68/32 mol% copolymer increase with the sample annealing temperature.

The crystallization process in the copolymer is also influenced by the mobility as well as the stereoirregularity of the polymer chains (48). For PVDF homopolymer, the

Figure 9. Polarization hysteresis loops measured at 10 Hz under different electric fields for unstretched (a) solution cast 68/32 mol%, and (b) 50/50 mol% extruded P(VDF-TrFE) copolymer films.

crystallinity is at about 50% (49). With increased TrFE content, because of the larger size of the TrFE monomer unit, the lattice spacing between the polymer chain expands and thus facilitates and enhances the crystallization process. Hence, in the copolymer of 75/25 mol%, the degree of crystallinity can reach 90%. In contrast, in polymer with higher TrFE content, the stereoirregularity introduced by

Figure 10. Effect of annealing temperature on the remanent polarization and crystallinity measured for extruded unstretched P(VDF-TrFE) 68/32 mol% copolymer films.

TrFE reduces the stability of the crystalline phase with respect to the amorphous and leads to a lowering of the crystallinity. The dependence of the crystallinity with VDF content is depicted in Fig. 11(a). Similarly, the dependence of the remanent polarization and coercive field on VDF content is illustrated in Fig. 11(b).

One of the interesting features of the data in Fig. 9(a) and (b) is that the coercive field observed here is far below that estimated from thermodynamic theory. In a recent experiment, S. Ducharme et al. (50) demonstrated that for P(VDF-TrFE) 70/30 mol% copolymer, the intrinsic coercive field at room temperature should exceed 0.5 GV/m, in substantial agreement with the thermodynamic theory that predicts a value about 10 times higher than that measured from the polarization hysteresis loop in bulk samples (50). The major reason for this difference is that polarization switching in most ferroelectric materials is through the nucleation of new domains at interfaces and surfaces. Nucleation and growth of nuclei under field are processes that typically require much lower electric fields (46,47). By taking the ultrathin film approach where the film thickness is below the critical nucleation size, S. Ducharme et al. achieved switching fields approaching values predicted from the thermodynamic theory by suppressing the nucleation process in polarization switching (50).

Figure 12. Polarization hysteresis loop of P(VDF-TrFE) 37/63 mol% copolymer film.

Besides the crystallinity and remanent polarization, the F–P transition temperature for a given P(VDF-TrFE) copolymer can also be varied by carefully selecting conditions for sample processing (51–53). For instance, J. Green et al. demonstrated that for P(VDF-TrFE) 60/40 mol% copolymer, the F–P transition can occur in the temperature range from 65 to 85°C (52). The sample processing methods used in this investigation included melt crystallization as well as crystallization and recrystallization from cast solutions of dimethylacetamide (DMA), dimethylformamide (DMF), cyclohexanone. The authors attributed this behavior to variations in the TrFE concentration in the crystalline phase for samples prepared under different conditions. Such variations lead to different F–P transition temperatures. But it is also quite possible that the polar ordering in the crystalline region is affected by these differing processing conditions.

Interestingly, for copolymers at compositions below about 50 mol% VDF, there is no clear transition signal with temperature, and a double polarization hysteresis loop is observed as illustrated in Fig. 12 (54,55). The latter observation seems to be quite similar to those observed in an antiferroelectric phase of a ceramic system where a ferroelectric state can be induced under a high electric field (56). It should be noted that for copolymers with VDF below 60 mol%, the cooled low (CL) temperature phase mentioned earlier was observed where the X-ray data show a double peak structure. In Fig. 13, this is near the angular position of (110,200) reflections, which are not characteristic of a ferroelectric phase (32,42,43). Structural analysis has indicated that the most probable structure of this phase is a mixture of two disordered crystalline phases, one *trans* planar and the other 3/1 helical (frozen high temperature phase) (42–45). For copolymers at VDF content higher than 50 mol%, this phase can be converted into the ferroelectric β -phase by drawing or poling (Fig. 13). However, for copolymers with VDF below 50 mol%, this CL phase will persist even after the poling field is removed, resulting in the observed double hysteresis polarization loop. It

Figure 13. X-ray diffraction scans of stretched and unstretched P(VDF-TrFE) 50/50 mol% copolymer films.

should be noted that an antiferroelectric material should satisfy two criteria: (1) it must have a unit cell with anti-parallel arrangement of the dipoles, and (2) the dipoles can be switched under external fields to yield a ferroelectric phase (46).

Ferroelectricity is a collective phenomenon that involves long-range interactions in the system that include dipolar interactions in PVDF and its copolymer. One may expect that there will be a finite size effect; that is, the ferroelectricity in a small size system can be very different from that in a large bulk system. One such system, which is of great theoretical and technical interest, embodies polymer thin films. Using spin-casting techniques, Ohigash et al. prepared P(VDF-TrFE) copolymer films and showed that even at a film of 60 nm, the ferroelectric polarization switching can still be observed, but the coercive field becomes much higher than that in bulk sample (23,57). Shown in Fig. 14 is the polarization loop measured at 10 Hz for spin cast 75/25 mol% copolymer film at 65 nm thickness.

Figure 14. Polarization hysteresis loop measured at 10 Hz for 65 nm thick spin cast P(VDF-TrFE) 75/25 mol% copolymer film.

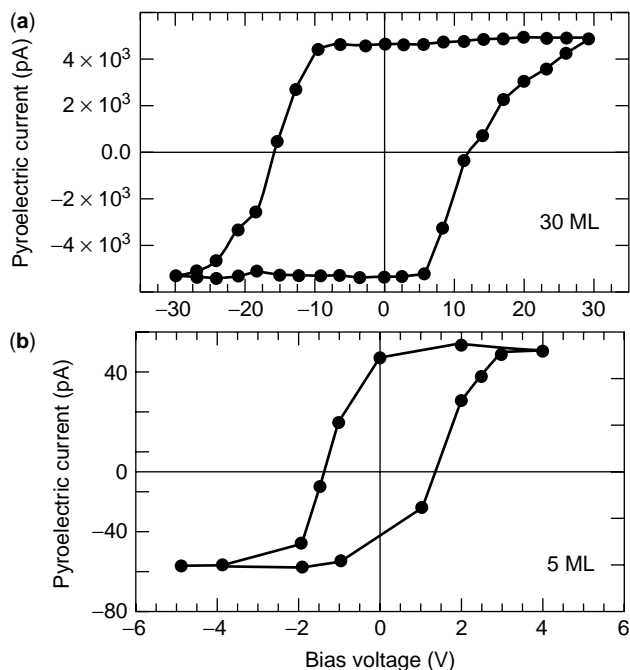

Figure 15. Polarization hysteresis loops measured at room temperature by pyroelectric technique of P(VDF-TrFE) 70/30 mol% copolymer films with different thickness: (a) 30 ML and (b) 5 ML.

More recently, ultrathin Langmuir-Blodgett (L-B) copolymer films were prepared by a Russian group (58). In this study it was shown that ferroelectricity persists even in films as thin as five molecular layers. In Fig. 15, the polarization hysteresis loops measured for these films are displayed (59). In addition, a surface ferroelectric transition was observed. The results here raise an interesting issue that concerns the role of the interchain dipolar interaction in controlling the ferroelectric behavior in this class of materials.

ELECTROMECHANICAL PROPERTIES IN NORMAL FERROELECTRIC PVDF AND ITS COPOLYMERS

In the ferroelectric phase, the copolymer is in the all-*trans* conformation, resulting in a unit cell with a large lattice constant along the polymer chain direction and a smaller unit cell dimensions perpendicular to the chain. In the paraelectric phase, however, where the crystallites adopt conformations containing a mixture of *trans* and *gauche* bonding, the unit cell dimension along the chain direction is significantly shortened while the cell dimension perpendicular to the chain expands. As a result, when the copolymer goes through the F-P transition, there is a large lattice constant change as depicted in Fig. 16 for the 65/35 mol% copolymer (31). In fact, this phenomenon has been observed for copolymers exhibiting F-P transitions. The corresponding lattice strain change through the transition perpendicular to the polymer chain is presented in Fig. 7 with VDF content. All of these results indicate that strains up to 10% can be achieved as the polymer goes through the transition.

Figure 16. Lattice strain along polymer chain direction [(001)] and perpendicular to the chain [(200), (110)] obtained from the X-ray data for P(VDF-TrFE) 65/35 mol% copolymer.

The results presented indicate a strong coupling between the polarization and strain in P(VDF-TrFE) copolymer, which is the most attractive feature of this polymer. For PVDF and its copolymers, this coupling is electrostriction in nature where the strain S_i ($i = 1$ to 6) is directly proportional to the induced polarization P_j ($j = 1$ to 3) in the material (60),

$$S_i = Q_{ij} P_j^2. \quad (1)$$

For the poled P(VDF-TrFE) copolymer, the polarization is along the 3-direction (P_3). However, in the polarization switching process, it has been observed that Eq. (1) does not adequately describe the strain-polarization relationship. This is primarily due to the fact that the polarization switching is through the domain wall motion. With this in mind, it must be stated that understanding and establishing relationships between strain and polarization in the domain wall motion continue to draw intense research interest (61). One notes, for example, the polarization switching loop for 65/35 mol% copolymer and the corresponding strain changes in Fig. 17. As can be seen, there is very little strain change as the polarization switches from *A* to *B*. Early FT-IR and X-ray studies demonstrated that the switching is primarily through successive 60° domain wall motions (62–67). Owing to the pseudo-hexagonal symmetry of the unit cell in the directions perpendicular to the polymer chain, the 60° domain wall motions are not expected to generate very high strains. Therefore, to achieve a high strain response in ferroelectric materials through the polarization switching mechanism, efforts should be expended to suppress the domain wall motions that do not generate much strain response. As also shown in Fig. 17, a linear relationship of strain versus P^2 is observed in the nonswitching part of the polarization response.

Most of the electromechanical applications that use PVDF and its copolymers exploit their piezoelectric properties. For ferroelectric PVDF and its copolymers, the samples as prepared usually have negligible piezoelectric

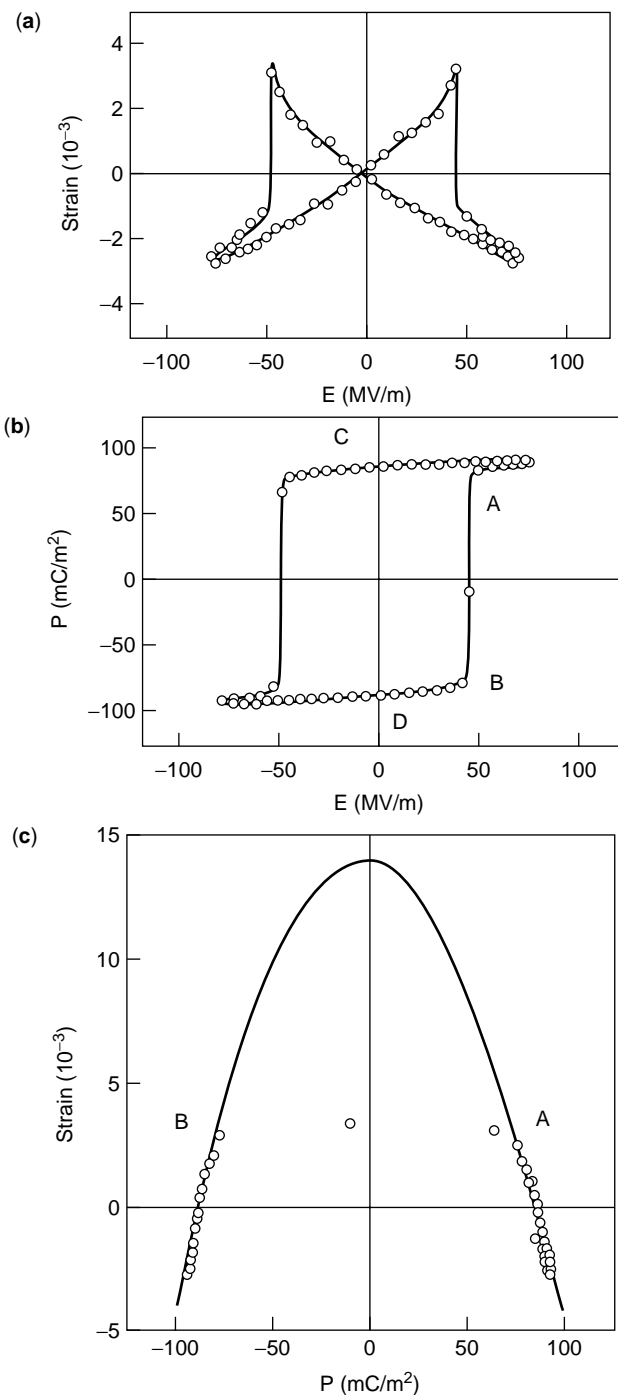

Figure 17. (a) Electric field induced strain; (b) polarization versus electric field; (c) strain versus the square of polarization of unstretched P(VDF-TrFE) 65/35 mol% copolymer films.

responses due to the fact that the polarization at each domain orientates randomly, implying that the net sample polarization is zero. In order to establish the piezoelectric state, the polymers can be poled under a field several times higher than the coercive field to induce a stable remanent polarization (at point C or D of the polarization loop in Fig. 17). For poled copolymers under a weak field (a field several times smaller than the coercive field), the strain and polarization (or field E) relationship is piezoelectric, namely a linear relationship. In addition, in the

piezoelectric state, an applied stress σ can also induce a polarization change. These responses can be written as

$$S = dE, \quad (2a)$$

$$D = d\sigma, \quad (2b)$$

where d is the piezoelectric coefficient and $D = \varepsilon_0 E + P$ is the electric displacement, ε_0 is the vacuum permittivity ($= 8.85 \times 10^{-12}$ F/m). From the Maxwell relation, it can be shown that the coefficient d in the two equations is the same. In the literature, the effect in Eq. (2a) is referred as the converse piezoelectric effect (for actuation) and in Eq. (2b) as the direct piezoelectric effect (for sensing). Adding the linear elastic (Hook's law) and dielectric relations to Eq. (2) and writing out it in the full tensor form, one obtains

$$S_{ij} = d_{kij} E_k + s_{ijkl}^E \sigma_{kl}, \quad (3a)$$

$$D_i = \varepsilon_{ik}^T E_k + d_{ikl} \sigma_{kl}, \quad (3b)$$

where s_{ijkl}^E is the elastic compliance and ε_{ik}^T is the dielectric permittivity (68,69). The superscripts E and T refer to the conditions under which these quantities are measured. That is, compliance is measured under a constant electric field and dielectric constant under a constant stress. Owing to the electromechanical coupling in a piezoelectric material, the elastic compliance under constant electric field can be quite different from that under constant charge. Using a compressed matrix (Voigt notation), Eq. (3) can be simplified and ij or kl is replaced by p or q as

$$\begin{aligned} 11 \rightarrow 1, \quad 22 \rightarrow 2, \quad 33 \rightarrow 3, \quad 23 \text{ or } 32 \rightarrow 4, \\ 31 \text{ or } 13 \rightarrow 5, \quad \text{and} \quad 12 \text{ or } 21 \rightarrow 6. \end{aligned}$$

Equation (3) is the complete constitutive equation for a piezoelectric material. In view of the symmetry relations that apply for specific piezoelectric materials, the number of independent coefficients in the equation can be reduced. For example, for an unstretched and poled piezoelectric P(VDF-TrFE) copolymer, which possesses a point group symmetry ∞m , the piezoelectric coefficient, the dielectric permittivity, and elastic compliance matrices are (68)

$$\begin{pmatrix} 0 & 0 & 0 & 0 & d_{15} & 0 \\ 0 & 0 & 0 & d_{15} & 0 & 0 \\ d_{31} & d_{31} & d_{33} & 0 & 0 & 0 \end{pmatrix}, \begin{pmatrix} K_{11} & 0 & 0 \\ 0 & K_{11} & 0 \\ 0 & 0 & K_{33} \end{pmatrix},$$

$$\begin{pmatrix} s_{11} & s_{12} & s_{13} & 0 & 0 & 0 \\ s_{12} & s_{11} & s_{13} & 0 & 0 & 0 \\ s_{13} & s_{13} & s_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & s_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & s_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & s_{66} [= 2(s_{11} - s_{12})] \end{pmatrix}. \quad (4)$$

In many cases, processing conditions such as extrusion and stretching can induce anisotropy (preferred orientation of the polymer chain along the stretching or extrusion direction) in the plane perpendicular to the poling direction. As a consequence, the macroscopic symmetry of the

poled polymer is 2 mm, for which the nonzero matrix elements of the piezoelectric constitutive equation can be written as (68)

$$\begin{pmatrix} 0 & 0 & 0 & 0 & d_{15} & 0 \\ 0 & 0 & 0 & d_{24} & 0 & 0 \\ d_{31} & d_{32} & d_{33} & 0 & 0 & 0 \end{pmatrix}, \begin{pmatrix} K_{11} & 0 & 0 \\ 0 & K_{22} & 0 \\ 0 & 0 & K_{33} \end{pmatrix}, \begin{pmatrix} s_{11} & s_{12} & s_{13} & 0 & 0 & 0 \\ s_{12} & s_{22} & s_{23} & 0 & 0 & 0 \\ s_{13} & s_{23} & s_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & s_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & s_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & s_{66} \end{pmatrix}. \quad (5)$$

For electromechanical application, the electromechanical coupling factor k , which measures the ability of a material to interconvert electrical and mechanical energy, is one of the fundamental parameters (69),

$$k^2 = \frac{\text{Converted mechanical energy}}{\text{Input electric energy}} \quad (6a)$$

or

$$k^2 = \frac{\text{Converted electrical energy}}{\text{Input mechanic energy}}. \quad (6b)$$

It should be noted that in electromechanical applications, an electric field is applied along a certain direction, Eq. (3), and the electromechanical actuation along the same direction or other direction is used. For example, if a polymer actuator can be made with the electric field along the 3-direction, Eq. (3), the actuation along the same direction is used. In this case, the coupling factor is the longitudinal electromechanical coupling factor k_{33} , which is related to the parameters in Eq. (3) as (69)

$$k_{33}^2 = \frac{d_{33}^2}{(\epsilon_{33}^T s_{33}^E)} \quad (7)$$

The coupling factor can also be related to the material coefficient measured under different conditions. For example, the elastic compliance s_{33}^E is related to s_{33}^D (measured under constant charge or an open circuit condition) as (69)

$$s_{33}^D = (1 - k_{33}^2) s_{33}^E \quad (8)$$

Therefore, a polymer with a large coupling factor will see a large difference in the elastic compliance when used under different external electric conditions.

The quasi-static and resonance methods are among several techniques recommended by IEEE to determine the coefficients in the piezoelectric constitutive equations as well as the coupling factors (69). For determining piezoelectric coefficients, a convenient means is to use the dilatometer technique where the strain change induced by an applied electric field under stress-free conditions can be measured, and the ratio of the strain to field yields the piezoelectric coefficient (70). A stress signal σ can also be applied to a sample. In this case, the charge output Q between the electrodes, which are shorted together, is measured to obtain the piezoelectric coefficient (71). One of the difficulties with the latter method is applying a uniaxial

stress uniformly to a sample without introducing other complications such as stress components along other directions. To obtain accurate results using the stress-induced charge method, one may also have to take into account the deformation of the sample under stress. This is accomplished by introducing a correction term to the piezoelectric coefficient as pointed out by Dvey-Aharon and Taylor (72),

$$d = \frac{\partial P}{\partial \sigma} \Big|_E = \frac{1}{A} \frac{\partial Q}{\partial \sigma} - \frac{P}{A} \frac{\partial A}{\partial \sigma} \quad (9)$$

where A is the sample surface area. For PVDF and its copolymers at room temperature, it can be estimated that the contribution from the deformation is less than 10%. For a soft piezoelectric polymer, this correction term can be quite high. On the other hand, when comparing the measured results from the converse and direct piezoelectric effects, it can be shown from the Maxwell relation that (73,74)

$$\frac{1}{A} \frac{\partial Q}{\partial \sigma} \Big|_E = \frac{\partial S}{\partial E} \Big|_\sigma \quad (10)$$

Various coefficients in the piezoelectric constitutive equation for PVDF and P(VDF-TrFE) 75/25 copolymer are listed in Table 2, where the data are taken from several sources (70,75). In most polymers, the response to external stimulus often shows strong relaxation behavior (76); hence, the coefficients in the piezoelectric constitutive equation are frequency dependent and complex, that is (77).

$$d_{ij}^* = d'_{ij} - jd''_{ij}, \quad s_{ij}^* = s'_{ij} - js''_{ij}, \quad \text{and} \quad \epsilon_{ij}^* = \epsilon'_{ij} - j\epsilon''_{ij}. \quad (11)$$

In Table 2, both the real and imaginary parts of these coefficients for P(VDF-TrFE) 75/25 mol% copolymer are listed. Apparently, the imaginary part for the copolymer cannot be neglected.

The temperature dependence of the piezoelectric and dielectric constant of 75/25 copolymer is presented in Fig. 18 and 19. Such temperature dependence behavior, where the piezoelectric coefficient and dielectric constant

increase as the temperature is increased toward the F-P transition temperature, is a common phenomenon for all ferroelectric-based piezoelectric materials including many commercially available piezoceramics (47,78,79).

In semicrystalline copolymers, the piezoelectric properties can often be improved by raising the degree of crystallinity, given that the piezoelectric response is mainly from the crystalline region. For example, using high-pressure crystallization to increase the crystallinity and improve the quality of the crystalline phase, Ohigashi et al. reported an improved thickness coupling factor for 80/20 copolymer to near 0.3 ($k_t = 0.3$) (80). More recently, a

dielectric and piezoelectric properties and the electro-mechanical coupling factors for a copolymer single crystal.

RELAXOR FERROELECTRIC BEHAVIOR AND ELECTROSTRICTIVE RESPONSE IN P(VDF-TrFE) BASED COPOLYMERS

In addition to operating a ferroelectric polymer deep inside the ferroelectric phase (at temperatures far below the F–P transition temperature) where the piezoelectric response is the main source of the electromechanical response, one could also make use of the phase transition phenomenon where large changes in the properties can be realized. As has been shown above, the lattice strains in P(VDF-TrFE) copolymers experience large changes through the F–P transition, changes which far surpass those achievable from the piezoelectric effect. Besides the large strain response at F–P transition, there is another interesting feature associated with the F–P transition—the possibility that a very large electromechanical coupling factor ($k \sim 1$) can be obtained near a first-order F–P transition temperature (82).

Above the F–P transition temperature, a ferroelectric state can be induced by imposing an external field as schematically depicted in Fig. 23 (78,82). The first-order field-induced transition region terminates at a critical point. As shown by an earlier study based on thermodynamic theory, the coupling factor can approach 1 (near 100% energy conversion efficiency) at temperatures above the first-order transition and near the critical point (82). This is a general result for first-order F–P phase transformations despite the fact that the curves in Fig. 23 are from the parameters applicable to BaTiO_3 . For P(VDF-TrFE) copolymers, it has been shown that at compositions with VDF content $>60\%$ mol% the F–P transition is first order. Still the temperature range in which the electric field can induce the phase transition from nonpolar to polar phases depends strongly on the material. For most of the inorganic ferroelectrics, this temperature range is relatively narrow. For instance, the range is about 8°C for BaTiO_3 (as approximately measured by the temperature range between F–P transition and critical temperature) (47). For P(VDF-TrFE) copolymers, however, it has been reported that this temperature range exceeds 50°C as reported by a recent study on Langmuir-Blodgett film of P(VDF-TrFE) 70/30 mol% (83).

These results suggest that one may be able to improve the electromechanical response of P(VDF-TrFE) copolymer significantly by operating the polymer near the F–P transition. However, there are several issues associated with the first-order F–P transition in P(VDF-TrFE) copolymer that have to be addressed. As has been shown in the phase diagram (Fig. 5), the F–P transition in all P(VDF-TrFE) compositions occurs at temperatures higher than room temperature. The transition is also relatively sharp (over a relatively narrow temperature range). In addition, undesirably large hysteresis has been observed for the copolymers at the first order F–P transition. Therefore to make use of the unique opportunities near the first-order F–P transition in P(VDF-TrFE) copolymer systems, the copolymer should be modified as to broaden the phase transition

Figure 23. (a) Schematic of polarization as a function of temperature for a first-order ferroelectric-paraelectric transition under different dc bias field. The first-order polar to nonpolar transition terminates at a critical point. (b) electromechanical coupling coefficient (k_{33}) as a function of temperature under different dc bias field near a first-order F-P phase transition. The results are derived based on Landau-Devonshire theory using the parameter obtained on BaTiO₃.

region as well as to move it to room temperature while minimizing hysteresis.

To modify the phase transition behavior in P(VDF-TrFE) copolymer, one approach is to make use of high-energy irradiation. This has been demonstrated in several earlier studies. For example, Lovinger found that high-energy electron irradiation can convert the ferroelectric phase at room temperature to resemble a macroscopically paraelectric phase (84). Subsequently, Odajima et al. and Daudin et al. found that the sharp dielectric constant peak from the F-P transition can be broadened markedly and moved to near room temperature by irradiation (85,86). More recently, Zhang et al. showed that by high-energy electron irradiation, the normal ferroelectric P(VDF-TrFE) copolymers can be converted into a relaxor ferroelectric with high electrostrictive strains (87–90).

Figure 24 compares the polarization loops of P(VDF-TrFE) 50/50 mol% copolymer before and after irradiation (40 Mrad of 2.5 MeV electrons at 120°C). As shown, the irradiation effectively eliminates the room temperature polarization hysteresis. The dielectric data of the irradiated copolymer are presented in Fig. 25, where clearly the broad room temperature peak moves to higher temperature as the measuring frequency increases. In addition, it

Figure 24. Polarization hysteresis loop of P(VDF-TrFE) 50/50 mol% copolymer film measured at room temperature (a) before and (b) after irradiation with electrons of 2.5 MeV energy for 40 Mrad dose at 120°C.

Figure 25. The dielectric constant (solid lines) and dielectric loss (dashed lines) as a function of temperature of P(VDF-TrFE) 50/50 mol% copolymer films irradiated with 40 Mrad dose at 120°C using 2.55 MeV electrons. The inset shows the fitting of the Vogel-Fulcher law. Here the solid line is the fit and the circles are the data points.

Figure 26. Gradual increase in remanent polarization and hysteresis with lowering the temperature measured for P(VDF-TrFE) 50/50 mol% copolymer films irradiated with 40 Mrad dose at 120°C using 2.55 MeV electrons.

was found that the peak temperature T_m is related to the frequency f by the Vogel-Folcher (V-F) relation, as shown in the insert of Fig. 25,

$$f = f_0 \exp\left(\frac{-U}{k(T_m - T_f)}\right), \quad (12)$$

where T_f can be regarded as a freezing temperature of the system (91).

Polarization loop measurements also reveal that as the temperature is lowered, the irradiated copolymer shows a gradual increase of the polarization hysteresis, Fig. 26. Figure 27 compares the remanent polarization for the copolymer before and after irradiation. Evidently, P_r changes with temperature rather gradually after the irradiation. The peak of the derivative of P_r with respect to temperature is very close to T_f from the V-F law fitting (305 K

Figure 27. Comparison of change in remanent polarization (P_r) with temperature for P(VDF-TrFE) 50/50 mol% copolymer films before (dashed lines) and after (solid line) irradiating with 2.5 MeV electrons for 40 Mrad dose at 120°C.

versus $T_f = 307$ K). This result suggests a dipolar freezing process in the material. All of these features are reminiscent of those observed in ceramic $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$, which is the best-known relaxor ferroelectric in inorganic systems (92,93). Since the polarization response in P(VDF-TrFE) copolymer is from the dipoles, the irradiated copolymer should be an interesting system to study the relaxor ferroelectric behavior in a dipolar system.

The irradiated copolymer has been shown to possess a high electrostrictive strain. Figure 28(a) shows the longitudinal strain (S_3) for the copolymer 68/32 mol% after irradiation: a strain of -5% is achieved under a field of 150 MV/m (94). The plot of S_3 versus P^2 yields a straight line, indicating the response is electrostrictive in nature, $S_3 = Q_{33}P_3^2$, Fig. 28(b). For the irradiated copolymer, Q_{33} is found in the range between -4 to $-15 \text{ m}^4/\text{C}^2$, depending on the sample processing conditions. The strain response does not change appreciably with temperature as suggested by the plot in Fig. 28(c).

Of special interest is the finding that in P(VDF-TrFE) copolymers, large anisotropy in the strain responses exists along and perpendicular to the chain direction, as can be deduced from the change in the lattice parameters between the polar and nonpolar phases. Therefore, the transverse strain can be tuned over a large range by varying the film processing conditions (95,96). For unstretched films, the transverse strain is relatively small ($\sim +1\%$ level at ~ 100 MV/m), while the amplitude ratio between the transverse strain and longitudinal strain is less than 0.33. This feature is attractive for devices utilizing the longitudinal strain such as ultrasonic transducers in the thickness mode, and actuators and sensors making use of the longitudinal electromechanical responses of the material. For example, with a very weak transverse electromechanical response in comparison with the longitudinal, one can significantly reduce the influence of the lateral modes on the thickness resonance and improve the performance of the thickness transducer. On the other hand, for stretched films, a large transverse strain (S_1) along the stretching direction can be achieved as shown in Fig. 29, where the transverse strain about $+3.5\%$, as observed in the irradiated copolymer under an electric field of 110 MV/m. It is also found that for stretched films, the amplitude of the transverse strain along the stretching direction is comparable to the longitudinal strain, while the amplitude of the transverse strain in direction perpendicular to the stretching direction (S_2) is much less ($\sim 1\%$ at 100 MV/m).

It is also of interest that the strain along the thickness direction (parallel to the electric field) is always negative for P(VDF-TrFE) copolymers regardless of the sample processing conditions. In fact, this is a general feature for a system in which the polarization response originates from the dipolar interaction and is true for all polymeric piezoelectric and electrostrictive responses (97,98). The sign of the strains perpendicular to the applied field direction will depend on the sample processing conditions. For the anisotropically stretched films discussed here, the electric induced strain along the stretching direction, which is perpendicular to the applied field, is positive, whereas in the direction perpendicular to both stretching and applied field directions, the strain is negative. For unstretched samples

Figure 28. (a) Electric field induced strain along the thickness direction (longitudinal strain, S_3) versus electric field measured at room temperature and 1 Hz, (b) change in longitudinal strain (S_3) with square of polarization (P), and (c) temperature dependence of longitudinal strain induced under 14 MV/m and 1 Hz driving electric field, of unstretched P(VDF-TrFE) 68/32 mol% copolymer films irradiated at 105 $^{\circ}\text{C}$ with 70 Mrad dose using 1 MeV electrons.

Figure 29. Transverse strain along the stretching direction (S_1) as a function of driving electric field at different temperatures measured for stretched P(VDF-TrFE) 68/32 mol% copolymer films irradiated at 100 $^{\circ}\text{C}$ with 70 Mrad dose using 1.2 MeV electrons.

that are isotropic in the plane perpendicular to the applied field, the strain component in the plane is an average of the strains along the chain (positive) and perpendicular to the chain (negative) and is in general positive.

For electrostrictive materials, the electromechanical coupling factor (k_{ij}) has been derived by Hom et al. based on the consideration of electrical and mechanical energies generated in the material under external field (99):

$$k_{3j}^2 = \frac{kS_j^2}{s_{ij}^D \left[P_E \ln \left(\frac{P_S + P_E}{P_S - P_E} \right) + P_S \ln \left(1 - \left(\frac{P_E}{P_S} \right)^2 \right) \right]}, \quad (13)$$

where $j = 1$ or 3 correspond to the transverse or longitudinal direction (e.g., k_{31} , is the transverse coupling factor) and s_{ij}^D is the elastic compliance under constant polarization, S_j and P_E are the strain and polarization responses, respectively, for the material under an electric field of E . The coupling factor depends on E , the electric field level. In Eq. (13), it is assumed that the polarization-field (P - E) relationship follows approximately

$$|P_E| = P_S \tanh(k|E|), \quad (14)$$

where P_S is the saturation polarization and k is a constant. It is found that Eq. (14) describes the P - E relationship of the irradiated copolymers studied here quite well (94).

The electromechanical coupling factors for the irradiated copolymers have been determined based on the data on the field-induced strain, the elastic modulus (Fig. 30), and polarization. Presented in Fig. 31 are k_{33} for the unstretched sample and k_{31} for the stretched sample along the drawing direction. Near room temperature and under an electric field of 80 MV/m, k_{33} can reach more than 0.3, which is comparable to that obtained in a single-crystal P(VDF-TrFE) copolymer (81). More interestingly, k_{31} of 0.45 can be obtained in a stretched copolymer, which is

Figure 30. Temperature dependence of elastic modulus measured along the stretching direction for stretched P(VDF-TrFE) 68/32 mol% copolymer films irradiated at 100°C with 70 Mrad dose using 1.2 MeV electrons.

Figure 31. Dependence of electromechanical coupling coefficients on the applied electric field: (a) k_{33} for extruded unstretched P(VDF-TrFE) 68/32 mol% copolymer films irradiated at 105°C with 70 Mrad dose using 1 MeV electrons and (b) k_{31} for stretched P(VDF-TrFE) 68/32 mol% copolymer films irradiated with 70 Mrad dose using 1.2 MeV electrons at 100°C.

Figure 32. Effect of (a) tensile stress on transverse strains (S_1) for stretched film and (b) hydrostatic pressure on longitudinal strain (S_3) for unstretched film at room temperature under different driving electric fields. much higher than values measured in unirradiated P(VDF-TrFE) copolymers.

For a polymer, there is always a concern about the electromechanical response under high mechanical load; that is, whether the material can maintain high strain levels when subject to high external stresses. Figure 32(a) depicts the transverse strain of stretched and irradiated 65/35 copolymer under a tensile stress along the stretching direction and the longitudinal strain of unstretched and irradiated 65/35 copolymer under hydrostatic pressure (100,101). As can be seen from the figure, under a constant electric field, the transverse strain increases initially with the load and reaches a maximum at the tensile stress of about 20 MPa. Upon a further increase of the load, the field-induced strain is reduced. One important feature revealed by the data is that even under a tensile stress of 45 MPa, the strain generated is still nearly the same as

that without load, indicating that the material has a very high load capability. Shown in Fig. 32(b) is the longitudinal strain under hydrostatic pressure. At low electric fields, the strain does not change much with pressure, while at high fields it shows increase with pressure.

The results demonstrate that the electrostrictive P(VDF-TrFE) copolymer has a relatively high load capability. The observed change in the strain with load can be understood based on the consideration of the electrostrictive coupling in this relaxor ferroelectric material as has been considered and discussed in (100,101).

CONCLUDING REMARKS

A large number of studies are concerned with the electromechanical properties of PVDF and P(VDF-TrFE) polymers, including both the piezoelectric responses from polymers with semicrystalline and single-crystal forms and electrostrictive responses from the newly developed high-energy irradiated copolymers. This article has consolidated these studies and emphasized the different polarization responses in ferroelectric polymers such as polarization switching, phase transformation, and pure dielectric response. Optimizing the electromechanical responses from each type of polarization responses is a fruitful area of research. By proper polymer engineering, the electromechanical properties can be improved substantially as demonstrated in the high-energy irradiated copolymers.

The discussion has included the syntheses, stereochemistry, and major crystal structures as well as their interesting morphologies, phase diagrams and phase transitions. From a practical perspective, it should be quite evident that knowledge of their macromolecular properties and structures is quite desirable to successfully exploit their piezoelectric and electrostrictive properties. In particular, the molecular conformation, crystal structures, and polymer morphology can be controlled at the molecular and mesoscopic levels, and this can be accomplished by varying the composition and electroprocessing conditions, as well as utilizing defect modification. As a result, the properties of PVDF and its copolymer depend substantially on these conditions. Although traditional PVDF and the P(VDF-TrFE) polymers have been used in the piezoelectric mode, recent evidence was presented that demonstrates a remarkable enhancement in the strain of P(VDF-TrFE) films after exposure to high-energy irradiation, which involves electrostriction. Further study in this direction is certainly merited if only to identify alternative techniques to generate electrostrictive polymer films and other avenues to achieve high electromechanical effects.

POLYMER BLENDS, FUNCTIONALLY GRADED

YASUYUKI AGARI

Osaka Municipal Technical Research Institute

Joto-ku

Osaka, Japan

INTRODUCTION

Many reports have been published on functionally graded materials made of metals and ceramics (1). These graded materials have improved strength against thermal stress, electromagnetic, and optical properties. There have been particularly many reports on a functionally graded ceramic, which can be called a smart material. In this ceramic, the area of strong thermoelectric performance shifted with increasing temperature. Then, thermoelectric performance can be kept high across a wide temperature gradient.

There have been some reports on functionally graded polymeric materials (2–38). These functionally graded polymeric materials can be classified into four types based on the materials used, as shown in Table 1. Then, graded structures may be classified into six groups. However, reports on functionally graded polymer blends are few (4–9,14–25), although studies have been published on various types of blends. A functionally graded polymer blend has the structure shown in Fig. 1. The blend has two

different surfaces without an interface and can have both the advantages of a laminate and a homogenous blend.

Thus, we devised a new method, the dissolution–diffusion method for preparing functionally graded polymer blends (4–9,24,25). Here, graded polymer blends are classified into two types, and they were prepared by three methods except for our method, surface inclination in the melt state (14,15), surface inclination in solution (16,17), and diffusion in melt (19–23). The dissolution–diffusion method devised by us is only one method that can be used for preparing both types of graded polymer blends. Our method has the following advantages compared with other methods. The preparative time in our method is very short, 100 times shorter than the “diffusion in melt state” method. The optimum conditions can be easily determined because our method has many controllable factors. Further, chemical decomposition of molecules does not occur in preparation because the preparation is at a lower temperature. Therefore, our method is considered very useful.

In this report, I give a detailed description of the preparative mechanism for functionally graded polymer blends in the dissolution–diffusion method. Then, I explain how I determined the optimum conditions for the several types of functionally graded polymer blends, polyvinyl chloride (PVC)/(polymethyl methacrylate (PMMA), polyhexyl methacrylate (PHMA), or polycaprolactone (PCL), and bisphenol A type polycarbonate (PC)/polystyrene (PS), in characterizing graded structures of the blends by measuring FTIR spectra, Raman

microscopic spectra, thermal behaviors around the glass transition temperature (T_g) by the DSC method or by SEM-EDX (Scanning Electro Microscopy-Energy Dispersive X-ray Spectrometer) observation. Further, several types of functional properties, especially smart performance, are discussed, which result from the graded structure. Finally, the prospects of functionally graded polymer blends for applications are discussed.

MECHANISM OF DIFFUSION-DISSOLUTION METHOD

The mechanism of forming a graded structure is as follows. After a polymer B solution is poured on a polymer A film in a glass petri dish, polymer A begins to dissolve and diffuse in the solution to the air side (Fig. 2), but the diffusion is interrupted when all of the solvent evaporates. Thus, a blend film is produced that consists of a concentration gradient of polymer A/polymer B in the thickness direction.

Based on the steps of dissolution and diffusion of polymer A, the graded structures can be classified into three types (Fig. 3).

First Type. Polymer A begins to dissolve and then diffuses but does not yet reach the air side surface of the polymer B solution. The blend has three phases (polymer A, polymer B, and a thin graded structure).

Second Type. Just when all polymer A has finished dissolving, the diffusion frontier reaches to the air side surface of polymer B solution. The blend has one graded phase from

Figure 2. Schematic model of dissolution-diffusion method.

the surface to the other, and those surfaces are composed of polymer A only or polymer B only.

Third Type. After the dissolution and diffusion of polymer A reaches the air side surface of the polymer B solution, polymer A and polymer B molecules begin to mix with each other and become miscible. The concentration gradient begins to disappear.

The Formation of a concentration gradient depends on (1) the dissolution rate of polymer A in the polymer B solution, (2) the diffusion rate of polymer A in the polymer B solution, and (3) the interrupted time of the diffusion due to the completion of solvent evaporation. The factors that control these phenomena are (1) the type of solvent, (2) the casting temperature, (3) the molecular weight of polymer A, and (4) the amount of polymer B solution.

Until polymer A completely dissolves or reaches the surface of the polymer B solution in the formation of the first and second types of structure, the diffusion of polymer A in

Figure 3. Schematic models of various types of graded structures.

Figure 4. The change in PVC content in the thickness direction of PVC/PMMA graded blends.

the polymer B solution is considered to obey Fick's second law (Eq. 1) by assuming that the evaporation of the solvent from the polymer B solution can be neglected during diffusion:

$$\frac{\partial C_A}{\partial t} = D_{AB} \cdot \left(\frac{\partial^2 C_A}{\partial x^2} \right), \quad (1)$$

where C_A is the concentration of polymer A, t is time passed, x is the distance from the surface of the polymer A sheet, and D_{AB} is an apparent diffusion coefficient.

The point where C_A becomes one shifts to the petri glass side, as the dissolution of polymer A proceeds. Thus, by considering this effect and rearranging mathematically, Eq. (2), is obtained from Eq. (1):

$$C_A = \operatorname{erfc} \left(\frac{(x-b)}{2\sqrt{D_{AB}t}} \right), \quad (2)$$

$$\operatorname{erfc}(x) = \left(\frac{2}{\sqrt{\pi}} \right) \int_x^\infty \exp(-\xi^2) d\xi,$$

where b is the distance between the petri glass surface and the other side of the remainder of polymer A, which has not yet dissolved. Therefore, the gradient profile in the blend at t can be estimated from Eq. (2).

The fit of Eq. (2) to the experimental data was examined for the PVC/PMMA graded blend, and this is explained in detail in the next paragraph. The experimental data agreed approximately with the values predicted by Eq. (2), as shown in Fig. 4. D_{AB} and b were obtained as $6.38 \mu\text{m}^2/\text{s}$ and $57 \mu\text{m}$, respectively. The D_{AB} was much larger than the value in the "diffusion in melt state," and this means that this dissolution-diffusion method is very useful.

Further, a thicker and more excellently graded blend film can be prepared by the multiple step method, as illustrated in Fig. 5. Here, the graded blend was obtained by repeatedly changing the composition of the blend in the poured solution.

Figure 5. Schematic models of multiple step methods.

PREPARATION AND CHARACTERIZATION OF SEVERAL TYPES OF FUNCTIONALLY GRADED POLYMER BLENDS

Amorphous Polymer/Amorphous Polymer Miscible Blends

In the PVC/PMMA system (6,7), we prepared samples by changing the four controllable conditions: (1) the type of solvent, (2) the casting temperature, (3) the molecular weight of the PVC, and (4) the amount of the PMMA solution) and characterized the graded structures of the samples by FTIR-ATR, Raman microscopic spectroscopy, and DSC methods. Figure 6 shows the graded structure of the samples in the direction of thickness, measured by FTIR-ATR. In a similar blend that had graded structure 1, on a laminate, the PMMA content increased at 60% of the distance/thickness, and it was confirmed that it has a thin graded layer (about 10–20% of the distance/thickness). Then, in the blend of graded structure 3, the PMMA content was kept at about 50% in the entire range. However, in the blend of graded structure 2, the PMMA content gradually increased in the range from 0–100% of the distance/thickness. Thus, it was found that this blend had an excellently wide concentration gradient. Here, the PMMA content was estimated from the ratios of the absorption band intensities at 1728 cm^{-1} (stretching of the carbonyl group in PMMA) and 615 cm^{-1} (stretching of C–Cl bond in PVC). The change in PMMA content in the thickness direction of the blend film was estimated by measuring FTIR-ATR spectra on a sliced layer of the blend film.

The change in PVC content of the graded blend can be characterized by Raman microscopic spectroscopy method, similarly to the FTIR-ATR method, as shown in Fig. 4. Raman microscopic spectra were measured at the focused point, which was shifted by $10\text{ }\mu\text{m}$ from one surface area to the other. It was confirmed that the blend had a comparatively thick layer of a graded structure phase. This method is considered significantly useful because an easy and detailed estimate can be made for the graded profile of a blend.

Further, the graded structure was characterized by the DSC method. The DSC curve of the blend that has a widely graded structure (graded structure 2), shows more gradual steps around T_g than the others (Fig. 7). Similarly,

Figure 6. The change in PMMA content in the thickness direction of several types of PVC/PMMA graded blends.

Figure 7. The DSC curves of several types of PVC/PMMA blends.

the structures of the samples, which were prepared under several types of conditions were investigated, and the optimum conditions (molecular weight of PVC: $M_n = 35600$, MW = 60400; type of solvent: THF/toluene(5/1); volume of solvent: 0.23 mL/cm^2 ; temperature: 333K) were determined.

In the PVC/PHMA system (7), the graded structure of the sample could not be estimated by the FTIR-ATR and DSC methods, because PHMA was very soft at room temperature. Thus, the graded structure was measured by the SEM-EDX method (Fig. 8). The chlorine content in the sample increased gradually to the petri glass side, and then it was confirmed that it has a widely graded structure.

Further, the structures of the samples, which were prepared under several types of conditions were investigated, and the optimum conditions (molecular weight of PVC: $M_n = 35600$, MW = 60400; type of solvent: MEK; volume of solvent: 0.37 mL/cm^2 ; temperature: 313K) were determined.

Amorphous Polymer/Crystalline Polymer Miscible Blends

In the PVC/PCL system (25), we obtained the optimum conditions for preparing a graded polymer blend that had a wider compositional gradient, similar to that of

Figure 8. Chlorine content along the thickness of a PVC/PHMA graded blend (X 750, —; $20\text{ }\mu\text{m}$).

Figure 9. Graded structure of PVC/PCL graded blends.

the PVC/PMMA system. Figure 9 shows the PVC content of the samples in the direction of thickness, measured by the FTIR-ATR method. PVC began to decrease at about 70 μm from the petri glass side and decreased gradually until the surface of the air side, that is, about 240 μm away from the petri glass side in both solution volumes.

Then, the change of T_g in the thickness direction of the blend film was characterized by the DSC method (Fig. 10) for 0.364 mL/cm² of solution volume. T_g decreased at increasing distance from the petri glass side, similar to the PVC content. Thus, the graded structure in PVC content was confirmed by the graded profile in T_g .

Further, the change in PCL crystalline content was determined from the amount of heat diffusion of crystalline PCL, measured by the DSC method. The heat diffusion began to increase, after it was kept at zero until about 130 μm of the distance. Then, it increased immediately at about 180 μm . Thus, it was found that a graded structure in crystalline PCL was formed in the range from 130–240 μm of the distance. This means that the graded PVC/PCL blend obtained had both a gradient concentration of PVC and a gradient content of crystalline PCL, as shown in Fig. 11. The PCL content was about 30% at about 130 μm of the distance. This result indicates that crystalline PCL in the homogeneous PVC/PCL blend emerged at concentrations of more than 30% PCL (39). Then, it was concluded that the amorphous phase was made of a miscible amorphous

Figure 10. Graded structure of PVC/PCL graded blends (\bullet , T_g ; \circ , PVC content).

Figure 11. Graded structure of PVC/PCL graded blends (\bullet , PVC content; \circ , heat of diffusion).

PVC/amorphous PCL blend. Further, the PCL crystalline phase decreased again coming closer to the surface of the air side. It is thought that this phenomenon occurs because the formation of the amorphous phase is more thermodynamically stable than that of the crystalline phase. Therefore, it was believed that the graded structure of the PVC/PCL graded blend is as schematically illustrated in Fig. 12.

Amorphous Polymer/Amorphous Polymer Immiscible Blends

We attempted to prepare a graded PC/PS blend by the dissolution–diffusion method (24), similar to the PVC/PMMA system. In this case, PS solution was poured on PC film. However, we did not obtain a graded structure, but we did obtain a system of two homogeneous layers which were composed of about 50% and 0–10% PC, as shown in Fig. 13. Then, macrophase separation was observed in the former layer. It is believed that this results because of only three factors, the dissolution rate, diffusion rate, and evaporation time affect the process of forming a graded structure of a miscible blend. However, in forming a graded structure of an immiscible blend, three new factors, macrophase separation, surface inclination, and gravimetry, in addition to the former factors may significantly affect the process, as shown in Fig. 14. It is especially considered

Figure 12. Schematic model of PC/PS graded blend.

Figure 13. Graded structure of PC/PS graded blends with or without PS-b-PC block copolymer.

that macrophase separation may break a strongly graded structure on the way to formation, because it is concentrated by evaporation of solvent.

Thus, we attempted to protect the formation process of the graded structure from macrophase separation by adding a PS-b-PC copolymer (40) to the PS solution (PS-b-PC copolymer/PS = 1/9). Here, the PC segment content in the block copolymer was 46% (NMR measurement). It was found that the widely graded structure obtained in the

Figure 14. The other factors that affect the formation of a graded structure in an immiscible blend.

Figure 15. Graded structure of PC/PS graded blends when PC solution was poured on a PS film.

PC/PS blend was formed in the distance range of 0–100 μm from the petri glass side (Fig. 13).

Furthermore, we attempted to prepare a graded PC/PS blend by pouring a PC solution containing the block copolymer on the PS film. Figure 15 shows the change in PC content in the direction of the film thickness. The formation of a widely graded structure was confirmed at a long far distance from, and also, close to the petri glass side. This result was considered to mean that factor of surface inclination significantly influenced the formation of a graded structure.

Therefore, the graded immiscible PC/PS blend was obtained by adding a PC-b-PS copolymer. It is believed that the graded structure of the PC/PS graded blend is as schematically illustrated in Fig. 16.

FUNCTIONAL AND SMART PERFORMANCES AND THE PROSPECT FOR APPLICATION

Functional and Smart Performance

It was found in our study (6,7) that graded polymer blends had several types of functional properties, including smart performance. Thus, the functional properties of a PVC/PMMA blend that contains graded structure 2 (an extremely widely graded concentration) were explained by

Figure 16. Schematic model of PC/PS graded blend.

comparison with those of a blend that contains graded structure 1 (similar to a laminate system), perfectly miscible blends (1/1), PVC only, and PMMA only.

Tensile Properties. The tensile properties of PVC, PMMA, a perfectly miscible blend (1/1), blends that have graded structures 1 and 2 (blend types 1 and 2), in the vertical direction of thickness are summarized in Table 2. The tensile strength of the homogeneously miscible blend is the highest, and the next is blend type 2, surpassing PVC, PMMA, and blend type 1. This phenomenon means that formation of a graded structure suppresses a break at the interface and also gives properties superior to the source materials. It is believed that this occurs because the blend phase that has the concentration gradient has a sufficiently high tensile strength. For elongation at break, blend type 2 appeared sufficiently good. The tensile modulus of blend type 2 is higher than that of blend type 1. It was found, thus, that the break in tensile stress could be suppressed by formation of a concentration gradient.

Thermal Shock Resistance. Thermal shock resistance was tested by moving the specimens from a box to another (kept at 253 K and 373 K) repeatedly (5 times) every 30 min. The specimens were then evaluated for thermal shock resistance by measuring a maximum angle of warp, as illustrated in Fig. 17, and adhesive strength in shear by tension loading.

The thermal shock resistance of blend type 2 that had a graded structure 2 was tested and those results (maximum value of warp angle and adhesive strength in shear by tension loading) were compared with those of blend type 1 that had graded structure 1, as shown in Table 2.

The film of blend type 1 was highly warped, whereas that of blend type 2 almost did not warp. The adhesive

Figure 17. Method of measuring maximum angle of warp.

strength in shear by tension loading of blend type 2 was higher than that of blend type 1. It is believed that it occurs because the differences in the expansion of PVC (rubber state) and PMMA (glass state) at high temperature (395 K) concentrated the warp stress at the interface and decreased the strength of the interface. However, in blend type 2, the phase containing an excellently wide concentration gradient prevented the warp stress from concentrating. Thus, the thermal shock resistance of the blend (blend type 2) that has an excellently wide concentration gradient was superior to that of the similar blend (blend type 1) on a laminate film. It was found that the formation of an excellently wide concentration gradient improved the strength of the interface.

Smart Performance(DMA Properties). The change in tensile storage modulus and $\tan \delta$ of PVC/PMMA blend type 2 that has a wide concentration gradient around T_g was compared with the perfectly miscible blend (1/1) by a DMA measurement (rate of temperature increase: 1 K/min; frequency: 0.2 Hz). Then, the T_g width of storage modulus and half temperature of the T_g width of $\tan \delta$ were estimated, as shown in Table 2.

The half width of temperature of $\tan \delta$ for the former (16 K) was significantly larger than that of the latter (10 K). Thus, it was confirmed that blend type 2 has a continuous phase because of its wide range of T_g . Thus, $\tan \delta$ of the graded blends of PVC and several types of polyalkyl methacrylate(PMA) that contain graded structure 2 were measured, as shown in Fig. 18. $\tan \delta$ of the graded PVC/PHMA blend had the widest temperature range. Thus, it was confirmed that the wide temperature range is caused by the larger difference of the T_g in the polymer pairs of the graded PVC/PHMA blend.

Further, we investigated the optimum conditions for preparing a graded PVC /PHMA blend that had a wider temperature range of $\tan \delta$. Then, we obtained the PVC/PHMA blend that contained an excellently graded structure 2, which showed a peak of $\tan \delta$ in a much wider temperature range compared with those of a blend that contained graded structure 1 and a perfectly miscible blend (1/1), as shown in Fig. 19.

Figure 18. DMA data for PVC/PMA graded blend.

Figure 19. DMA data for PVC/PHMA graded blends.

Further, in both PVC/PMMA and PVC/PHMA blends, the tensile storage modulus of blend type 2 that contained an excellently graded structure 2 began to decrease at a lower temperature than that of a perfectly miscible blend (1/1) and did not have a terrace, whereas that of a similar blend that contained graded structure 1 on a laminate had some terraces.

Sandwiched steel beams combined by a polymer are used for damping materials (41), and it is known that the damping efficiency shows a maximum in the temperature range, at which the polymer used has a peak of $\tan \delta$. Then, it is expected that an excellently graded blend that has a peak of $\tan \delta$ in a much wider temperature range will be useful as a damping material in a wide temperature range. Graded polymer blends can be used as smart materials based on the following principle.

An excellently graded blend was used as the polymer that combined the steel plates shown at the right in Fig. 20. The T_g of the graded blend decreases with a shift from left to the right side of the figure. At the highest temperature, that is, the same temperature as the higher T_g of the polymer pairs in the blend, the area at the farthest left

Figure 20. Schematic model of so-called smart performance in the damping property of a steel plates combined by a functionally graded blend.

side shows the best damping performance. And then, the area shifts to the right side as the temperature decreases. Finally, at the lowest temperature, that is, the same temperature as the lower T_g of the polymer pair in the blend, the area at the farthest right side shows the best damping performance. Therefore, the area that shows high damping performance shifts as the temperature changes. This performance is considered one of the so-called smart performances.

The Prospects for Application of Functionally Graded Blends

Functionally graded polymer blends are expected to be used in place of laminates because of their superior strength and thermal shock resistance. The superiority results from the lack of an interface that suppresses the break at the interface and thermal stress. Further, the excellently wide compositional gradient results in a graded structure that has several types of improved physical properties. Therefore, new functional performance is expected because of these physical property gradients that can be applied in the various fields shown in Table 3.

Table 3. Possibility of Applications of Functionally Graded Polymer Blends

POLYMERS, BIOTECHNOLOGY AND MEDICAL APPLICATIONS

I. YU. GALAEV

Lund, Sweden

INTRODUCTION

Life is polymeric in its essence. The most important components of living cell, proteins, carbohydrates, and nucleic acids are polymers. Even lipids, which have lower molecular weights, can be regarded as methylene oligomers that have a polymerization degree around 20. Nature uses polymers as constructive elements and parts of complicated cell machinery. The salient feature of functional biopolymers is their all-or-nothing or at least highly nonlinear response to external stimuli. Small changes happen in response to varying parameters until the critical point is reached; then a transition occurs in the narrow range of the varied parameter, and after the transition is completed, there is no significant further response of the system. Such nonlinear response of biopolymers is warranted by highly cooperative interactions. Despite the weakness of each particular interaction in a separate monomer unit, these interactions, when summed through hundreds and thousands of monomer units, provide significant driving forces for the processes in such systems.

Not surprisingly, understanding the mechanism of cooperative interactions in biopolymers has opened the floodgates for attempts to mimic the cooperative behavior of biopolymers in synthetic systems. Recent decades witnessed the appearance of synthetic functional polymers, which respond in some desired way to a change in temperature, pH, electric, or magnetic fields or some other parameters. These polymers were nicknamed stimuli-responsive. The name "smart polymers" was coined due to the similarity of the stimuli-responsive polymers to biopolymers (1). We have a strong belief that nature has always striven for smart solutions in creating life. The goal of scientists is to mimic biological processes, and therefore understand them better, and also to create novel species and invent new processes.

The applications of smart polymer in biotechnology and medicine are discussed in this article. The highly nonlinear response of smart polymers to small changes in the external medium is of critical importance for the successful functioning of a system. Most applications of smart polymers in biotechnology and medicine include biorecognition and/or biocatalysis, which take place principally in aqueous solutions. Thus, only water-compatible smart polymers are considered; smart polymers in organic solvents or water/organic solvent mixtures are beyond the scope of the article. The systems discussed in the article are based on either soluble/insoluble transition of smart polymers in aqueous solution or on the conformational transition of macromolecules physically attached or chemically grafted to the surface. Systems that have covalently cross-linked networks of macromolecules, called smart hydrogels, are not considered.

One could define smart polymers used in biotechnology and medicine as *macromolecules that undergo fast and reversible changes from hydrophilic to hydrophobic microstructure triggered by small changes in their environments. These microscopic changes are apparent at the macroscopic level as precipitate formation in solutions of smart polymers or changes in the wettability of a surface to which a smart polymer is grafted. The changes are reversible, and the system returns to its initial state when the trigger is removed.*

SMART POLYMERS USED IN BIOTECHNOLOGY AND MEDICINE

The highly nonlinear transitions in smart polymers are driven by different factors, for example, neutralization of charged groups by either a pH shift (2) or the addition of an oppositely charged polymer (3), changes in the efficiency of hydrogen bonding and an increase in temperature or ionic strength (4), and critical phenomena in hydrogels and interpenetrating polymer networks (5). The polymer systems that have highly nonlinear response can be divided into three general groups: pH-sensitive smart polymers, thermosensitive smart polymers, and reversibly cross-linked networks.

pH-Sensitive Smart Polymers

The first group of smart polymers consists of polymers whose transition between the soluble and insoluble state is created by decreasing the net charge of the polymer molecule. The net charge can be decreased by changing the pH to neutralize the charges on the macromolecule and hence to reduce the hydrophilicity (increase the hydrophobicity) of the macromolecule. Copolymers of methylmethacrylate (hydrophobic part) and methacrylic acid (hydrophilic at high pH when carboxy groups are deprotonated but more hydrophobic when carboxy groups are protonated) precipitate from aqueous solutions by acidification to pH around 5, and copolymers of methyl methacrylate (hydrophobic part) with dimethylaminethyl methacrylate (hydrophilic at low pH when amino groups are protonated but more hydrophobic when amino groups are deprotonated) are soluble at low pH but precipitate in

Figure 1. pH-induced precipitation of a random copolymer of methacrylic acid and methacrylate (commercialized as Eudragit S 100 by Röhm Pharma GMBH, Weiterstadt, Germany) (open squares) and *p*-amino-phenyl- α -D-glucopyranoside-modified copolymer (open circles) measured as turbidity at 470 nm. Some decrease in turbidity at lower pH values is caused by flocculation and sedimentation of the polymer precipitate [redrawn from (8)].

slightly alkaline conditions (6). Hydrophobically modified cellulose derivatives that have pending carboxy groups, for example, hydroxypropyl methyl cellulose acetate succinate are also soluble in basic conditions but precipitate in slightly acidic media (7).

The pH-induced precipitation of smart polymers is very sharp and usually requires a change in pH of not more than 0.2–0.3 units (Fig. 1). When some carboxy groups

are used to couple a biorecognition element, for example, noncharged sugar, the increased hydrophobicity of the copolymer results in precipitation at a higher pH (8). The copolymerization of *N*-acryloyl sulfametazine with *N,N*-dimethylacrylamide results in a pH-sensitive polymer whose reversible transition is in the physiological range of pH 7.0–7.5 (9).

The charges on the macromolecule can also be neutralized by adding an efficient counterion, for example, a low molecular weight counterion or a polymer molecule of opposite charges. The latter systems are combined under the name of polycomplexes. The cooperative nature of interaction between two polymers of opposite charges makes polycomplexes very sensitive to changes in pH or ionic strength (10). The complex formed by poly(methacrylic acid) (polyanion) and poly(*N*-ethyl-4-vinyl-pyridinium bromide) (polycation) undergoes reversible precipitation from aqueous solution at any desired pH value in the range 4.5–6.5 that depends on the ionic strength and polycation/polyanion ratio in the complex (Fig. 2) (11). Polyelectrolyte complexes formed by poly(ethylene imine) and poly(acrylic acid) undergo soluble–insoluble transition in an even broader pH range from pH 3–11 (12).

The pH of the transition of pH-sensitive polymers such as poly(methylmethacrylate-*co*-methacrylic acid) or poly(*N*-acryloyl sulfametazine-*co*-*N,N*-dimethylacrylamide) is strictly fixed for the given composition of comonomers. Thus, a new polymer should be synthesized for each desired pH value. The advantage of polyelectrolyte complexes is that by using only two different polymers and mixing them in different ratios, reversible precipitation can be achieved at any desired pH value in a rather broad pH-range.

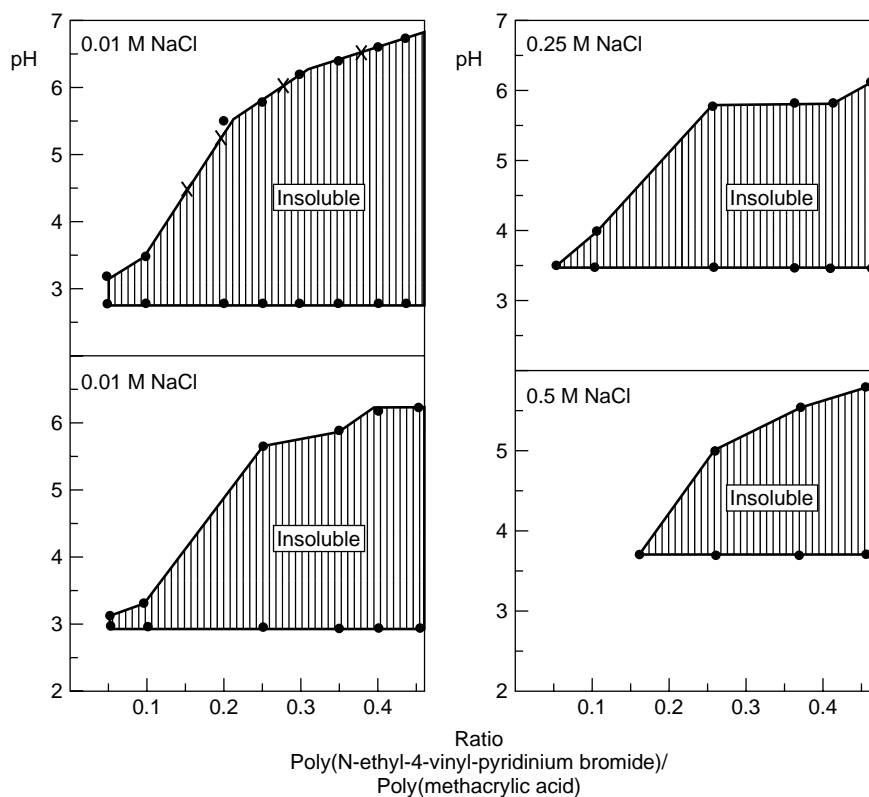

Figure 2. Phase diagram for the polyelectrolyte complex formed by poly(*N*-ethyl-4-vinyl-pyridinium bromide) (polymerization degree 530) and poly(methacrylic acid) (polymerization degree 1830). The dots (present pH values at which the turbidity of the polymer solutions was first observed at 470 nm. Ionic strength was 0.01 M NaCl (a), 0.1 M NaCl (b), 0.25 M NaCl (c) and 0.5 M NaCl (d). Dashed area represents pH/composition range where the complex is insoluble [reproduced from (11) with permission].

Thermosensitive Smart Polymers

The reversible solubility of thermosensitive smart polymers is caused by changes in the hydrophobic-hydrophilic balance of uncharged polymers induced by increasing temperature or ionic strength. Uncharged polymers are soluble in water due to hydrogen bonding with water molecules. The efficiency of hydrogen bonding lessens as temperature increases. The phase separation of a polymer occurs when the efficiency of hydrogen bonding becomes insufficient for the solubility of macro-molecule.

When the temperature of an aqueous solution of a smart polymer is raised above a certain critical temperature (which is often referred to as the transition temperature, lower critical solution temperature (LCST), or "cloud point"), phase separation takes place. An aqueous phase that contains practically no polymer and a polymer-enriched phase are formed. Both phases can be easily separated by decanting, centrifugation, or filtration. The temperature of the phase transitions depends on the polymer concentration and molecular weight (MW) (Fig. 3) (13,14). The phase separation is completely reversible, and the smart polymer dissolves in water when the temperature is reduced below the transition temperature.

Two groups of thermosensitive smart polymers are most widely studied and used:

- Poly(*N*-alkyl substituted acrylamides) and the most well-known of them, poly(*N*-isopropyl acrylamide) (poly(NIPAAM)), whose transition temperature is 32°C (14), and
- Poly(*N*-vinylalkylamides) such as poly(*N*-vinylisobutyramide) whose transition temperature is

39°C (15) or poly(*N*-vinyl caprolactam) whose transition temperature is 32–33°C (depending on the polymers molecular weight) (13)

A variety of polymers that have different transition temperatures from 4–5°C for poly(*N*-vinyl piperidine) to 100°C for poly(ethylene glycol) are available at present (16).

pH-sensitive smart polymers usually contain carboxy or amino groups that can be used for covalent coupling of biorecognition or biocatalytic elements (ligands). Thermosensitive polymers, on the contrary, do not have inherent reactive groups which could be used for ligand coupling. Thus, copolymers that contain reactive groups can be synthesized. *N*-Acryloylhydroxysuccinimide (17) or glycidyl methacrylate (18) have often been used as active comonomers in copolymerization with NIPAAM allowing further coupling of amino-group-containing ligands to the synthesized copolymers. The use of an initiator of polymerization (19) or chain transfer agent (20) that has an active group results in a polymer modified only at the end of the macromolecule. An alternative strategy is to incorporate a polymerizable double bond into the ligand, for example, by modification with acryoyl group, and then to copolymerize the modified ligand with NIPAAM (21,22).

An increase in the hydrophilicity of the polymer-accompanied incorporation of hydrophilic comonomers or coupling to hydrophilic ligands increases the transition temperature, whereas hydrophobic comonomers and ligands have the opposite effect (4). The pH-induced change in ligand hydrophobicity could have a dramatic effect on the thermoseparation of the ligand-polymer conjugate. A copolymer of NIPAAM and vinyl imidazole precipitates at about 35°C at pH 8.0 where imidazole moieties are non-charged and relatively hydrophobic, but no precipitation occurs even when heating the polymer solution to 80°C at pH 6 where imidazole groups are protonated and very hydrophilic (23).

Ligand-ligand interactions in a ligand-polymer conjugate also have a significant effect on the thermoseparation. The precipitation temperature for the previously mentioned copolymers of NIPAAM and vinyl imidazole increases as the imidazole content in the copolymer increases. On the contrary, the precipitation temperature decreases as the increase of imidazole content increases, when the polymer forms a Cu(II)-complex (23). Each Cu(II) ion interacts with two to three imidazole groups to cross-link the segments of the polymer molecule (24). The restricted mobility of the polymer segments results in a lower precipitation temperature.

Block copolymers that have a thermosensitive "smart" part that consists of poly(NIPAAM) form reversible gels on an increase in temperature, whereas random copolymers separate from aqueous solutions by forming a concentrated polymer phase (25). Thus, the properties of smart polymers that are important for biotechnological and medical applications could be controlled by the composition of comonomers and also by the polymer architecture.

The phase transition of thermosensitive polymers at increased temperature results from hydrophobic interactions between polymer molecules. Because hydrophobic interactions are promoted by high salt concentrations, the addition of salts shifts the cloud point to lower temperatures.

Figure 3. Phase diagram for poly(NIPAAM) in aqueous solution. The area under the binodal curve presents the range of temperatures/polymer concentrations for homogeneous solution. Separation into polymer-enriched and polymer-depleted phases takes place for any polymer concentration/temperature above the binodal curve [reproduced from (14) with permission].

When the transition temperature is below room temperature, polymer precipitation is achieved by just a salt addition without any heating. The addition of organic solvents, detergents, and chaotropic agents increases the transition temperature because these compounds deteriorate hydrophobic interactions.

Reversibly Cross-Linked Polymer Networks

Systems that have reversible noncovalent cross-linking of separate polymer molecules into a polymer network belong to the third group of smart polymers. When formed, reversibly cross-linked polymers either precipitate or form a physical gel. Polymers that have sugar ligands cross-linked by lectins with multibinding sites (26) and boronate-polyols (27–29) are the most widely used systems of this type. The reversible response in these systems is achieved by addition/removal of a low molecular weight analog of the polymer. For example, small sugars added at high concentrations compete with sugar-containing polymers for binding to lectin and destroy intrapolymer cross-links that result in disengagement of the network.

Heterogeneous Systems Using Smart Polymers

A solid surface acquires new properties when modified by adsorption or chemical grafting of smart polymers. Smart polymer that have terminal (only single-point attachment possible) or random (multipoint attachment possible) could be covalently coupled to the respective active groups on the surface (30). Single-point attachment could also be achieved by covalent modification of the surface using an initiator of polymerization and then carrying out polymerization of monomers in the solution that surrounds the support. The growth of polymer chains occurs only at the sites where initiator was coupled (31). Alternatively, the solid support is irradiated by light (32) or a plasma beam (33) when monomer is in the surrounding solution. Active radical sites on the surface, which appear as a result of irradiation, initiate the growth of polymer macromolecules. As a rule, irradiation methods give a higher density of grafted polymer, but polymerization is less controlled as in covalent coupling or using a covalently coupled initiator. Irradiation, especially at high monomer concentrations, could produce a cross-linked polymer gel attached to the solid support (34).

A separate group of smart polymers is represented by particulate systems. Liposomes that reversibly precipitate on salt addition and removal were prepared from a synthetic phospholipid that had a diacetylene moiety in the hydrophobic chain and an amino group in the hydrophilic head of the phospholipid, followed by polymerization of diacetylene bonds (35). Latices composed of thermosensitive polymers or a layer of thermosensitive polymer at the surface represent another example of insoluble but reversibly suspended particulate systems that respond to increasing/decreasing temperature (31).

APPLICATIONS

There are numerous potential applications for smart polymers in biotechnology and medicine. The main commercial

application of smart polymers is the production of “smart” pills where the shell of the smart polymer protects the pill from the harmful action of the stomach contents but allows the pill to dissolve in the intestine. There is not yet any other product on the market that applies smart polymers, but the interest in these applications is growing in both the academic community and industry. The following applications are considered in this article:

- smart pills that have an enteric coating
- smart polymers for affinity precipitation of proteins
- aqueous two-phase polymer systems formed by smart polymers and their application for protein purification
- smart surfaces for mild detachment of cultivated mammalian cells
- smart chromatographic matrices that respond to temperature
- smart polymers for controlled porosity of systems—“chemical valve”
- liposomes that trigger the release of their contents
- smart polymers for bioanalytical applications
- reversibly soluble biocatalysts

Smart Pills That Have an Enteric Coating

It is common knowledge that *peroral* introduction of medical preparations is the most convenient method compared to subcutaneous or intravenous injection and even to nasal sprays or eye droplets. The absorption of a swallowed pill takes place predominantly in the intestine and to reach the intestine the medicine must pass unharmed through the stomach that has a very low pH value of 1.4 and abundant hydrolytic enzymes that can degrade a broad variety of chemical structures. Many medicines are susceptible to damage in the stomach environment. The ideal condition for *peroral* introduction is to have a smart pill, which is insoluble in the stomach and hence passes through the stomach unaffected but easily dissolves at the higher pH in the intestine where the medicine is absorbed. Smart polymers provide the solution. Hydrophobic polymers such as poly(methylmethacrylate) or hydrophobically modified celluloses are insoluble in water *per se*, but the introduction of carboxy groups (either by partial hydrolysis of ester groups in methylmethacrylate or modification of cellulose HO groups by dicarboxylic acids such as succinic or phthalic acid) endows the polymers with pH-dependent solubility. The pill covered by a shell of such a polymer (enteric coating) is insoluble at low pH when the carboxy groups are protonated and uncharged, but easily soluble at a pH above 6 when carboxy groups are protonated and charged. Industrially produced polymers for enteric coating belong to two main groups, synthetic copolymers of methylmethacrylate and methacrylic acid and modified derivatives of cellulose, a natural polymer (Table 1). The first group of polymers is used mainly by European and U.S. manufacturers, and the second group is more popular in Japan.

Whenever the charge-bearing comonomer has an amino group instead of a carboxy group, the solubility of the polymer acquires opposite pH-dependence. The polymer is soluble at low pH values but insoluble in neutral

Table 1. Industrially Manufactured Smart Polymers for Producing Smart Pills

Polymer	Trade Name	Manufacturer	Country
Poly(methacrylic acid- <i>co</i> -methylmethacrylate) 1:1 monomer ratio, MW 135 000	Eudragit L	Röhm Pharma GmbH	U.S., Germany
Poly(methacrylic acid- <i>co</i> -methylmethacrylate) 1:2 monomer ratio, MW 135 000	Eudragit S	Röhm Pharma GmbH	U.S., Germany
Carboxymethylcellulose	CMEC	Freund Sangyo Co., Ltd.	Japan
Cellulose acetate phthalate	CAP	Wako Pure Chemicals Ltd.	Japan
Hydroxypropylmethylcellulose phthalate	HP-50, HP-55	Shin-Etsu Chemical Co., Ltd.	Japan
Hydroxypropylmethylcellulose acetate succinate	ASM, AS-H	Shin-Etsu Chemical Co., Ltd.	Japan
Poly(diethylaminoethyl methacrylate- <i>co</i> -methylmethacrylate) MW 150 000	Eudragit E	Röhm Pharma GmbH	U.S., Germany

and alkaline media. Poly(diethylaminoethylmethacrylate-*co*-methylmethacrylate) (commercialized as Eudragit E) is an example of such a polymer. The shell that is composed of this polymer protects the tablet against dissolution in the neutral saliva, and the mouth is not affected by the unpleasant taste of bitter medicine, but the polymer dissolves readily in the stomach.

Bioseparation—Affinity Precipitation

All bioseparation processes include three stages: preferential partitioning of target substance and impurities between two phases (liquid–liquid or liquid–solid), mechanical separation of the phases (e.g., separation of the stationary and mobile phases in a chromatographic column), and recovery of the target substance from the enriched phase. Because smart polymers can undergo phase transitions, they could facilitate the second and the third stages of bioseparation processes.

The ability of smart polymers to form *in situ* heterogeneous systems is exploited in affinity precipitation (Fig. 4). The technique is based on using a conjugate of a smart polymer that has a covalently coupled biorecognition moiety, that is, a ligand specific for a target protein. The conjugate forms a complex with the target protein but not with the other proteins in the crude extract. Phase separation of the complex is triggered by small changes in the environment resulting in transition of the polymer backbone into an insoluble state. The target protein specifically coprecipitates with the smart polymer, and the impurities in the crude remain in solution. Then, the target protein is either eluted from the insoluble macroligand–protein complex or the precipitate is dissolved. The protein is dissociated from the macroligand, and the ligand–polymer conjugate is precipitated again. Now without the protein that remains in the supernatant in purified form. A variety of different ligands such as triazine dyes, sugars, protease inhibitors, antibodies, nucleotides, double- or single-stranded DNA, and chelated metal ions were successfully used for affinity

precipitation (36). After elution of the target protein the ligand–polymer conjugate could be recovered and used in the next purification cycle (37).

Triazine dyes, robust affinity ligands for many nucleotide-dependent enzymes, were successfully used in conjugates with the pH-sensitive copolymer of methacrylic acid and methylmethacrylate which precipitates when pH decreases (Eudragit S 100) for purification of dehydrogenases from various sources by affinity precipitation (38,39). Sugar ligands constitute another attractive alternative and have been used in combination with Eudragit S 100 for bioseparation of lectins (40). Restriction endonuclease Hind III was successfully isolated using the thermosensitive conjugate of poly (NIPAAm) with phage λ DNA (21). Human IgG was specifically precipitated with a conjugate of protein A and galactomannan. Galactomannan polymer was reversibly precipitated by adding tetraborate (41).

The efficient precipitation of Cu(II)-loaded poly(*N*-vinylimidazole-*co*-NIPAAm) by high salt concentrations at mild temperature is very convenient for metal affinity precipitation of proteins that have inherent histidine residues at the surface or for recombinant proteins artificially provided with histidine tags (usually four to six residues). High salt concentration does not interfere with protein–metal ion–chelate interaction, and, on the other hand, it reduces the possibility of nonspecific binding of foreign proteins to the polymer both in solution and when precipitated (23). The flexibility of polymer chains in solution allows several imidazole ligands on a polymer molecule to come close enough to interact with the same Cu(II) ion and thus to provide sufficient strength of polymer–Cu(II) interactions to purify a variety of histidine-containing proteins (37).

Polyelectrolyte complexes that have pH-dependent solubility were successfully used in different bioseparation procedures. When an antigen, inactivated glyceraldehyde-3-phosphate dehydrogenase, from rabbit was covalently coupled to a polycation, the resulting complex was used to purify monoclonal antibodies specific toward

Figure 4. Schematic of affinity precipitation technique for protein purification.

inactivated glyceraldehyde-3-phosphate dehydrogenase (11). The successful affinity precipitation of antibodies using glyceraldehyde-3-phosphate dehydrogenase bound to a polyelectrolyte complex indicates that the ligand is exposed to the solution. This fact was used to develop a new method for producing monovalent Fab fragments of antibodies. Traditionally, Fab fragments are produced by proteolytic digestion of antibodies in solution followed by isolation of Fab fragments. In the case of monoclonal antibodies against inactivated subunits of glyceraldehyde-3-phosphate dehydrogenase, digestion with papain resulted in significant damage of binding sites of the Fab fragment. Proteolysis of monoclonal antibodies in the presence of the antigen–polycation conjugate followed by (1) precipitation induced by adding polyanion, poly(methacrylic) acid, and a pH shift from 7.3 to 6.5 and (2) elution at pH 3.0 that resulted in 90% immunologically competent Fab fragments. Moreover, the papain concentration required for proteolysis was 10 times less for antibodies bound to the antigen–polycation conjugate compared to that for free antibodies in solution (42). Active glyceraldehyde-3-phosphate dehydrogenase from rabbit muscle was separated from the inactivated enzyme by using monoclonal antibodies specific for the inactivated enzyme covalently coupled to the polyanion component of the polyelectrolyte complex. This system can be regarded as a simplified model of chaperone action in living cells that assist in separating active protein molecules from misfolded ones (43).

Apart from specific interactions between a target protein and a ligand–polymer conjugate, nonspecific interactions of protein impurities with the polymer backbone could take place. The nonspecific interactions limit the efficiency of the affinity precipitation technique, and

significant efforts were made to reduce these interactions. The advantage of polyelectrolyte complexes as carriers for affinity precipitation is low nonspecific coprecipitation of proteins when the polymer undergoes a soluble–insoluble transition (10).

Smart particles capable of reversible transition between aggregated and dispersed states were used for affinity precipitation of proteins. Thermosensitive (44) or pH-sensitive latices (45) or salt-sensitive liposomes that have polymerized membranes (35) are examples of such systems.

Two elements are required for successful affinity precipitation. The backbone of a smart polymer provides precipitation at the desired conditions (temperature, pH, ionic strength), and the biorecognition element is responsible for selective binding of the protein of interest. By proper choice of a smart polymer, precipitation could be achieved practically at any desired pH or temperature. For example, poly(*N*-acryloylpiperidine) terminally modified with maltose has an extremely low critical temperature (soluble below 4°C and completely insoluble above 8°C) and was used to purify thermolabile α -glucosidase (46).

Bioseparation—Partitioning in Aqueous Polymer Two-Phase Systems

Two aqueous polymer solutions become mutually incompatible when the threshold concentrations of polymers are exceeded. Both of the polymer phases formed contain about 90% water and hence present a very friendly environment for proteins and other biomolecules. Proteins partition selectively between two phases depending on their size, charge, hydrophobicity, nature, and the concentration of the phase-forming polymers. The partitioning could be also

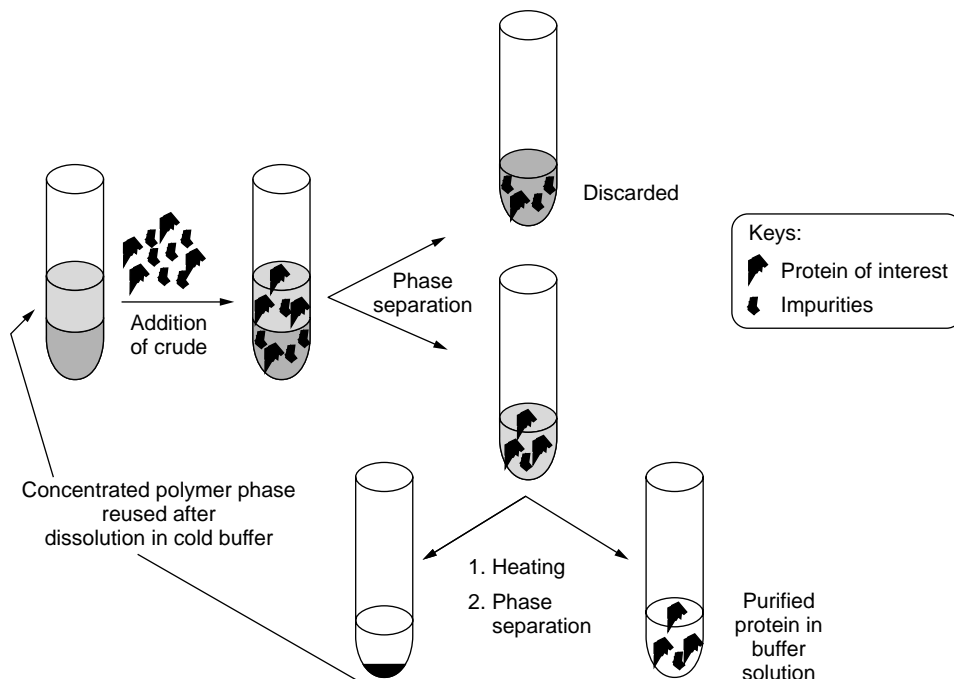

Figure 5. Schematic presentation of protein partitioning in aqueous two-phase polymer system formed by a smart (thermosensitive polymer) [reproduced from (140) with permission].

directed by adding some salt or coupling an affinity ligand specific for a given protein to one of the phase-forming polymers (47). The selective partitioning of proteins between the two phases formed has proven to be an efficient tool for purifying proteins and some low molecular weight substances. The main problem of the method—how to separate the target protein from the phase-forming polymer—has not yet been completely solved. Smart polymers provide an elegant solution to this problem—simple precipitation of the phase-forming polymer leaves protein in the supernatant (Fig. 5): (1) The crude protein extract is mixed with the aqueous two-phase polymer system, and the conditions are selected so that the protein of interest partitions into a phase formed by a smart polymer (for example by coupling affinity ligand to the smart polymer), and the impurities concentrate in the other phase. (2) The phases are separated mechanically and the phase formed by the smart polymer is subjected to conditions (pH or temperature) where the polymer undergoes phase separation; (3) two new phases are formed, a polymer-enriched phase of high polymer and low water concentration, which contains practically no protein, and a polymer-depleted aqueous phase that contains most of the purified protein and minute amounts of the polymer left after phase separation.

pH-sensitive acrylic copolymers (48) or thermoresponsive polymers, poly(ethylene oxide-co-propylene oxide) (49,50) or poly(*N*-vinyl caprolactam-co-vinyl imidazole) (51), form two-phase systems from relatively hydrophilic polymers such as dextran or modified starch and have been successfully used for protein purification. The pH- or thermoprecipitated polymer opposite dextran could be regenerated by dissolution at a lower temperature. Quite recently, an aqueous two-phase polymer system was developed where both phase-forming polymers, poly(*N*-isopropylacrylamide-co-vinyl imidazole) and poly(ethylene oxide-co-propylene oxide) end modified by

hydrophobic $C_{14}H_{29}$ groups, are thermoresponsive and could be recycled (52).

Smart Surfaces—Cell Detachment

The driving force behind phase separation of smart polymers is a sharp increase in hydrophobicity after a small change in environmental conditions. The hydrophobic “collapsed” polymer aggregates form a separate phase. When grafted to the surface, macromolecules of the smart polymer cannot aggregate, but the conformational transition from the hydrophilic to the hydrophobic state endows the surface with regulated hydrophobicity: the surface is hydrophilic when the smart polymer is in the expanded “soluble” conformation and hydrophobic when the polymer is in the collapsed “insoluble” conformation. The change of hydrophobicity of the surface by grafted poly(*N*-isopropylacrylamide) was demonstrated by contact angle measurements (53) and water absorbency (54).

The transition temperature for adsorbed (presumably via multipoint attachment) poly(NIPAAm) molecules is lower than that in bulk solution, and the properties of the layer of collapsed macromolecules formed above the transition temperature depend strongly on the speed by which the temperature increases. At a low speed of temperature increase, the “liquid-like” polymer layer is formed, whereas at high speeds, the polymer layer has more “solid-like” properties (55). When cooling, the collapsed polymer molecules return to the initial loopy adsorbed conformation via transitional extended conformation. The relaxation process for the extended-to-loopy adsorbed conformational transition occurs slowly and depends on the temperature observance of an Arrhenius law. Kinetic constraints, it is proposed, play an important role in this transition (56).

The change of surface properties from hydrophobic above the critical temperature of the polymer grafted

to hydrophilic below it has been successfully used for detaching mammalian cells. Mammalian cells are normally cultivated on a hydrophobic solid substrate and are detached from the substrate by protease treatment, which often damages the cells by hydrolyzing various membrane-associated protein molecules. The poly(NIPAAm)-grafted surface is hydrophobic at 37°C because this temperature is above the critical temperature for the grafted polymer and that cells that are growing well on it. A decrease in temperature results in transition of the surface to the hydrophilic state, where the cells can be easily detached from the solid substrate without any damage. Poly(NIPAAm) was grafted to polystyrene culture dishes using an electron beam. Bovine hepatocytes, cells that are highly sensitive to enzymatic treatment, were cultivated for 2 days at 37°C and detached by incubation at 4°C for 1 h. Nearly 100% of the hepatocytes was detached and recovered from the poly(NIPAAm)-grafted dishes by low-temperature treatment, whereas only about 8% of the cells was detached from the control dish (57). The technique has been extended to different cell types (58,59). It is noteworthy that hepatocytes recovered by cooling retained their native form had numerous bulges and dips, and attach well to the hydrophobic surface again, for example, when the temperature was increased above the conformational transition of poly(NIPAAm). On the contrary, enzyme-treated cells had a smooth outer surface and had lost their ability to attach to the surface. Thus, cells recovered by a temperature shift from poly(NIPAAm)-grafted surfaces have an intact structure and maintain normal cell functions (58).

The molecular machinery involved in cell-surface detachment was investigated using temperature-responsive surfaces (60). Poly(NIPAAm)-grafted and nongrafted surfaces showed no difference in attachment, spreading, growth, confluent cell density, or morphology of bovine aortic endothelial cells at 37°C. Stress fibers, peripheral bands, and focal contacts were established in similar ways. When the temperature was decreased to 20°C, the cells grown on poly(NIPAAm)-grafted support lost their flattened morphology and acquired a rounded appearance similar to that of cells immediately after plating. Mild agitation makes the cells float free from the surface without a trypsin treatment. Neither changes in cell morphology nor cell detachment occurred on ungrafted surfaces. Sodium azide, an ATP synthesis inhibitor, and genistein, a tyrosine kinase inhibitor, suppressed changes in cell morphology and cell detachment, whereas cycloheximide, a protein synthesis inhibitor, slightly enhanced cell detachment. Phalloidin, an actin filament stabilizer, and its depolymerizer, cytochalasin D, also inhibited cell detachment. These findings suggest that cell detachment from grafted surfaces is mediated by intracellular signal transduction and reorganization of the cytoskeleton, rather than by a simple changes in the "stickiness" of the cells to the surface when the hydrophobicity of the surface is changed.

One could imagine producing artificial organs using temperature-induced detachment of cells. Artificial skin could be produced as the cells are detached from the support not as a suspension (the usual result of protease-induced detachment) but preserving their intercellular contacts. Fibroblasts were cultured on the poly(NIPAAm)-collagen support until the cells completely covered the

surface at 37°C, followed by a decrease in temperature to about 15°C. The sheets of fibroblasts detached from the dish and within about 15 min floated in the culture medium (57). The detached cells could be transplanted to another culture surface without functional and structural changes (34). Grafting of poly(NIPAAm) onto a polystyrene surface by photolithographic technique creates a special pattern on the surface, and by decreasing temperature, cultured mouse fibroblast STO cells are detached only from the surface area on which poly(NIPAAm) was grafted (61). Lithographed films of smart polymer present supports for controlled interactions of cells with surfaces and can direct the attachment and spreading of cells (62). One could envisage producing artificial cell assemblies of complex architecture using this technique.

Smart Surfaces—Temperature Controlled Chromatography

Surfaces that have thermoresponsive hydrophobic/hydrophilic properties have been used in chromatography. HPLC columns with grafted poly(NIPAAm) have been used for separating steroids (63) and drugs (64). The chromatographic retention and resolution of the solutes was strongly dependent on temperature and increased as temperature increased from 5 to 50°C, whereas the reference column packed with nonmodified silica displayed much shorter retention times that decreased as temperature decreased. Hydrophobic interactions dominate in retaining solutes at higher temperature, and the preferential retention of hydrogen-bond acceptors was observed at low temperatures. The effect of temperature increase on the retention behavior of solutes separated on the poly(NIPAAm)-grafted silica chromatographic matrix was similar to the addition of methanol to the mobile phase at constant temperature (65).

The temperature response of the poly(NIPAAm)-silica matrices depends drastically on the architecture of the grafted polymer molecules. Surface wettability changes dramatically as temperature changes across the range 32–35°C (corresponding to the phase-transition temperature for NIPAAm in aqueous media) for surfaces where poly(NIPAAm) is terminally grafted either directly to the surface or to the looped chain copolymer of NIPAAm and *N*-acryloylhydroxysuccinimide which was initially coupled to the surface. The wettability changes for the loop-grafted surface itself were relatively large but had a slightly lower transition temperature (~27°C). The restricted conformational transitions for multipoint grafted macromolecules are probably the reason for the reduced transition temperature. The largest surface free energy changes among three surfaces was observed for the combination of both loops and terminally grafted chains (30).

Introduction of a hydrophobic comonomer, butylmethacrylate, in the polymer resulted in a decreased transition temperature of about 20°C. Retention of steroids in poly(NIPAAm-co-butylmethacrylate)-grafted columns increases as column temperature increases. The capacity factors for steroids on the copolymer-modified silica beads was much larger than that on poly(NIPAAm)-grafted columns. The effect of temperature on steroid retention on poly(NIPAAm-co-butylmethacrylate)-grafted stationary phases was more pronounced compared

to supports modified with poly(NIPAAm). Furthermore, retention times for steroids increased remarkably as the butylmethacrylate content increased in the copolymer. The temperature-responsive elution of steroids was strongly affected by the hydrophobicity of the grafted polymer chains on silica surfaces (63).

The mixture of polypeptides, consisting of 21–30 amino acid residues (insulin chain A, β -endorphin fragment 1–27 and insulin chain B) could not be separated at 5°C (below the transition temperature) on copolymer-grafted matrix. At this temperature, the copolymer is in an extended hydrophilic conformation that results in decreased interactions with peptides and hence short retention times insufficient to resolve them. The mixture has been easily separated at 30°C, when the copolymer is collapsed, hydrophobic interactions are more pronounced, and retention times sufficiently long for resolving polypeptides (66). Large protein molecules such as immunoglobulin G demonstrate less pronounced changes in adsorption above and below the transition temperature. Only about 20% of the protein adsorbed on poly(NIPAAm)-grafted silica at 37°C (above the LCST) were eluted after decreasing temperature to 24°C (below the transition temperature) (67). Quantitative elution of proteins adsorbed on the matrix via hydrophobic interactions has not yet been demonstrated, although protein adsorption on poly(NIPAAm)-grafted matrices could be somewhat controlled by a temperature shift. A successful strategy for temperature-controlled protein chromatography proved to be a combination of temperature-responsive polymeric grafts and biorecognition element, for example, affinity ligands.

The access of the protein molecules to the ligands on the surface of the matrix is affected by the transition of the polymer macromolecule grafted or attached to the chromatographic matrix. Triazine dyes, for example, Cibacron Blue, are often used as ligands for dye-affinity chromatography of various nucleotide-dependent enzymes (68). Poly(*N*-vinyl caprolactam), a thermoresponsive polymer whose critical temperature is about 35°C interacts efficiently with triazine dyes. Polymer molecules of 40000 MW are capable of binding up to seven to eight dye molecules hence, the polymer binds via multipoint interaction to the dye ligands available on the chromatographic matrix. At elevated temperature, polymer molecules are in a compact globule conformation that can bind only to a few ligands on the matrix. Lactate dehydrogenase, an enzyme from porcine muscle has good access to the ligands that are not occupied by the polymer and binds to the column. Poly(*N*-vinyl caprolactam) macromolecules undergo transition to a more expanded coil conformation as temperature decreases. Now, the polymer molecules interact with more ligands and begin to compete with the bound enzyme for the ligands. Finally, the bound enzyme is displaced by the expanded polymer chains. The temperature-induced elution was quantitative, and the first reported in the literature when temperature change was used as the only eluting factor without any changes in buffer composition (69). Small changes in temperature, as the only eluting factor, are quite promising because there is no need in this case to separate the target protein from an eluent, usually a competing nucleotide or high salt concentration in dye-affinity chromatography.

Smart Surfaces—Controlled Porosity, “Chemical Valve”

Environmentally controlled change in macromolecular size from a compact hydrophobic globule to an expanded hydrophilic coil is exploited when smart polymers are used in systems of environmentally controlled porosity, so called “chemical valves.” When a smart polymer is grafted to the surface of the pores in a porous membrane or chromatographic matrix, the transition in the macromolecule affects the total free volume of the pores available for the solvent and hence presents a means to regulate the porosity of the system.

Membranes of pH-sensitive permeability were constructed by grafting smart polymers such as poly(methacrylic acid) (70), poly(benzyl glutamate), poly(2-ethylacrylic acid) (71), poly(4-vinylpyridine) (72), which change their conformation in response to pH. Thermosensitive chemical valves have been developed by grafting poly(*N*-acryloylpyrrolidine), poly(*N*-*n*-propylacrylamide), or poly(acryloylpiperidine) (73), poly(NIPAAm) alone (33,74) or in copolymers with poly(methacrylic acid) (74) inside the pores. For example, grafted molecules of poly(benzyl glutamate) at high pH are charged and are in extended conformation. The efficient pore size is reduced, and the flow through the membrane is low (“off-state” of the membrane). As pH decreases, the macromolecules are protonated, lose their charge, and adopt a compact conformation. The efficient pore size and hence the flow through the membrane increases (“on-state” of the membrane) (71). The fluxes of bigger molecules (dextrans of molecular weights 4400–50600) across a temperature-sensitive, poly(NIPAAm)-grafted membrane were effectively controlled by temperature, environmental ionic strength, and degree of grafting of the membrane, while the flux of smaller molecules such as mannitol was not affected by temperature even at high degree of membrane grafting (75). The on-off permeability ratio for different molecules (water, Cl⁻ ion, choline, insulin, and albumin) ranged between 3 and 10 and increased as molecular weight increased (76). An even more abrupt change of the on-off permeability ratio was observed for a membrane that had narrow pores formed by heavy ion beams when poly(NIPAAm) or poly(acryloyl-L-proline methyl ester) were grafted (77).

Different stimuli could trigger the transition of the smart polymer making it possible to produce membranes whose permeabilities respond to these stimuli. When a copolymer of NIPAAm with triphenylmethane leucocyanide was grafted to the membrane, it acquires photosensitivity—UV irradiation increases permeation through the membrane (78). Fully reversible, pH-switchable permselectivity for both cationic and anionic redox-active probe molecules was achieved by depositing composite films formed from multilayers of amine-terminated dendrimers and poly(maleic anhydride-co-methylvinyl ether) on gold-coated silicon (79).

When the smart polymer is grafted inside the pores of the chromatographic matrix for gel permeation chromatography, the transition of grafted macromolecules regulates the pore size and as a result, the elution profile of substances of different molecular weights. As the temperature is raised, the substances are eluted progressively earlier indicating shrinking of the pores of the hydrogel

Figure 6. Schematic of a “chemical valve.” Glucose oxidase is immobilized on a pH-responsive polyacrylic acid grafted onto a porous polycarbonate membrane: (a) poly(acrylic acid) is in an expanded conformation that blocks insulin transport; (b) the oxidation of glucose is accompanied by a decrease in pH and the transition of poly(acrylic acid) into a compact conformation that results in opening of the pores and transport of insulin [redrawn from (82)].

beads composed of cross-linked poly(acrylamide-*co*-*N*-isopropylacrylamide) (80) or porous polymer beads with grafted poly(NIPAAM) (81).

When using a specific biorecognition element, which recognizes specific substances and translates the signal into a change of physicochemical properties, for example, pH, a smart membrane that changes its permeability in response to particular substances can be constructed. Specific insulin release in response to increasing glucose concentration, that is, an artificial pancreas, presents an everlasting challenge to bioengineers. One of the potential solutions is a “chemical valve” (Fig. 6). The enzyme, glucose oxidase, was used as a biorecognition element, capable of specific oxidation of glucose accompanied by a decrease in pH. The enzyme was immobilized on pH-responsive poly(acrylic acid) graft on a porous polycarbonate membrane. In neutral conditions, polymer chains are densely charged and have extended conformation that prevents insulin transport through the membrane by blocking the pores. Under exposure to glucose, the pH drops as the result of glucose oxidation by the immobilized enzyme, the polymer chains adopt a more compact conformation that diminishes the blockage of the pores, and insulin is transported through the membrane (82). Systems such as this could be used for efficient drug delivery that responds to the needs of the organism. A membrane that consists of poly(2-hydroxyethyl acrylate-*co*-*N,N*-diethylaminomethacrylate-*co*-4-trimethylsilylstyrene) undergoes a sharp transition

from a shrunken state at pH 6.3 to a swollen state at pH 6.15. The transition between the two states changes the membrane permeability to insulin 42-fold. Copolymer capsules that contain glucose oxidase and insulin increase insulin release five fold in response to 0.2 M glucose. After glucose removal, the rate of insulin release falls back to the initial value (83).

Alternatively, reversible cross-linking of polymer macromolecules could be used to control the porosity in a system. Two polymers, poly(*m*-acrylamidophenylboronic acid-*co*-vinylpyrrolidone) and poly(vinyl alcohol) form a gel because of strong interactions between boronate groups and the hydroxy groups of poly(vinyl alcohol). When a low molecular weight polyalcohol such as glucose is added to the gel, it competes with poly(vinyl alcohol) for boronate groups. The boronate–poly(vinyl alcohol) complex changes to a boronate–glucose complex that results in eventual dissolution of the gel (84). In addition to a glucose oxidase-based artificial pancreas, the boronate–poly(vinyl alcohol) system has been used for constructing glucose-sensitive systems for insulin delivery (29,85–87). The glucose-induced transition from a gel to a sol state drastically increases the release of insulin from the gel. The reversible response to glucose has also been designed using another glucose-sensitive biorecognition element, Concanavalin A, a protein that contains four sites that can bind glucose. Polymers that have glucose groups in the side chain such as poly(vinylpyrrolidone-*co*-allylglucose) (26) or poly(glucosyloxyethyl methacrylate) (88), are reversibly cross-linked by Concanavalin A and form a gel. The addition of glucose results in displacing the glucose-bearing polymer from the complex with Concanavalin A and dissolving the gel.

Reversible gel-formation of thermosensitive block copolymers in response to temperature could be utilized in different applications. Poly(NIPAAM) block copolymers with poly(ethylene oxide) which undergo a temperature-induced reversible gel–sol transition were patented as the basis for cosmetics such as depilatories and bleaching agents (89). The copolymer solution is liquid at room temperature and easily applied to the skin where it forms a gel within 1 min. Commercially available ethyl(hydroxyethyl)celluloses that have cloud points of 65–70°C have been used as redeposition agents in washing powders. Adsorption of the precipitated polymer on the laundry during the initial rinsing period counteracts read-sorption of dirt when the detergent is diluted (90).

Liposomes That Trigger Release of the Contents

When a smart polymer is attached somehow to a lipid membrane, the transition in the macromolecule affects the properties of the membrane and renders the system sensitive to environmental changes. To attach a smart polymer to a lipid membrane, a suitable “anchor” which could be incorporated in the membrane, should be introduced into the macromolecule. This could be achieved by copolymerizing poly(NIPAAM) with comonomers that have large hydrophobic tails such as *N,N*-didodecylacrylamide (91), using a lipophilic radical initiator (92) modifying copolymers (93), or polymers that have terminally active groups (94)

with a phospholipid. Alternatively, smart polymers have been covalently coupled to the active groups in the hydrophilic heads of the lipid-forming membrane (95).

Interesting and practically relevant materials for studying the behavior of smart polymers attached to lipid membranes, are liposomes, self assembled 50–200 nm vesicles that have one or more (phospho)lipid bilayers which encapsulate a fraction of the solvent. Liposomes are stable in aqueous suspension due to the repulsive forces that appear when two liposomes approach each other. Liposomes are widely used for drug delivery and in cosmetics (96).

The results of a temperature-induced conformational transition of a smart polymer on the liposomal surface depend significantly on the fluidity of the liposomal membrane. When the membrane is in a fluid state at temperatures both above and below the polymer transition temperature, the collapse of the polymer molecule forces anchor groups to move closer together by lateral diffusion within the membrane. The compact globules of collapsed polymer cover only a small part of the liposomal surface. Such liposomes have a low tendency to aggregate because the most of their surface is not covered by the polymer. Naked surfaces contribute to the repulsion between liposomes. On the other hand, when the liposomal membrane is in a solid state at temperatures both above and below the polymer transition temperature, the lateral diffusion of anchor groups is impossible, and the collapsed polymer cannot adopt a compact globule conformation but spreads over the most of the liposomal surface (97). Liposomes whose surfaces are covered to a large degree by a collapsed polymer repel each other less efficiently than intact liposomes. The stability of a liposomal suspension is thereby decreased, and aggregation and fusion of liposomes takes place, which is often accompanied by the release of the liposomal content into the surrounding medium (98).

When the liposomal membrane is perturbed by the conformational transition of the polymer, both the aggregation tendency and liposomal permeability for incorporated substances are affected. Poly(ethacrylic acid) undergoes a transition from an expanded to a compact conformation in the physiological pH range of 7.4–6.5 (99). The pH-induced transition of poly(ethacrylic acid) covalently coupled to the surface of liposomes formed from phosphatidylcholine results in liposomal reorganization into more compact micelles and concomitant release of the liposomal content into the external medium. The temperature-induced transition of poly(NIPAAM-*co*-*N,N*-didoceylacrylamide) (100) or poly(NIPAAM-*co*-octadecylacrylate) (101), incorporated into the liposomal membrane, enhanced the release of the fluorescent marker, calcein, encapsulated in copolymer-coated liposomes. Liposomes hardly release any marker at temperatures below 32°C (the polymer transition temperature), whereas the liposomal content is released completely within less than a minute at 40°C. To increase the speed of liposomal response to temperature change, the smart polymer was attached to the outer and inner sides of the lipid membrane. The polymer bound only to the outer surface if the liposomes were treated with the polymer after liposomal formation. When the liposomes were formed directly from the lipid-polymer mixture, the polymer was present on both sides of the liposomal membrane (91).

Changes of liposomal surface properties caused by polymer collapse affect liposomal interaction with cells. Liposomes modified by a pH-sensitive polymer, partially succinylated poly(glycidol), deliver calcein into cultured kidney cells of the African green monkey more efficiently compared to liposomes not treated with the polymer (102). Polymeric micelles formed by smart polymers and liposomes modified by smart polymers could be used for targeted drug delivery. Polymeric micelles have been prepared from amphiphilic block copolymers of styrene (forming a hydrophobic core) and NIPAAM (forming a thermosensitive outer shell). The polymeric micelles were very stable in aqueous media and had long blood circulation because of small diameter, unimodal size distribution (24 ± 4 nm), and, a low critical micellar concentration of around 10 $\mu\text{g/mL}$. At temperatures above the polymer transition temperature (32°C), the polymer chains that form an outer shell collapse, become more hydrophobic, and allow aggregation between micelles and favoring binding interactions with the surface of cell membranes. Thus, hydrophobic molecules incorporated into the micelles are delivered into the cell membranes. These micelles are capable of site-specific delivery of drugs to the sites as temperature changes, for example, to inflammation sites of increased temperature (103).

Smart Polymers in Bioanalytical Systems

Because smart polymers can recognize small changes in environmental properties and respond to them in a pronounced way, they could be used directly as sensors of these changes, for example, a series of polymer solutions that have different LCSTs could be used as a simple thermometer. As salts promote hydrophobic interactions and decrease the LCST, the polymer system could “sense” the salt concentration needed to decrease the LCST below room temperature. A poly(NIPAAM)-based system that can sense NaCl concentrations above 1.5% was patented (104). The response of the polymer is controlled by a balance of hydrophilic and hydrophobic interactions in the macromolecule. Using a recognition element that can sense external stimuli and translate the signal into the changes of the hydrophilic/hydrophobic balance of the smart polymer, the resulting system presents a sensor for the stimulus. If the conjugate of a smart polymer and a recognition element has a transition temperature T_1 in the absence and T_2 in the presence of stimuli, fixing the temperature T in the range $T_1 < T < T_2$ allows achieving the transition of a smart polymer isothermally by the external stimulus (105). An example of such a sensor was constructed using *trans-cis* isomerization of the azobenzene chromophore when irradiated by UV light. The transition is accomplished by an increase in the dipole moment of azobenzene from 0.5 D (for the *trans*-form) to 3.1 D (for the *cis*-form) and hence a significant decrease of hydrophobicity. Irradiation with UV light results in increasing the LCST from 19.4 to 26.0°C for the conjugate of the chromophore with poly(NIPAAM). The solution of the conjugate is turbid at $19.4^\circ\text{C} < T < 26.0^\circ\text{C}$, but when irradiated, the conjugate dissolves because the *cis*-form is below the LCST at this temperature. The system responds to UV light by transition from a turbid to

transparent solution. The termination of UV irradiation results in a slow return of the system to its initial turbid state (105). A few other light-sensitive systems were proposed that use different chromophores: triarylmethylcyanide (106) and leuconitriles (107).

The hydrophobicity of the recognition molecule was also changed by chemical signals. Poly(NIPAAm) containing 11.6 mol% of crown ether 9 has a LCST of 31.5°C in the absence of Na⁺ or K⁺ ions, 32°C in the presence of Na⁺, and 38.9°C in the presence of K⁺. Thus, the introduction of both Na⁺ and K⁺ ions leads to the dissolution of the insoluble polymer at that temperature. At 37°C, this effect is achieved only by K⁺ ions (108).

From better understanding of ligand–host interactions and development of new highly selective binding pairs (e.g., by using combinatorial libraries to find ligands of high affinity for particular biomolecules), one could expect that smart polymer systems will be used as “signal amplifiers” to visualize a physicochemical event, which takes place in a recognition element, by a pronounced change in the system—conversion of a transparent solution into a turbid one or vice versa.

Antibody–antigen interactions present nearly ideal analytical selectivity and sensitivity developed by nature. Not surprisingly, they are increasingly used for a broad variety of bioanalytical applications. Different analytical formats have been developed. The common feature of the most of them is the requirement for separating an antibody–antigen complex from a nonbound antibody or antigen. Traditionally, the separation is achieved by coupling one of the components of antibody–antigen pair to a solid support. The binding step is followed by washing nonbound material. Interactions of the soluble partner of the binding pair with the partner coupled to the support are often accompanied by undesired diffusional limitations, and hence, incubation times of several hours are required for analysis. Because smart polymers can undergo transition from the soluble to the insoluble state, they allow combining the advantages of homogeneous binding and, after the phase transition of the smart polymer has taken place, easy separation of the polymer precipitate from the supernatant. The essential features of an immunoassay that uses smart polymers (named PRECIPIA) are as follows. The covalent conjugate of poly(NIPAAm) with monoclonal antibodies to the κ -chain of human immunoglobulin G (IgG) are incubated for 1 h at room temperature (below the LCST of the conjugate), and the IgG solution is analyzed. Then plain poly(NIPAAm) (to facilitate thermoprecipitation of polymer–antibody conjugates) and fluorescently labeled monoclonal antibodies to the γ -chain of human IgG are added. The temperature is raised to 45°C, the precipitated polymer is separated by centrifugation, and fluorescence is measured in the supernatant (109). Immunoassay systems that use temperature-induced precipitation of poly(NIPAAm) conjugates with monoclonal antibodies are not inferior in sensitivity to the traditional heterogenous immunoassay methods, but because the antigen–antibody interaction takes place in solution, the incubation can be shortened to about 1 h (110,111). The limitations of PRECIPIA as an immunoassay technique are essentially the same as those of affinity precipitation, namely, nonspecific coprecipitation of analyzed

protein when poly(NIPAAm) precipitates. Polyelectrolyte complexes that have a low degree of nonspecific protein coprecipitation have also been successfully used as reversibly soluble carriers for PRECIPIA-type immunoassays (112). The conjugate of antibody and polyanion poly(methacrylic acid) binds to the antigen within a few minutes, and the polymer hardly exerts any effect on the rate of antigen–antibody binding. Subsequent addition of a polycation, poly(*N*-ethyl-4-vinyl-pyridinium bromide) in conditions where the polyelectrolyte is insoluble, results in quantitative precipitation of the antibody–polymer conjugate within 1 min. The total assay time is less than 15 min (10).

In principle, PRECIPIA-type immunoassays could be used for simultaneous assay of different analytes in one sample, provided that conjugates specific toward these analytes are coupled covalently to different smart polymers that have different precipitating conditions, for example, precipitation of one conjugate by adding a polymeric counterion followed by thermoprecipitation of the second conjugate by increasing temperature.

Reversibly Soluble Biocatalysts

The transition between the soluble and insoluble state of stimuli-responsive polymers has been used to develop reversibly soluble biocatalysts. A reversibly soluble biocatalyst catalyzes an enzymatic reaction in a soluble state and hence could be used in reactions of insoluble or poorly soluble substrates/products. As soon as the reaction is completed and the products are separated, the conditions (pH, temperature) are changed to promote precipitation of the biocatalyst. The precipitated biocatalyst is separated and can be used in the next cycle after dissolution. The reversibly soluble biocatalyst acquires the advantages of immobilized enzymes (ease of separation from the reaction mixture after the reaction is completed and the possibility for biocatalyst recovery and repeated use in many reaction cycles) but at the same time overcomes the disadvantages of enzymes immobilized onto solid matrices such as diffusional limitations and the impossibility of using them in reactions of insoluble substrates or products.

Biocatalysts that are reversibly soluble as a function of pH have been obtained by the covalent coupling of lysozyme to alginate (113); of trypsin to poly(acrolein-*co*-acrylic acid) (114); and of cellulase (115); amylase (115); α -chymotrypsin, and papain (116) to poly(methylmethacrylate-*co*-methacrylic acid). A reversibly soluble cofactor has been produced by the covalent binding of NAD to alginate (117). Reversibly soluble α -chymotrypsin, penicillin acylase, and alcohol dehydrogenase were produced by coupling to the polycation component of polyelectrolyte complexes formed by poly(methacrylic acid) and poly(*N*-ethyl-4-vinyl-pyridinium bromide) (118).

Biocatalysts that are reversibly soluble as a function of temperature have been obtained by the covalent coupling of α -chymotrypsin and penicillin acylase to a partially hydrolysed poly(*N*-vinylcaprolactam) (119); and of trypsin (120); alkaline phosphatase (121), α -chymotrypsin (122), and thermolysin (123,124) to NIPAAm copolymers that contain active groups suitable for covalent coupling of biomolecules. Lipase was coupled to a graft copolymer composed of NIPAAm grafts on a poly(acrylamide-*co*-acrylic

acid) copolymer (125). No significant differences in biocatalytic properties were found for α -amylase coupled to poly(NIPAAm) via single-point or multipoint mode. Both enzyme preparations demonstrated increased thermostability and the absence of diffusional limitation when hydrolyzing starch, a high molecular weight substrate (126). The temperature of a protein–ligand interaction was controlled by site-directed coupling of terminally modified poly(NIPAAm) to a specifically constructed site (close to a biotin binding site) on a genetically modified streptavidin (127).

Biocatalysts which are reversibly soluble as a function of Ca^{2+} concentration were produced by covalent coupling of phosphoglyceromutase, enolase, peroxidase, and pyruvate kinase to α_{s1} -casein. The enzyme casein conjugates are soluble at a Ca^{2+} concentration below 20 mM but precipitate completely at a Ca^{2+} concentration above 50 mM. The precipitate redissolves when EDTA, a strong Ca^{2+} -binding agent is added (128).

The reversible flocculation of latices has been used to produce thermosensitive reversibly soluble (more precisely reversibly dispersible) biocatalysts using trypsin (129), papain (130), and α -amylase (131). Latices sensitive to a magnetic field have been used to immobilize trypsin and β -galactosidase (132). Liposomes that have a polymerized membrane, that reversibly aggregates on changing salt concentration have been used to immobilize α -chymotrypsin (133).

The most attractive application of reversibly soluble biocatalysts is repeated use in a reaction which is difficult or even impossible to carry out using enzymes immobilized onto insoluble matrices, for example, hydrolysis of water-insoluble phlorizidin (134); hydrolysis of high molecular weight substrates such as casein (123,130) and starch (115); hydrolysis of insoluble substrates such as cellulose (135) and raw starch (corn flour) (7,134,136–138); production of insoluble products such as peptide, benzyloxycarbonyl-L-tyrosyl- N^{ω} -nitro-L-arginine (116) and phenylglycine (139).

The hydrolytic cleavage of corn flour to glucose is an example of successfully using a reversibly soluble biocatalyst, amylase coupled to poly(methylmethacrylate-co-methacrylic acid), in an industrially interesting process (136). The reaction product of the process, glucose, inhibits the hydrolysis. The use of a reversibly soluble biocatalyst improves the efficiency of the hydrolysis which is carried out at pH 5, at which the amylase–polymer conjugate is soluble. After each 24 h, the pH is reduced to 3.5, the unhydrolyzed solid residue and the precipitated conjugate are separated by centrifugation, the conjugate is resuspended in a fresh portion of the substrate at pH 5, and the hydrolysis is continued. The conversion achieved after 5 cycles is 67%, and the activity of the amylase after the fifth cycle was 96% of the initial value (136).

CONCLUSION

In the future, one looks forward to further developments and the commercial introduction of new smart polymers whose transition temperatures and pH are compatible with physiological conditions or conditions for maximal stability

of target biomolecules, such as temperatures of 4–15°C and pH values of 5–8. Additional prospects will stem from a better understanding of the mechanism of cooperative interactions in polymers and increasing knowledge of structure–property correlations to enable rational synthesis of smart polymers that have predefined properties. Due to the possibility of combining a variety of biorecognition or biocatalytic systems and the unique features of smart polymers, expectations are running high in this area. Only time and more experimentation will determine whether smart polymers will live up to their generous promises.

POLYMERS, FERROELECTRIC LIQUID CRYSTALLINE ELASTOMERS

RUDOLF ZENTEL
University of Mainz
Mainz, Germany

INTRODUCTION

Ferroelectric materials are a subclass of pyro- and piezoelectric materials (Fig. 1). They are very rarely found in crystalline organic or polymeric materials because ferroelectric hysteresis requires enough molecular mobility to reorient molecular dipoles in space. So semicrystalline polyvinylidene fluoride (PVDF) is nearly the only known compound (1). On the contrary, ferroelectric behavior is very often observed in chiral liquid crystalline materials, both low molar mass and polymeric. For an overview of ferroelectric liquid crystals, see (2). Tilted smectic liquid crystals that are made from chiral molecules lack the symmetry plane perpendicular to the smectic layer structure (Fig. 2). Therefore, they develop a spontaneous electric polarization, which is oriented perpendicular to the layer normal and perpendicular to the tilt direction. Due to the liquid-like structure inside the smectic layers, the direction of the tilt and thus the polar axis can be easily switched in external electric fields (see Figs. 2 and 4).

Here, we discuss materials (LC-elastomers) that combine a liquid crystalline phase and ferroelectric properties (preferable the chiral smectic C^* phase) in a polymer network structure (see Fig. 3). The coupling of the liquid crystalline director to the network or the softness of the network is chosen so that reorientation of the polar axis is still possible. Thus densely cross-linked systems, that possess a polar axis but cannot be switched (3) will be excluded.

Figure 1. Ferroelectric hysteresis that shows the spontaneous polarization P_s of a ferroelectric material reversed by an applied electric field E .

It is the role of the network (1) to form a rubbery matrix for the liquid crystalline phase and (2) to stabilize a director configuration. LC-materials that have these properties can be made either (see Fig. 3) by covalently linking the mesogenic groups to a slightly cross-linked rubbery polymer network structure (see Fig. 3a) (4–6) or by dispersing a phase-separated polymer network structure within a low molar mass liquid crystal (see Fig. 3b) (8,9). Both systems possess locally a very different structure. They may show, however, macroscopically similar properties.

LC-elastomers (see Fig. 3a) have been investigated in detail (4–7). Although the liquid crystalline phase transitions are nearly unaffected by the network, the network retains the memory of the phase and director pattern during cross-linking (7). In addition, it freezes fluctuations of the smectic layers and leads to a real long range order in one dimension (11). An attempt to change the director pattern by electric or magnetic fields in LC-elastomers leads to a deformation of the network and to an elastic response (see Fig. 4). As a consequence of this, nematic LC-elastomers could never be switched in electric fields, if the shape of the elastomer was kept fixed. For freely suspended pieces of nematic LC-elastomers, shape variations in electric fields have been observed sometimes (12,13). In ferroelectric liquid crystals, the interaction with the electric field is, however, much larger. Thus, it has been possible to prepare real ferroelectric LC-elastomers (see Fig. 4) (14,15). In these systems, the polymer network stabilizes one switching state like a soft spring. It is, however, soft enough to allow ferroelectric switching. Therefore the ferroelectric hysteresis can therefore be measured in these systems. It is, however, shifted away from zero voltage (see Fig. 4).

SYNTHESIS OF FERROELECTRIC LC-ELASTOMERS

The ferroelectric LC-elastomers described so far (14–17, 44–46) are mostly prepared from cross-linkable ferroelectric polysiloxanes (see Fig. 5), which are prepared by hydrosilylation of precursor polysiloxanes (18). The cross-linking is finally initiated by irradiating a photoradiation generator, which leads to oligomerization of acrylamide or acrylate groups (see Fig. 5). The functionality of the net points is thus high (equal to the degree of polymerization) and varies with the cross-linking conditions.

The advantage of this photochemical-initiated cross-linking is that the crosslinking can be started—at will after the liquid crystalline polymer is oriented and sufficiently characterized in the uncross-linked state (see Fig. 6). The advantage of using polymerizable groups (acrylates) for cross-linking is that small amounts of these groups are sufficient to transform a soluble polymer into a polymer gel and that the chemical reactions happens far away from the mesogen. Cinnamoyl moieties, on the other hand (19), require a high concentration of these groups for cross-linking. The dimers thus formed are, in addition, nonmesogenic. Figure 7 summarizes the ferroelectric LC-elastomers discussed in this article. Two different positions of cross-linkable groups are used. In polymer P1, the cross-linking group is close to the siloxane chains, which are known to

Figure 2. Schematic of the bistable switching of a ferroelectric liquid crystal in the “surface stabilized FLC” configuration.

Figure 3. Network: soft, can be transformed like rubber band, but retains its shape and couples to director orientation because (a) director is preferably parallel (or perpendicular) to polymer chains (LC-elastomer) (4–8). (b) Director aligns (parallel) to chains in oriented phase-separated polymer network structure (low molar mass LC in LC-thermoset) (8,37).

microphase separate from the mesogenic groups (18,19). Therefore, the crosslinking should proceed mostly within the siloxane sublayers. In polymers P2 and P3, the crosslinking group is located at the end of mesogens. Therefore, the crosslinking should proceed mostly between different siloxane layers (see Fig. 7). A comparison of these elastomers allows evaluating structure–property relationships (17,23,26).

Properties and Characterization

Ferroelectric Characterization (Uncross-linked Systems). Before cross-linking, polarization, tilt angle, and switching times can be determined in the usual way (17,18,21). Figure 8 shows the temperature dependence of the spontaneous polarization for polymers P1–P3. For the homopolymer related to polymer P2, all relevant parameters

Figure 4. Schematic of the ferroelectric LC-elastomer and its two switching states (14): (a) A polymer chain acts as cross-linking point by connecting different mesogenic groups attached to the main polymer chains. A ferroelectric switching in this elastomer extends polymer chains. (b) The entropy elasticity arising from this acts like a spring that stabilizes one state. (c) For the uncrosslinked system (left) the hysteresis is symmetrical to zero voltage and both states are equal. After cross-linking in one polar state (right), only that state is stable with no electric field, and the hysteresis is no longer symmetrical to zero voltage.

were determined in a careful study by Kocot et al. (22). It seems that the electroclinic effect is especially strong in these polysiloxanes (15). This has implications for the freezing of a memory of the tilt angle present during cross-linking. Therefore, ferroelectric elastomers, which have been crosslinked in the smectic A phase while applying an electric field, produce a stable macroscopic polarization (tilt) after cooling into the smectic C* phase (17).

Properties of Ferroelectric LC-Elastomers. The crosslinking reactions of a series of copolymers analogous to polymer P2, but differing in the amount of cross-linkable groups were studied by FTIR spectroscopy (16). These measurements show a decrease of the acrylamide double bond on irradiation. Conversions between 60 to 84% were observed. The uncertainty of the conversion, however, is high because only very few double bonds are present in polymer

P2 and they are visible in the infrared spectrum at rather low intensity.

Mechanical measurements, which show how this photochemical crosslinking (conversion of double bonds) leads to an elastic response of the network are, however, still at the beginning because photo-cross-linking can be performed only in thin layers of some microns. It is best performed between two glass slides to exclude oxygen.

AFM measurements of photo-cross-linked free standing films show changes in topology during stretching (see Properties of Ferroelectric LC-Elastomers—AFM Imaging of Thin Films) (23). They do, however, not allow measuring elastic moduli.

The most promising approach to obtaining elastic data for these ferroelectric elastomers is investigation of LC-elastomer balloons (25,26). For this purpose, an experimental setup was developed on the basis of an apparatus

Figure 5. Synthetic route to the cross-linkable polysiloxane P2 and the following preparation of the oriented smectic C^* network using UV light in the presence of a photoinitiator (1,1-dimethoxy-1-phenylacetophenone) (14).

Figure 6. Preparation of polar smectic C* monodomains (14,15) (ITO: indium tin oxide).

designed to study smectic bubbles (25). Freely suspended films of the uncross-linked material behave like ordinary smectic films. They can be inflated to spherical bubbles several mm in diameter (the thickness of a smectic-layer skin is about 50 nm). These bubbles are stabilized by the smectic-layer structure and their inner pressure p is related to the surface tension and the bubble radius R by the Laplace–Young equation, $p \propto 1/R$. After exposure to UV light, the material is cross-linked, and an anisotropic elastomer is formed. When the cross-linked bubbles are inflated/ deflated, the radius–pressure curve reverses its slope and gives direct access to the elastic moduli of the material (26). Because the deformation during inflation of the balloon is isotropic in the layer plane, the material should contract in the direction of the layer normal.

Mechanical measurements of chemically crosslinked LC-elastomers have been made extensively (4,5,27,28, 36,41–43). For these systems, it can be shown that stretching allows orientation of the liquid crystalline phase. In ideal situations, it is thus possible to prepare a ferroelectric monodomain by stretching (28,30,36). This result can be rationalized as a two-stage deformation process (see Fig. 9) (36). This possibility of orienting or reorienting the polar axis mechanically is the basis for the piezoelectric properties to be discussed later. Ferroelectric switching could not be observed for any of the chemically crosslinked systems.

This may occur because chemically cross-linked films are too thick (several 100 μm compared to about 10 μm for photochemically cross-linked systems) and the electric field applied is therefore too small. In addition, the cross-linking density in chemically cross-linked systems is presumably higher.

Ferroelectric Properties LC-Elastomers. The ferroelectric properties of the photochemically crosslinked elastomers E1 to E3 differ significantly and depend on the topology of the network formed. For the systems that have interlayer cross-linking (see Fig. 7, E2 and E3), the switching time is increased greatly. Therefore, spontaneous polarization can no longer be determined by the triangular wave method. Slow switching is, however, still possible and therefore ferroelectric hysteresis can be measured optically (see Figs. 4c and 10) (14,15). After photochemical cross-linking in a ferroelectric monodomain, the ferroelectric hysteresis shows stabilization of the orientation present during cross-linking. At zero external voltage, only this state is stable. The second switching state can, however, be reached. Therefore, the network acts like a spring that stabilized one state because switching to the other state leads to a deviation from the most probable conformation of the polymer chain (32) (see Fig. 10). Then, the shift of the center of the hysteretic loop away from zero voltage gives the magnitude of the electric field necessary to balance the mechanical field of the network. The asymmetry of the hysteresis increases with the cross-linking density (17). For high cross-linking densities, switching remains possible only if the spontaneous polarization is rather high (17). Otherwise, the network prohibits switching. The asymmetry of ferroelectric switching could also be proven by polarized FT-IR spectroscopy (33). Increasing the temperature of this ferroelectric elastomer leads to narrowing of the hysteretic loop, which is lost at the transition to the smectic A phase (see Fig. 10).

This behavior is best interpreted by plotting the liquid crystalline potential, the elastic potential of the network, and their superposition in one graph (15) (see Fig. 11). As the network is formed in the smectic C* phase, an internal elastic field is created, which has its minimum value for the tilt angle and tilt direction during cross-linking. Other tilt angles are destabilized.

The elastomer that has preferable intralayer cross-linking (E1, see Fig. 7) shows completely different behavior (see Fig. 12) (17,34). In this case, the switching time increases by less than a factor of 2, the polarization can still be determined, and measurement of the ferroelectric hysteresis shows no stabilization of the switching state present during cross-linking. Then, the coupling between the orientation of the mesogens and the network conformation is obviously very weak. The network stabilizes the smectic layer structure (see Properties of Ferroelectric LC-Elastomers—AFM Imaging of Thin Films), but it does not stabilize the tilt direction. Therefore, the polar axis can be switched easily. This is the result of the network topology (see Fig. 7) in which interlayer cross-linking is rare.

uncross-linked polymers (see also the smectic balloons in this context). They can be photo-cross-linked and transferred to a solid substrate. Thereafter, the topology of the films can be imaged by AFM, which gives direct visualization of the smectic layer structure at low temperatures. The uncross-linked polymers can only be imaged at low temperatures, deep inside the smectic phase and in the tapping mode, which does not induce strong lateral forces. At higher temperatures, the sample is too soft and mobile to allow imaging. Cross-linked elastomers, on the other hand, are mechanically stable, and films sustain the tapping mode and also the contact mode of the atomic force microscope (35). This holds both for intra- and interlayer cross-linked systems. Because measurements can be done in all phases, it is also possible to determine the change of the smectic layer thickness at the phase transitions directly. For elastomer E1, for example, the smectic layer thickness is 4.2 nm in the smectic C^* phase (36°C, tilt angle about 30°). It increases to 4.4 nm at 50°C in the smectic A phase (35). This corresponds to X-ray measurements.

To analyze the impact of the molecular structure on network properties, elastomers are compared, which are identical except for the molecular position of the cross-linkable group: (1) elastomer E1 that has cross-linkable groups attached to the backbone via a short spacer (intralayer cross-linking) and (2) elastomer E2 where the cross-linkable group is in the terminal position of a mesogenic side group (intralayer cross-linking) (23,24). When mechanical stress (stretching) is imposed on thin films in homeotropic orientation, the two elastomers react differently to the deformation (23,24), as seen by AFM imaging of the surface topology (see Fig. 13). For elastomer E1, “intralayer” cross-linking results in two-dimensional networks in the backbone layers, separated by liquid-like FLC side-group layers. Because there are practically no vertical connections in this intralayer network, no vertical distortions occur. Therefore, this elastomer can be stretched up to 100%, the surface remains smooth, and the layers deform

Figure 13. Surface topography of as prepared and stretched transferred films of elastomer $E1_{x=0.1}$ (a: $\lambda = 0$, b: $\lambda = 10\%$), $E2_{x=0.07}$ (c: $\lambda = 0$, d: $\lambda = 12\%$), and $E2_{x=0.25}$ (e: $\lambda = 0$, f: $\lambda = 2\%$). Scale bars $1\ \mu\text{m}$, height scale $25\ \text{nm}$ valid for all images. The surface of all polymers show plateau patterns. In the E2 samples, the lateral strain leads to surface deformation (24).

affinely. In elastomer E2, a three-dimensional, “interlayer” network is formed; the system reacts by distorting the smectic layering. Therefore, only smaller stretching ratios are accessible and the surface roughens and buckles during stretching. The distortion strength increases with a higher cross-linking density.

Piezoelectric Properties of Ferroelectric LC-Elastomers.

Because a ferroelectric material has to be piezoelectric (see Fig. 1), observation of a piezoresponse is natural. It has been observed for ferroelectric LC-elastomers (14,15,44–46) and also for more densely cross-linked systems (36–39) for which no ferroelectric switching could be observed. For the elastomers described here it is, however, possible to change the piezoresponse (14) by reorienting the polar axis in an external field (see E2 in Fig. 14). For this

experiment, the polar axis was kept in one orientation during cross-linking. This resulted in a positive piezoresponse (see Fig. 14). Thereafter, the direction of the polar axis was inverted by applying an external field of opposite direction. Then, the external field was removed and the piezocoefficient was measured. At first, a piezoresponse of opposite sign (negative) but identical value is determined (see Fig. 14). In the field-free state, this piezoresponse continuously decreases, it goes through zero, increases again, and finally reaches the original positive value. This experiment is comparable to the hysteresis measurements of Figs. 4 and 10 because it shows that two polar states are accessible, but the one present during cross-linking is stabilized.

The shape variation under application of an external electric field was most intensively studied for microtomed

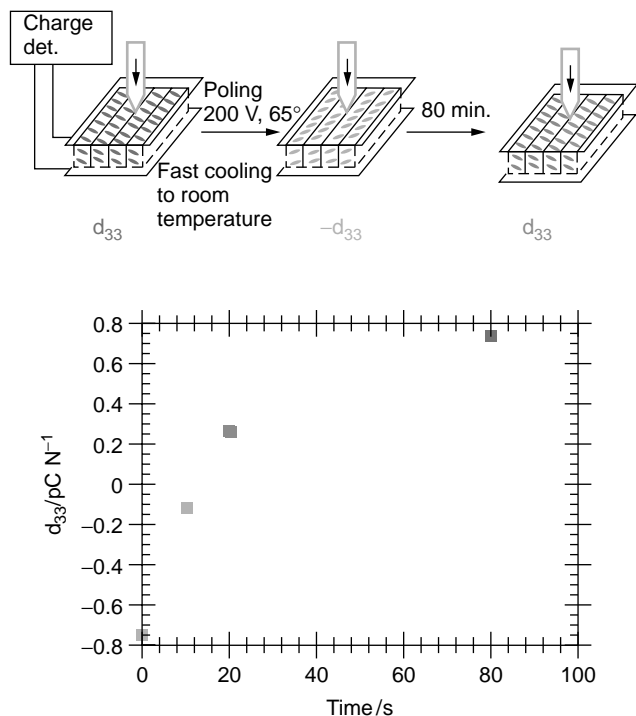

Figure 14. Relaxation of the piezoelectric coefficient d_{33} of elastomer E2 at room temperature after reversal poling at 65°C (S_A phase) (14).

piezes of ferroelectric elastomers, which had been oriented by drawing (44–46). These experiments show only a small shape variation if the field is applied parallel to the polar axis of the monodomain. The effects become, on the other hand, rather large if the smectic layer structure (chevron

Figure 15. In the S_A^* phase, the mesogenic parts (depicted as ellipsoids) of the elastomeric macromolecule stand upright ($\theta = 0^\circ$) inside the single smectic layers. By applying a lateral electric field (perpendicular to the plane of the paper), a tilt angle θ that is proportional to the electric field E can be induced (electroclinic effect). The sign of the tilt depends on the sign of the electric field E . Hence, each smectic layer shrinks by $\Delta h/z$ twice during one period of the electric field. The shrinkage Δh of the whole film is measured by the interferometer as an optical phase shift between the sample beam and the reference beam.

Table 1.

Material	Electrostrictive strain ε (at electric field strength E)	Ref.
Free-standing FLCE film	4% lateral strain (1.5 MV/m)	40
Spin-coated FLCE	~1% lateral layer thickness shrinkage (2.0 MV/m)	40
PMN _{0.7} PT _{0.3}	0.15% (1 MV/m)	47
Lead magnesium niobate— Lead titanate ceramics		
P(VDF-TrFE)	4% (150 MV/m)	47
electron irradiated poly(vinylidene fluoride trifluoroethylene) copolymer		
PBLG monomolecular, grafted layer of poly- γ -benzyl-L-glutamate	0.005% (300 MV/m)	49

texture) rearranges (44,46). To get a large electrostrictive response, which can be understood on a molecular level, the geometry presented in Fig. 15 was chosen (40). The application of an electric field parallel to a smectic layer leads to a tilt of the mesogens (electroclinic effect). Thereby, the thickness of the layer decreases. For a stack of layers, the effect sums up over all layers. As a result, the thickness perpendicular to the smectic layers decreases if a field is applied parallel to the layers (see Fig. 15). Because the electroclinic effect is relatively large in these polymers (15,33), a large variation in thickness is expected.

X-ray diffraction measurements prove the electrically induced shrinkage of single smectic layers. A freestanding ultrathin (75 nm) film of a ferroelectric liquid crystalline elastomer (similar to E2) was used to measure the shape variation (electrostrictive response) associated with this (40). It was measured by a high precision (± 3 pm at 133 Hz) Michelson interferometer. The measurements (see Fig. 16) exhibit extremely high electrostrictive strains of 4% in an electric field of only 1.5 MV/m, which is, to our knowledge, a new world record for the corresponding electrostrictive coefficient a . The effect exhibits typical electroclinic behavior, which means that it is caused by an electrically induced tilt of the chiral LC molecules. As a consequence of chirality, the primary strain is perpendicular to the applied field. Hence, a new material that has a giant electrostriction effect is introduced, where the effect can be fully understood on a molecular level. The characterization of these materials is summarized in Table 1.

CONCLUSION

Ferroelectric LC-elastomers represent an interesting class of material because they combine the ordering of liquid crystalline ferroelectric phases and the rubber elasticity of polymer networks. Switching of the electric polarization leads to deformation of the polymer network, equivalent to

Figure 16. Electrostriction of a ferroelectric LC-elastomer (40). Big diagram: Thickness variation Δh as a function of the applied ac voltage U_{ac} . Interferometric data were obtained at the fundamental frequency of the electric field (piezoelectricity, first harmonic: +) and at twice the frequency (electrostriction, second harmonic: o). Sample temperature: 60°C. Inset: Electrostrictive coefficient a (+) versus temperature. At the temperature where the non-cross-linked polymer would have its phase transition $S_C^* - S_A^*$ (about 62.5°C), the tilt angle of 0° is unstable. That is why the electroclinic effect is most effective at this temperature. An electric field of only 1.5 MV/m is sufficient to induce lateral strains of more than 4%.

stretching a spring, and creates a stress in the network of polymer chains.

The interaction of mesogens and the network can be varied by using different topologies of net points: Crosslinking is carried out either within the siloxane sublayers (leading to fast switching elastomers) or between the siloxane sublayers (resulting in an elastomer that favors the ferroelectric switching state in which the cross-linking reaction took place).

Because the orientation of the smectic phase couples to the polymer network, electromechanical measurements show a piezoelectric effect. Mechanical deformation leads to polarization or an external electric field to deformation of the sample. Applying the electric field parallel to the smectic layer structure leads to an extremely high electrostrictive strain of 4% in an electric field of only 1.5 MV/m.

ACKNOWLEDGMENT

The work in this summary was possible only by close cooperation with several groups from physics and physical chemistry. We give special thanks to the groups of Profs. F. Kremer and R. Stannarius (Leipzig). A. Helfer is thanked for setting up the manuscript.

INTRODUCTION

Piezoelectric polymers have been known for more than forty years, but in recent years they have gained repute as a valuable class of “smart materials.” There is no standard definition for smart materials, and terms such as intelligent materials, smart materials, adaptive materials, active devices, and smart systems are often used interchangeably. The term “smart material” generally designates a material that changes one or more of its properties in response to an external stimulus.

The most popular smart materials are piezoelectric materials, magnetostrictive materials, shape-memory alloys, electrorheological fluids, electrostrictive materials, and optical fibers. Magnetostrictives, electrostrictives, shape-memory alloys, and electrorheological fluids are used as actuators; optical fibers are used primarily as sensors.

Among these active materials, piezoelectric materials are most widely used because of their wide bandwidth, fast electromechanical response, relatively low power requirements, and high generative forces. A classical definition of piezoelectricity, a Greek term for “pressure electricity,” is the generation of electrical polarization in a material in response to mechanical stress. This phenomenon is known as the direct effect. Piezoelectric materials also display the converse effect: mechanical deformation upon application of an electrical charge or signal. Piezoelectricity is a property of many noncentrosymmetric ceramics, polymers, and other biological systems. Pyroelectricity is a subset of piezoelectricity, whereby the polarization is a function of temperature. Some pyroelectric materials are ferroelectric, although not all ferroelectrics are pyroelectric. Ferroelectricity is a property of certain dielectrics that exhibit spontaneous electric polarization (separation of the center of positive and negative electric charge that makes one side of the crystal positive and the opposite side negative) that can be reversed in direction by applying an appropriate electric field. Ferroelectricity is named by analogy with ferromagnetism, which occurs in materials such as iron. Traditionally, ferroelectricity is defined for crystalline materials, or at least in the crystalline region of semicrystalline materials. In the last couple of years, however, a number of researchers have explored the possibility of ferroelectricity in amorphous polymers, that is, ferroelectricity without a crystal lattice structure (1).

Table 1. Comparison of Properties of Standard Piezoelectric Polymer and Ceramic Materials

	d_{31}^a (pm/V)	g_{31}^a (mV-m/N)	k_{31}	Salient Features
Polyvinylidene fluoride (PVDF)	28	240	0.12	Flexible, lightweight, low acoustic and mechanical impedance
Lead zirconium titanate (PZT)	175	11	0.34	Brittle, heavy, toxic

^aValues shown are absolute values of constants.

Characteristics of Piezoelectric Polymers

The properties of polymers are very different from those of inorganics (Table 1), and they are uniquely qualified to fill niche areas where single crystals and ceramics cannot perform as effectively. As noted in Table 1, the piezoelectric strain constant (d_{31}) for the polymer is lower than that of the ceramic. However, piezoelectric polymers have much higher piezoelectric stress constants (g_{31}) which indicates that they are much better sensors than ceramics. Piezoelectric polymeric sensors and actuators offer the advantage of processing flexibility because they are lightweight, tough, readily manufactured in large areas, and can be cut and formed into complex shapes. Polymers also exhibit high strength and high impact resistance (2). Other notable features of polymers are low dielectric constant, low elastic stiffness, and low density, which result in high voltage sensitivity (excellent sensor characteristic) and low acoustic and mechanical impedance (crucial for medical and underwater applications). Polymers also typically possess high dielectric breakdown and high operating field strength, which means that they can withstand much higher driving fields than ceramics. Polymers offer the ability to pattern electrodes on the film surface and pole only selected regions. Based on these features, piezoelectric polymers possess their own established area for technical applications and useful device configurations.

Structural Requirements for Piezoelectric Polymers

The piezoelectric mechanisms for semicrystalline and amorphous polymers differ. Although the differences are distinct, particularly with respect to polarization stability, in the simplest terms, four critical elements exist for all piezoelectric polymers, regardless of morphology. These essential elements are: (1) the presence of permanent molecular dipoles, (2) the ability to orient or align the molecular dipoles, (3) the ability to sustain this dipole alignment once it is achieved, and (4) the ability of the material to undergo large strains when mechanically stressed (3).

SEMICRYSTALLINE POLYMERS

Mechanism of Piezoelectricity in Semicrystalline Polymers

Semicrystalline polymers must have a polar crystalline phase to render them piezoelectric. The morphology of such

polymers consists of crystallites dispersed within amorphous regions, as shown in Fig. 1a. The amorphous region has a glass transition temperature that dictates the mechanical properties of the polymer, and the melting temperature of the crystallites dictates the upper limit of the use

Figure 1. Schematic illustration of random stacks of amorphous and crystal lamellae in the PVDF polymer: (a) the morphology after the film is melt cast; (b) after orientation of the film by mechanically stretching several times its original length; and (c) after depositing metal electrodes and poling through the film thickness.

temperature. The degree of crystallinity in such polymers depends on the method of preparation and thermal history. Most semicrystalline polymers have several polymorphic phases, some of which may be polar. Mechanical orientation, thermal annealing, and high-voltage treatment are all it has been shown, effective in inducing crystalline phase transformations. Stretching the polymer aligns the amorphous strands in the film plane, as shown in Fig. 1b, and facilitates uniform rotation of the crystallites by an electric field. Depending on whether stretching is uniaxial or biaxial, the electrical and mechanical properties (and therefore the transduction response) are either highly anisotropic or isotropic in the plane of the polymer sheet. Electrical poling is accomplished by applying an electric field across the thickness of the polymer, as depicted in Fig. 1c. An electric field of the order of 50 MV/m is typically sufficient to effect crystalline orientation. Polymers can be poled by using a direct contact method or corona discharge. The latter is advantageous because contacting electrodes is not required and samples of large area can be poled continuously. This method is used to manufacture commercial poly(vinylidene fluoride) (PVDF) film. Some researchers have also successfully poled large areas of polymer films by sandwiching them between polished metal plates under a vacuum. This method eliminates electrical arcing of samples and the need for depositing metal electrodes on the film surface. The amorphous phase of semicrystalline polymers supports the crystal orientation, and polarization is stable up to the Curie temperature. This polarization can remain constant for many years if it is not degraded by moisture uptake or elevated temperatures.

Piezoelectric Constitutive Relationships

The constitutive relationships that describe piezoelectric behavior in materials can be derived from thermodynamic

Figure 2. Tensor directions for defining the constitutive relationships.

principles (4). A tensor notation is adopted to identify the coupling between the various entities through mechanical and electrical coefficients. The common practice is to label directions as depicted in Fig. 2. The stretch direction is denoted as “1.” The “2” axis is orthogonal to the stretch direction in the plane of the film. The polarization axis (perpendicular to the surface of the film) is denoted “3.” The shear planes, indicated by the subscripts “4,” “5,” and “6,” are perpendicular to the directions “1,” “2,” and “3,” respectively. By reducing the tensor elements and using standard notations (5), the resulting equations can be displayed in matrix form as follows:

$$\begin{Bmatrix} S_1 \\ S_2 \\ S_3 \\ S_4 \\ S_5 \\ S_6 \end{Bmatrix} = \begin{bmatrix} d_{11} & d_{12} & d_{13} \\ d_{21} & d_{22} & d_{23} \\ d_{31} & d_{32} & d_{33} \\ d_{41} & d_{42} & d_{43} \\ d_{51} & d_{52} & d_{53} \\ d_{61} & d_{62} & d_{63} \end{bmatrix} \begin{Bmatrix} E_1 \\ E_2 \\ E_3 \end{Bmatrix} + \begin{bmatrix} s_{11}^E & s_{12}^E & s_{13}^E & s_{14}^E & s_{15}^E & s_{16}^E \\ s_{21}^E & s_{22}^E & s_{23}^E & s_{24}^E & s_{25}^E & s_{26}^E \\ s_{31}^E & s_{32}^E & s_{33}^E & s_{34}^E & s_{35}^E & s_{36}^E \\ s_{41}^E & s_{42}^E & s_{43}^E & s_{44}^E & s_{45}^E & s_{46}^E \\ s_{51}^E & s_{52}^E & s_{53}^E & s_{54}^E & s_{55}^E & s_{56}^E \\ s_{61}^E & s_{62}^E & s_{63}^E & s_{64}^E & s_{65}^E & s_{66}^E \end{bmatrix} \begin{Bmatrix} X_1 \\ X_2 \\ X_3 \\ X_4 \\ X_5 \\ X_6 \end{Bmatrix}, \quad (1)$$

$$\begin{Bmatrix} D_1 \\ D_2 \\ D_3 \end{Bmatrix} = \begin{bmatrix} \varepsilon_{11}^T & \varepsilon_{12}^T & \varepsilon_{13}^T \\ \varepsilon_{21}^T & \varepsilon_{22}^T & \varepsilon_{23}^T \\ \varepsilon_{31}^T & \varepsilon_{32}^T & \varepsilon_{33}^T \end{bmatrix} \begin{Bmatrix} E_1 \\ E_2 \\ E_3 \end{Bmatrix} + \begin{bmatrix} d_{11} & d_{12} & d_{13} & d_{14} & d_{15} & d_{16} \\ d_{21} & d_{22} & d_{23} & d_{24} & d_{25} & d_{26} \\ d_{31} & d_{32} & d_{33} & d_{34} & d_{35} & d_{36} \end{bmatrix} \begin{Bmatrix} X_1 \\ X_2 \\ X_3 \\ X_4 \\ X_5 \\ X_6 \end{Bmatrix}. \quad (2)$$

Piezoelectricity is a cross coupling among the elastic variables, stress X , and strain S , and the dielectric variables, electric charge density D and electric field E . Note that D is named in analogy to the B field in ferromagnetism, although some authors also refer to it as dielectric or electric displacement. There does not seem to be a standard nomenclature; however, it is the opinion of the authors of this article that electric charge density is a better description of this property. The combinations of these variables define the piezoelectric strain constant d , the material compliance s , and the permittivity ε . Other piezoelectric properties are the piezoelectric voltage constant g , stress constant e , and strain constant h given by the equations in Table 2. For a given constant, the first definition in the table refers to the direct effect, and the second refers to the converse effect. The piezoelectric constants are interrelated through the electrical and mechanical properties

Table 2. Definitions of Piezoelectric Constants

Equations	Units
$d = (dD/dX)_E = (dS/dE)_X$	(C/N or m/V)
$e = (dD/dS)_E = -(dX/dE)_S$	(C/m or N/Vm)
$g = (dE/dX)_D = (dS/dD)_X$	(Vm/N or m ² /C)
$h = (dE/dS)_D = -(dX/dD)_S$	(V/m or N/C)

of the material. Electric field strength and displacement charge density are related through the dielectric constant, $\epsilon\epsilon_0$ (where ϵ_0 is the permittivity of free space), and stress and strain are related through the compliance according to

$$d_{ij} = \epsilon_0\epsilon_i g_{ij}, \quad (3)$$

$$e_{ij} = s_{ij}d_{ij}. \quad (4)$$

The polarization P is a measure of the degree of piezoelectricity in a given material. In a piezoelectric material, a change in polarization ΔP results from an applied stress X or strain S under conditions of constant temperature and zero electric field. A linear relationship exists between ΔP and the piezoelectric constants. Due to material anisotropy, P is a vector that has three orthogonal components in the 1, 2, and 3 directions. Alternatively, the piezoelectric constants can be defined as

$$\Delta P_i = d_{ij}X_j, \quad (5)$$

$$\Delta P_i = g_{ij}S_j. \quad (6)$$

The electrical response of a piezoelectric material is a function of the electrode configuration relative to the direction of the applied mechanical stress. For a coefficient d_{ij} , the first subscript is the direction of the electric field or charge displacement, and the second subscript gives the direction of the mechanical deformation or stress. The C_{2v} crystallographic symmetry typical of synthetic oriented, poled polymer film leads to cancellation of all but five of the d_{ij} components (d_{31} , d_{32} , d_{33} , d_{15} , and d_{24}). If the film is poled and biaxially oriented or unoriented, $d_{31} = d_{32}$, and $d_{15} = d_{24}$. Most natural biopolymers possess D_∞ symmetry which yields a matrix that possesses only the shear piezoelectricity components d_{13} and d_{25} . Because the d_{33} constant is difficult to measure without constraining the lateral dimension of the sample, it is typically determined from Eq. (7) which relates the constants to the hydrostatic piezoelectric constant, d_{3h} .

$$d_{3h} = d_{31} + d_{32} + d_{33}. \quad (7)$$

The electromechanical coupling coefficient k_{ij} represents the conversion of electrical energy into mechanical energy and vice versa. The electromechanical coupling can be considered a measure of transduction efficiency and is always less than unity as shown here:

$$k^2 = \frac{\text{electrical energy converted to mechanical energy}}{\text{input electrical energy}}, \quad (8a)$$

$$k^2 = \frac{\text{mechanical energy converted to electrical energy}}{\text{input mechanical energy}}. \quad (8b)$$

Figure 3. Typical ferroelectric hysteresis behavior for PVDF.

Some k coefficients can be obtained from a measured d constant as follows:

$$k_{31} = \frac{d_{31}}{\sqrt{s_{11}^E \epsilon_3^T}}. \quad (9)$$

Ferroelectricity in Semicrystalline Polymers

At high electric fields, the polarization in semicrystalline polymers such as PVDF is nonlinear with the applied electric field. This nonlinearity in polarization is defined as hysteresis. The existence of spontaneous polarization together with polarization reversal (as illustrated by a hysteresis loop) is generally accepted as proof of ferroelectricity. Figure 3 is an example of the typical hysteresis behavior of PVDF. Two other key properties typically reported for ferroelectric materials are the coercive field and the remanent polarization. The coercive field E_c , which marks the point where the hysteresis intersects the horizontal axis, is about 50 MV/m at room temperature for many ferroelectric polymers. The remanent polarization P_r corresponds to the point where the loop intersects the vertical axis. The values of E_c and P_r depend on temperature and frequency. The Curie temperature T_c , is generally lower than but close to the melting temperature of the polymer. Below T_c , the polymer is ferroelectric and above T_c , the polymer loses its noncentrosymmetric nature.

Although ferroelectric phenomenon has been well documented in ceramic crystals, the question of whether polymer crystallites could exhibit dipole switching was debated for about a decade after the discovery of piezoelectricity in PVDF. Inhomogeneous polarization through the film thickness that yielded higher polarization on the positive electrode side of the polymer led to speculations that PVDF was simply a trapped charge electret. These speculations were dispelled when X-ray studies (6) demonstrated that polarization anisotropy vanishes due to high poling field strengths and that true ferroelectric dipole reorientation occurs in PVDF. Luongo used infrared to attribute the polarization reversal in PVDF to 180° dipole rotation (7). Scheinbeim documented the same via X-ray

pole analysis and infrared techniques for odd-numbered nylons (8).

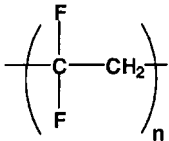

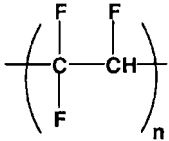

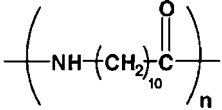

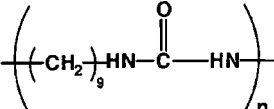

State of the Art

Pioneering work in the area of piezoelectric polymers (9) led to the development of strong piezoelectric activity in polyvinylidene fluoride (PVDF) and its copolymers with trifluoroethylene (TrFE) and tetrafluoroethylene (TFE). These semicrystalline fluoropolymers represent the state of the art in piezoelectric polymers and are currently the only commercial piezoelectric polymers. Odd-numbered nylons, the next most widely investigated semicrystalline piezoelectric polymers, have excellent piezoelectric properties at elevated temperatures but have not yet been embraced in practical application. Other semicrystalline polymers including polyureas, liquid crystalline polymers, biopolymers and an array of blends have been studied for their piezoelectric potential and are summarized in the following section. The chemical repeat unit and piezoelectric constants of several semicrystalline polymers are listed in Table 3.

Polyvinylidene Fluoride (PVDF). Interest in the electrical properties of PVDF began in 1969 when it was shown (9) that poled thin films exhibit a very large piezoelectric coefficient, 6–7 pC/N⁻¹, a value about ten times larger than had been observed in any other polymer. As seen in Table 3, PVDF is inherently polar. The spatially symmetrical disposition of the hydrogen and fluorine atoms along the polymer chain gives rise to unique polar effects that influence the electromechanical response, solubility, dielectric properties, and crystal morphology and yield an unusually high dielectric constant. The dielectric constant of PVDF is about

12, which is four times greater than that of most polymers, and makes PVDF attractive for integration into devices because the signal-to-noise ratio is smaller for higher dielectric materials. The amorphous phase in PVDF has a glass transition that is well below room temperature (–35°C); hence, the material is quite flexible and readily strained at room temperature. PVDF is typically 50–60% crystalline, depending on thermal and processing history, and has at least four crystal phases (α , β , γ , and δ); at least three are polar. The most stable, nonpolar α phase results upon casting PVDF from a melt and can be transformed into the polar β phase by mechanical stretching at elevated temperatures or into the polar δ phase by rotating the molecular chain axis in a high electric field (~ 130 MV/m) (10). The β phase is most important for piezoelectricity and has a dipole moment perpendicular to the chain axis of 2.1 D that corresponds to a dipole concentration of 7×10^{-30} Cm. After poling PVDF, the room temperature polarization stability is excellent; however, polarization and piezoelectricity degrade as temperature increases and are erased at its Curie temperature. Previously, it was believed that polarization stability was defined only by the melting temperature of the PVDF crystals. Recently, however, some researchers suggest that the polarization stability of PVDF and its copolymers is associated with coulombic interactions between injected, trapped charges and oriented dipoles in the crystals (11). They hypothesize that the thermal decay of the polarization is caused by the thermally activated removal of the trapped charges from the traps at the surface of the crystals. The role of trapped charges in stabilizing orientation in both semicrystalline and amorphous polymers is still a subject that needs further study. The electromechanical properties of PVDF have been widely investigated. For more details, the

Table 3. Comparison of Piezoelectric Properties of Some Semicrystalline Polymeric Materials

reader is referred to the wealth of literature that exists on the subjects of piezoelectric, pyroelectric, and ferroelectric properties (2,6,12,13), and the morphology (14–16) of this polymer.

Poly(Vinylidene Fluoride–Trifluoroethylene and Tetrafluoroethylene) Copolymers. Copolymers of polyvinylidene fluoride with trifluoroethylene (TrFE) and tetrafluoroethylene (TFE) also exhibit strong piezoelectric, pyroelectric, and ferroelectric effects. These polymers are discussed together here because they behave similarly when copolymerized with PVDF. An attractive morphological feature of the comonomers is that they force the polymer into an all-trans conformation that has a polar crystalline phase, which eliminates the need for mechanical stretching to yield a polar phase. P(VDF–TrFE) crystallizes to a much greater extent than PVDF (up to 90% crystalline) and yields a higher remanent polarization, a lower coercive field, and much sharper hysteretic loops. TrFE also extends the use temperature by about 20°C to close to 100°C. Conversely, copolymers with TFE exhibit a lower degree of crystallinity and a suppressed melting temperature, compared to the PVDF homopolymer. Although the piezoelectric constants for the copolymers are not as large as those of the homopolymer, the advantages of P(VDF–TrFE) in processibility, enhanced crystallinity, and higher use temperature make it favorable for applications.

Researchers have recently reported that highly ordered, lamellar crystals of P(VDF–TrFE) can be made by annealing the material at temperatures between the Curie temperature and the melting point. They refer to this material as a “single crystalline film.” A relatively large single crystal of P(VDF–TrFE) 75/25 mol% copolymer was grown that exhibits a room temperature $d_{33} = -38$ pm/V and a coupling factor $k_{33} = 0.33$ (17).

The result of introducing defects into the crystalline structure of P(VDF–TrFE) copolymer on electroactive actuation has been studied using high electron irradiation (18). Extensive structural investigations indicate that electron irradiation disrupts the coherence of polarization domains (all-trans chains) and forms localized polar regions (nanometer-sized, all-trans chains interrupted by trans and gauche bonds). After irradiation, the material exhibits behavior analogous to that of relaxor ferroelectric systems in inorganic materials. The resulting material is no longer piezoelectric but rather exhibits a large electric field-induced strain (5% strain) due to electrostriction. The basis for such large electrostriction is the large change in the lattice strain as the polymer traverses the ferroelectric to paraelectric phase transition and the expansion and contraction of the polar regions. Piezoelectricity can be measured in these and other electrostrictives when a dc bias field is applied. Irradiation is typically accomplished in a nitrogen atmosphere at elevated temperatures using irradiation dosages up to 120 Mrad.

Polyamides. A low level of piezoelectricity was first reported in polyamides (also known as nylons) in 1970 (19).

Figure 4. Schematic depiction of hydrogen-bonded sheets showing dipole directions in the crystal lattices of (a) even (nylon 4) and (b) odd polyamides (nylon 5).

A systematic study of odd-numbered nylons, however, initiated in 1980 (20), served as the impetus for more than 20 years of subsequent investigations of piezoelectric and ferroelectric activity in these polymers. The monomer unit of odd nylons consists of even numbers of methylene groups and one amide group whose dipole moment is 3.7 D. Polyamides crystallize in all-trans conformations and are packed to maximize hydrogen bonding between adjacent amine and carbonyl groups, as seen in Fig. 4 for an even-numbered and an odd-numbered polyamide. The amide dipoles align synergistically in the odd-numbered monomer, resulting in a net dipole moment. The amide dipole cancels in an even-numbered nylon, although remanent polarizations have been measured for some even-numbered nylons, as discussed later in this article. The unit dipole density depends on the number of methylene groups present, and polarization increases from 58 mC/m² for nylon-11 to 125 mC/m² for nylon-5 as the number of methylene groups decreases (8).

Polyamides are known hydrophilics. Because water absorption is associated with hydrogen bonding to the polar amide groups, the hydrophilicity increases as the density of amide groups increases. Water absorption in nylon-11 and nylon-7 has been shown to be as high as 4.5% (by weight) and more than 12% for nylon-5 (21), whereas it is less than 0.02% for PVDF and its copolymers. Studies have shown that water absorption can have a dramatic effect on the dielectric and piezoelectric properties of nylons; however, water does not affect the crystallinity or orientation in thermally annealed films (21). Thus, films can be dried to restore their original properties.

At room temperature, odd-numbered nylons have lower piezoelectric constants than PVDF; however, when

examined above their glass transition temperatures, they exhibit comparable ferroelectric and piezoelectric properties and much higher thermal stability. The piezoelectric d and e constants increase rapidly as temperature increases. Maximum stable d_{31} values of 17 pC/N and 14 pC/N are reported for nylon-7 and nylon-11, respectively. Corresponding values of the electromechanical coupling constant k_{31} are 0.054 and 0.049. Studies have also shown that annealing nylon films enhances their polarization stability because it promotes denser packing of the hydrogen-bonded sheet structure in the crystalline regions and hinders dipole switching due to lowered free volume for rotation (22).

Though widely studied, piezoelectric polyamides have not been widely used in applications due in part to their low room temperature piezoelectric response and the problem of moisture uptake.

Liquid Crystalline Polymers. Liquid crystals consist of highly ordered rodlike or disklike molecules. At their melting points they partially lose crystalline order and generate a fluid but ordered state. They can form layered structures called smectic phases or nematic phases that have an approximately parallel orientation of the molecular long axis. It was first predicted in 1975 that spontaneous polarization could be achieved in liquid crystals based on symmetry arguments (23). Subsequently, it has been shown that liquid crystalline molecules whose chiral carbon atoms link a mesogenic group and end alkyl chains may exhibit ferroelectric behavior in the smectic C phase (SmC^*) (24). In this phase, the molecular axis tilts from the normal to the layer plane, and the molecular dipoles align in the same direction, yielding a net polarization. If such liquid crystalline molecules are introduced into the backbone or as a side group on a polymer, a ferroelectric liquid crystalline polymer can be obtained. There are three requirements for spontaneous polarization in a liquid crystal: a center of chirality, a dipole moment positioned at the chiral center that acts transverse to the molecular long axis, and a tilted smectic phase (25).

Polyureas. Polyureas are thermosets, long used as insulators in a number of applications. Until a few years ago, ureas were available mostly as insoluble powders or highly cross-linked resins. In 1987, a vapor deposition polymerization method was successfully developed that was later applied to synthesizing polyureas (26a,27). Typically, a vapor deposition technique is used by evaporating $\text{OCN-R}_1\text{-NH}_2$ and $\text{H}_2\text{N-R}_2\text{-NH}_2$ monomers simultaneously on a substrate (where R_1 and R_2 are various aliphatic or aromatic groups). This prevents cross-linking and allows processing thicknesses in the hundreds of nanometers to tens of micrometers.

An exploration (27) of the dielectric and pyroelectric properties of polyureas films led to the discovery of their piezoelectricity. From the early 1990s to the present, various aromatic and aliphatic polyureas were synthesized, and it was shown that they are piezoelectric (28,29). Aromatic polyureas were the first polyurea structures identified as piezoelectric. They exhibit a piezoelectric

e constant of 15 mC/m^2 and have high temperature stability which remains independent of temperature up to 200°C . Their pyroelectric coefficient is high due to their low dielectric loss compared to other polymers. The d constant is about 5 pC/N at room temperature and increases as temperature increases (28).

Owing to their structures, aliphatic polyureas possess higher flexibility in their molecular chains. Similarly to polyamides, hydrogen bonds play a large role in stabilizing the orientation polarization that is imparted. Polyureas that have an odd number of methyl groups exhibit overall nonzero polarization. Polyurea-9 was synthesized and processed first, and an e constant of 5 mC/m^2 was reported (28). Then, polyureas that have a smaller number of carbons were attempted because it was surmised that they should lead to a higher density of urea bond dipoles. Toward that end, polyurea-5 was synthesized, and it was found that the e and d constants are twice those of polyurea-9. Aliphatic polyureas exhibit ferroelectric hysteresis and in addition, are piezoelectric when they have odd numbers of methyl groups. Their thermal stability and piezoelectric coefficients depend highly on the poling temperature (typically $70\text{--}150^\circ\text{C}$) but are lower than those of aromatic polyureas.

Biopolymers. Piezoelectricity of biopolymers was first reported in keratin in 1941 (30). When a bundle of hair was immersed in liquid air, an electric voltage of a few volts was generated between the tip and the root. When pressure was applied on the cross section of the bundle, an electric voltage was generated. Subsequently piezoelectricity has been observed in a wide range of other biopolymers including collagen (31,32), polypeptides like poly- γ -methylglutamate and poly- γ -benzyl-L-glutamate (33,34), oriented films of DNA (35), poly-lactic acid (36), and chitin (37). Most natural biopolymers possess D_∞ symmetry, so they exhibit shear piezoelectricity. A shear stress in the plane of polarization produces an electric displacement perpendicular to the plane of the applied stress and results in a $-d_{14} = d_{25}$ piezoelectric constant. The piezoelectric constants of biopolymers are small relative to synthetic polymers; they range in value from 0.01 pC/N for DNA to 2.5 pC/N for collagen. The electromechanical effect in such polymers is attributed to the internal rotation of polar atomic groups linked to asymmetrical carbon atoms. Keratin and some polypeptide molecules assume an α -helical or a β -crystalline structure in which the CONH dipoles align synergistically in the axial direction.

Currently, the physiological significance of piezoelectricity in many biopolymers is not well understood, but it is believed that such electromechanical phenomena may have a distinct role in biochemical processes. For example, it is known that electric polarization in bone influences bone growth (38). In one study, a piezoelectric PVDF film was wrapped around the femur of a monkey. Within weeks, a remarkable formation of new bone was observed. The motion of the animal caused deformation of the film that produced a neutralizing ionic current in the surrounding tissue. This minute fluctuating current appears to stimulate the metabolic activity of bone cells and leads to the proliferation of bone.

AMORPHOUS POLYMERS

The purpose of this section is to explain the mechanism and key components required for developing piezoelectricity in amorphous polymers and to present a summary of the polarization and electromechanical properties of the amorphous polymers currently under investigation.

Mechanism of Piezoelectricity

Dielectric Theory. The piezoelectricity in amorphous polymers differs from that in semicrystalline polymers and inorganic crystals in that the polarization is not in a state of thermal equilibrium, but rather a quasi-stable state due to the freezing-in of molecular dipoles. The result is a piezoelectric-like effect. A theoretical model for polymers that have frozen-in dipolar orientation was presented to explain piezoelectricity and pyroelectricity in amorphous polymers such as polyvinyl chloride (39).

One of the most important properties of an amorphous piezoelectric polymer is its glass transition temperature (the temperature below which the material exhibits glass-like characteristics, and above which it has rubber-like properties) because it dictates use temperature and defines the poling process conditions. Orientation polarization of molecular dipoles is responsible for piezoelectricity in amorphous polymers. It is induced, as shown in Fig. 5, by applying an electric field E_p at an elevated temperature ($T_p \geq T_g$) where the molecular chains are sufficiently mobile and allow dipole alignment with the electric field. Partial retention of this orientation is achieved by lowering the temperature below T_g in the presence of E_p , resulting in a piezoelectric-like effect. The remanent polarization P_r is

Figure 5. Poling profile of an amorphous polymer.

directly proportional to E_p and the piezoelectric response. The procedure used to prepare a piezoelectric amorphous polymer clearly results in both oriented dipoles and space or real charge injection. The real charges are usually concentrated near the surface of the polymer, and they are introduced due to the presence of the electrodes. Interestingly, some researchers (40,41) have shown that the presence of space charges does not significantly affect piezoelectric behavior. The reason is twofold. The magnitude of space charges is usually not significant with respect to polarization charges. Secondly, space charges are essentially symmetrical with respect to the thickness of the polymer; therefore, when the material is strained uniformly, the contribution to the piezoelectric effect is negligible.

In what follows, the origins of the dielectric contribution to the piezoelectric response of amorphous polymers are addressed. The potential energy U of a dipole μ at an angle θ with the applied electric field is $U = \mu \mathbf{E} \cos \theta$. Using statistical mechanics and assuming Boltzmann's distribution of dipole energies, the mean projection of the dipole moment $\langle \mu_E \rangle$ in the direction of the applied electric field is obtained:

$$\frac{\langle \mu_E \rangle}{\mu} = \coth \frac{\mu E_p}{kT} - \frac{kT}{\mu E}. \quad (8)$$

This is the Langevin equation that describes the degree of polarization in a sample when an electric field E is applied at temperature T . Experimentally, a poling temperature in the vicinity of T_g is used to maximize dipole motion. The maximum electric field that may be applied, typically 100 MV/m, is determined by the dielectric breakdown strength of the polymer. For amorphous polymers, $\mu E/kT$ is much less than one; this places these systems well within the linear region of the Langevin function. The remanent polarization P_r is simply the polarization during poling minus the electronic and atomic polarizations that relax at room temperature, once the field E_p is removed. The following linear equation for remanent polarization results when the Clausius–Mossotti equation is used to relate the dielectric constant to the dipole moment (42):

$$P_r = \Delta \epsilon \epsilon_0 E_p. \quad (9)$$

It can be concluded that remanent polarization and hence the piezoelectric response of a material are determined by $\Delta \epsilon$; this makes it a practical criterion to use when designing piezoelectric amorphous polymers. The dielectric relaxation strength $\Delta \epsilon$ may be the result of either free or cooperative dipole motion. Dielectric theory yields a mathematical approach for examining the dielectric relaxation $\Delta \epsilon$ due to free rotation of the dipoles. The equation incorporates Debye's work based on statistical mechanics, the Clausius–Mossotti equation, and the Onsager local field and neglects short range interactions (43):

$$\Delta \epsilon_{\text{calculated}} = \frac{N \mu^2}{3kT \epsilon_0} \left(\frac{n^2 + 2}{3} \right)^2 \left[\frac{3\epsilon(0)}{2\epsilon(0) + n^2} \right]^2, \quad (10)$$

where N is the number of dipoles per unit volume, k is the Boltzmann constant, $\epsilon(0)$ is the static dielectric constant,

and n is the refractive index. One way to measure P_r in amorphous polymers is the thermally stimulated current (TSC) method (refer to section on characterization). P_r can be calculated from the liberated charge during TSC, and by reconciling that with the Onsager relationship, the dipole density can be calculated:

$$P_r = \frac{N\mu^2 E_p}{3kT_p} \left(\frac{\varepsilon_\infty + 2}{3} \right)^2 \left[\frac{3\varepsilon(0)}{2\varepsilon(0) + \varepsilon_\infty} \right]. \quad (11)$$

The piezoelectric constants are related to the polarization. From basic thermodynamics,

$$d_{3i} = \left(\frac{\partial P}{\partial \sigma_i} \right)_{\gamma, T}. \quad (12)$$

A molecular theory of the direct piezoelectric effect in poled amorphous piezoelectric polymers has been developed. An expression for the hydrostatic coefficient appears in the original paper (41). Later, this theory was extended, and an equation for d_{31} was obtained (44,45). By differentiating Eq. (11) and modifying it to account for dimensional effects such as stretching (44,46),

$$d_{31} = P_r(1 - \gamma)S_{11} + \frac{P_r(1 - \gamma)}{3}(\varepsilon_\infty - 1)S_{11}, \quad (13)$$

where γ is Poisson's ratio, ε_∞ is the permittivity at high frequencies, and S_{11} is the compliance of the polymer. The first term accounts for dimensional effects, and the second term gives the contribution of the local field effect.

Polarizability and Poling Conditions. Designing an amorphous polymer that has a large dielectric relaxation strength and hence piezoelectric response requires the ability to incorporate highly polar groups at high concentrations and cooperative dipole motion. A study of the relationship between relaxation times, poling temperatures, and poling fields is crucial to achieving optimal dipole alignment. Theoretically, the higher the electric field, the better the dipole alignment. The value of the electric field is limited, however, by the dielectric breakdown of the polymer. In practice, 100 MV/m is the maximum field that can be applied to these materials. Poling times need to be of the order of the relaxation time of the polymer at the poling temperature.

During poling, the temperature is lowered to room temperature, while the field is still on, to freeze in the dipole alignment. In a semicrystalline material, however, locking in the polarization is supported by the crystalline structure of the polymer, and it is therefore stable above the glass transition temperature of the polymer. Because the remanent polarization in amorphous polymers is lost in the vicinity of T_g , their use is limited to temperatures well below T_g . This means that the polymers are used in their glassy state, where they are quite stiff and thus limit the ability of the polymer to strain as stress is applied. A piezoelectric amorphous polymer may be used at temperatures near its T_g to optimize its mechanical properties, but not too close so as to maintain the remanent polarization.

Although there are few data that address the stability of piezoelectric activity in amorphous polymers, it is clear that time, pressure, and temperature can contribute to dipole relaxation in these polymers. For a given application and use temperature, the effect of these parameters on the stability of the frozen-in dipole alignment should be determined.

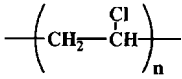

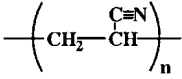

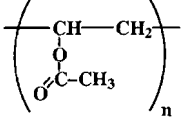

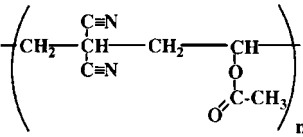

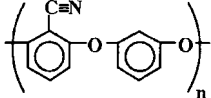

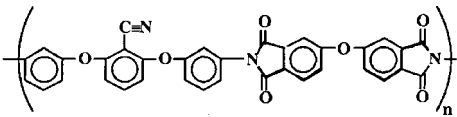

Examples of Amorphous Piezoelectric Polymers

The literature on amorphous piezoelectric polymers is much more limited than that for semicrystalline systems this is in part because no amorphous piezoelectric polymers; have responses high enough to attract commercial interest. Much of the previous work on amorphous piezoelectric polymers was in nitrile-substituted polymers, including polyacrylonitrile (PAN) (47–49), poly(vinylidene cyanide vinyl acetate) (PVDCN/VAc) (50–54), polyphenylethynitrile (PPEN) (55,56), and poly(1-bicyclobutanecarbonitrile) (57). Weak piezoelectric activity in polyvinyl chloride (PVC) and polyvinyl acetate (PVAc) has also been found (11,41,58,59). The most promising of these materials are vinylidene cyanide copolymers that exhibit large dielectric relaxation strengths and strong piezoelectricity. Table 4 shows the molecular structures of the most commonly encountered amorphous piezoelectric polymers.

Polyvinylidene Chloride. The carbon–chlorine dipole in polyvinylidene chloride (PVC) has been oriented to produce a low level of piezoelectricity. The piezoelectric and pyroelectric activities generated in PVC are stable and reproducible. PVC has been used as a basis for understanding and studying piezoelectricity in amorphous polymers (39). The piezoelectric coefficients d_{31} of PVC are reportedly in the range of 0.5–1.3 pC/N. This response was improved by simultaneous stretching and corona poling of film (44). The enhanced piezoelectric coefficient d_{31} ranged from 1.5–5.0 pC/N.

PVDCN Copolymers. In 1980, exceptionally strong piezoelectric activity was found (50) in the amorphous copolymer of VDCN and VAc. The copolymer was poled at 150°C (20°C below its T_g) and cooled to room temperature in the electric field. A $P_r = 55$ mC/m² was obtained in a poling field of 50 MV/m. That is comparable to the P_r of PVDF. When local ordering, or paracrystallinity, is inherent in the polymer or is induced by mechanical stretching, an increase in the value of the remanent polarization is observed. For example, some researchers (51) assert that the large discrepancy between the measured and calculated $\Delta\varepsilon$ for PVDCN-VAc may be attributed to locally ordered regions in the polymer. $\Delta\varepsilon_{\text{calculated}} = 30$ for the copolymer PVDCN/VAc, and $\Delta\varepsilon_{\text{measured}} = 125$ (51). This large discrepancy in the values of $\Delta\varepsilon$ is indicative of cooperative motion of several nitrile dipoles within the locally ordered regions of the polymers. Cooperativity means that multiple nitrile dipoles respond to the applied electric field in a unified manner, instead of each dipole acting independently. Although the existence of cooperative dipole motion clearly increases the piezoelectric response of amorphous polymers, the mechanisms by which cooperativity can be

Table 4. Structure, Polarization, and T_g of Piezoelectric Amorphous Polymers

Polymer	Structure	T_g (°C)	d_{31} (pC/N)	P_r (mCm ²)	Ref.
PVC		80	5	16	44
PAN		90	2	25	49
PVAc		30	—	5	59
P(VDCN-VAc)		170	10	50	51
PPEN		145	—	12	55
(β -CN) APB/ODPA		220	5 at 150°C	20	59

systematically incorporated into the polymer structure remain unclear at this time (59).

The large relaxation strength exhibited by PVDCN/VAc gives it the largest value of P_r and hence d_{31} of all of the amorphous polymers. A number of authors have suggested that PVDCN-VAc also exhibits ferroelectric-like behavior (51–53) due to switching of the nitrile dipoles in an ac field. The switching time is long compared to that of a normal ferroelectric polymer.

Other VDCN Polymers. The homopolymer of vinylidene cyanide is thermally unstable (60) and highly sensitive to moisture, but VDCN can be polymerized with a variety of monomers in addition to VAc, such as vinyl benzoate (VBz), methyl methacrylate (MMA) and others that form highly alternating chains. All of these copolymers show some degree of piezoelectricity although lower than PVDCN-VAc, which is explained by different activation energies for dipole orientation in the glassy state and different chain mobility that depends on the side group.

Polyacrylonitrile. Polyacrylonitrile (PAN) is one of the most widely used polymers. Shortly after it was shown that the PVDCN-VAc system is piezoelectric, researchers turned their attention to PAN due to its similarity to the aforementioned polymers. The presence of the large nitrile dipole in PAN indicated that it can be oriented by an applied electric field. PAN presented some challenges not encountered in other nitrile-substituted polymers, however. Although theoretical calculations predicted strong piezoelectric behavior, it was difficult to pole. Several investigators (47–49) proposed that the difficulty of poling PAN in

the unstretched state is related to the strong dipole–dipole interaction of nitrile groups of the same molecule that repel each other, and thus prevent normal polarization. Upon stretching, the intermolecular dipole interactions facilitate packing of the individual chains and give rise to ordered zones. The remanent polarization of both unstretched and stretched PAN has been measured using the thermally stimulated current method (TSC), and a twofold increase in remanent polarization (TSC peak at 90°C) was observed for PAN that was stretched to four times its original length (47). Another approach is the copolymerization of PAN with another monomer. Researchers have reported reduction of the hindering effect of the dipole–dipole interactions and enhancement of the internal mobility of the polymer segments when PAN is copolymerized with polystyrene or methyl methacrylate. Ferroelectric behavior has been observed in P(AN-MMA), where, for given temperature and field conditions, a characteristic hysteretic loop is obtained (49). It was concluded that it may be one rare example where both ferroelectric and frozen-in dipole orientations are superimposed.

Nitrile-Substituted Polyimide. Amorphous polyimides that contain polar functional groups were synthesized (61–63) and investigated for use as high temperature piezoelectric sensors. (β -CN) APB/ODPA polyimide is one such system. The (β -CN) APB/ODPA polyimide possesses the three dipole functionalities shown in Table 5. Typically, the functional groups in amorphous polymers are pendent to the main chain. The dipoles, however, may also reside within the main chain of the polymer, such as the anhydride units in the (β -CN) APB/ODPA polyimide. The nitrile

Table 5. Values of Dipole Moments Within Nitrile-Substituted Polyimide

Dipoles	Dipole Identity	Dipole Moment (Debye)
	Pendent nitrile group	4.18
	Main chain dianhydride group	2.34
	Main chain diphenylether group	1.30

to dipole is pendent a phenyl ring ($\mu = 4.2$ D), and the two anhydride dipoles ($\mu = 2.34$ D) are within the chain, resulting in a total dipole moment of 8.8 D per repeat unit.

The remanent polarization P_r of the (β -CN)APB/ODPA polymer found by the thermally stimulated current method (TSC) was approximately 20 mC/m² when poled at 80 MV/m above the T_g for 1 hour (64). Excellent thermal stability was observed up to 100°C, and no loss of the piezoelectric response was seen after aging at 50°C and 100°C for as long as 500 hrs.

Partially cured films of the (β -CN)APB/ODPA system were simultaneously corona poled and cured to enhance dipolar orientation and minimize localized arcing during poling. The aligned polar groups should be immobilized by additional imidization and subsequent cooling in an electric field. Both the T_g and the degree of imidization increase almost linearly as the final cure temperature is increased (64). The value of P_r was higher for films cured at lower temperatures. The mobility of the molecules in a partially imidized state should be higher than that in the fully cured state and therefore produce a higher degree of dipole orientation.

The importance of dipole concentration in ultimate polarization is evident from a comparison of polyacrylonitrile (PAN) and the polyimide (β -CN) APB/ODPA. PAN has a single nitrile dipole per repeat unit ($\mu = 3.5$ D) resulting in a dipole concentration of 1.34×10^{28} m⁻³. This translates into an ultimate polarization of 152 mC/m² (20). The (β -CN) APB/ODPA polyimide, on the other hand, has a total dipole moment of 8.8 D per monomer. The dipole concentration of (β -CN) APB/ODPA, however, is only 0.136×10^{28} m⁻³, resulting in an ultimate polarization of 40 mC/m², which is less than a fourth of that of PAN. As a result, similar polyimides that have increased nitrile concentrations were synthesized and characterized. Studies of these polymers show that polarization is significantly increased by increasing dipole concentration. Structure-property investigations designed to assess the effects of these dipoles on T_g , thermal stability, and overall polarization behavior are currently being pursued.

Even-Numbered Nylons. Nylon 6I and 6I/6T exhibit a D - E hysteretic loop across a temperature range of 30–65°C at a fixed maximum field of 168 MV/m (65). The remanent polarization increases as the temperature increases. Note that nylon 6I and 6I/6T are completely amorphous. The P_r is about 30 mC/m².

Aliphatic Polyurethane. Some researchers (1) have suggested that aliphatic polyurethane systems exhibit ferroelectricity that stems from the amorphous part at temperatures above the glass transition temperature. This “liquid state” ferroelectricity is very peculiar, seems to exist, and is supported by the hydrogen bonds present.

CHARACTERIZATION AND MODELING

Most piezoelectric characterization methods were developed for crystalline ceramics and had to be adapted for piezoelectric polymers. Methods based on resonance analysis and equivalent circuits that can be used to characterize semicrystalline PVDF and its copolymers are outlined in IEEE standards (66). Details for applying resonance analysis to piezoelectric polymers have recently been explored (67). Due to the lossy nature of some polymers, the IEEE standards are not adequate, and other techniques are needed to describe piezoelectric properties more accurately.

Quasi-static direct methods are both versatile and well suited to investigating fully the piezoelectric response of polymers. Direct methods of this type are especially appropriate for amorphous polymers. Thermally stimulated current measurements (TSC) (68) are used to measure the remanent polarization imparted to a polymer, and direct strain or charge measurements are used to investigate the piezoelectric coefficients with respect to the electric field, frequency, and stress.

TSC is a valuable tool for characterizing piezoelectric polymers. After poling a polymer, a measure of the current dissipation and the remanent polarization as a function temperature can be obtained by TSC. As the sample is heated through its glass transition temperature (or Curie temperature for a semicrystalline polymer) at a slow rate (typically 1–4°C/min), the depolarization current is measured by an electrometer. The remanent polarization is equal to the charge per unit area and is obtained from the data by integrating the current with respect to time and plotting it as a function of temperature:

$$P_r = \frac{Q}{A} = \frac{1}{A} \int I(t) dt. \quad (14)$$

Figure 6 illustrates a typical TSC result. Because permanent dipoles are immobile at temperatures well below T_g , the current discharge remains low in this temperature range. As temperature increases to and beyond the T_g , however, the onset of dipole mobility contributes to a significant increase in the current peak. The peak in the current and the subsequent polarization maximum usually occurs in the vicinity of the T_g .

Direct methods for measuring the strain that results from applying a field or vice versa, applying a strain, and measuring the accumulated charge, are abundant. Interferometers, dilatometers, fiber-optic sensors, optical levers, linear variable displacement transducers, and optical methods are employed to evaluate the piezoelectric strain (converse effect) (69–72). The “out-of-plane” or thickness piezoelectric coefficient d_{33} can be ascertained as a function of the driving field and frequency. The coefficient

Figure 6. Plot of thermally stimulated current for a typical amorphous poled polymer.

is measured based on the equation,

$$S_{33} = d_{33}E_3, \quad (15)$$

where S_{33} is the strain and E_3 is the applied electric field.

A modified Rheovibron, or similar techniques, have been used to measure the direct piezoelectric effect, where charges accumulated on the surfaces of the polymer are measured (59). The piezoelectric coefficient d_{31} can be obtained by straining the polymer in the direction of applied stress using a force F . A charge Q is generated on the surface of the electrodes. A geometric factor is used to produce a geometrically independent parameter, surface charge density per unit applied stress:

$$d_{31} = \frac{Q/(WL)}{F/(Wt)}, \quad (16)$$

which has units of pC/N. W , L , and t are the width, length, and thickness of the sample, respectively.

Modeling

The methodology for modeling piezoelectric behavior in polymers varies, depending on the targeted properties. Approaches cover the range from macroscale to micro and atomistic scales. A detailed review of computational methods applied to electroactive polymers has been published (73).

Figure 7. Direct effect in polymers.

In some cases, modeling can predict behavior where experiments cannot. Using molecular dynamics, the orientation polarization of the (β -CN) APB/ODPA polymer was assessed by monitoring the angle θ that the dipoles make with an applied electric field (74). The bulk P_r was calculated, and the results agreed extremely well with experimental results (61). Computational modeling, however, gave insight into the contributions of the various dipoles present in a way experimental results could not. The model predicted that 40% of the orientation polarization was due to the dianhydride within the backbone of the ODPA monomer and demonstrated the importance of the flexible ether linkage (oxygen atom) in facilitating dipole alignment. Modeling insight of this kind is invaluable in guiding the synthesis of new materials.

Modeling of PVDCN-VAc can also play a role in understanding the cooperative motion responsible for the high dielectric relaxation strength of this class of polymers, not possible experimentally (75). Recently, mesoscale simulation was used to describe polarization reversal in PVDF films (76).

Applications and Future Considerations

The potential for applying piezoelectric and other electroactive polymers is immense. To date, ferroelectric polymers have been incorporated into numerous sensing and actuating devices for a wide array of applications. Typical applications include devices in medical instrumentation, robotics, optics, computers, and ultrasonic, underwater, and electroacoustic transducers. One important emerging application area for electroactive polymers is the biomedical field where polymers are being explored as artificial muscle actuators, as invasive medical robots for diagnostics and microsurgery, as actuator implants to stimulate tissue and bone growth, and as sensors to monitor vascular grafts and to prevent blockages (77,78). Such applications are ideal for polymers because they can be made biocompatible, and they have excellent conformability and impedance that match body fluids and human tissue. The intent of this article is not to detail specific applications; the interested reader may consult excellent sources on the applications of piezoelectric and ferroelectric polymers (79–81).

In the future, we believe that fertile research areas for piezoelectric polymers will include work to enhance their properties, to improve their processibility for incorporation in devices, and to develop materials that have a broader use temperature range. Fundamental structure–property understanding has enabled the development of numerous semicrystalline and amorphous polymers. Based on this knowledge, future research that focuses on property enhancement via new chemistries that have higher dipole concentrations and incorporate dipole cooperativity may yield improved materials. Property enhancements may also be gained from processing studies to alter polymer morphology such as those used to make “single crystalline” fluoropolymers. Development of materials that can operate in extreme environments (high temperature and subambient temperature) is also important for expanding the use of piezoelectric polymers. Piezoelectric and pyroelectric constants of polymers are considerably lower than those of

ferroelectric inorganic ceramics. Improvements in properties by incorporating polymers in composites with inorganics to obtain higher electromechanical properties and better mechanical properties are also valuable. To date, piezoelectric polymer-ceramic composites have been made wherein the polymer serves only as an inactive matrix for the active ceramic phase. This is due to the mismatch in permittivity between the polymer and ceramic which makes it difficult to pole both phases. Research that results in active polymer and ceramic phases could yield interesting electromechanical properties.

ACKNOWLEDGMENTS

The authors express sincere appreciation to Dr. J.A. Young (Lawrence Livermore) for her technical insight in the area of amorphous piezoelectric polymers. The authors thank Suzanne Waltz (NASA Langley) for graphics assistance.

INTRODUCTION

Many industrial and commercial sectors are made up of separate, relatively small components: aerospace and ground transport, for example. In such applications, truly smart materials systems (SMS) are defined as those that respond autonomously to changes in their operating conditions. That is, they detect the onset of “illness” and take steps to effect a cure. In contrast, the electric power industry is a vast, interconnected enterprise, not a collection of individual entities. It is a far-flung grid, fed and drained continuously at variable rates. SMS must be consistent with this character: owing to the extent of the grid and the way it operates, just detecting illness *and determining its location* constitutes smartness. Moreover, users of electricity expect reliability everywhere the grid reaches, so avoiding failures (outages) is paramount. Thus, *distributed* SMS are often required to achieve reliability. Some other sectors (e.g., highways) also will rely on distributed SMS, but in electricity systems the SMS must function under more hostile conditions of temperature, pressure, aggressive chemicals, and especially, intense electric and/or magnetic fields. Early detection of deviations or trouble is vital. In a sense, successful performances of SMS in the power industry equates to buying time for a rational response. Whatever else they might do by way of autonomous responses (derating a unit, eliminating an ailing component from a redundant set, etc.), the crucial action for SMS in electricity systems is to notify a central authority about an (impending) illness and where that illness is.

Although investment in SMS research by the power industry has been substantial, utilization of SMS within the industry is still in the early stages. There is little doubt, however, that the influence of SMS will be profound in the future.

Table 1. Electric Power Industry Segments

Segment	Number of Entities	% of U.S. Consumers Served	Median Number of Customers per Organization
Investor-owned utilities	264	75%	~210,000
Rural electric cooperatives	947	10%	~8000
	888 (distribution only)		
	59 (generation and transmission)		
Public power	~2,000	15%	~1750
Federal systems	10	<0.1%	n/a
		(supplier to other segments)	

OVERVIEW OF THE ELECTRIC POWER INDUSTRY

Size, Composition, and Economic Pressures

There are four sectors in the electric power industry: investor-owned utilities, rural electric cooperatives, public power systems, and federal power agencies. The number of organizations in each category, percentage of U.S. customers served by each segment, and the median number of customers served by each are summarized in Table 1. Total installed capacity is on the order of 750 GW (1), with approximately 627,400 miles of transmission lines of 11 kV or more (2), and 3,600,000 miles of distribution lines (3). Annual expenditures for generation and for transmission and distribution are approximately equal at about \$12 billion each.

In the past, utilities have been highly regulated, with specified rates of return, protected service territories, and the obligation to provide power to any customer within a defined service territory. Over the last few years, protected markets and assured customers have come to an end, and nonutility generators (NUGs) have appeared on the scene. It is estimated that there are now over 3000 NUGs in the United States and that 75% of all new capacity since 1980 has been supplied by NUGs. Competitive pressure is pervasive; lowering costs, improving and expanding customer services, diversifying into other businesses, and striving for better utilization of corporate assets have become the primary drivers.

Problem Costs and Solution Benefits

A principal role for smart materials in the power industry would be to lower costs and improve system reliability. An indication of the scale of the challenge is provided by the three rules of thumb that follow.

1. A typical coal-fired power plant is approximately 35% efficient. For a 500 MW generating unit, loaded at 70% plant factor, a 0.1% efficiency improvement would reduce annual costs by about \$150,000 at a typical busbar electricity cost of \$0.017/kWh. For a six-unit plant, annual savings would therefore be about \$900,000.
2. Most electricity is generated by large units and there is a high premium for keeping those units on line.

When high-merit units are out of service, replacement power must often be provided by less-efficient (more costly) sources. Unscheduled outages caused by equipment failure or significant unit degradation are particularly costly. Outage lengths depend on availability of spares, difficulty of access, degree of damage, and so on, and can range from hours to months. Replacement power cost for a one-day outage of a 500 MW unit is on the order of \$240,000 (at \$0.02/kWh). Emergency (unscheduled) power purchases can cost even more; \$0.03–0.04/kWh is not unusual.

3. Most generation and power delivery equipment is operated well below theoretical limits so as to provide reasonable factors of safety. Furthermore, when deterioration of structural or functional integrity is suspected, the afflicted equipment is derated, that is, operated at a lower level of performance. Derating a 500 MW unit by 5% (25 MW) is equivalent to \$12,000 per day or \$4,380,000 per year of lost revenue (at \$0.02/kWh). A transmission line that must be operated below its normal thermal limit can reduce revenues by \$1,750,000 per year.

The Power Industry Environment

Although combustion turbines, often combined with heat-recovery boilers, are increasingly popular for new installations, the generation of power from thermal sources is still preponderantly by steam turbines. Hence, a primary activity for many utilities is the raising of steam. Fossil-fueled boilers in large central stations produce as much as 1260 kg of steam per second (10,000,000 lb of steam per hour) at pressures ranging from 13.8 to 24.8 MPa (2000 to 3600 psig) and temperatures up to 580°C (1100°F). Nuclear-fueled, pressurized-water reactors operate at coolant pressures of 15.2 to 15.9 MPa (2200–2300 psig) and a temperature of about 316°C (600°F) to produce steam at 6.2 to 7.3 MPa (900–1050 psig). In other words, steam plants are characterized by hostile environments: high temperatures, high pressures, and aggressive fluids. The damage mechanisms that ensue when plant components are exposed to these conditions are summarized in Table 2.

Steam plant environments are demanding, but most of them are not unique; high temperatures and pressures,

and reactive process streams, are also found, for instance, in the chemical processing and metal production industries. In contrast, the environments associated with electricity generation and delivery are special in that they involve strong electromagnetic fields and large electric currents. As a consequence, the health of insulation materials, with their extreme sensitivity to relatively low temperatures (100–180°C, or 212–356°F) and mild mechanical forces, dominates concerns about reliability and failure avoidance. Of course, there are also the usual threats to integrity, such as cyclic stresses, corrosion, and wear. Damage mechanisms operative in this sector of the power industry are given in Table 3.

A final point about the power industry environment: electricity suppliers keep their primary equipment (boilers, turbines, transformers, transmission and distribution lines) in service for longer times than is common for most other industries. Plant and equipment designs aim for a 40-year life, and nowadays the utilities often strive for life extension to even longer times. Inevitably, even normal wear and tear take their toll and apparatus becomes increasingly fragile with age. However, the reliability requirement is not relaxed for these older components, so that early warning of impending dysfunction becomes even more critical. In addition, there are implications about longevity and redundancy requirements for SMS,

since SMS embedded in the insulation of overhead conductors or in concrete structures, for example, cannot be replaced.

Constraints on SMS Development for the Power Industry

All of the foregoing environmental factors, especially the extended nature of the electricity grid and the pervasive presence of strong electromagnetic fields, impose limitations on SMS solutions to power industry challenges. In the first place, SMS from other industries will not, in general, be directly transferable in their original form either because they have not been designed for the specific tasks of the contemplated application or because electrically based SMS cannot function properly in intense electromagnetic fields. Second, the spatial extent of electricity systems dictates that the most urgent job for SMS is to detect damage or deviant conditions and report the location to a central authority. Autonomous actions by SMS are less important. The SMS constituent that matches this requirement is smart sensors. In fact, smart sensors are the aspect of the SMS that has been most thoroughly investigated for utility applications. Here, transference from another industry was vital: without the R&D base built by the communications industry, the technology of fiber-optic sensors might not have matured.

Undoubtedly, a wide variety of power industry problems will someday be addressed by truly smart, autonomous, fully integrated SMS. At this juncture, however, the main thrust for SMS in utility systems has been aimed at developing and applying smart sensors and, to less extent, smart sensor-actuators.

SMART SENSORS

Requirements and Scope

Need for Better Measurements. In recent years, advances in electronics (signal processing and conditioning) have resulted in improved instrumentation and controls for power plants. Many utilities have replaced analog and pneumatic controls with distributed digital control systems (DCSs) in order to reduce operating costs and to increase the capability to respond to system dispatch. A DCS can regulate processes with less than 0.25% uncertainty, compared with 2% to 3% uncertainty for analog controls. However, the conventional sensors used in power plants cannot, without frequent calibration, provide the levels of accuracy appropriate for sophisticated DCSs. Thus, smart sensors offer the means to increase measurement accuracy and thereby realize the benefits of DCSs.

Opportunities for better measurements are numerous in every sector of the power industry. For example, Sachdeva (4) lists 1393 essential sensors in a typical 500 MW coal-fired power plant. Of these, approximately 1150 are devoted to sensing temperature and pressure. In forward-looking utilities that are developing methodologies for early diagnosis of problems, monitoring of critical components has resulted in 4000 sensors in some generating units (5). Likewise, an NSF workshop (6) identified

26 utility problems associated with transmission and distribution that could be alleviated with improved sensors; affected components included lattice steel towers, wooden poles, overhead conductors and insulators, underground transmission and distribution facilities, and substations. Of course, not all of these sensors need to be smart; for many of them the smartness can be in central control. Still, a significant portion must be smart in order to overcome the effects of difficult environments.

Performance in the Environment. The utility industry can be thought of as the agency for three sequential operations: (1) converting thermal energy to mechanical energy, (2) converting mechanical energy to electrical energy, and (3) electricity delivery. The environments characteristic of each sector are summarized in Table 4. For the purposes of this article the second and third functions are similar enough in their environments that they are discussed together as electricity systems in what follows.

The first prerequisite for SMS in the power industry is that they be able to perform reliably in the environment. That is, they must produce accurate signals under normal as well as perturbed conditions for prolonged periods of time. Again, their priority is to inform a central authority that there is a problem or that damage has occurred, and where. Autonomous action can also be part of the SMS mandate; electricity systems are quite redundant, for example, so a smart sensor could initiate close-down of a redundant component that is about to fail. But a report of illness is the primary responsibility. As will be seen, most smart sensors intended for power-industry applications are based on fiber optics because of their immunity to electromagnetic interference (including lightning strikes and ground faults), as well as their small size and light weight.

Thermal Plant Environments

Pressure Sensing. Many pressure transmitters now installed in power plants rely on fill fluids to separate process fluids from the gauge mechanisms. These devices are subject to failures when fill fluids leak, failures that are difficult to detect. In addition, all conventional pressure sensors drift with time, a condition that necessitates disproportionately large efforts to restore accuracy and verify operability. These concerns have prompted an assessment of modern sensor technologies to select candidates for adaptation to use in power plants (7). Among the findings is the conclusion that fiber-optic pressure sensors *could* provide more extensive sampling of process pressures, an improved mode of signal transmission and processing, and freedom from electromagnetic and radio-frequency interference in nuclear and fossil-fueled steam plants.

As a step toward implementing improvements in pressure sensing, a fiber-optic transducer based on the micro-bend attenuation of light transmitted through an optical fiber (Fig. 1) has been developed (8). Since the diaphragm deflects linearly with pressure, process pressure is measured by the diminution of light transmission through an aluminum-coated fiber with core/clad/coating dimensions of 150/180/210 μm . Performance of the transducer was

Table 4. Classification of Environments in the Power Industry

Function	Apparatus	Environment
Convert thermal to mechanical energy	<ul style="list-style-type: none"> • Steam plant • Combustion turbines 	<ul style="list-style-type: none"> • High temperatures • High pressures • Aggressive fluids • Relatively close to central control
Convert mechanical to electrical energy	<ul style="list-style-type: none"> • Generators 	<ul style="list-style-type: none"> • Near-ambient temperatures and pressures • High electrical and magnetic fields • High mechanical forces • Relatively close to central control
Electricity delivery	<ul style="list-style-type: none"> • Transformers • Switchgear • Overhead transmission lines • Underground cable 	<ul style="list-style-type: none"> • Near-ambient temperatures and pressures • High electrical and magnetic fields • High electrical currents through contacts • Often far from central control

characterized in laboratory and field trials at pressures to 22.75 MPa (3300 psig) and temperatures to 438°C (820°F), with measurement error calculated to be 1.2% of full scale. This smart sensor, developed for coal liquefaction service by the U.S. Department of Energy, would be

suitable for pressure measurements in nuclear steam generators.

Strain Measurement. Strain sensing as an indicator of structural health in high-temperature components is

Figure 1. Diagram of the fiber-optic pressure transducer (8).

Figure 2. Schematic of interferometric strain sensor (9).

becoming more important as power-generating equipment ages. Conventional foil and wire strain gauges are not reliable at temperatures above 250°C (482°F) for long times, largely owing to the unavailability of adhesives that can withstand those temperatures. Therefore, a fiber-optic sensor to monitor strain in boilers, headers, steam pipes, and other high-temperature structures has been developed for operation at temperatures up to 650°C (1202°F).

Based on the Fabry-Perot interferometric technique, the system is shown schematically in Fig. 2. A broadband optical beam is conducted into a quartz tube containing two fibers, each with a partially reflecting mirror at the end. A small air gap or resonance cavity between the two mirrors forms an extrinsic Fabry-Perot interferometer (Fig. 3). Beams reflected from the two mirrors interfere, travel back toward the detector, and enter an optical wedge (Fizeau analyzer). Reflected light from the Fabry-Perot sensor is transmitted maximally where the optical path length matches the dimension of the Fabry-Perot cavity. Thus, when strain changes the cavity length, there is a corresponding shift in the intensity maximum transmitted through the optical wedge. A linear photodiode array at the back of the optical wedge detects the transmitted beam. Because this is a frequency-modulated sensor, it is insensitive to light attenuation; the signal reaching the photodiode array need only contain enough information for decoding (10).

Figure 3. Schematic of Fabry-Perot interferometer (9).

This small, lightweight device has been field tested in two applications at a power station: a spot welded on a main steam line operating at 565°C (1049°F), and in a thermowell inside a reheat steam line at 538°C (1000°F). Feasibility of on-line monitoring of strain in structures at high temperatures was clearly demonstrated.

Measurements with Fiber Bragg Gratings. A potentially more versatile sensor technology is embodied by wavelength-modulated fiber Bragg gratings (FBG), which are created in low-cost, commercially available fibers. Each FBG reflects a characteristic wavelength that changes as the grating periodicity changes with temperature and/or strain. Research sponsored by the power industry has concluded that, in principle, FBGs can serve as generic transducer elements to measure temperature, pressure, strain, vibration, acoustical disturbances, electrical and magnetic field strengths, and the concentrations of certain chemical species (11).

A primary issue in developing FBGs for utility use in high-temperature environments is their stability. Exposures to high temperatures and temperature cycling has demonstrated that FBGs are quite robust: FBGs endured long-time cycling between ambient and 427°C (800°F) without degradation. Use temperature can be extended to 650°C (1202°F) only if very low loads (strains) are imposed on the fiber (11). FBGs for measuring temperature, pressure, and strain are now in prototype development. Although several approaches to chemical sensing with FBGs have been explored in laboratory studies, they are not yet ready for prototyping.

Sensors for Combustion Processes. Accurate and reliable sensors for very high temperature environments would have multiple benefits for thermal plant: avoidance of damage to heat-transfer surfaces, combustion controls for individual burners (not possible at present), reduction of noxious emissions, and structural health monitoring of critical components, to name a few. The chief barrier to developing smart systems based on fiber optics for combustion environments is the temperature constraint on silica fibers. Fiber function is limited by the temperatures at

which (1) the dopants in conventional silica begin to diffuse rapidly enough to affect adversely both signal attenuation and wave-guiding properties, and (2) the silica softens. These temperatures are approximately 800 to 900°C (1472–1652°F).

Since crystalline sapphire has reasonable optical propagation properties, melts above 2000°C (3632°F), and is corrosion resistant, it is the basis for research aimed at developing fiber-optic sensors capable of operating above 1500°C (2732°F). Schemes under investigation include sapphire-fiber-based Fabry-Perot interferometers, FBGs, and intensity-based sensors, as well as ways to modify fiber coatings and claddings that make sensors able to function in combustion gases and superheated water environments (9).

One especially important challenge for high-temperature sensing is management of emissions from combustion. In control systems for nitrogen oxides (NO_x), ammonia (NH_3) or urea ($\text{NH}_2\text{-CO-NH}_2$) is injected into combustion gas to react with NO_x and produce molecular nitrogen and water. Postcombustion NO_x reduction must avoid significant NH_3 in the exhaust, both to comply with emission regulations and to keep from fouling downstream components. A feedback control system is needed, but no reliable, real-time NO_x or NH_3 sensors have been available.

An investigation is exploring measurement of nitric oxide (NO) levels on the basis of radiative emissions from single molecular transitions that are well separated from emission features associated with other constituents in the flow. The system consists of feedback-stabilized, scanning Fabry-Perot interferometers linked with thermoelectrically cooled wavelength detectors. A digital system controls cavity lengths for wavelength scanning. One detector monitors NO upstream of the injection plane and a second monitors NH_3 downstream. Signals from both are fed into the injection system controller, which then determines in real time the quantity of NH_3 or urea to be injected for optimal NO removal. Tests of the prototype system are underway at a utility power station (9).

pH Measurement. Corrosion behavior of steam-plant materials is determined to a large extent by the pH and electrochemical potential of the circulating water. Since the physicochemical properties of water are highly sensitive to temperature, there is strong incentive to develop on-line sensors for pH that can be used at system temperatures, rather than relying on analytical extrapolations from grab samples cooled to ambient, as is the current practice. However, attempts to develop on-line sensors for pH at elevated temperatures must confront two problems: degradation of the sensor materials by hot water; and, in the high-purity water characteristic of cooling loops, interactions of the sensor with the water can affect the pH being measured.

A sensor was developed by incorporating a pH-sensitive organic dye (8-hydroxypyrene-1,3,6-trisulphonic acid) in a polyacrylamide polymer at the end of an optical fiber (Fig. 4). By choosing a dye with two absorption peaks, the sensor indicates the pH as the ratio of the two peaks; long-term leaching of the dye does not compromise the

Figure 4. Schematic of the fiber-optic pH sensor (12).

measurements. pH determinations were made successfully over the course of a one-year immersion at 38°C (100°F), and pH changes associated with addition of 1 ppm morpholine were measured consistently (12).

Water at higher temperatures exacerbates stability problems for fiber-optic reflectors. A 250 nm thick, multilayer (titanium-platinum-gold) coating for sapphire was found to be stable to 180°C (356°F). In conjunction with an azo chromophore (dinitrophenyl-azo-naphthol) as an indicator, pH was measured reproducibly in the laboratory for 160 hours at 50°C (122°F), which was the stability limit of the cellulose acetate waveguide (13). In any case, azo-based indicators are stable only to about 100°C (212°F). While none of the pH-sensing systems devised so far are acceptable for use in high-temperature water, preliminary experiments have shown that a copper phthalocyanine chromophore is stable to at least 200°C (392°F). It is expected that the next step, an incremental improvement, will be a fiber-optic pH probe that is usable to 150°C (302°F).

Electricity Systems Environments

Distributed Fiber-Optic Temperature Sensor (DFOTS). Insulator temperature is a key factor in the safe and reliable operation of motor and generator windings, transformers, circuit breakers, underground cables, and overhead transmission lines. Although temporary overload conditions do not normally cause thermal damage to conductors, higher than normal temperatures do have a cumulative effect of shortening insulation life. On-line methods to locate and measure “hot spots” have traditionally not been available, largely owing to the fact that most transducers are electrically based. In other words, conventional sensing devices are usually incompatible with the environment of an electrical system. Furthermore, local temperature measurements (e.g., 0.1 m [4 in] long or less) need to be made throughout an electrical system that may be hundreds of meters (feet) long.

Figure 5. Schematic of the DFOTS system for sensing hot spots in electrical windings (9).

Motors, Generators, and Circuit Breakers. To address this challenge, the DFOTS system has been developed for detecting hot spots in low-temperature ($\leq 150^{\circ}\text{C}$ [302°F]), high-voltage environments. It is based on optical time domain reflectometry (OTDR), which was devised by the telecommunications industry for fault location in fiber-optic telephone lines. A light pulse transmitted by an optical fiber is gradually attenuated by absorption and Rayleigh scattering. The scattered light returns in a direction opposite to that of the injected light pulse. To make a DFOTS, the fiber must be modified along its length such that the local backscattering changes as a function of the local temperature change. This was accomplished by coating the fiber with a UV-curable polymer that changes refractive index reversibly with temperature (14). A change in the local intensity of backscattered light serves as a sensitive indicator of temperature, and the elapsed time of the returned pulse indicates the location of the temperature change, as shown in Fig. 5.

The DFOTS system has monitored winding temperatures in rotor and stator windings of motors and generators in trials at power plants (15) and in switchgear (14). It is accurate to within 5°C (9°F) over the range 0 to 150°C (32 to 302°F). A 100 ps laser pulse is capable of resolving hot spots only 2 cm (0.8 in) long over a fiber length of 40 m (131 ft). In retrofit applications, the DFOTS fiber can be strung between windings bars and slot wedges; in new windings, the sensor can be incorporated in the high-voltage groundwall insulation in direct contact with the conductors. In either application, impending generator problems could be diagnosed rapidly and major winding failures prevented. Improved remaining-life assessments would also ensue from knowing real thermal histories of insulation.

Underground Cables. A similar DFOTS has been devised for temperature monitoring of underground power cables. The power transfer capability of a buried cable is strongly affected by thermal conditions along the length of the circuit: burial depth, ambient earth temperature, soil thermal resistivity, and the like. Power transfer could be optimized if actual temperatures along the cable are known in real time.

When a sharply pulsed laser beam (1050 nm) is injected into a standard multimode fiber, very weak, thermally dependent, molecular vibrations produce reflections

along the fiber length. These reflections, known as Raman backscattering (in contrast to Rayleigh backscattering in the previous example), can be detected by OTDR and the signals processed to determine temperature along the length of the optical fiber. A commercial system (York Sensors, Ltd., DTS-80) based on Raman scattering was installed in a duct containing 66 kV power cables. Ampacity analysis of the measurements enabled the utility to uprate the cable circuit by 8%, without exceeding the 90°C (194°F) maximum design temperature for the cables (16).

Strain in End Windings. The stator winding of an AC generator is comprised of conductors (coil sides or bars) that are housed in slots in the stator core. At the end regions adjoining the active length of the machine, pairs of conductors are linked by end connections to form coils. The complete set of end connections at each end constitutes an end winding. End windings cannot be supported as securely as the conductors, which are in slots; if blocks and lashings become loosened by the forces of starting and stopping or system faults, the end windings can vibrate and progressively damage insulation. Undetected end-winding vibration can lead to a forced outage in a relatively short time. Standard strain gauges (metal foil or wire) cannot function in the strong electromagnetic environment of an operating generator.

A fiber-optic sensor based on microbending has been developed to measure strain in end windings during operation (9). The sensor attaches directly to an end turn and converts deflection to strain. Output of the device is linear over the range $\pm 1000 \mu\text{m/m}$ (1000 microstrain) and 5 to 100 Hz, with a resolution of $\pm 5 \mu\text{m/m}$.

Monitoring Transformers. Substation transformers are large, oil-filled devices and are among the most expensive components in an electric-power network. The cost of a failure, or an outage to repair a unit, can exceed the original cost of the transformer within five days if the cost of replacement power from a less-efficient station is accounted. Deterioration of transformer oil results from excessive temperature, aging, and electrical discharges through the oil. Oil has an effective lifetime of about one million hours at 90°C (194°F) but only about 100 hours at 180°C (356°F).

Winding Temperatures. In principle, temperatures in transformer windings could be measured by DFOTS based on Rayleigh or Raman backscattering. However, it has been found that transformer oil penetrates the fiber jacket and is absorbed by the polymer cladding of Rayleigh-based sensors, and all-silica Raman-based sensors have inadequate spatial resolution (about 5 m [16.4 ft]) at their present stage of development. Point monitoring of winding temperatures in real time is the best that can be done right now by measuring the temperature-dependent fluorescent decay time of a photoluminescent sensor material (manganese-activated magnesium fluorogermanate). Pulses of blue light power the phosphors; fluorescence returning in the all-silica fiber is detected and interpreted in terms of sensor temperature (17). Decay time is a well-characterized, intensity-dependent property of

the sensor material. This is a commercial device (Luxtron Corp.) capable of continuous operation in 60°C (140°F) surroundings.

Partial Discharges. Partial discharges are precursors to full discharge and breakdown of the insulation. If they are not stopped, gas generation leads to explosions and fires in high-voltage transformers. Partial discharges in transformer oil indicate aging caused by thermal degradation, moisture, and acidity.

A partial discharge in the depths of a transformer generates a radio-frequency (RF) signal and an ultrasonic (US) signal. A sensing system has been devised to detect paired RF and US signals: the RF detector responds first, followed by the US detector. The time interval between them depends on the distance from the partial discharge to the integrated detectors. Only a series of paired RF and US signals with the same time interval is accepted by the signal-processing circuitry as an indicator of partial discharge (18). The US sensors are specially fabricated from lead zirconate titanate (PZT) ceramic-epoxy composites that are tailored to have resonant frequencies in the range 200 to 400 kHz, which is above core magnetostriction spectra and below the AM broadcasting band. After suitable encapsulation, the PZT composite is mounted and integrated mechanically with the RF detector, a compact annular metal ring (18). This device is unaffected by contact with transformer oil and functions over the temperature range -10 to 120°C (14–248°F).

Voltage and Current Measurements. Knowledge about electric fields and currents in generators, transformers, and power lines is of obvious importance to the power industry, not only for understanding normal behavior of system elements but for identifying defective or malfunctioning apparatus. Optical sensors for voltage have in the past been based on electro-optical crystal transducers (e.g., bismuth germanate) that exhibit linear birefringence in electric fields (Pockels effect), which can be detected by a suitably polarized light beam (19). Pockels effect sensors have not yet been miniaturized, a step that would be required for distributed sensing.

Another approach to measuring electric fields is through electrostatic forces, which arise from electron rearrangements in conductors subject to external electric fields. Charges induced at conductor surfaces interact with the external field to produce weak electrostatic forces normal to the surface. By constructing a variable-gap Fabry-Perot microsensor as a conductive Faraday cage with a flexible silicon diaphragm (Fig. 6), these forces can be measured quite accurately (20). Dual-wavelength referencing makes the sensor system insensitive to bending and transmission losses in the fiber; electric field strength is thus related to change in the intensity *ratio* at two different wavelengths. dc fields from 0 to 500 kV/m and ac fields for energizing voltages up to 80 kV were successfully measured. This device is a microsensor suitable for emplacement at important locations throughout an electric-power system.

Almost all optical sensors for current rely on the Faraday effect, which is circular birefringence (i.e., a difference in refractive index for left and right circular

Figure 6. Fabry-Perot microcavity for measuring electric fields: (a) Top view and (b) cross section (20).

polarization) that is proportional to the magnetic field associated with current flow. Commercial fiber-optic current sensors (Square D Company) have been shown to be reliable at utility switchyards: metering accuracy is $\pm 0.2\%$ from 100 A to 1400 A and 0 to 40°C (32–104°F) temperature range (21). As with Pockels-effect sensors, Faraday-rotation transducers are still bulk optical devices.

Chemical Sensing. Ensuring compliance with environmental regulations that govern stack-gas emissions, waste streams, and process streams will require real-time in-situ, monitoring methods. Currently, samples are collected, stored, and transported from the field before they are analyzed in the laboratory. Thus, analyses are neither timely nor always reliable, since samples can change chemically between collection and laboratory. Fiber-optic chemical sensing is one remedy for this problem.

An optical chemical sensor consists of a chemically sensitive indicator and a physical transducer. The indicator interacts with the chemical species of interest (analyte) and undergoes a reversible change in absorbance, refractive index, polarization, and the like, that is a function of change in the analyte. The transducer converts this optical change into usable information. One embodiment of this technology is a fiber-optic hydrocarbon sensor (FiberChem, Inc.). Portions of the conventional (low refractive index) cladding are replaced by thin metal coatings with the desired selective affinity and refractive index. Typical responses to common hydrocarbons are shown in Fig. 7. Sensitivity is in the low ppb range and hydrocarbons can be detected

Figure 7. General response of fiber-optic chemical sensor to hydrocarbons.

and quantified in vapors, droplets, thin films on water, dissolved in water, or as water-hydrocarbon emulsions (22).

Structural Integrity of Dams. Dams for hydroelectric stations, whether concrete or rock filled, are very conservatively designed. Nevertheless, seismic events or other unforeseen geologic instabilities can threaten structural integrity. The consequences of failure are so severe that early warning of malfunction or collapse is vital. Embedded fiber-optic sensors are a logical answer.

Feasibility of this approach was demonstrated by installation of over 6.4 km (4 miles) of multiplexed simple and multifunction fiber sensors in a 7.5 MW dam during the construction phase (23). Over 90% of the embedded fibers survived placement, casting, pouring, and curing of the concrete, as well as framework removal and installation of generating machinery. Among the embedded fiber optics were sensors for simultaneous monitoring of water pressure and vibrations at structurally critical locations. Baseline vibration signatures were determined by statistical interpretation of speckle patterns (24). During “shake-down” of the facility, comparison of baseline vibration spectra with dynamic output of sensors within the powerhouse structure identified a vibration spike that was attributed to an out-of-round main gear in the power train. Replacement of the gear eliminated the troubling vibration.

Dams are a likely venue for a more complete smart system: self-repairing concrete. Dry (25) has developed several variations on the theme of injecting hardenable liquids into concrete. One that is completely autonomous involves embedding hollow glass fibers filled with adhesives in the concrete. Overloads on the concrete create microcracks that break the fibers, release adhesives into the cracks, and result in concrete as tough or tougher than the original. Fiber optics will still be needed to detect such occurrences and report their locations to a central authority.

Structural Behavior of Wind Turbine Blades. Windmills are large composite structures, usually located at remote sites, and subject to strong dynamic loads. In-service inspection involves dismantling the blades, a lengthy and

labor-intensive procedure, so windmills are overdesigned to compensate for infrequent inspections. Traditional sensors (e.g., strain gauges and accelerometers) are too bulky to be embedded for real-time monitoring, but fiber optics and piezoelectrics are not.

Thirteen fiber Bragg gratings were installed in a 12 m (39.4 ft) long wind turbine blade during initial layup of glass fiber reinforced polymer, and six piezoelectric micro-sensors were bonded to the blade surface (26). Good agreement up to at least 7000 microstrain was obtained between conventional and fiber Bragg grating sensors in controlled tests, with no fiber-optic failures. Modal frequencies were measured with high efficiency by the piezoelectric sensors. After six months in actual service, the sensors remained functional, with no measurable drift or necessity for recalibration.

SMART SENSOR-ACTUATORS

Several classes of smart materials can function as combined sensor-actuators: piezoelectrics, electrostrictives, magnetostrictives, and shape-memory alloys (SMAs). Eventually, smart materials in all of these categories will find roles in utility systems. Up to the present time, however, interest in applying smart sensor-actuators to power-industry concerns has been mostly focused on SMAs, owing in part to the large reversible deformations and large forces obtainable with SMAs, and in part to the capability of SMAs to perform actuations (shape changes) induced only by the thermal environment, that is, without supervision. In this regard, incorporation of SMAs in utility systems is a step toward autonomous responses, which can offset high-cost maintenance labor to some degree. Examples of applications that have been tested in prototype, mostly in Russia, Ukraine, and Scandinavia, follow.

Compression of Transformer Cores

Electrical coupling in large transformers is improved by compressing the core layers. During conventional manufacture, the core is compressed between the yokes by tightening the bolts, and the entire assembly is then subjected to alternate cycles of vacuum and kerosene spray at 125°C (257°F) to remove air from between the core sheets. As the core layers, compact, the compressive forces decrease, so that when the assembly is taken out of the vacuum chamber, some air reenters the core stack and optimum coupling is lost. Somehow, the maximum compressive pressure has to be maintained during the heating cycles. Making the yoke bolts out of SMA can, in principle, remedy the problem, as depicted in Fig. 8(a). Properly designed SMA bolts, axially prestrained, transform during heating in vacuum and maintain pressure as air is sucked out, as has been demonstrated in Russia (27). A difficulty with this solution stems from the large bolt sizes (50–75 mm [1.97–2.95 in] diameter), which makes homogeneity and heat treatment of the SMA problematic. An alternative has been devised in Sweden that involves conventional steel bolts with a series of precompressed SMA studs between the yoke and core package, Fig. 8(b). As temperature is raised in the

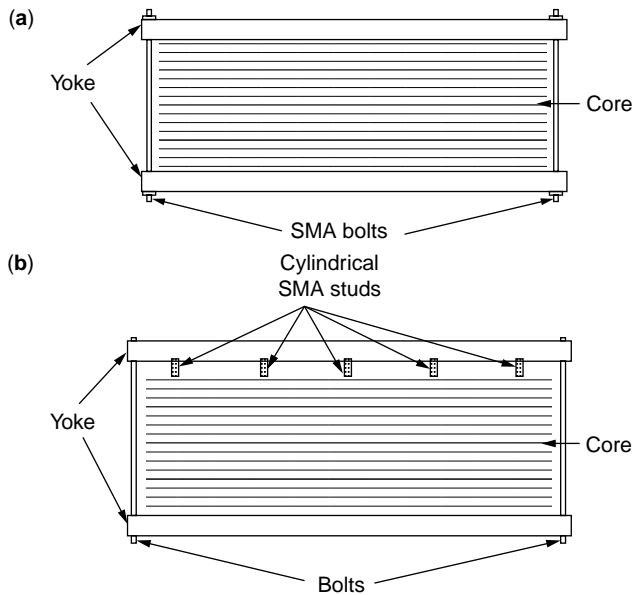

Figure 8. Transformer core compression with SMA elements (27): (a) Yoke bolts; (b) studs.

vacuum chamber, the studs expand axially to maintain well-distributed pressure (27).

Inducing Compressive Stresses in Pipes

The basic idea is to apply circumferential compressive forces on critical regions of piping to counteract tensile stresses caused by welding and service loads. One such arrangement consists of axially extended SMA wire wound on slotted sleeves. The sleeves are slipped on the pipe, positioned over at-risk circumferential welds, and heated above the transformation temperature of the SMA wire (27). Since the operating temperature of the pipe is also above the SMA transformation temperature, stress-corrosion cracking is forestalled and propagation of pre-existing cracks is inhibited by the resulting compressive stresses. In addition, pipe ends are prevented from separating should a break occur. This application, intended mainly for nuclear power plants, has been tested in Sweden.

Sag Control of Overhead Conductors

Aerial power lines sag when they are warmed by high electrical loads, especially in combination with high ambient temperatures. Performance is degraded when overhead lines sag to the extent that ground capacitance becomes excessive. This is a difficult problem, given the many thousands of miles of transmission lines. A solution that is being tested in Canada, Ukraine, Russia, and Japan has several embodiments (27,28); a typical one is to attach an SMA member electrically and mechanically in parallel with the overhead conductor. At low temperatures, the martensitic SMA is easily extended in tension. Upon heating, however, the SMA reverts to the strong austenitic phase and shortens, forming a loop in the overhead conductor and thereby maintaining acceptable ground clearance.

Galloping Control for Transmission Lines

Occasionally, under conditions of line icing combined with high wind speeds, transmission lines experience severe oscillations (galloping) that can be 9 m (29.5 ft) over spans of 185 to 365 m (607–1198 ft). Such occurrences often result in destruction of affected portions of the lines. Among the suggested approaches to galloping control are damping by vertical connectors made of SMA inserted between suspended conductors, and altering tower stiffness with suitably-positioned, externally energized SMA springs (29).

Mitigation of Erosion Caused by Cavitation and Liquid Droplets

Cavitation ensues when the local pressure in a fluid-flow field falls below a critical value that is a function of temperature, surface tension, vapor pressure, and external pressure. Vapor-filled cavities or bubbles form in the liquid at regions of low pressure and collapse as they move into regions of higher pressure. Bubble collapse is associated with very intense local impulses that can be destructive to nearby solid surfaces. Machinery subject to cavitation erosion and closely related liquid-droplet erosion include boiler feed pumps, valves, recirculation pumps in pressurized-water reactors, hydroturbine runners and guide vanes, and last-stage blades in steam turbines.

An investigation conducted for EPRI showed that on the basis of their anomalous resistance to low-cycle fatigue, near-equiatomic alloys of nickel and titanium (NiTi) are very resistant to both cavitation and liquid-droplet erosion. High resistance to fatigue and erosion is ascribable to the ability of NiTi, either as austenite or martensite, to deform reversibly without accumulating much residual damage in the constituent crystallites. Since building large machines entirely out of NiTi is impractical, thin plates of NiTi were explosively bonded to structural steel and the erosion resistance of the resultant clads was demonstrated (30), as indicated by Fig. 9.

Figure 9. Comparison among cast austenitic steel (CA6NM), wrought stainless steel (304L), duplex stainless steel (FER-255), and NiTi cladding on steel in vibratory cavitation.

Table 5. Other Contemplated Uses of SMAs in the Electric Power Industry

Device	Function/Operational Principle	Reference
Couplings and connectors	SMA tubes are expanded “cold” to fit over members to be joined, then warmed to induce phase transformation and shape recovery. Heat-to-shrink devices apply high clamping forces for pipes and electrical connections.	(28,31,32)
Seals	Similar to couplings, circumferential stresses are induced by shape recovery of pre-strained rings. Hermetic seals are used for electronics and for attaching braid sheathing to terminal plugs.	(31)
Circuit breakers	Traditionally, electricity is activated by bimetal strips capable of only small forces and motions, SMA actuator, in series with locking mechanisms and a vacuum or SF6 chamber, provides much larger actuation that makes a cascade of latches unnecessary.	(28,31)
Fuses and fuse protectors	Similar to circuit breakers, SMA fuses are advantageous in that they can be reset. Quick-acting fuses for lightning protection can blow when heavy line usage causes a temperature rise. An SMA shunt, normally open, closes during heavy usage, thereby avoiding a premature blow.	(31,33)
Thermomarkers	SMA flags bend at a predetermined temperature and signal which phase has blown or which electrical joint is hot.	(28,31)
Switches and valves	Typically, SMA spring operates against a bias spring: under normal conditions the bias spring is stronger than the SMA spring; heat causes the SMA spring to transform, overcoming the bias spring, and operating the switch or valve.	(27,31,33)
Bolted electrical connections	SMA washers in Belleville configuration under bolt heads maintain contact pressure when thermally activated by increased contact resistance. Applied in transformer connectors, aluminum buses, and disconnects.	(27,28)
Thermal actuators for valves, clutches, dampers, and flues	Linear motion devices rely on shape recovery of prestrained SMA elements. They are initiated by externally controlled electrical heating of the SMA. Typically, bias springs reset these devices to their default positions.	(32,34)
Steam pipe hangers	Traditionally, a three-spring device with complicated mechanical linkages provides constant support under thermal conditions. Can be replaced by a single SMA rod or a stack of SMA Belleville washers.	(27)
Steam trap flush	When a trap fills with condensate, a bimetal-actuated mechanism opens the trap. The linear motion of the actuator allows leakage before full opening or closing. SMA Belleville washer is faster and nonlinear, so leakage does not occur.	(33)
Plugs in pipe ends and tubesheets	Pre-strained SMA plugs are inserted cold, then heated to form leak-proof seals.	(32)
De-icing of transmission lines	Externally energized SMA devices apply cyclic loads to overhead conductors to de-ice them.	(28)
Bolt breakers	Explosive bolts are used in safety mechanisms in nuclear power plants and petrochemical plants. They can be accidentally discharged under electrical fault conditions. Pre-strained SMA tubes can serve the same purpose by breaking notched bolts during shape recovery.	(31)

Other Applications of SMAs

A variety of concepts involving SMAs have been suggested as solutions to power-industry problems. Some that have been demonstrated under laboratory conditions or evaluated in engineering analyses are described briefly in Table 5.

CHALLENGES AWAITING SMART MATERIALS SOLUTIONS

The preceding two sections describe applications of smart sensors and smart sensor-actuators to power industry problems. Besides their favorable impact on utility operations, these applications are important steps in the

progression to smart *systems*. At the most sophisticated level, smart systems will feature highly integrated and embedded combinations of sensors, actuators, and processors, which will enable those systems to respond intelligently and *autonomously* to dynamically changing environments. Inasmuch as smart systems with those kinds of capabilities have not yet been implemented in the power industry, it is appropriate to consider the kinds of problems that might motivate development of such smart systems, either as adaptations from other industries, as new ways of organizing existing smart materials, or even as entirely new concepts.

Utility challenges that seem especially suited to solution by smart materials and systems are listed in Table 6, which is meant to be illustrative, not inclusive. Each problem is identified in the first column and a subjective ranking of severity is provided in the second column. The last column differentiates among innovations for which most of the constituents are at least in prototype (near-term), those that are only partially in prototype (midterm), those in early proof-of-concept stages (long-term), or intriguing concepts (vision) perhaps without solution by smart systems. Five of these challenges, chosen because they represent the whole spectrum of power-industry needs and possible solutions with smart materials, are discussed briefly in the balance of this section.

Real-Time Condition Assessment of Equipment

A topic of major concern for utilities is in-service deterioration of critical components (35). Detailed information about equipment condition is an essential part of life-management programs for generating units; such information also provides early warning of structural impairment, and therefore it is crucial for avoidance of forced outages. Obtaining that information is a serious challenge. For example, it has been estimated that about one-half of all forced outages in steam-generating plants are caused by corrosion. Whereas generalized corrosion is readily detected and measured, environmentally induced cracking (e.g., stress-corrosion cracking and corrosion fatigue) is hard to detect and respond to. Damage caused by creep and creep-fatigue is even more difficult to assess.

Another aspect of condition assessment is remaining-life analysis. Nowadays, many utilities opt to keep a component in service after the expiry of its “design life.” In order to do so without jeopardizing personnel safety or system reliability, the following quantities must be determined (36): the amount of damage currently in the component, the rate that damage is accumulating, and the degree of damage that will cause failure. At least three factors inhibit those determinations. First, the amount of damage or size of the largest defect (depending on the damage type) may be hard to measure; where to look and what might have been missed are subsets of this difficulty. All traditional inspection technologies suffer from inaccessibility constraints, such as, detecting corrosion of reinforcing bars in concrete or finding creep-fatigue cracks inside steam-turbine rotors. Second, actual material properties can be hard to measure, especially without destroying the component. This is a principal reason for conservative

design practices such as factors of safety, code limits, and use of class minima. Such conservatisms are responsible for overdesign of structures to meet “worst-case” loadings, with attendant increases in equipment size and cost. Third, some damage mechanisms are not well understood or are not time dependent, and therefore they frustrate calculations of remaining life.

In recognition of the importance of this topic, millions of dollars have been spent on characterizing various damage mechanisms, developing models and confirming mitigation options, developing and testing the efficacy of new designs and materials, refining inspection methods, and specifying repair technologies. With such an extensive knowledge base available, improved condition assessment, remaining-life evaluations, self-diagnosis, and even self-repair should be fertile ground for innovations based on smart materials and systems.

Control of Power-Plant Cycle Chemistry and Atmospheric Emissions

The health of water-touched and steam-touched components in fossil-fueled or nuclear-fueled power plants depends critically on the purity of process fluids (37). Dissolved oxygen, chloride ions, and a host of other impurities must be controlled at parts-per-billion levels, which is a tremendous challenge, since a large steam generator circulates millions of kilograms (pounds) of water and steam per hour. Opportunities for impurity ingress, corrosion, and deposition are pervasive, as shown in Fig. 10 for a typical drum boiler cycle. Rapid response to cycle-chemistry upsets is crucial. Penalties for exceeding well-established limits on contaminants are severe: boiler tube failures, localized corrosion, cracked steam-turbine disks and blades, and increased erosion of turbine components by oxide particles spalled from steam-touched tubes and pipes. Any of these ills can cause forced outages of substantial duration. Clear needs exist for smart systems to address this challenge: distributed on-line chemical sensors capable of functioning in high-temperature water and steam, injectors of chemicals to counter pollutants or chemical imbalances, and processors to coordinate multifunctional sensors and actuators.

Similarly, there are sizable financial and environmental benefits from reducing pollutant releases to the atmosphere. Various configurations of sensors, processors, and actuators can be envisaged; an ideal system would be capable of analyzing fuel as it enters a combustor, changing the combustion conditions in real time to minimize formation of pollutant species, and selectively activating control devices that extract residual pollutants from the stack gas. Such systems would also calculate the effects of operational changes on equipment life and on overall unit performance and efficiency.

Systems Issues in Resonance Control

One particularly insidious form of vibration in rotating machinery is that caused by subsynchronous resonance (SSR), which results from a match between the natural frequencies of mechanical components in a generating unit and

Table 6. Power-Industry Challenges and Possible Solutions with Smart Materials

Power-Industry Challenge	Problem Size ^a	Applicable Smart Materials Technologies; Possible Approaches	Time Frame
<i>Generation</i>			
In-service deterioration of machinery and apparatus caused by cyclic loading and high temperatures; need for real-time condition assessments and decision-making tools in order to schedule orderly repairs or replacements.	1	Distributed, embedded sensors for detecting cracks, voids, deformations, and changes in material properties; integrated systems for self-diagnosis, on-line estimates of remaining life, and (eventually) self-repair.	Long-term to vision
Corrosion of power-plant components, particularly by mechanisms that frustrate conventional NDE methods.	1	Sensors that can detect corrosion-induced cracking and identify corrosive species; on-line analysis to locate damage and warn of incipient failure, as appropriate. Eventually, develop systems that release neutralizing chemicals at damage sites.	Midterm to vision
Overdesign of structures to resist hypothetical "worst-case" loads.	2	Detect onset of unusual loads and deploy auxiliary members that supplement load-bearing capability.	Long-term
Integrity of civil structures, especially concrete dams.	2	Determine state of cure and structural defects in fresh concrete; monitor loads and structural responses throughout life; actuate mitigation and repair strategies, e.g., "smart" concrete.	Near-term to midterm
Vibration of rotating machinery, leading to lower efficiencies and premature failure.	1	• Active vibration-control methods from aerospace practice to suppress vibration in individual machines.	Near-term
		• Systems issues, e.g., subsynchronous resonance, requires new technologies to detect onset and actuate adjustments to transmission system parameters.	Long-term
Efficiency of blades in steam turbines and wind turbines.	2	"Smart wing," "adaptive skins," and/or individual helicopter-blade control technologies to change airfoil shapes as a function of operation regime.	Long-term
Monitoring and controlling impurity levels in water and steam.	2	Requires chemical sensors, stable in high-purity water/steam at high temperatures and pressures, to measure pH and dissolved species; processors for coordinating signals and decision-making; actuators for injecting appropriate reagents to maintain or restore proper cycle chemistry.	Mid- to long-term
Optimizing combustion and control of emissions.	1	On-line analysis of fuel entering combustors (by x-ray fluorescence, neutron backscattering, etc.); high-temperature chemical sensors for combustion gases; real-time control of individual burners by integrating sensor signals and calculating combustion adjustments that balance heat rate minimization and stack-gas composition; actuate ammonia/urea injectors, as needed, to react with NO _x .	Long-term
Noise abatement in power plants and substations.	3	• Main source of noise in power plants is ventilation of auxiliary motor drives; new suppression approach needed.	Long-term
		• Noise cancellation by secondary acoustic technology for transformer hum.	Near-term
Protection of dams and nuclear plants during seismic events.	2	Flexible connections with smart dampers and selectively augment structures with smart tendons.	Vision

^aProblem size scale:

1. Extremely important, widespread throughout industry, costly for each occurrence, or a majority safety concern.
2. Very important, either widespread or very costly per occurrence; may be a major safety concern.
3. Modestly important.
4. Troublesome, but either relatively infrequent or not very costly per occurrence.

resonant electrical frequencies of the interconnected transmission system. When these frequencies match, there is the possibility for uncontrolled interchange of energy and reinforcement of mechanical and electrical perturbations. Where SSR has occurred it has resulted in unit-years of downtime (38).

The power-transfer capability of transmission lines is limited by either thermal characteristics or by electrical stability characteristics of the system. The stable power-transfer limit of transmission lines is given by

$$P = \frac{(V_l)(V_s) \sin \delta}{X}$$

where V_l and V_s are the load-end and source voltages, respectively, δ is the phase angle difference between the two voltages, and X is the reactance of the line. Inductive reactance (X) can be reduced by installing series-connected capacitors, and the transfer capability of the transmission line is thereby increased. Unfortunately, installing series-connected capacitors for compensation can create an electrical resonance circuit and thus establish conditions for SSR. SSR is a phenomenon so catastrophic that situations that might lead to its occurrence must be avoided. Avoidance starts with computer simulations that evaluate the chance of SSR for all likely combinations of transmission circuits and rotating machinery. If there is a possibility

Figure 10. Major unit components and locations of impurity ingress, corrosion, and deposition in drum cycles (37).

for SSR, series-connected capacitors are reduced in size and electrical filters tuned to calculated subsynchronous frequencies are installed. These steps effectively de-tune the circuit to eliminate critical mechanical frequencies. They also reduce the transfer capability of these important power links.

Protection against SSR would seem to be an ideal application of smart material systems to deal with a complex mechanical-electrical control problem. It has been estimated that, under favorable circumstances, the transfer capability of a transmission line can be doubled by incorporating series compensation (39). A smart system for enabling that capability might consist of distributed sensors on all key mechanical and transmission line components to detect incipient SSR, an intelligent processor to analyze signals and coordinate responses, and appropriate actuation of switchable parallel filters and series capacitors.

Temperatures of High-Voltage Transmission Lines

One of the primary constraints on the amount of power that can be pushed down a transmission line is thermal capacity. Operating limits are set by computer models that incorporate factors such as air temperature, wind velocity, incident sunlight, and a derating factor to ensure safe operation. It has been estimated that 5% to 15% higher loading would be possible if actual thermal conditions were known on a continuous basis instead of relying on traditional loading guidelines (40).

Transmission capacity is insufficient in several areas of the United States. Significant benefit would accrue if more power could be transmitted without building new lines. The size of the benefits is estimated as follows: A typical high voltage (345–765 kV) transmission line has a capacity of 1000 MW. A 5% decrease in power equates to 50 MW. If the line is thermally limited 20% of the time, the amount of power lost is $50,000 \text{ kW} \times 8760 \text{ h/yr} \times 0.2 = 87.5 \times 10^6 \text{ kWh/yr}$. At a wholesale price of \$0.02/kWh, the increased revenue that would eventuate from knowing the actual temperature of a line is \$1,750,000 per year.

Temperature measurement in real time is the first element of a smart system for which fiber optics seems admirably suited (41). Huston and Fuhr (42) cite several additional opportunities for the application of fiber-optic systems to electric power transmission lines: detecting overheating, detecting galloping, flaw detection in lines, and control of circuit breakers along a broken transmission line where electromagnetic interference might make conventional control systems inoperable.

Deterioration of Underground Cable

There are now about one million miles of underground distribution lines in the United States, and there is growing pressure to put more of the distribution system underground. This presents serious challenges to utilities, related mostly to difficulty of access for detecting damage or for repairing it. As a consequence, cables are often operated until they fail, an undesirable situation that is becoming intolerable with increasing demand for electricity.

Cable materials, underground conditions, and system age are all factors in maintaining reliable service. Cable is

Figure 11. Typical construction of distribution-line cable.

typically composed of phase conductors embedded in concentric insulation (usually a polymer such as polyethylene) that is surrounded by return ground conductors (the neutral, usually copper), as shown in Fig. 11. The sensitivity of cable insulation to temperature was discussed earlier; knowledge of actual temperatures along a cable via a distributed fiber-optic sensor allowed power transfer through the cable to be optimized. Thermal conditions are not the only threat to cable integrity, however. Underground conditions almost always involve the presence of moisture, prolonged exposure to which causes insulation breakdown by void formation and “water treeing” or corrosion of the copper neutral. Water treeing is the development of small semiconductive paths that are believed to originate at particles or voids. Tree growth proceeds by partial discharges and ionization at these electrical stress concentrations. When a tree extends between two conductors at different potentials, the conductivity of the treeing path increases rapidly and culminates in a catastrophic fault (43). These problems are widespread, detection is difficult, and repair practices are unwieldy. Repair generally consists of injecting pressurized silicone into the dielectric in an attempt to drive out water. Routes to solutions are not obvious, but the benefits of self-analysis, and especially of self-repair, would be substantial for either the dielectric or the neutral.

SELF-DIAGNOSING OF DAMAGE IN CERAMICS AND LARGE-SCALE STRUCTURES

HIDEAKI MATSUBARA

YOSHIKI OKUHARA

HIROAKI YANAGIDA

Atsuta-ku, Nagoya, Japan

INTRODUCTION

The government is always faced with problems of maintaining municipal buildings and infrastructure facilities that support modern urban existence. Buildings, bridges, highways, tunnels, and other large or important structures need to be assessed objectively or scientifically to ensure their safety and long-term utilization. Today new systems and materials are being developed that can assist in such tasks. Currently most tested ideas and materials are too complicated or too expensive to be utilized in real situations. The concept behind the development of new systems is that materials should have the ability to evaluate their own condition after serious loading or relatively long service times. In particular, there are numerous strong demands for a means of monitoring in situ relative to how damage and fracture accumulate in large structures like buildings and tunnels. Until now there haven't been any good methods for judging objectively the amount of damage inflicted upon buildings during earthquakes or accidents in high-speed railway tunnels.

The study of smart or intelligent materials has grown enormously throughout the world. The means of introducing self-diagnosis or self-monitoring functions into modern materials have become various and wide-ranging. For example, piezoelectric ceramics, shape-memory alloys, and optical fibers can all be used to give materials a certain degree of intelligence. In heavy construction, however, where large volumes of material are required, it is essential to avoid high complexity and high cost. The use of electrical conductivity or resistance is perhaps the most straightforward way of obtaining a relatively simple material system as compared with other high-tech materials.

Yanagida, Muto, and co-workers have reported fracture detection using fiber-reinforced plastics (FRP) embedded in structural materials as a reinforcement (1). The electrical resistance change of carbon-fiber glass-fiber reinforced plastics (CFGFRP) indicates the local or partial damage in a composite prior to its fatal fracture. Although the CFGFRP showed appreciable resistance change in the strain range above 0.7% to 1.5% (due to fracture of the carbon fiber), the detectable strain level is too large for diagnosing local damage in structural materials such as concrete (where typical strains are about 0.05%). It is therefore necessary to develop a self-diagnosis material with higher sensitivity in the low strain region if it is possible to achieve a simple health monitoring system.

In our recent work (2–6), composites containing a continuous structure of electrically conductive particles, or a so-called percolation structure, have been designed and fabricated. We have successfully produced the FRP composites and ceramic matrix composites (CMC) with high performances in the low-strain region caused by the “percolation structure” of conductive particles in a matrix phase. These self-diagnosis functions were evaluated from the changes in resistance with applied strain. It was found that the FRP composites with a self-diagnosis function are fairly useful for the measurement of damage and fracture in concrete blocks and piles.

SELF-DIAGNOSIS FUNCTION OF FIBER-REINFORCED COMPOSITE WITH CONDUCTIVE PARTICLES

Electrically conductive composites having a continuous structure of conductive particles, a so-called percolation structure, were designed in an FRP and ceramic matrix composite (CMC). The diagnosis of micro cracks in concrete structures is one of the objectives in using the self-diagnosis FRP. The FRP has proved to be highly sensitivity to small strain levels and at the same time provide the high strength to reinforce concrete structures. CMCs have been attracting attention because of their necessary toughness, which can significantly enhance the reliability of ceramic materials. Hence the research into the self-diagnosis function in CMCs is important for the achievement of higher reliability. This article considers the design of the conductive phases in these composites and investigates their self-diagnosis function during their deformation. These self-diagnosis functions are evaluated by measurements of their resistance changes with applied strain in normal or cyclic loading tests.

Design and Fabrication of Specimens

Figure 1 shows the structural design for two conductive FRPs in the shape of rods, which basically consist of vinyl ester resin (Showa High Polymer Co., Ltd. RIPOXY R-804), and glass fiber (Asahi glass fiber Co., Ltd. ER2220). The resin is hardened at room temperature by adding a curing agent (NOF Co., Ltd. PERCURE VL). In the first composite, the carbon fiber (pitch-based CF, Toho Rayon Co., Ltd. BESFIGHT UM63) was introduced by removing some of the glass fiber. This formed a conductive path and enhanced the strength of the composite in the longitudinal direction. The second composite obtained its conductivity by the formation of a percolation structure consisting of the carbon particles (graphite, SEC Co., Ltd. SPG5) dispersed in part of the matrix. The volume fraction of carbon particles in the conductive phase is 20%. The size of the carbon particle, whose shape is a flake, is 5 μm , on average. The composite containing carbon particles was composed of carbon particles and glass-fiber reinforced plastics (CPGFRP).

Figure 1. Schematics of the structural design for CFGFRP (a) and CPGFRP (b) in the shape of rod.

The CFGFRP and CPGFRP consisting of unidirectional reinforced fiber have a diameter of 3 mm.

The schematic structural designs for the CMC are shown in Fig. 2. The composites were fabricated by the filament winding method using Si_3N_4 particles (Ube Industries Co., Ltd. SN-COA) as the matrix and SiC fiber (Nippon Carbon Co., Ltd. NL-401) as the reinforcement for strengthening or toughening the composite. A portion of the fibers was replaced with tungsten wire (Nippon tungsten Co., Ltd. ϕ 30 μm). The conductive particles of TiN (Japan New Metals Co., Ltd.) were dispersed in part of the Si_3N_4 matrix. The volume fraction of the conductive phase, which includes 40 vol% of TiN particles, was 0.13%. These conductive phases were formed near the surface (500 μm in

depth) which was the tensile surface in the bending tests. These composites were hot-pressed under 40 MPa at 1773 K in N_2 atmosphere for one hour. The sintered specimens were cut into $3 \times 4 \times 45$ mm bars for bending test pieces.

Self-Diagnosis Function of FRP

Figure 3 presents two scanning electron micrographs of a polished transverse section and of a longitudinal section of CPGFRP (2). The circles in Fig. 3(a) and the white lines in Fig. 3(b) denote glass fibers. The bright gray flakes are the dispersed carbon particles. Note that the carbon particles are sufficiently dispersed in the matrix and that the matrix is well impregnated between glass fibers. This means that a percolation structure consisting of conductive particles has been successfully achieved.

The self-diagnosis functions of these materials were evaluated through simultaneous measurements of stress and electrical resistance change as a function of applied strain in tensile loading tests. The resistance change was defined as relative change in resistance $(R - R_0)/R_0$, indicated by $\Delta R/R_0$ in which R_0 denotes initial resistance before loading. The two types of loading selected were (1) a normal tensile test until specimen fracture and (2) a cyclic loading-unloading test below the maximum stress level. Figure 4 shows the electrical resistance changes and the applied stress for CFGFRP and CPGFRP as a function of the applied strain in the tensile tests. The stresses in both specimens were increased linearly in proportion to the strains until fracture occurred of the carbon fiber or the glass fiber. The CFGFRP indicates a slight change in resistance below a 0.6% strain due to the elongation of carbon fiber and shows a tremendous change around 0.7% strain owing to the fracture of the conductive fiber; namely the resistance of CFGFRP exhibits a nonlinear response to the applied strain as shown in Fig. 4(a). The initial resistance R_0 for CPGFRP was higher than that for CFGFRP because of a slight electrical contact between carbon particles in the percolation structure. As can be seen from Fig. 4(b), the CPGFRP indicates a linear increase in resistance with increasing tensile strain. The response of the resistance to applied strain appears at 0.01% strain (100 μ strain) or lower. The linear increase in the resistance continues until the fracture of the composite. Comparing Fig. 4(a) with (b) illustrates CPGFRP's higher sensitivity at the small strain level and the wider detectable strain range compared to CFGFRP. These results mean that the percolation

Figure 2. Structural design for CMC containing tungsten wire (a) and TiN particles (b).

Figure 3. SEM photographs of polished transverse section (a) and longitudinal section (b) of CPGFRP with unidirectional glass fiber.

structure formed with the carbon particle enables more sensitive and adaptable diagnosis of damage than the structure consisting of carbon fiber. The strong response of resistance for CPGFRP was attributed to a local break in electrical contact between carbon particles because of the micro crack formation in the matrix or in the rearrangement in the percolation structure under tensile stress. It should be noted that the dispersion of the carbon particles had no effect on the strength of the composite, since the fracture stress and mode for CPGFRP were similar to those of GFRP without carbon particles.

Figure 5 shows the change of resistance to the applied strain as a function of time in the cyclic loading tests for CFGFRP and CPGFRP. These FRP were loaded and unloaded cyclically under a gradual increase in stress. The resistance of CFGFRP showed poor response below 0.6% strain and a drastic increase above 0.7% strain as shown in Fig. 5(a). From Fig. 5(b), it can be seen that the change in resistance of CPGFRP corresponded well with strain fluctuation (3). It is noteworthy that the resistance decreased

but did not completely return to zero at the unloading state. The residual resistance in CPGFRP appeared after the application of 0.2% strain, and then increased with the increase to the maximum applied strain. The maximum resistance during loading, indicated by ΔR_{\max} , and the residual resistance change after unloading, denoted by ΔR_{res} , were arranged according to the maximum strain applied in the past as shown in Fig. 6. The residual resistance of CFGFRP appeared around the 0.4% strain and increased discontinuously above 0.6%. The appearance of residual resistance for CFGFRP owing to fracture of the carbon fiber was limited in a narrow strain range. The change in residual resistance of CPGFRP correlated closely with previous maximum strain over the wide strain range as shown in Fig. 6(b), suggesting that the CPGFRP has the ability to diagnose the maximum strain based on measurements of past residual resistance at an unloading state (3). A comparison of Fig. 6(a) and (b) shows that the CPGFRP performs a more useful diagnostic function of damage history over the wide strain range than does the CFGFRP.

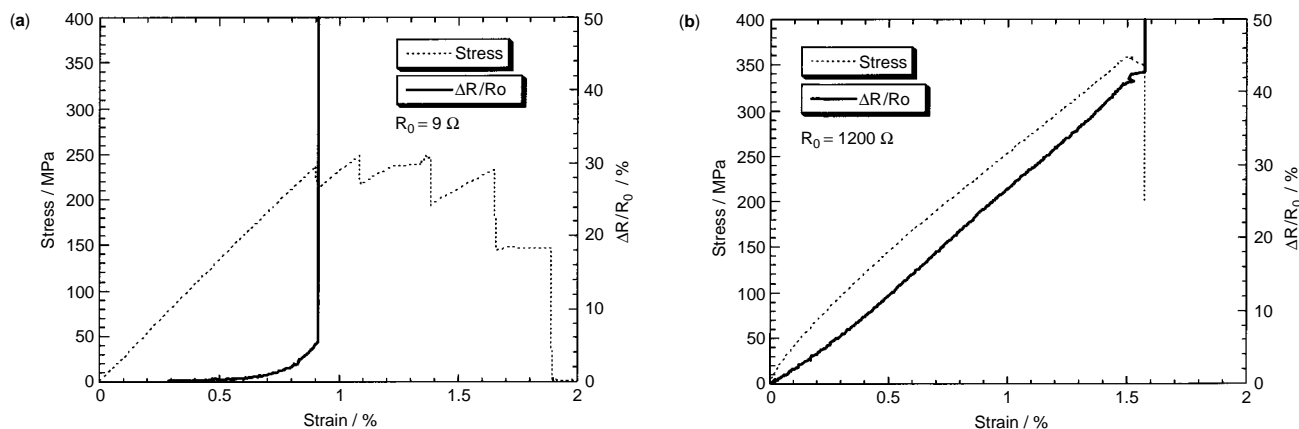

Figure 4. Changes in electrical resistance (solid line) and applied stress (dashed line) as a function of applied strain in tensile tests for CFGFRP (a) and CPGFRP (b).

Figure 5. Change in resistance (solid line) and applied strain (dashed line) as a function of time in cyclic loading test for the CFGFRP (a) and CPGFRP (b).

The microstructure of CPGFRP after the loading–unloading cycle induced 0.6% strain and 2.1% strain was observed by scanning electron microscopy (SEM) as shown in Fig. 7 (2). Clearly, the number of micro cracks in the matrix increased with the increase in applied strain. Although the elongation of CPGFRP affected the elasticity after unloading, the percolation structure did not return reversibly

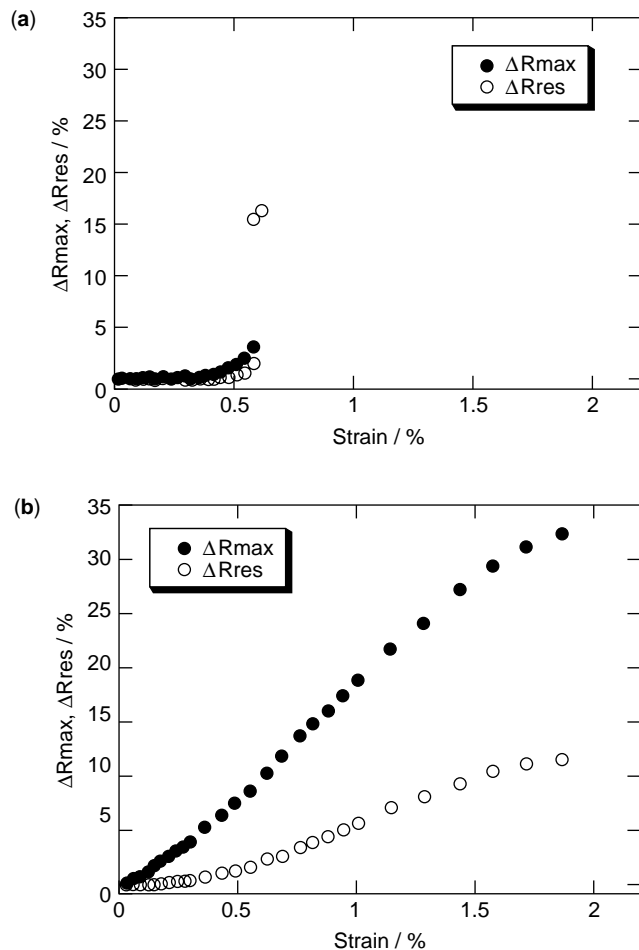

Figure 6. Maximum resistance change at loading state and residual resistance change at unloading state as a function of applied strain in cyclic loading tests for the CFGFRP (a) and CPGFRP (b).

to the initial state because of the micro crack formation in the matrix. The irreversible change in the percolation structure in the conductive phase was partly responsible for the appearance of obvious residual resistance over a wide strain range.

Figure 7. Scanning electron micrographs of CPGFRP after removing 0.6% strain (a) and 2.1% strain (b).

Figure 8. SEM cross sections of polished CMC specimens. The arrows point to the tungsten wire (a) or to the area containing TiN particles (b).

Self-Diagnosis Function of CMC

The conductive phases in the CMC observed by SEM are shown in Fig. 8 (4). Three tungsten wires were embedded near the tensile surface. The conductive phase containing dispersed TiN particles and SiC fibers was observed as the bright area. Some voids (white bareas) appeared in the conductive phase; however, these defects were thought to be insignificant for the damage diagnosis function because the amount was negligible. The interface between these conductive phases and the Si_3N_4 matrix did not show a remarkable reaction and exhibited good adhesiveness.

The self-diagnosis functions of the CMC were evaluated by simultaneous measurements of stress and electrical resistance change ΔR as a function of applied strain in four-point bending tests. The loading was performed two ways: (1) a normal bending test until specimen fracture and (2) cyclic loading-unloading tests below the maximum stress level. The dependence of the applied load and change in resistance on displacement for the CMC is shown in Fig. 9 (4).

Similar fracture behavior peculiar to CMCs was observed in both composites in which a part of the ultimate load was kept after fracture at a displacement of about 0.1 mm. The peculiar load-displacement curve explained from the extraction of SiC fibers from the Si_3N_4 matrix is shown in Fig. 10. The difference in the ultimate load and in the load-displacement curve for both composites was thought to be due to the uneven quality of SiC- Si_3N_4 phase, and not to the difference in conductive phase. The nonlinear response of resistance changes to displacement was exhibited in both composites. The CMC with tungsten wire showed a slight change in resistance in a small deformation, and then a drastic change was accompanied by their own fracture as shown in Fig. 9(a). The CMC containing TiN particles exhibited a distinct change in resistance from a small displacement to the fracture in the composite as shown in Fig. 9(b). These results suggest that the monitoring of resistance for CMCs with percolation structures is advantageous for diagnosing damages to the composites.

Figure 11 shows the hysteresis of resistance change in loading-unloading bending tests under the ultimate

Figure 9. Change in load and resistance as a function of displacement in the four-point bending tests for the CMC containing tungsten wire (a) or TiN particles (b).

Figure 10. SEM images of fractured surface for the CMC specimens containing tungsten wire (a) or TiN particles (b).

load (4). The resistance of CMCs containing tungsten wire showed no change at the loading and unloading state, which was expected from Fig. 9(a). The applied load of some 50% of the ultimate load induced the increase in the resistance for the CMCs containing TiN particles, and then the increased resistance remained at about 80% of the maximum resistance after unloading. It should be noted that the loading–unloading cycle induced elastic deformation for the CMCs without residual strain. Hence, the residual resistance was thought to be due to irreversible local fracture in the conductive phase. The residual phenomenon in resistance change for the CMCs was more remarkable than that for FRP shown in Fig. 5(b), which was attributed to the brittleness of the ceramic in the matrix.

Figure 12 presents an attempt at repeatedly varying the resistance for the CMC with tungsten wire or TiN

particles in cyclic bending test. The applied load was, however, kept constant at 150 kN. The residual resistance for the CMCs with tungsten wire indicated no change, while that for the composites containing TiN particles after unloading rapidly increased up to 10 cycles. It should be noted that the residual resistance proportionally increased with an increasing number of repetitions after 20 cycles. The linear response of residual resistance was thought to be attributed to the propagation of micro cracking in the conductive Si_3N_4 –TiN phase. This result further confirms that the CMCs containing TiN particles have the ability to diagnose cumulative damage to the composite through measurements of the residual resistance.

The electrical conductive FRP and CMC were designed and produced by adding a conductive fiber or

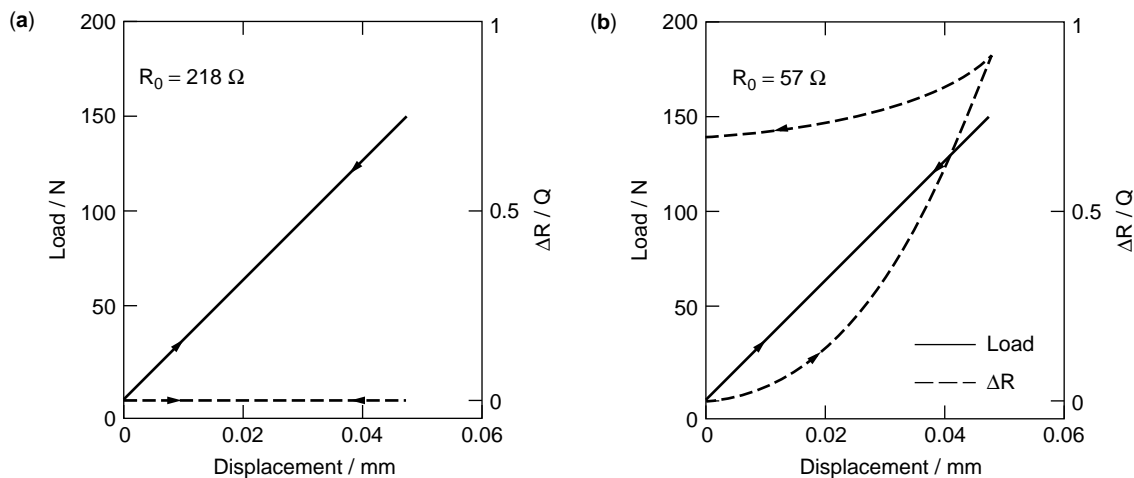

Figure 11. Change in load and resistance as a function of displacement in the loading–unloading tests for the CMC containing tungsten wire (a) or TiN particles (b). The applied maximum load was 150 kN.

Figure 12. Change in resistance as a function of number of repetitions in the cyclic bending tests for the CMC containing tungsten wire and TiN particles.

particles, and the self-diagnosis functions for these conductive composites were investigated. Compared with the composites that include conductive fiber or wire the composites with the percolation structure consisting of conductive particles were found to be capable of diagnosing deformation or damage in the composites. The composites containing carbon particles appeared capable of diagnosing damage at the sensitivity level of a small strain and in a detectable strain range. Concerning the detectable strain level, the FRP showed an excellent response to the resistance change and to the applied strain. This is a suitable range for the health monitoring of structural materials such as concrete construction. It was also found through measurements of the residual resistance that the FRP composites are capable of memorizing the maximum applied strain or stress. The CMCs with percolation structures consisting of TiN particles exhibited superior resistance to small deformation changes. It should finally be noted that the CMC materials proved capable of diagnosing cumulative damage for the composites by evaluating the residual resistance, and that these self-diagnosis functions are easily obtained by simple measurements of electrical resistance.

APPLICATION OF THE SELF-DIAGNOSIS COMPOSITE TO CONCRETE STRUCTURES

A new type composite was developed that had a self-diagnosis function for health monitoring and damage detection in materials (1–7). The composite, which has electrical conductivity as well as reinforced fibers, provides a signal of electrical resistance change corresponding to the degree of damage in the material. This self-diagnosis composite offers also some advantages in properties, cost, and simplicity, compared with other materials or systems such as the optical fiber and the strain gauge. A concrete

structure is the best application for the self-diagnosis composite because the composite has a good sensitivity to micro cracking in concrete materials, shows high strength in reinforcing concrete material, and provides ease both in its attachment and in the measurement of electrical conductivity. The study was aimed at determining whether the composite was useful for measuring damage and fracture in concrete blocks and piles. Particularly, the application into concrete construction limiting the direct observation of damage or fracture after a serious load has been applied in its utilization. Also investigated, by bending tests and electrical resistance measurements were the function and performance of the composites when embedded in mortar/concrete blocks and concrete piles.

Specimen and Experiment

Two kinds of glass-fiber reinforced plastics composites were fabricated in this study. The first composite included carbon fibers substituted for some of the glass fibers; its electrical conductivity was called CF. The second composite involved carbon powders dispersed in a part of the plastic that formed the percolation structures as a conductive path (CP). The CF and CP composites were embedded into mortar specimens and concrete specimens reinforced by steel bars or rods by the following procedures. Figure 13(a–c) shows the structure and arrangement of the composites in the three concrete specimens types. The first type is a rectangular mortar block specimen with the CP composites. The second type is a rectangular concrete block specimen with the CP and CF composites and two steel bars. The third type is a concrete pile specimen having the CP composites and 16 steel bars. The pile type specimens have been pre-stressed at 14.3 MPa applied by the tension stress of the steel bars, while the block type was free from pre-stress.

Figure 14 illustrates the methods used for bending tests for the block and the pile type specimens with different lengths and distances. The electrical resistance change ($\Delta R/R_0$, where ΔR is an increase of resistance and R_0 is an initial resistance) of the composites was measured simultaneously in the loading tests. The strain gauge measurement attached on the tension-side surface of the specimen was also used. Photographs the actual bending tests for the block and the pile specimens are shown in Fig. 15.

Mortar Block Tests

The CP composite was embedded in the tensile side of the mortar specimens in order to demonstrate the self-diagnosis function. Figure 16 shows the applied load and resistance change of the CP composite as a function of displacement in a bending test. The embedded CP composite was located 8 mm apart from the tensile surface of the mortar. The load–displacement curve indicates discontinuous changes at points A and B, which correspond to the crack formation and propagation in the mortar specimen, respectively. The crack formation and propagation are shown in photographs of the mortar specimen. The resistance of the CP composite begins to increase

Figure 13. Structure and arrangement of the composites in the three types of concrete specimens. (a) Type-1, a rectangular mortar block specimen with the CP composite. (b) Type-2, a rectangular concrete block specimen with the CP and CF composites. (c) Type-3, a concrete pile specimen with CP composite.

Type	Bending test	L / mm	D ₁ / mm	D ₂ / mm	D ₃ / mm
1	3 points	160	50	-	50
2	4 points	400	100	100	100
3	4 points	8000	3000	1000	3000

Figure 14. Different bending tests for the block-and-pile type specimens with different length and distances corresponding to type-1, type-2, and type-3.

slightly before crack formation. Note that the increase in resistance appears simultaneously with the micro crack formation and that a discontinuous resistance change is generated in response to the crack propagation. The residual resistance was observed in the FRP material after unloading at point *D*. The resistance change of embedded CP composite corresponds well to the propagation of damage inflicted on the mortar specimen. Once again, the results demonstrate that the embedded CP composite has the ability to diagnose micro crack formation/propagation and loading history in cement-based structural materials.

The behavior of residual resistance for the CP composite embedded in a mortar specimen was investigated in detail by cyclic bending tests. Figure 17 presents the hysteresis of resistance changes by cyclic loading–unloading tests under 40% of ultimate load. The application of load caused micro crack formation, and then the crack was closed at an unloading state as shown in Fig. 17. It should be noted that the crack was eliminated, but the behavior of the micro crack induced residual resistance after unloading. The application of higher load (60% of ultimate load) made higher residual resistance after unloading. These results suggested that the CP composite embedded in the mortar specimen has the ability to diagnose the closed micro crack, namely the hysteresis of micro crack formation by evaluation of the residual resistance even after the crack has closed.

Figure 15. Bending tests in progress for the mortar block specimens (a), the concrete block specimens (b), and the pile specimens (c).

Figure 17. Changes in resistance (dashed line) and applied load (solid line) in the cyclic loading–unloading tests, under 40% of the ultimate load.

Concrete Block Tests

Figure 18 shows the results of load, strain, and $\Delta R/R_0$ of CP and CF composites as a function of time in the bending test for the concrete block (6). The strain change, which followed closely the loading curve, indicates that a micro crack formed at about 200μ strain and the steel bars yielded at about 1000μ strain. The strain gauge was broken in the loading test owing to the crack propagation in the surface of the concrete specimen. The $\Delta R/R_0$ of the CP composite is initiated at about 300 s, which corresponds to the stage of crack formation. The $\Delta R/R_0$ of the CP composite increased with an increased load up to the maximum load at about 1000 s. The $\Delta R/R_0$ of CF is scarcely detected until the high load level when it increases suddenly near the maximum load. Both the CP and CF composites do not break in the test because of their high strength and flexibility. It should be noted that the CP composite shows good sensitivity in the small strain range as well as a continuous response in the wide strain range up to the final fracture of the specimen.

Figure 19 provides the results of a cyclic loading test for the block-type specimen (6). In all, eight cycles of loading and unloading with an increased load level were carried out in this test. The strain change and the $\Delta R/R_0$ of CP composite responded well to the load curve from a lower load level, while the $\Delta R/R_0$ of CF did not act until a higher load was applied. It was also found that the CP composite's residual resistance appeared only after the cycles of the medium load level.

The block specimen is shown in Fig. 20 (a–c) as it appeared in the cyclic bending test (6). The cracks are clearly initiated from the tension-side surface at a low load, and they grow with an increased load level until the specimen finally breaks owing to steel bar fracture.

Concrete Pile Tests

Figure 21 gives the results of the cyclic bending test for the type-3 concrete pile specimen (6). The specimen included

only the CP composite because of the sensitivity it showed under a small load, which was higher than that for the CF composite as confirmed in Figs. 18 and 19. This test aimed to increase the sensitivity of the CP composite, which is arranged near the tension-side surface of the pile specimen. Figure 21(d) is the result from the enlarged $\Delta R/R_0$ axis of the CP composite in Fig. 21(c). The $\Delta R/R_0$ of the CP composite in the pile responds well in a wide range of loading as shown in Fig. 21(c). The CP composite located near the tension-side surface of the pile specimen indicates good sensitivity in the lower load levels as shown in Fig. 21(d). The $\Delta R/R_0$ of the CP composite in the lower load range is very similar to the strain change in Fig. 21(b), which means that the CP composite can signal a smaller strain before the crack forms in the pile surface. In these pile tests there is no clear indication of residual resistance phenomena as detected in the block tests, probably because of the effect of pre-stress in the pile specimens.

The appearances of the pile specimen in the cyclic bending test are shown in Fig. 22(a–c) (6). The crack forms at a low load, its growth occurs with an increased load, and finally the pile fractures after the test has ended.

Performance of the Self-diagnosis Composites

In the bending tests of the concrete block, the CP composite produced good results compared to the CF composite. Remarkably, the electrical resistance of the CP composite increased under a small strain to detect a micro crack formation at about 200μ , and it responded well to small deformations before the crack formation. The CP composite showed continuous resistance change up to a large strain level near the final fracture of the concrete structures reinforced by steel bars. It was also found that the CP composites embedded in mortar/cement block specimens have the ability to diagnose the hysteresis of micro crack formation by the evaluation of the residual resistance even after unloading.

Figure 18. Load (a), strain (b), and $\Delta R/R_0$ (c, d) of CP and CF composites as a function of time in the bending test for the block-type specimen.

Figure 19. Load (a), strain (b), and $\Delta R/R_0$ (c, d) of CP and CF composites in the cyclic loading test for of the block type specimen.

Figure 20. Appearances of the block specimen during the cyclic bending test (a) A low load level; (b) a high load level; (c) after the test.

Such excellent properties can be attributed to the percolation structure of the carbon particles dispersed within a section of the plastic matrix phase. The conductive path in the percolation structure of carbon particles, which is very different from the conductive path in carbon continuous fibers, can react to small strains that are lower than 200μ . This may be due to its flexible structure which is filled with faint gaps and cracks as seen in the microstructures of the carbon particles mixed with plastics. The phenomenon of the residual electrical resistance at the unloading state suggests that the distorted structure at the loading state does not completely return to its original shape at the unloading state. The residual resistance phenomenon has a possibility for the hysteresis function of an applied load.

Figure 21. Load (a), strain (b) and $\Delta R/R_0$ (c, d) of CP composite in.

Figure 22. Appearances of the pile specimen in the cyclic bending test of type-3 (a) A low load level; (b) a high load level; (c) after the test.

The continuous change of resistance in the CP composite contributes to the damage detection of concrete structures. The percolation structure in the fiber-reinforced structure can keep its flexible structure up to the final fracture.

It is necessary to arrange the CP composite in concrete specimens to optimize the function. The location near a tension-side surface and far from steel bars is effective in order to obtain a quick response to applied stress and crack formation. The existence of prestress (compression) in concrete structures can dull the sensitivity of the composite. For the CP composite near the tension-side surface in the pile specimen, its clear sensitivity proves that the performance of the composite overcomes the influence of prestress.

Two kinds of glass-fiber reinforced plastic composites with carbon powder (CP) or carbon-fiber (CF) were introduced into the mortar/concrete specimens, with block and concrete pile types and electrical resistance change ($\Delta R/R_0$) of the composites being measured in the bending tests. The $\Delta R/R_0$ of the CP composite in the block specimen showed a good sensitivity in a small strain range to detect crack formation in the mortar/concrete and a continuous change in a large strain range up to the final fracture of the specimen, while the $\Delta R/R_0$ of the CF composite increased

suddenly at a certain strain of the specimen. The CP composite had the good response to cyclic load patterns in the bending test of the block specimen and indicated the residual resistance at an unloading state. The $\Delta R/R_0$ of the CP composite in the pile specimen with prestress showed good results to the loading patterns before and after micro crack formation in the bending test. The arrangement of the CP composite near the tension-side's surface, and far from the steel bars in the pile, effectively improved the sensitivity of the composite. The excellent self-diagnosis function of the CP composite in the concrete structures was considered to be mainly caused by the flexibility in the percolation structure of carbon particles.

SENSOR ARRAY TECHNOLOGY, ARMY

JEFFREY SCHOESS

Honeywell Technology Center
Minneapolis, MN

INTRODUCTION

Today's commercial and military aircraft require significant manpower to provide operational readiness and flight safety. Aging aircraft fleets are much in need of new and innovative health-monitoring methods to prevent catastrophic failure and reduce life-cycle costs. The key needs for characterizing *in situ* structural integrity characteristics of corrosion and barely visible impact damage (BVID) to determine "damage susceptibility" must be addressed. This article presents a new concept for onboard real-time monitoring using conductive polymer sensor array technology.

BACKGROUND

Both commercial and military service personnel currently employ "walk-around" structural inspection as a cornerstone of condition-based maintenance. This means that a hierarchy of inspections is required to ensure that fleet readiness and availability requirements are met. Structural inspection includes daily inspection, phased maintenance based on aircraft operating time, conditional

Figure 1. Key sensing locations on aircraft.

inspection based on the mission and location of the aircraft, and calendar-based inspection.

Although condition-based maintenance inspection is mature and is reliable in most cases, its application in future military and commercial systems has significant drawbacks notably high cost and intensive effort. Currently, the cost to maintain a Navy aircraft is up to \$200,000 per year. A 1996 Naval Center for Cost Analysis AMOSC report indicates that the direct cost of maintaining Navy aircraft and ships is at least \$15.0 B per year. As much as 25 to 30% of operating revenue is spent on maintenance for commercial air carriers. According to a 1995 study by the office of the Under Secretary of Defense, 47% of the Navy's active duty enlisted force (173,000 sailors) and 24% of the Marine Corps (37,600 marines) are assigned to maintenance functions. The mandate to reduce manpower while performing duties faster, cheaper, better, and more reliably is a reality in both military and commercial transportation.

In addition to these issues, problem areas exist specifically for maintaining structural integrity, including BVID and hidden and inaccessible corrosion. The increased use of composite materials in aircraft structures introduces the potential for BVID, a maintenance-induced damage effect. At least 30% of all maintenance is related to structural repair due to tool dropping and in-service damage. A significant amount of the loss of structural integrity is due to hidden corrosion as well as corrosion located in inaccessible areas (wheel wells, landing gear areas, and fuel tanks). The practice of applying surface treatments of various types to provide adequate protection, in some cases overcoating the surface with several layers, causes considerable weight increase. This increase results in loss of fuel savings and proved aircraft performance.

TECHNICAL APPROACH

A trade study was performed to identify and assess potential aircraft inspection areas that could benefit from conductive polymer sensor array technology. The trade study involved the identification of seven key areas of a

generic fighter aircraft (F-18 or equivalent). The areas addressed in the study were external wing structure, internal wing and fuselage structure, including landing gear and cockpit canopy, communications, external stores, and empennage structure. The study addressed specific parts of these identified areas and included a problem definition, a proposed sensing layout approach, and a sensing configuration. Figure 1 is a drawing of the F-18 aircraft that shows the functional layout of the seven aircraft sensing areas for possible future technology insertion. The sensing areas are mapped to the aircraft geometry, labeled by area, and keyed to the full-scale trade study chart shown in Table 1. The chart highlights the details of the trade study effort and contains specifics on subassemblies, including a general problem description. It maps the problems using three different types of sensing: "M/C" refers to moisture/corrosion sensing, "ID" refers to impact detection, and LBA refers to "load-bearing antenna." For each sensing approach, three packaging options exist: (1) a conformal sensor array, which would cover a larger surface area such as an external wing area of more than several square feet; (2) a conformal sensor applique to provide sensing coverage in a smaller area (a few square inches, possibly with significant contour shapes); and (3) a conformal boot assembly. The conformal boot design would involve fabricating a preformed structure—a sensory boot that fits the spatial constraints of the aircraft contour. An example of this configuration would be a preformed boot fit over the leading edge or radome bulkhead assembly.

Sensor Development

A conductive polymer sensor array design provides the capability for multifunction conformal sensing. Honeywell has developed polymer sensors to sense moisture (i.e., electrolyte) conditions and the presence of moisture/fluids across an extended surface area. A primary maintenance concern is the need to sense and quantify moisture trapped between the protectant system layer and the aircraft surface that could cause corrosion. Typically, the moisture is an electrolyte, an electrically conducting fluid that has ions in solution. The polymer sensor array has been designed to

Table 1. Aircraft Trade Study Chart

Aircraft Area	Part/Assembly	Problem Definition	Sensing Approach ^a	Sensing Configuration
① Wing external	•Leading edges	•Flap and drive assembly	•M/C	•Conformal array
	•Trailing edges	•Impact (BVID)	•ID	•Conformal boot
		•Corrosion—wing attach fitting		
	•External skin (upper and lower)	•Impact (BVID due to maintenance/repair)	•M/C	•Conformal array

detect the “presence” of an electrolyte, which can be seawater, acid rain, lavatory fluids, fuel, hydraulic fluid, chemicals, or cargo by-products.

The basic design is implemented by printing a specific pattern design on a flexible substrate material, curing it, and layering it using a pressure-sensitive adhesive. A typical pattern developed for electrolyte sensing is a transducer design that has alternating electrode pairs. Figure 2 illustrates the pattern layout for a polymer sensor array. The figure shows a set of dedicated electrode pairs, each of which operates as a sensory element. The sensor is designed to function as a linear 2-D array that measures the “location” where the electrolyte is sensed and the “amount” of electrolyte based on exposure across the sensor array.

Figure 2. Pattern layout of polymer sensor array.

Detection of Corrosivity. Four conditions must exist before corrosion can occur: (1) the presence of a metal that will corrode an anode; (2) the presence of a dissimilar conductive material (i.e., cathode) that has less tendency to corrode; (3) the presence of a conductive liquid (electrolyte); and (4) an electrical path between anode and cathode. A corrosion cell is formed because of the electrochemical effect, if these four conditions exist, as shown in Fig. 3. In a typical aircraft coating application, paint applied to the surface of the metal acts as a moisture barrier to protect the bare metal from exposure to an electrolyte. The paint film prevents the corrosion cell from functioning by separating the electrolyte from the anodic and cathodic sites on the metal surface. If this paint layer is damaged by erosion, heat exposure, or aging, the cell is activated, and corrosion occurs.

Figure 3 also highlights the concept of using a polymer sensor array to detect corrosivity when a corrosion cell is formed in an aircraft lap joint. As shown, the linear sensor array senses the “conductivity” of the trapped fluid by conducting a current through the fluid that is between IDT electrode pairs. The fluid’s conductive property is, by definition, “the ability to act like an electrolyte and conduct a current, or a measure of its corrosivity.”

The concept of performing corrosive environmental “exposure susceptibility” index monitoring to minimize scheduled inspections and provide direct cost savings is shown in Fig. 4. The basic idea is continuous monitoring of the actual exposure of each aircraft to corrosive

Figure 3. Simplified corrosion cell and lap joint application.

environmental factors (moisture ingress into protective coating, type of corrosive agent, etc.) and then scheduling corrosion inspections based on these measurements, rather than on preset rules that are only loosely related to corrosion. Typical preset rules that an exposure susceptibility index would replace are calendar-based (i.e., inspection every 30 days) or usage-based (i.e., inspection every 10 h of operation) inspections. One can think of the system as a “corrosion odometer” whose a readout steadily increases according to the corrosiveness of the environment to which the aircraft is exposed. Maintenance personnel can intermittently check the odometer and inspect as needed. The exposure susceptibility index provides a reliable method for scheduling corrosion inspections that (1) is based on the true exposure of the aircraft, which leads to a higher degree of susceptibility to corrosion; (2) appropriately reflect variations in exposure due to short-term weather patterns; and (3) can be consistently applied to aircraft of a given type at any location in the world.

The sensor array approach can sense and calculate an exposure index to ingress of an electrolyte (i.e., water) and the “wetness” effect of the electrolyte. The wet/dry cycle of exposure is a strong indicator of how susceptible an aircraft is to corrosion; wetness is a basic requirement for corrosion

Figure 4. Exposure susceptibility index.

to occur. The wetness exposure index is defined as the integral over time of the function $F_W(W)$. Here W is the time-varying output of a “wetness” sensor (1 = wet, 0 = dry) that quantifies the total corrosive effect of wetness. F_W is a simple function that gives the exposure index on a convenient scale, so an abbreviated inspection is called for each time the index passes through a multiple of 100, for example. Thus, for severe environments such as Puerto Rico, an increase by 100 every 15 days could occur, compared to an increase by 100 every 90 days in Denver.

Further improvement of the exposure susceptibility index can be obtained by adding other environmental factors that influence corrosion, including the concentration of the electrolyte, the temperature, and the conductivity (corrosivity factor).

Figure 5 illustrates the index calculation concept and shows the maintenance cost saving concept in detail. The design approach is set up to collect and analyze the environmental factors related to structural health (moisture ingress, impact forces, etc.) that could lead to loss of structural integrity. These factors are collected and integrated as a “cumulative index” to determine (1) the level of “susceptibility” to failure and (2) whether maintenance is required at a given location in the aircraft. The cumulative index value, it is envisioned, will be represented as a simple

Figure 5. Maintenance cost saving tutorial.

Figure 6. Force-sensing resistor (FSR).

Figure 8. Example of off-the-shelf FSR product.

whole number from 0 to 100 (which indicates the level of susceptibility; a higher number indicates that more potential for damage may exist) that could be read out by maintenance personnel from the aircraft maintenance debriefing interface at scheduled inspection intervals. The crew could then decide to perform scheduled maintenance or bypass the action. This would directly reduce the cost of maintaining the aircraft by eliminating or reducing the number of inspections. In addition, reducing the time for a maintenance procedure based on the polymer sensor system's ability to identify the general structural location where the repairs may be needed and the type of repair required (i.e., impact damage vs. corrosion) will result in additional operational cost savings.

Impact Detection. The polymer sensor for moisture/corrosion sensing can also sense impact forces caused by maintenance-induced damage or operational servicing. To provide sensing for impact forces, the polymer sensor array is configured with an additional semiconductor polymer layer, as shown in Fig. 6. The design approach is set up to operate as a force-sensing resistor (FSR). An FSR operates on the principle of converting force applied via

a structural impact to an equivalent voltage output. As pressure is applied, individual electrode pairs are shunted, causing a decrease in electrical resistance. The measurement of impact force magnitude, impact direction vector along the sensor array, and impact surface area can be quantified, depending on polymer composition, shunt pattern and shunt shape, and the method for applying pressure (hemispherical vs. flat). Figure 7 shows a typical curve of sensor response. The figure is a plot of electrical resistivity versus applied force and has an active sensing region of two to three orders of magnitude from low impedance (kilohms) to high impedance (megohms). The sensor response is approximately a linear function of force across a wide range of applied pressure. The first abrupt transition that occurs is at low pressure. This point is called the "breakover point" where the slope changes. Above this region, the force is approximately proportional to $1/R$ until

Figure 7. FSR response vs. applied force.

Figure 9. Polymer matrix sensor.

Table 2. PTF Resistor Versus Other Resistor Technology^a

Resistor Type	Gauge Factor (G)	TCR (ppm/°C)	Application Method	Relative Cost
Continuous metallic films	2.0	20.0	Spin cast	High
Thin film	50.0	20.0	RF sputter	High
Semiconductor	50.0	1500.0	Evaporation Diffused	Medium
Thick film (PTF)	10.0	50.0–500.0	Implanted Screen print Stencil Spin cast	Low

^aSource: G. Harsanyi, ed., *Polymer Films in Sensor Applications—Technology, Materials, Devices and Their Characteristics*. Technomic, 1995.

a saturation region is reached. When the force reaches this magnitude, applying additional force does not decrease the resistance substantially.

Figure 8 is a photo illustration of a commercially available off-the-shelf FSR product called Uniforce, which has an operating range of 0–1000 psi.

Another type of conductive polymer sensor is a polymer matrix sensor that consists of electrically conducting and nonconducting particles suspended in a matrix binder. Figure 9 shows a cross-sectional view of a polymer matrix sensor. Typical design construction includes a matrix binder and filler. Matrix binders include polyimides, polyesters, polyethylene, silicone, and other nonconducting materials. Some typical fillers include carbon black, copper, silver, gold, and silica. Particle sizes typically are of the order of fractions of microns in diameter and are formulated to reduce temperature dependence, improve mechanical properties, and increase surface durability. Applying an external force to the surface of a sensing film causes

particles to touch each other and decreases the overall electrical resistance.

Table 2 illustrates the typical performance of polymer thick-film (PTF) resistor technology and other resistor technologies. The table includes a summary for thin films, semiconductor, and continuous metal films. The significant advantage of PTF resistor technology over all other resistor sensing is the cost to fabricate devices. The PTF cost factor is achieved by the ability to print resistive material via stencil, screen printing, and ink-jet printing techniques.

A prime example of using FSR technology for aerospace sensing is structural integrity monitoring. Today’s commercial and aerospace structures incorporate a large amount of composite materials to reduce structural weight and increase load-bearing properties. Composites are susceptible to damage from impact forces experienced in operation, including debris picked up from runways and maintenance-induced damage caused by dropped tools. Figure 10 illustrates the system-level concept of

Figure 10. Structural impact damage tutorial.

Figure 11. Example of conformal antenna.

impact-damage-detection-based applied force versus damage for a composite aircraft panel. A matrix array of FSR elements integrated into the aircraft panel is shown. Panel construction involves printing FSR elements directly on the panel surface or on a film layer, which is then bonded to the panel using a pressure-sensitive adhesive layer. The polymer patterns incorporated on the panel include a combination of sensor elements and electrical interconnects implemented with conductive polymer materials.

To measure and record impact forces in real time, the output of each FSR element is converted to an equivalent voltage via a simple voltage divider circuit and is provided as input for a dedicated data acquisition system. Each FSR element output is routed to an analog multiplexer.

An analog-to-digital converter sequentially digitizes each FSR value into an equivalent digital word for processing by a dedicated system controller. The illustration on the right-hand side of Fig. 10 shows what happens if structural damage occurs. An external force event (i.e., a tool dropped on the surface) causes an impact. Structural damage usually consists of multilayer delaminating or microcracking of individual composite layers. In composite structure applications, the curve for quantifying structural damage is an exponential relationship and is detected by setting a force threshold value. A value that exceeds the threshold value f_x indicates that barely visible structural damage has occurred. The effects of detected damage can be read out by maintenance personnel periodically to determine if structural repair is needed it or is marked as suspect, and the vehicle is returned to active service. A set of damage identification threshold values could be retained for each major structural component of the aircraft in a 3-D map database to perform maintenance on demand.

Conformal Antennas. A significant feature of polymer sensor array technology is the arrays' ability to operate as a low observable (LO) conformal antenna. The polymer sensor has been tested in laboratory conditions to detect broadband frequencies of several megahertz without any optimization of the polymer circuit pattern. The conformal antenna capability offers a significant benefit of increasing detection of "bad guy" signature threats. Tests performed by aircraft primes have indicated that conformal load-bearing antennas improve detection by a factor of 6 to 14 times. In addition, the conformal polymer construction makes it suitable for phased-array antenna

Figure 12. Conformal antenna concept.

Figure 13. Wireless transceiver module for self-contained communications.

Figure 14. Wireless structural panel sensor web.

design for munitions and guided projectiles. Figure 11 illustrates the feasibility of using the polymer design for antenna functions. Figure 12 highlights the use of a broadband EMI source and detection of electromagnetic wave pickup at increasing distances up to 10 ft from the antenna.

Communications Debriefing

A significant system-level issue is how to obtain data on environmental factors during aircraft inspections without increasing the workloads of maintenance personnel. This can be achieved by providing a wireless link for data access. Figure 13 illustrates a photo of a $2 \times 3 \times 0.125$ in wireless transceiver module for field maintenance communications. The module consists of a low-frequency (128 kHz) receiver

interface, a dedicated high-frequency (315 MHz) transmitter interface, dedicated control logic, and internal RAM memory. The radio-frequency (RF) system can be read at ranges of 6–30 ft and operates at $2 \mu\text{A}$ in standby mode. The RF module is powered by a high-energy-density lithium button-cell battery. Future applications will include an RF module that features a very low profile height of 4 mils and capability for RF power scavenging. This unique capability implies that no batteries will be required to communicate and debrief the sensor suite. Up to 100 RF modules can be read simultaneously by a dedicated wireless RF reader.

Figure 14 illustrates a concept for wireless sensor communications to debrief a suite of aircraft structural components. A field maintenance technician is shown holding a personal data assistant that has a wireless interface. The status of the structural integrity of each component could be assessed by issuing a polling command to search and identify the health status of a designated structural panel. The wireless interface within each structural component would read the poll message, determine if the message request is intended for that component, and the designated panel will then return the health status to the maintenance technician.

SENSORS, SURFACE ACOUSTIC WAVE SENSORS

DAVID W. GALIPEAU
South Dakota State University
Brookings, SD

INTRODUCTION

Surface acoustic wave microsensors are microchips that usually have a sensing film applied to the substrate surface. They differ from silicon-based microcircuits that form the basis for most integrated circuit technology today, in that they are based on piezoelectric versus semiconductor substrates and are usually much less complex. Microsensors are usually defined as sensors of micron dimensions or are made by the same fabrication techniques that are used for integrated circuits. Microsensors have several advantages over older sensor technologies, including small size, low cost, and typically better performance (1). The relatively rapid development of surface acoustic wave (SAW) microsensors has resulted from the demand for low-cost, high-performance sensors to measure such things as hazardous gases, biological pathogens, chemical and biological weapons, automotive emissions, and indoor air quality. Additionally, there is strong interest in developing an electronic nose for both industrial and laboratory applications. As a result of these advantages and the strong demand, the development of SAW microsensors has grown rapidly during the last twenty years.

BACKGROUND

SAW devices were originally developed and are still widely used as high-performance signal processing elements such as filters and delay lines in electronic circuits (2,3). The

term acoustic wave refers to the class of waves that displaces particles of the solid, liquid, or gas medium in which they propagate. Therefore, acoustic waves are considered mechanical waves compared to electromagnetic waves, which can propagate in a vacuum because they do not require a medium or have related particle displacements. The term surface acoustic wave (SAW) usually refers to the class of acoustic waves that propagates at a solid surface, versus bulk waves, which propagate within a solid. The first type of SAW was discovered by Rayleigh in 1885. It has longitudinal particle displacements (in the propagative direction) and transverse particle displacements (perpendicular to the propagative direction) that are normal to the substrate surface. This type of SAW is called a Rayleigh wave. There are several other types of SAWs that are distinguished primarily by their wave particle displacements and are usually allowed only for certain crystallographic orientations. For example, a wave that has transverse particle displacements in the plane of the substrate and propagates just below the surface is called a surface skimming bulk wave (SSBW). It occurs on ST-cut quartz. Bulk waves are also classified as longitudinal or transverse (shear) based on particle displacements. Classic reviews of acoustic waves in solids are provided by Auld (4) and Kino (5).

A SAW microsensor normally consists of two metal interdigital transducers (IDTs) fabricated on a piezoelectric substrate. The IDTs are patterned from a thin metal film (usually aluminum) that has been deposited on the substrate. The patterning is done by using standard photolithographic techniques. Figure 1 illustrates a single delay line (channel) SAW sensor. The term delay line is used for this design because it can be used for this application in signal processing. The operation of a SAW microsensor is as follows. SAWs are launched onto the delay path (Fig. 2a) via the reverse piezoelectric effect when an RF signal at the microsensor's operating frequency is applied to the input IDT. These SAWs travel across the delay path (Fig. 2b) to the output IDT where they are converted back into electrical signals via the piezoelectric effect (Fig. 2c). The velocity and amplitude of the SAWs are the sensor outputs.

The acoustic velocity V of any material is a function of the elastic constant c and density ρ of the material. For the simplest (isotropic) case, the velocity is given by $V = (c/\rho)^{1/2}$ (5). The relationship between the SAW velocity, frequency f , and wavelength λ , is given by $V = f\lambda$. The attenuation of the waves is primarily a function of the viscosity

Figure 1. Diagram of a single channel (delay line) SAW microsensor.

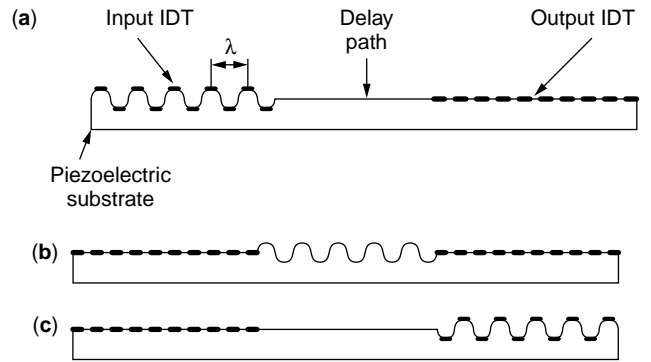

Figure 2. The generation and propagation of SAWs on a sensor surface.

of the material in which the waves propagate. The SAW velocity or amplitude can be changed by a film or deposit on the sensor surface or other disturbances at or near the sensor surface because the density, elastic constant, and viscosity (viscoelasticity) of the film or deposit are usually different from those of the SAW substrate. The SAW velocity or amplitude can also be affected by the conductivity or permittivity of the deposit because the SAW also has an electrical component on a piezoelectric substrate. Secondary physical parameters that affect the previously mentioned (primary) parameters also affect the SAWs' characteristics. They include temperature, stress, pressure, and electric and magnetic fields. A change in the SAW velocity due to mass on the surface is commonly referred to as "mass loading." Mass loading and amplitude attenuation are the most commonly used sensing mechanisms for SAW sensors and are the primary focus of this review article.

The change in SAW velocity ΔV_R has been related to the mass of a thin nonviscous (lossless) film on the sensor surface by Wohltjen (6).

$$\frac{\Delta V_R}{V_R} = (k_1 + k_2) f h \rho', \quad (1)$$

where V_R is the SAW velocity, k_1 and k_2 are substrate material constants, f is the SAW frequency, and h and ρ' are the height and density of the thin film layer, respectively. Therefore, the change in SAW velocity due to a layer depends on $h\rho'$ of the layer. Because the units of $h\rho'$ are kg/m^2 , this is also the layer surface density ρ_s . The change in SAW velocity is determined experimentally by measuring the phase shift, $\Delta\phi$ or the frequency shift Δf of the SAWs that are related to the change in SAW velocity by (6)

$$\frac{\Delta V_R}{V_R} = \frac{\Delta f}{f_o} = -\frac{\Delta\phi}{\phi_o}. \quad (2)$$

The relationship between the attenuation of the SAWs and the viscosity of the mass or film on the sensor surface has been described by Martin et al. (7) for acoustically thin ($< 1 \mu\text{m}$ thick) hard polymer films as

$$\Delta\alpha = \omega^2 \frac{n}{V_R^3} C G'', \quad (3)$$

where $\Delta\alpha$ is the attenuation change, ω^2 is the angular frequency ($2\pi f$), C is a SAW-film coupling constant, and G'' is the loss modulus (complex part of the shear modulus) of the film which is directly related to its viscosity. The term acoustically thin denotes a film that does not resonate at the SAW microsensor's operating frequency. As film thickness increases, it can resonate at the operating frequencies. A macroscopic analogy for a resonant film would be a plate of Jello which, if shaken at a certain frequency, will also resonate when the Jello is high enough.

The earliest uses of SAW devices as microsensors were reported by Das in 1978 (8) for measuring pressure (physical) and by Wohltjen in 1979 (9) for measuring thin film properties (chemical). These sensor applications resulted from the observed high sensitivity of SAW signal processing devices to "external" physical parameters such as temperature changes and package stress, as well as "internal" properties of the films deposited on the SAW substrate. A major application of SAW sensors has been highly sensitive mass detectors (microbalances). Wohltjen stated that SAW sensors have a potential mass sensitivity 200 times greater than the better known quartz crystal microbalance due to their higher operating frequency (6). The effect of frequency on SAW velocity is illustrated by Eq. (1). SAW devices can operate at frequencies higher than 1 GHz, compared to about 10 to 50 MHz for the quartz microbalance which operates by using bulk (shear) acoustic waves. However, because noise in measurement electronics increases as frequency increases, the practical frequency limit for SAW sensors may be closer to 500 MHz. SAW and bulk wave devices have significantly different geometries and fabrication techniques. SAW devices are fabricated by standard microelectronic fabrication methods, whereas bulk wave devices are manufactured individually as small disks that have thin metal film electrodes on each side. Thus, SAW devices are typically less expensive and have a much wider range of designs than bulk devices. The following are additional advantages of SAW sensors. (1) They can be configured in "smart" designs by using two sensing channels on the same substrate where one is a reference. This allows the sensor to be self-compensating for interfering environmental parameters such as temperature (10). (2) Because SAW microsensors are sensitive to several parameters, they can provide an amplified sensor response via multiple detection mechanisms. (3) They are easy to use in wireless sensing applications in both the active mode, as the frequency control element in a transmitter (8), and the passive mode, as an energy reflector (11). The passive mode is particularly interesting because the sensor does not need a power source but is read using a special FM radar type system. SAW devices are also considered one of the earliest types of microelectromechanical systems, or MEMS devices. MEMS devices are usually defined by having both mechanical and electrical components or functions in a single unit and are fabricated using microelectronic fabrication techniques. SAW devices fit this description because they have acoustic waves (mechanical) that are launched and detected electrically.

Commercial SAW microsensor based systems are currently available for gas and biological sensing, gas-chromatography vapor sensing, and chilled-surface,

dew-point hygrometry. All of these systems capitalize on the high sensitivity of the SAW microsensor to small mass changes. Systems for chemical and biological sensing have been developed by Microsensor Systems (now a subsidiary of Sawtek) (12). These include "Vaporlab," which uses an array of SAW microsensors coated with proprietary films and pattern recognition to identify the vapor, and the SAW "Minicad," which uses the same techniques to detect chemical warfare agents. The SAW gas-chromatography system was developed by Electronic Sensor Technology (13). This system uses a single bare SAW microsensor and can be used as an electronic nose in several gas sensing applications that have been validated by the EPA. The SAW dew-point hygrometer was developed by Microconversion Technologies Co. (14). This hygrometer, the "Ultra DP5," also uses a bare SAW microsensor, in this case to provide precision measurements of water vapor concentration.

This article presents a fairly wide range of SAW microsensor applications that are based on the personal research and development experience of the author. These applications include detection of water vapor and other gases; thin polymer film characterization, including adhesion, surface properties, and curing; chilled-surface dew-point measurements; measurement of surface energy and cleanliness; and temperature measurement. A review of acoustic wave biosensors has been provided by Andle and Vetelino (15). Additional SAW microsensor applications are reviewed in books by Ballantine et al. (16) and Thomson and Stone (17). These books also provide more comprehensive descriptions of SAW microsensor theory, design, and applications. SAW device design procedures can also be found in the literature (2,3).

EXPERIMENTAL PROCEDURES FOR SAW SENSING

The two most common methods for measuring SAW velocity are the *phase* and *frequency* techniques (9,16). The experimental setup for the phase technique requires applying an RF signal (from a signal generator) to the input IDT of the SAW sensor. A vector voltmeter is then used to monitor both the phase and amplitude of the SAWs, as shown in Fig. 3. The experimental setup for the frequency technique requires using the SAW sensor as the frequency control element in an oscillator circuit. A frequency counter is then used to monitor the oscillatory frequency, as shown in Fig. 4. The advantages of the phase technique are ease of use, stability, and easily obtainable amplitude information.

Figure 3. The experimental setup for the phase (vector voltmeter) technique.

Figure 4. The experimental setup for the frequency (oscillator) technique.

However, this technique typically involves relatively expensive laboratory equipment. The advantages of the frequency technique are high sensitivity and less expensive equipment; however, oscillatory stability can be a problem, and additional circuitry is required to obtain the amplitude information.

DISCRIPTION OF APPLICATIONS AND EXPERIMENTAL RESULTS

Gas Detection: Water Vapor and Hydrocarbons

One of the most widely studied applications of SAW microsensors has been measuring gas concentration. The most commonly used configuration consists of a very thin film ($<1\ \mu\text{m}$) applied to the SAW microsensor. These films are carefully selected or designed to provide both high sensitivity and selectivity to the gas of interest and also long-term reliability. To study the response of the SAW sensor to gas concentration, the sensors are placed in a chamber in which the atmosphere is controlled by a gas delivery system.

The measurement of water vapor concentration and relative humidity have been of high interest for many years because of their effect on human comfort and health. More recently, the measurement of water vapor has become very important in several other fields, including meteorology, agriculture, and manufacturing due to the effects of water vapor on weather forecasting, product quality, and the large energy costs of drying processes. Polymer-coated SAW devices have been studied as an improved means to measure relative humidity. Polymers are good candidates for sensing films due to their ease of processing, widely customizable properties, and relatively low cost. Polyimide is a readily available polymer that is widely used in microelectronic applications. It has the advantages of durability at high temperatures, low dielectric constants, and ease of application. Therefore, it was chosen for this work.

Figure 5. Water vapor response of photosensitive and nonphotosensitive polyimide films (15).

In addition, photosensitive polyimides have recently been developed that reduce the number of processing steps required for patterning. The major drawback of polyimide in microelectronic applications is that it typically absorbs more than 2% by weight of water vapor when placed in high humidity. However, this property allows its use as a humidity sensing film.

Figure 5 (18) shows the response to water vapor of two SAW microsensors coated by different polyimide films, one that was photosensitive and one that was nonphotosensitive. The photosensitive polyimide had about twice the sensitive to water vapor as the nonphotosensitive polyimide, as indicated by the maximum phase shifts (at 100% relative humidity) of 35° and 18° , respectively. The difference in the responses was attributed to the more open molecular structure of the photosensitive polyimide (which comes in precured form). The higher sensitivity suggests that the photosensitive polyimide would be preferred for a relative humidity sensor. However the long-term stability of the film needs to be studied. A comparison of a SAW humidity sensor with other types of low cost humidity sensors indicated that SAW sensors have the potential for the highest sensitivity at low relative humidities but would probably be more expensive than capacitive or resistive types when signal conditioning circuitry is considered (19).

Polyimide has also been used to measure hydrocarbon and alcohol vapors. Selective hydrocarbon measurement is of high interest to the petroleum refining industry. Table 1 summarizes the results of studies that used SAW microsensors coated by nonphotosensitive and photosensitive polyimides to detect three different hydrocarbons, methyl ethyl ketone (MEK) vapor, and water vapor. The maximum SAW

	Aged	37°	27°	17°	25°	1050°

^aRef. 18

microsensor phase responses are shown for polyimide films before and after 4 months of aging (18). The responses were similar in shape to those for water vapor (Fig. 5) but differ in magnitude. Neither polyimide was selective among isooctane, *n*-octane, and *n*-heptane, but the nonphotosensitive polyimide had good selectivity between water vapor and MEK (large responses) versus *n*-octane, *n*-heptane, and isooctane (small responses). Aging had a significant effect on water and MEK responses for both polyimide types. However, only aging significantly affected the heptane and octane responses of the photosensitive polyimide. These results suggest that the structure of the photosensitive film may become more open or that its viscoelastic properties changed due to additional curing, as the polyimide film aged. Other investigators have used a similar polyimide as a light guide (20) and have shown that polyimide film can select between *n*-heptane and isooctane gas molecules. This selectivity was attributed to the different cross-sectional areas of these molecules. The poor selectivity of the SAW microsensor between *n*-heptane and isooctane was attributed to a different molecular structure of the film caused by the differences in film processing or thickness from that of the light guide work. These results illustrate some of the key difficulties in developing appropriate films for chemical sensors, namely, poor selectivity and long-term stability. The most promising approach to the selectivity problem for many gases appears to be the use of a sensor array using pattern recognition such as that used by Microsensor Systems or a chromatography system that uses pattern recognition such as that of Electronic Sensor Systems. There is also room for SAW sensor-based systems designed for specific gases or applications such as the Microconversion Technologies Co. hygrometer.

Polymer Film Characterization: Surface Treatments and Adhesion

The SAW microsensor has been used to characterize the effects of surface treatments on thin polyimide films and as a nondestructive indicator of film adhesion. Surface treatments are of high interest because they are commonly used to modify film properties, particularly surface energy. The surface energy is important because it is directly related to the adhesion of additional layers to the film and to the film's ability to absorb vapors. This is particularly important in the microelectronics industry. The characterization method consisted of measuring changes in the water vapor response of the films as a function of the film parameter of interest.

The effects of plasma and chemical surface treatments on the water uptake of polyimide films are illustrated in Table 2 (21) which shows the maximum water vapor response (100% relative humidity) for polyimide films that were untreated, sputtered, exposed to KOH, and coated by Teflon-AF. The maximum phase shift for untreated film was about 40°. This compares to the smallest response of about 5° for Teflon-AF treated film, to about 12° for sputtered film, to a maximum response of about 80° for KOH treated film. These results indicate that the surface treatments significantly affect the water uptake of polyimide

Table 2. Maximum Water Vapor Response for Polyimide Film Subjected to Various Surface Treatments

Surface Treatment	Phase Change (degrees)
Teflon-AF	5
Argon sputtered	12
None	40
KOH	80

^aRef. 21.

film and that these changes can easily be measured by a SAW microsensor. A small water vapor response may be desirable when polyimide is used as a protective coating, and the large response would be desirable when the polyimide is used as a sensing film.

Adhesion of thin films is directly related to film reliability. Therefore, a method that can measure the adhesion of thin films nondestructively would be extremely useful. The water uptake response of thin polyimide films was examined as a possible nondestructive indicator of film-substrate interfacial characteristics and adhesion. The water uptake response was measured for two polyimide films which were identical except for the surface treatment used to prepare the substrates before film application. For this work, a dual channel SAW microsensor was used because it can directly measure the response *difference* between two films. The experimental setup used for this study is a slightly modified version of the vector voltmeter (phase) setup previously described (Fig. 3). The modifications include applying the signal generator output to both SAW microsensor channels by using a splitter and putting one of the vector voltmeter probes at each of the two output IDTs, as shown in Fig. 6. The *difference* in the water uptake responses of two polyimide films, one applied over silane adhesion promoter and one applied without promoter is shown in Fig. 7 (22). The positive phase shift indicates that less water was absorbed in the film that used promoter. Because the two films were identical except for the interfacial region, these results suggest that the adhesion promoter prevented water from entering the interface and that a significant amount of water was present at the interfacial region of the film/substrate without promoter.

This agrees with neutron scattering studies of water adsorption at similarly treated polyimide/silicon interfaces (23) and suggests that the SAW technique may provide a simple and nondestructive indication of adhesion that could be used in process control.

Figure 6. A dual delay line SAW microsensor that has two polyimide film samples and the experimental setup for the comparative phase technique.

Figure 7. The difference in the water uptake of polyimide films applied with and without silane adhesion promoter (22).

Note that this dual channel design has been widely studied as a method of adjusting SAW microsensors for undesirable effects and can be considered a “smart design.” For example, the most common application of the dual channel design has been for temperature compensation which is necessary because the SAW velocity for many SAW substrates is sensitive to temperature. When the dual channel design, is used in conjunction with the vector voltmeter setup in Fig. 6, it results in canceling the temperature response of the substrate because it is the same for both channels. However, because only one channel can be coated by a sensing film, the temperature response of the film itself is not compensated for.

Polymer Film Characterization: Curing and Glass Transition Temperature

Polymer films are widely used in microelectronics as replacements for more traditional materials such as inorganic coatings on integrated circuits and ceramic printed circuit boards (PCBs). This is due to their low cost, ease of fabrication, and the ability to modify their properties easily to ensure compatibility with fabrication processes. The increased use of thin polymer films in microelectronic applications has resulted in the need for new characterization methods because these films are much smaller and thinner than polymer films used previously and are therefore not always compatible with existing characterization techniques. For example, the curing processes of some new high-temperature polymer films are not fully understood. Of particular interest are changes in mass and viscoelasticity during curing. Thermogravimetry, a common method used to study curing, is the measurement of mass changes caused by outgassing of solvents and other chemical changes in polymers during curing. It involves heating the sample while simultaneously weighing it on a precision balance. The balances currently used can measure mass changes of the order of micrograms. The mass changes in thin polymer films are in the parts per million range, so, a relatively large amount of the polymer must be tested to obtain mass changes that are measurable by these balances. This results in measuring the bulk properties of the polymer which can be significantly different from the

Figure 8. The temperature-compensated phase and amplitude response of a polyimide film during cure (24).

thin film properties. Therefore, a highly sensitive technique is needed to monitor mass and viscoelastic changes in thin polymer films during curing. A surface acoustic wave (SAW) system was developed that can measure the mass lost due to water outgassing during the cure of thin polymer films in a temperature range of 20 to 400°C. It can also measure the apparent glass transition temperature of acoustically thin films and film resonance of acoustically thick films. The principle limitations of the system were the limited accuracy of temperature compensation and the limited ability to separate mass loss effects from viscoelastic effects.

The SAW sensor used was similar to that in Fig. 1, and the polymer film to be tested was applied to the delay path. A sensor test chamber contained the SAW sensor and a heater and allowed dry nitrogen gas purging to prevent water sorption by the polymers. The temperature compensation was done by curve fitting the temperature response data of an uncoated sensor because this provided much better compensation than the dual delay line technique at this high temperature range.

Figure 8 (24) shows the temperature-compensated amplitude and phase responses for a 1.2- μm thick polyimide film. Both the phase and amplitude initially decreased with increasing temperature, indicating that the polymer was softening, until a minimum in amplitude was reached at about 135°C. Because the phase continued to decrease at this temperature, this corresponds to the apparent glass transition temperature (a function of the sensor operating frequency) described by Martin et al. (7). The first film resonance point is indicated by the second amplitude minimum at 255°C because it corresponds to a sharp increase in phase. There was also a phase increase of 43° between 175 and 210°C which was attributed to water outgassing caused by the reaction of the polyamic acid to form polyimide monomers. This agrees reasonably with the predicted 65° phase change based on the expected mass lost due to water outgassing. It also agrees with work done by others (25) which showed that the water outgassing of polyimide during cure occurs between 175 and 225°C. The difference in the measured and theoretical phase change may be accounted for by partial imidization during the soft bake of the polymer application process or by further softening of the polymer. A second resonance point was also

observed at the third amplitude minimum (and a concurrent phase increase) at 335°C. This is the first harmonic of film resonance. This was predicted by others (17), but it was not previously observed because their studies did not exceed 150°C. The further large increase in phase at higher temperatures may indicate the curing reaction of the polyimide in which polyimide monomers combine to form polymer chains. This would cause hardening of the polymer and therefore, an increase in phase.

In summary, this system can measure the mass lost due to water outgassing during cure of thin polymer films to 2% of total polymer mass in a temperature range of 20 to 400°C. It can also measure the apparent glass transition temperature of acoustically thin films, and film resonance including the first harmonic of acoustically thick films. The principle limitations of the system are the accuracy of temperature compensation, how well mass losses can be separated from viscoelastic effects, and how well the glass transition temperature can be separated from acoustic resonance. When water outgasses, the apparent glass transition temperature and film resonance occur at different temperatures as they did in this polyimide study, and the responses are distinguishable. However, should a polymer be tested in which the mass loss occurs at the same temperature as film resonance, the mass loss is most likely to be masked by the larger film resonance response. Therefore, this system can provide a powerful technique for thin polymer film analysis, but the user must have some idea what to expect and the system's limitations. Improvements to this system could include identifying SAW substrate materials by linear temperature responses using lithium niobate or lithium tantalate.

Dew-Point Measurement

The SAW microsensor has proven to be a very useful tool for studying water vapor condensation and measuring the dew point. Dew-point measurement provides one of the most accurate and widely used methods for measuring the absolute water vapor content of a gas. This has traditionally been done by using an optical chilled-mirror, dew-point hygrometer (25). These instruments detect condensation and dew-point by measuring changes in the reflectivity of a condensing surface (26). Although dew-point hygrometers perform better than polymer-film based and other types of resistive and capacitive humidity sensors, they have some drawbacks, including instability due to mirror contamination, inability to detect the frost-point transition, limited resolution, and high cost. A SAW microsensor-based, dew-point hygrometer offers a chilled-surface technique for dew-point measurements that has improved performance at lower cost. The SAW microsensors' small size also suggests its application for dew-point measurements inside small structures such as microelectronic packages where water vapor can affect yield and device reliability. A description of the SAW dew-point hygrometer and some examples of the SAW dewpoint hygrometer's advantages follow.

To study condensation using the SAW microsensor, two changes were made to the previous test setups. First, the frequency technique was used for some of the studies due to its expectedly higher sensitivity. The principal design

difference between a frequency device and the phase device shown in Fig. 1 is a much shorter delay path. This allows only one mode of oscillation. Sensitivity comparisons, based on theory, indicate that a surface density of $1 \mu\text{g}/\text{cm}^2$ results in a 10° SAW phase shift for a 80 MHz phase device versus a 1.43 kHz frequency shift for a 50 MHz frequency device. Assuming a 0.1° phase resolution and 1 Hz frequency resolution for the phase and frequency systems, respectively, the frequency system would provide about 10 times better resolution. The second change was adding a temperature control system which was required to lower the temperature of the SAW sensor until water (dew) condensed on its surface. The temperature at which this occurs is defined as the dew point (26). A thermoelectric cooler and a PC-based data acquisition and control system were included that detected the amount of condensation on the SAW sensor and then maintained the desired amount of condensation so that an accurate reading of the temperature could be made. The SAW velocity change, which corresponds directly to the condensation density on the sensor, was used as the feedback parameter to maintain the predetermined condensation density that was specified via the control software. The desired condensation density was determined by balancing the need for fast response time (less condensation) and minimizing dew-point measurement error (more condensation). Dew-point error is discussed in the section on surface energy and cleaning. The temperature of the sensor was measured by using a resistive temperature device (RTD). A diagram of this system is shown in Fig. 9, and includes an optical microscope that was used to image the condensation and a LED-phototransistor setup that is discussed later.

The ability of the SAW microsensors to measure condensation density accurately was examined by correlating SAW microsensors measurements of condensation with optical microscope images (27). The condensation density (g/cm^2) was determined from the optical images by estimating the total mass of all water drops in a specified area of the image using drop diameter and contact angle information. The contact angle of the water drops was used to obtain drop height. The SAW frequency was linearly related to the condensation density, the sensitivity was about $1.5 \text{ Hz}/\text{ng}/\text{cm}^2$, and the minimum mass resolution was $18.5 \text{ ng}/\text{cm}^2$. This mass resolution is more than an order of magnitude smaller than optical techniques.

Figure 9. Diagram of the hybrid SAW/optical dew-point measurement system.

A novel hybrid SAW-optical system was developed to obtain meaningful comparisons between the performance of the SAW and optical chilled-mirror, dew-point measurement techniques. This system permitted simultaneous measurement of condensation using both the SAW and optical methods. The design of this system involved adding a light emitting diode (LED), a phototransistor light detector, and an aluminum-mirror film to the SAW sensor delay path. Condensation on the aluminum mirror changed the phototransistor output voltage which was used in a feedback control system, similar to that used for SAW velocity, to maintain the mirror at the dew point. This setup is also shown in Fig. 9. The hybrid SAW/optical system allowed direct comparisons between the SAW and optical chilled-mirror techniques of sensitivity and the effects of surface contamination and the frost-point transition on dew-point measurements. One of the key findings was that the SAW system could maintain a constant condensation density on the sensor without the dew coalescing (small dew drops combining into fewer large drops). This was observed by microscope while controlling the condensation density by using the SAW velocity. Conversely, the optical technique could not maintain a constant condensation density, and coalescence of the dew deposit resulted along with an increase in the SAW phase. Figure 10 (27) shows the reflection voltage and condensation density plotted as a function of time as the dew point was lowered from -10 to -20°C . These data indicate that the condensation density increased by approximately 100% while the reflection voltage was held constant (to within 0.1%). Microscopic imaging indicated that the condensate was dew (supercooled) and not frost. The condensation density change for a constant reflection voltage indicated that reflection voltage was not proportional to condensation density. This lack of a direct relationship can adversely affect control system stability and result in coalescence of the dew which, in turn, can further adversely affect control system stability. These effects typically result in the need for a dry-off cycle when using optical techniques. Therefore, an advantage of the SAW velocity technique is direct measurement of condensation surface density which results

in a more stable system than the indirect measurements provided by the optical and SAW attenuation techniques.

The effect of surface contamination on dew-point measurements was also examined. The amount of condensation which caused the same (60 mV) change in the optical detector voltage for clean and contaminated surfaces, respectively, was studied by using SAW phase and microscopic images (27). The clean surface had $5.5 \mu\text{g}/\text{cm}^2$ of condensation versus more than $30 \mu\text{g}/\text{cm}^2$ for the contaminated surface. By comparison, when the SAW sensor was used to measure the dew point, the condensation density (measured with microscopic images) did not change as the surface became contaminated. This indicates that a SAW dew-point sensor can provide more stable and accurate dew-point measurements in dirty environments.

The dew to frost-point transition and its effect on SAW velocity and amplitude and optical detector voltage were also examined (27). The frost-point transition observed by a microscope began at about -23.5°C , as indicated by a mixture of dew and ice crystals on the sensor surface. Therefore, supercooled dew was present before frost formed. The dew became completely frozen at -24.2°C . This transition occurred during a period of about six minutes. Detection of the frost-point transition around -23°C is in agreement with that of other investigators who reported frost-point transition temperatures ranging from -18 to 28°C , depending on the condensation density and gas flow rate (28,29). As the dew deposit froze, it also coalesced, whereas the SAW velocity simultaneously returned (increased) to approximately the same value as that when no condensation was present. This increase was attributed to the different acoustic velocities of ice versus water and the observed coalesced state of the frost deposit, which resulted in a much smaller contact area with the sensor surface. This resulted in significant instability of dew-point measurements during the frost-point transition. Similar instability occurred when controlling the condensation density by using the optical reflection voltage. However, it was found that SAW amplitude could be used to maintain constant condensation density during the frost-point transition, thus providing continuous dew-point measurements, as well as an indication of the frost-point transition.

The resolution of the SAW dew-point hygrometer (MCT) was compared with those of EG&G (now Edgetech) Model 2000 and General Eastern Model Hygro-M3 optical dew-point hygrometer. Figure 11 (13) shows a constant dew point measured by the three hygrometers. The resolution of the SAW microsensors was about $\pm 0.02^{\circ}\text{C}$ versus $\pm 0.2^{\circ}\text{C}$ for the EG&G and $\pm 0.5^{\circ}\text{C}$ for the General Eastern. The superior performance to the SAW hygrometer was attributed to its direct and more precise measurement of condensation density. The accuracy differences were expected to be resolved by recalibration.

The Measurement of Surface Energy and Effects of Surface Cleaning

A SAW microsensors technique based on the dew-point system was also examined as a novel method for measuring surface energy and the effects of surface cleaning. The

Figure 10. Condensation density variation when controlled by optical detector voltage (27).

Figure 11. The dew point measured by the SAW-based hygrometer and two commercial optical dew-point hygrometers (EG&G Model 2000 and General Eastern Model Hygro-M3) (14).

measurement of the surface energy of thin metal and polymer films is of high interest in the microelectronics industry due to its relationship to film cleanliness and adhesion and ultimately, to microelectronic device reliability (31). Surface energy is also important for determining the biocompatibility of materials and for developing a better understanding of gas sorption on sensing surfaces. Surface energy is defined as the energy spent to create a surface and is closely related to the reactivity or wettability of that surface. Wettability indicates how well a liquid spreads across a solid surface (32). The presence of organic films or contamination on a surface can also be measured because they usually change the surface energy of a material. Plasma cleaning is commonly used to remove organic and mobile ion contamination from integrated circuits and multichip modules (MCMs) before encapsulation, as an alternative to solvents and detergents that typically contain chlorofluorohydrocarbons (CFCs) and other hazardous materials. Plasma treatments have also been used to improve the adhesion of conductors and insulators by changing the surface structure and energy of the metal or polymer layer (33). Improved methods for measuring the results of plasma treatments and cleaning are important for optimizing these processes.

The traditional method for obtaining information about contamination, surface energy, and wettability of solid materials and the effects of plasma treatments is contact angle measurements. The contact angle is the angle created at the liquid–solid–vapor interface when a drop is placed on a solid surface. A surface that has a small contact angle wets better and has a higher surface energy than a surface that has a large contact angle. Small and large contact angles and the effects of surface treatments on them can easily be observed by examining the interface of water drops on the hood of a car before and after it is waxed, respectively. Contact angle is commonly measured by dispensing a fluid on the surface in question and observing the drop by using a goniometer. The advancing angle is measured as the drop volume is increased, and the receding angle is measured as

the drop volume is decreased. The difference between the advancing and receding angle is known as contact angle hysteresis. Contact angle hysteresis is caused by surface microroughness and heterogeneity and by chemical interactions between the surface and the fluid (32). The principal limitations of contact angle measurements are hysteresis, difficulty in measuring angles less than 20° , and poor reproducibility resulting from variations in operator technique. Detailed reviews of contact angle and surface energy are provided in (32,34).

The purpose of these SAW microsensor studies was to determine if a technique for measuring the surface energy and the effects of surface treatments for common electronic materials could be developed that did not suffer from the errors typical of contact angle measurements. The experimental technique used was to measure the dew point while maintaining extremely small condensation densities on the sensor surface. This resulted in a measured dew point that was higher than the true dew point, dewpoint error, which can then be compared for various surfaces. Alternatively, the condensation density on various surfaces at a specific temperature above the dew point can also be compared. The ability of the SAW microsensor to measure a dewpoint error was first demonstrated by coating a SAW sensor with known highly hydrophobic (low surface energy and high contact angle) or hydrophilic (high surface energy and low contact angle) materials. Films of Teflon-AF and polyimide $1\ \mu$ thick were used, respectively. Figure 12 shows the deviation from the dew point (dew-point error) as a function of condensation density for quartz, polyimide, and Teflon-AF surfaces (27). The dew-point error was greater for the hydrophilic material (polyimide) than for the hydrophobic material (Teflon-AF).

For example, at a condensation density of $0.2\ \mu\text{g}/\text{cm}^2$, the dew-point error for polyimide was approximately 2°C versus 0°C for the Teflon-AF. This inversely correlates with the contact angles of 30° and 90° for polyimide and Teflon-AF, respectively, as expected. Noted that the temperature of the SAW sensor was at the true dew point for all surfaces

Figure 12. Deviation from the dew point (dew-point error) as a function of condensation density for quartz, polyimide, and Teflon-AF surfaces (27).

when the condensation density exceeded $0.8 \mu\text{g}/\text{cm}^2$. A dew-point measurement error does not occur when large dew densities are present because condensation forms on existing drops of water.

The ability of SAW dew-point error measurements to measure surface energy and the effects of various surface treatments on quartz is illustrated in Table 3 (35), which shows contact angles and dew-point errors at $0.1 \mu\text{g}/\text{cm}^2$ for several sensor surface treatments listed in order of decreasing contact angle. There appears to be reasonably good correlation between decreasing contact angle and increasing dew-point error, considering the previously mentioned limitations of contact angle measurements. The most significant deviation was HCI which had the largest contact angle but not the smallest dew-point error. Contamination between experiments is a possible source of error for all measurements. These results suggest that dew-point error may provide a measurement of surface energy which does not suffer from hysteresis, however, more work is necessary in this area to establish a more definitive relationship.

Temperature Measurement

Acoustic temperature sensors (ATSs) use the temperature dependence of the acoustic velocity in a piezoelectric substrate to measure temperature. Their principle advantages

Figure 13. The frequency versus temperature response for an SSBW ATS (36).

over other types of temperature sensors are ease of integration with other acoustic sensors, low self-heating, robustness, wide temperature range, a digital form of output, low noise susceptibility when used in an oscillator, relatively low cost, high resolution, and short response times. Their main disadvantage is that they require hermetic packaging to prevent inaccuracies caused by sensor contamination. This slows the response time and increases cost. Surface skimming bulk wave (SSBW) devices have been found much less sensitive to surface contamination than other acoustic devices because the waves have horizontal displacements and can propagate just beneath the surface of the substrate. Therefore, they may not require hermetic packaging. However, these devices have not been studied as temperature sensors. The objectives of this work were to study the temperature characteristics and contamination sensitivity of an SSBW ATS. The introductory section provides a description of this wave.

Figure 13 shows the frequency versus temperature response for an ATS characterized in a Styrofoam chamber (36). A second-order curve fit yielded a first-order temperature coefficient of frequency (TCF) of approximately $31.5 \text{ ppm}/^\circ\text{C}$. The temperature deviation from the second-order curve fit indicated a resolution of $\pm 0.22^\circ\text{C}$ across a 78°C temperature range. The TCF of $31.5 \text{ ppm}/^\circ\text{C}$ could provide a theoretical temperature resolution of better than 0.0003°C if a 1 Hz frequency resolution is available. Figure 14 shows the test setup used to compare the

Figure 14. The test setup used to compare the mass sensitivities of SSBW and SAW microsensors (36,37).

mass sensitivities of SSBW and SAW acoustic delay lines (36). A novel dual delay line design was used where a SAW channel was aligned at 90° to the SSBW channel (37). The phase shift of the SSBW due to mass loading was determined by maintaining a fixed surface density of condensed water by using the SAW device (as described in the previous section) while monitoring the phase shift of the SSBW device using a vector voltmeter. Figure 15 (36) shows the phase shift due to mass loading for the SSBW and SAW delay lines. The SSBW phase shift was more than an order of magnitude less than that of the SAW for the same mass loading. Assuming a TCD of $32 \text{ ppm}/^\circ\text{C}$, $5 \mu\text{g}/\text{cm}^2$ of contamination would result in a temperature error of 16°C for SAW versus 0.4°C for SSBW ATs, respectively. The SSBW response was attributed more to the effect of the water on IDT capacitance than mass loading, and therefore, it is most likely that it can be significantly reduced by a protective coating. These results suggest that SSBW ATs may have applications in acoustic chemical sensing where temperature information is also desired. Note that ATs do require calibration and that the procedures are not simple because SAW microsensor calibration can be affected by the electronic circuitry used.

Figure 15. The SSBW phase versus SAW phase due to mass loading (36).

CONCLUSIONS

It has been shown that the SAW microsensor provides a highly sensitive and versatile sensing platform for both commercial applications and as a laboratory tool. Of the systems and applications described in this article, the SAW microsensor-based dew-point hygrometer is the only one that is currently commercialized. It offers clear advantages over existing chilled-mirror technology, including significantly better dew-point measurement resolution and stability. This results from the SAW microsensor's high sensitivity and its ability to measure condensation density directly. This ability also prevented ripening and coalescence of the condensate which makes the instrument more stable. The SAW technique can also detect the frost-point transition and is much less susceptible than optical systems to instability caused by surface contamination.

The ATS is the application most likely to be commercialized next. It will be most useful when used in conjunction with other SAW-based chemical sensors due to cost considerations. Commercial applications for coated SAW microsensors beyond those described in the introduction hinge on the other key chemical sensor requirements of selectivity and long-term reliability. Further advances here are most likely to come from improved film chemistry which has been a relatively slow process. The high sensitivity of the SAW microsensor to condensation at temperatures slightly above the dew point and the lack of hysteresis of the dew-point measurement suggest that it may have advantages over contact angle for measuring surface energy and for characterizing certain polymers, metal surfaces, and surface treatments, if further developed. Possible applications of this SAW microsensor system include *in situ* monitoring of surface and interfacial treatments for process control in microelectronics manufacturing. Similarly, the use of a SAW microsensor for characterizing thin polymer films is also promising but requires further development.

SHAPE MEMORY ALLOYS, APPLICATIONS

CAROLYN RICE
Cordis-NDC
Fremont, CA

INTRODUCTION

Shape-memory alloys have been engineered for applications and devices since the first discovery of the shape-memory effect in the 1930s. The majority of this design activity was initiated by the discovery of Nitinol (nickel–titanium alloy) in 1962, and since then more than 10,000 patents have been issued for applications using shape-memory alloys (1). This article reviews a number of these applications, discusses aspects of design, and illustrates representative examples.

TYPES OF SHAPE-MEMORY ALLOYS

General Theory

Shape-memory alloys (SMAs) are known primarily for one fundamental and unique property—the ability to remember and recover from large strains without permanent deformation. Unlike most conventional metals that recover less than 1% strain before plastic deformation, SMAs undergo a diffusionless, thermoelastic martensitic phase transformation that enables the material to deform via a twinning process rather than the conventional dislocation slip mechanism and allows complete recovery of strains as large as 8%. The metallurgical phenomena that explain these martensitic transformations are detailed in many sources (2–5). The discussion to follow includes only a brief summary of SMA behavior to review its basic properties.

Shape-Memory Effect. The most well-known form of transformation behavior exploited in SMAs is thermally induced shape change, often labeled the shape-memory effect (SME). A material component may be deformed, or strained, at low temperatures, and when heated, it reverses this strain and remembers its prestrained shape. The low-temperature, deformable martensite phase transforms to a more stable austenite phase at higher temperatures. This transformation occurs across a temperature range, known as a transformation temperature range (TTR). This range for Nitinol (Ni–Ti) is approximately 30 to 50°C, and is also known as temperature hysteresis. The A_s (austenitic start) temperature is the beginning of the transformation to austenite upon heating, the A_f (austenitic finish) is the finish of the transformation to austenite, M_s (martensitic start) is the beginning of the martensitic transformation upon cooling, and M_f (martensitic finish) is the finish of the transformation to martensite. A typical SMA stress–strain curve, depicted in Fig. 1a, demonstrates shape-memory behavior at temperatures below the material M_f temperature. A schematic example of a shape-memory application is shown in Fig. 1b.

Figure 1. Typical SMA behavior in tensile tests and bending applications: (a) stress-strain curve of shape memory (martensite) material, (b) schematic of a shape memory application, (c) stress-strain curve of superelastic (austenite) in tension, (d) superelastic behavior in a bending application.

Shape-memory alloys may also be trained to exhibit a two-way shape memory effect. Similar to the thermal shape-memory effect, two-way shape memory (TWSM) requires special thermomechanical processing to impart shape memory in both martensitic and austenitic phases. A trained shape in the austenitic phase reverts to a second trained shape upon cooling, allowing the material to cycle between two different shapes. This TWSM is theoretically ideal for many shape-memory applications; however, practical uses are limited due to behavior instability and complex processing requirements.

Superelastic Effect. This effect, known also as pseudoelastic, describes material strains that are recovered isothermally to yield mechanical shape-memory behavior. The phenomenon is essentially the same as the thermal shape-memory effect, although the phase transformation to austenite (A_f) occurs at temperatures below the expected operating temperature. If the austenitic phase is strained by an applied load, a martensitic phase is induced by stress, and the twinning process occurs as if the material had been cooled to its martensitic temperature. When the applied load is removed, the material inherently prefers the austenitic phase at the operating temperature, and its strain is instantly recovered. A typical stress-strain

curve is depicted in Fig. 1c, and a schematic example of a superelastic application is shown in Fig. 1d. The stress-strain curve indicates a difference in stress levels during loading and unloading, that is known as superelastic stress-strain hysteresis.

Alloys

Several alloys have been developed that display varying degrees and types of shape-memory behavior. The most commercially successful have been Ni-Ti, Ni-Ti-X and Cu-based alloys, although Ni-Ti and ternary Ni-Ti-X alloys are used in more than 90% of new SMA applications (6). Ni-Ti alloys are more expensive to melt and produce than copper alloys, but they are preferred for their ductility, stability in cyclic applications, corrosion resistance, biocompatibility, and higher electrical resistivity for resistive heating in actuator applications (6).

The most common Cu-based alloys, Cu-Al-Ni and Cu-Zn-Al, are used for their narrow thermal hysteresis and adaptability to two-way memory training. Ni-Ti ternary alloys are used to enhance other parameters. Examples include Ni-Ti-Nb for wide thermal hysteresis, Ni-Ti-Fe for extremely low TTR, Ni-Ti-Cr for TTR stability during thermomechanical processing, and Ni-Ti-Cu for narrow thermal hysteresis and cyclic stability (7).

Material Forms

SMA are manufactured in many of the conventional forms expected of metal alloys: drawn round wire, flat wire, tubing, rolled sheet, and sputtered thin films. Additional forms include shaped components, centerless ground tapered wires and tubing, alternate core wire (Ni–Ti filled with a conductive or radiopaque material), PTFE coated wire, stranded wire, and embedded composites. At present, Ni–Ti–X alloys are the most readily available in all of these forms.

The processing of SMA material is critical for optimizing shape-memory behavior. Many adjustments can be made to optimize the properties of a material form for a particular application; however, most efforts are made to optimize a balance of strain recovery, ductility, and tensile strength. SMAs such as Ni–Ti are melted using extreme purity and composition control, hot worked to bars or plates, cold worked to their final form, and subjected to specialized thermomechanical treatments to enhance their shape-memory properties.

DESIGNING WITH SHAPE MEMORY ALLOYS

Shape-memory alloys have intrigued engineers and inventors for more than 30 years. One might conclude from the large number of SMA patents that have been issued and the knowledge that relatively few of the ideas have been commercially successful that the majority of these designs have not fully accounted for the unique behaviors, limitations, and constraints of SMAs. The focus of this section is to highlight the properties best used in SMA applications and to discuss SMA design considerations.

Functional Properties

SMA applications are often categorized in terms of the specific material property used. The majority of these properties are either thermal shape memory or mechanical shape memory (superelastic), but some unique properties are only indirectly related to these shape-memory effects. General categories of applications are classified according to these properties.

Shape Memory. The thermally activated ability of a shape memory material to change shape yields several types of applications that can be summarized in three distinct categories: applications that use the shape change to display motion, those that actuate, and those that harness stresses produced from constraining the recovery of the shape-memory material.

Displayed motion, also referred to as free recovery, describes applications that exploit the pure motion of thermal shape memory (8). An example of this application, a moving butterfly, is displayed in Fig. 2. These butterflies, produced by Dynalloy, Inc., use a specially processed form of Ni–Ti wire to move wings back and forth for thousands of cycles without significant signs of fatigue. This processed wire, known as Flexinol™, changes shape via cyclic heating by electric current. The small mass of the butterfly body is sufficient to extend the Ni–Ti wire when cooled, but the

Ni–Ti wire can contract and close the wings when heated to its stronger austenitic shape.

Actuation applications are designed to perform work. A simplified example is a mass suspended from a shape-memory tension spring. When cooled, the weaker martensitic phase deforms, and the spring is extended by the mass. When heated to austenite, the spring recovers its shape with forces sufficient to lift the weight, resulting in actuation that performs work.

Constrained recovery applications use the change in material strength from martensite to austenite to produce a stress that can be harnessed as a clamping force. A popular example of a constrained recovery application is a shape-memory coupling which is expanded at low temperatures, then heated to shrink and clamp to join two pipes.

Superelasticity. Unlike thermal shape-memory applications, which can be categorized into several types, applications that exploit this mechanical shape memory are defined as those that require high strain recovery at

Figure 2. Photograph of a Flexinol™ actuated butterfly (courtesy of Dynalloy, Inc.).

Figure 3. Suture retrieval loops designed to recover their shape once deployed from a 6 fr. cannula (courtesy of Shape Memory Applications, Inc.).

operating temperatures. Many examples of applications that use superelasticity are found in the medical industry (Fig. 3), but one of the most well known is found in consumer eyeglass frames marketed as Flexon[®] by Marchon Eyewear, Inc. (Fig. 4).

Energy Absorption for Vibrational Damping. An energy absorbing ability found in both the martensitic and austenitic phases of SMAs is indirectly related to their shape-memory behavior. The energy absorption of SMA materials has demonstrated excellent vibrational damping characteristics, which can be harnessed for use in various damping applications. The types of devices that exploit this property are classified in three categories of damping: martensitic, martensitic transformation, and superelastic.

Martensitic damping devices operate by using only the martensitic phase of SMAs. Energy is absorbed by the martensite during its twin reorientation process, and accommodates large strains for high-amplitude, low-frequency

loading. They offer the best damping characteristics of the three categories, and although they cannot recover large strains without subsequent heating, they provide excellent damping properties across a broad temperature range.

Martensitic transformation damping elements are designed to operate near martensitic transition temperatures for peak performance in vibrational attenuation. This peak is due to a sharp increase in internal friction during the martensitic phase transformation. These damping elements offer ideal properties for low-amplitude, high-frequency vibrations within a small operating temperature range (9). This type of device could be used in ski materials to damp vibrations when the ski is in contact with snow (6).

Superelastic damping devices use the plateau hysteresis portion of the stress-strain curve for properties similar to those of a rubber band. Superelastic SMA materials are pretensioned to reach this stress-strain plateau, and any additional strains are accommodated easily by changes in

Figure 4. Deformation resistant eyeglass frames (courtesy of Marchon Eyewear, Inc.).

the applied load. This property optimizes a combination of damping capacity, shape recovery, and temperature range of operation (9). Unlike martensitic damping elements, superelastic devices recover their original shape when vibrational loading is removed. Suggested superelastic tensioning devices are presented in a U.S. patent regarding hysteretic damping (10); one example is shown in Fig. 5 (9). These SMA tension elements cycle through a superelastic stress-strain hysteresis to dissipate energy and serve as a damping mechanism. Vibrations due to environmental impacts such as violent winds and earthquakes deform the tensioned elements, and when the vibrational impact is lessened, the elements recover their shapes.

Cavitation-Erosion Resistance. Cavitation erosion is a phenomenon that affects equipment and machinery in many industries. Small bubbles explode with large

Figure 5. Schematic of a superelastic damping device, using loops of SMA wire in tension. Reprinted with permission from D.E. Hodgson and R.C. Krumme, *Damping in Structural Applications, SMST Proceedings*, 1994.

impacts, causing pitting and erosion in metallic surfaces and reducing the service life of expensive equipment. Both the martensitic and austenitic phases of SMAs have displayed cavitation-erosion resistance; they recover from impact and minimize material loss when exposed to vibratory cavitation. Studies that explored the performance of Ni-Ti on stainless steels have indicated that both martensitic and austenitic Ni-Ti have significant potential for covering and protecting equipment that suffers wear from cavitation erosion. Ni-Ti cladding could be used in applications such as machinery, hydraulics, large hydroelectric generator turbines, and ship propellers (11).

Low Elastic Modulus. The martensitic phase of SMA materials is soft and pliable, in contrast to the stiff, springy characteristics of the austenitic phase. This softness, or low effective (nonlinear) elastic modulus, is often used in applications that require deformability and excellent fatigue characteristics. This property is exploited alone or in conjunction with a shape-memory effect in fatigue-resistant applications.

An example of a low elastic modulus application is shown in Fig. 6: a martensitic tool developed by St. Jude Medical, Inc., is used by surgeons during open heart surgery to orient a tissue-restraining device. During this procedure, surgeons must make adjustments to optimize the tool geometry for each patient, and the use of SMAs allow surgeons to bend the martensitic handle to an appropriate angle. Upon completing the operation, the tool is sterilized in an autoclave where it is exposed to elevated temperatures and reverts to its trained, austenitic shape. Due to its ability to recover large strains repeatedly, these tools are marketed for both fatigue resistance and shape-memory properties.

Design Constraints and Considerations

When assessing a potential design challenge, designers are often anxious to develop a solution that uses the unique and exciting properties of SMAs. It is critical, however, for designers to understand the complexity of SMA behavior. As a general rule, if conventional materials and designs can be applied to yield an acceptable and desirable result, the use of SMAs to provide an alternative solution will increase complexity and cost. SMAs are best used when their unique properties are necessary for design success—when conventional materials cannot meet the demands of the application.

The design of SMA applications requires more than traditional design techniques and textbook methods. Due to the many unique properties of SMA materials, several considerations specific to SMA design must be addressed and accounted for. This section discusses the majority of issues that should be addressed before designing an application using SMAs.

General Guidelines

Recoverable Strain. The expected recoverable strain of SMA material must be within the limitations of the alloy

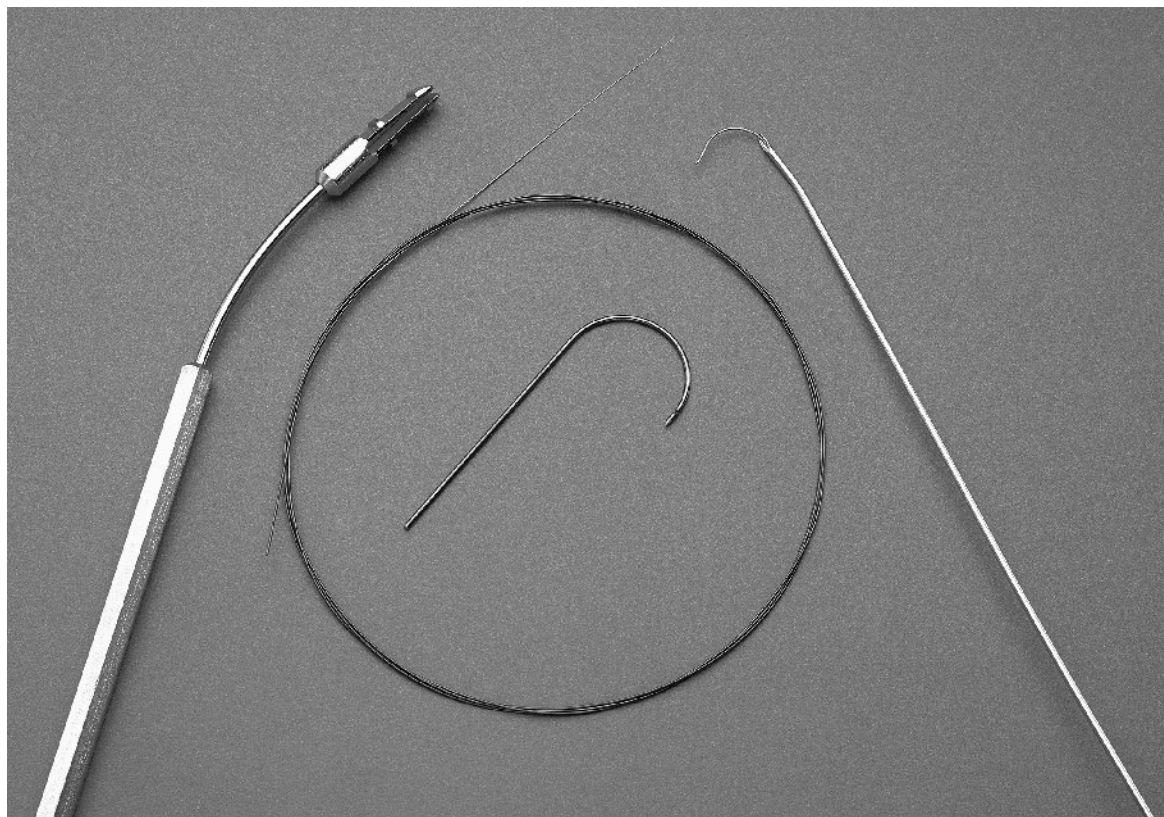

Figure 6. Medical tools and devices. *Left to right:* Flexible martensitic, Ni-Ti handle developed by St. Jude Medical for open heart surgery procedures; superelastic, tapered guidewire core; shaped Ni-Ti tubing component; retractable, superelastic component within a small diameter cannula (courtesy of Shape Memory Applications, Inc.).

chosen. For example, Ni-Ti may recover 8% strain for a single cycle application, but less than 4% for higher cycle applications. Recommended strain limits are 6% for Ni-Ti and 2% for Cu-Zn-Al for lower cycle applications and 2% and 0.5% for higher cycle applications, respectively (3). A maximum strain recovery of about 2% is expected for applications that require two-way shape memory (12).

High Temperature Stability. Alloy stability must be considered when an application requires or will be subject to high operating temperatures. Ni-Ti alloys tend to be the most stable of all SMAs at elevated temperatures and can withstand exposure to temperatures up to approximately 250°C before previously memorized shaping is deleted. For Cu-Zn-Al, this maximum temperature is around 90°C.

Fatigue. SMA fatigue can be defined as degradation of any or all of its functional properties. SMAs affected by application cycle quantity, frequency, temperature range, stress, and strain may fatigue by fracture, decreasing recoverable strain, shifting transformation temperatures, or decreasing recovery stress.

Manufacturability. SMA materials are infamously difficult to machine. Tool wear is rapid for conventional

machining methods such as turning, milling, drilling, and tapping (2). Currently, the most successful machining techniques include surface grinding, abrasive cutting, EDM, and laser cutting. Component shaping must be considered as well; the memories of SMA shapes are trained at high temperatures, typically around 500°C (932°F). Unlike most conventional materials that may be cold formed, SMAs must be rigidly clamped in a desired shape and exposed to these elevated temperatures.

Designing for assembly is also an important manufacturing consideration. Fastening SMAs to other materials by bonding and joining presents additional challenges. Because SMAs are designed to exhibit strains up to 8% and other materials have a strain limit of less than 1%, when the two are rigidly joined, the conventional material may break during operation. This often causes problems in using plated or painted SMA materials because the coating on the SMA will often crack and flake during the strains of operation.

Cost. Most SMAs are inherently more expensive than conventional materials due to the higher cost of both raw material components and processing methods. The positional control necessary for the raw forms of SMA

Figure 7. Finite element analysis model of a self-expandable Ni-Ti stent: displays a quantified mapping of stress and strain amplitudes in both expanded and compressed positions (courtesy of Pacific Consultants, LLC).

material requires special furnaces and processes, the sequence of cold working and annealing to ensure optimal SMA properties is extensive, and the special tooling and fixturing required for producing the many forms and shapes of the materials increase the cost of using SMAs.

Computer Modeling Capability. Finite element analysis (FEA), often used in conventional material design, has also been used to model the behavior of SMAs. The analysis is difficult, however, and should not depend on standard material templates and subroutines because the functional properties of SMAs rely on nonstandard factors, such as composition and processing history. Highly specific and complex modeling techniques must account for the state of the SMA material once formed in its trained shape, and then must incorporate the nonlinearity of the stress-strain curve, the property dependence on temperature, and the difference between loading and unloading stress behavior. Figure 7 is an illustration of a FEA model of a superelastic coronary stent that was achieved by using custom modeling subroutines to predict mechanical properties.

Shape Memory Applications

Temperature Cycling. Thermally activated SMA applications require temperature control to optimize the effect of shape memory. To harness the unique properties obtained from martensitic transformations, temperatures usually cycle between the extremes of the SMA temperature hysteresis. Depending on the alloy selected, this hysteresis might be smaller than 1°C (1.8°F) or larger than 100°C (180°F). Applications must incorporate a method of heating and cooling SMA components through their

hystereses; the rate of cycling for a shape-memory device is limited by the rate of temperature cycling. The butterfly example of Fig. 2 has a hysteresis of about 30 to 50°C. The Flexinol™ actuator wire is heated to a temperature above 90°C to contract, but must be cooled to approximately 40°C to transform to martensite. This application uses ambient air for cooling—only a few seconds are required for the wire to cool and stretch with the mass of the butterfly body. A few alloys have been developed to reduce or to increase this temperature hysteresis, as mentioned earlier. In addition, a secondary martensitic phase transformation found in many SMAs, called an R-phase transformation, can be exploited for its hysteresis of less than 2°C. Although recoverable strains are limited to about 0.5% by this transformation, it may be ideal for certain applications (13).

Power. SMAs require thermal energy for memory activation that is most often delivered as direct heat or applied current for resistive heating. Applications that use thermal shape memory must account for the power requirements of the material, the connection of the power source to the SMA, space requirements to house the source, and any safety mechanisms necessary to prevent overheating.

Force Requirements. SMA applications typically exploit the strength differential between the martensitic and austenitic phases of the material. In many actuating devices, an SMA element is paired with a conventional material element to serve as a biasing mechanism. The conventional element, such as a steel coil spring, displaces the SMA element when martensitic, but yields to the SMA

when heated to its stronger austenitic phase. This enables a one-way shape memory element to behave as a two-way shape-memory device. The forces delivered at each of the temperature extremes must be considered in SMA design.

Superelastic Applications

Operating Temperature Range. The temperature range of operation for a superelastic application must be above the A_f temperature for optimal superelasticity, but must also be below its M_d temperature (the temperature at which martensite can no longer be stress induced). This range is typically 50 to 80°C above the A_f (14).

Force Requirements. As operating temperatures increase above the SMA A_f temperature, loading and unloading stresses increase as a function of the Clausius–Clapeyron equation (14). Due to variations in the latent heat of transformation among alloy types, the increase in stress, as temperature changes, ranges from 2.5 MPa/°C to more than 15 MPa/°C (15).

SMA APPLICATIONS

Applications that use each of the unique properties of SMAs have been designed, prototyped, and marketed throughout the world. This section provides examples of these applications and includes some discussion of design choices, material limitations, and SMA behavior. These examples are categorized by industry to demonstrate the varied and widespread use of SMA applications.

Aeronautics/Aerospace

Many of the initial product ideas and applications that incorporate SMAs were pioneered in the fields of aeronautics and aerospace. SMA materials are used in these industries to take advantage of properties such as high power-to-mass ratios and ideal actuating behavior in zero-gravity conditions. Designs that use these properties replace heavier, more complex conventional devices because of reduced weight, design simplicity, and reliability.

Cryofit® Hydraulic Pipe Couplings. SMA couplings were the first successful commercial application of shape-memory alloys (Fig. 8). In 1969, Raychem Corporation introduced shrink-to-fit hydraulic pipe couplings for F-14 jet fighters that were built by Grumman Aerospace Corporation. This coupling is fabricated from a Ni–Ti–Fe alloy whose martensitic transformation temperature is below –120°C. It is machined at room temperature to an inner diameter approximately 4% smaller than the outer diameter of the piping it is designed to join. When cooled below –120°C by liquid nitrogen, the coupling is forced to a diameter 4% greater than the pipe diameter for an overall

internal strain of about 8%. When warmed above its TTR, the coupling diameter decreases to form a tight seal between the pipes (16).

This shape-memory application of constrained recovery continues to be a commercial and financial success. Despite the difficulties of cooling the couplings to liquid nitrogen temperatures for expansion and storage, the aerospace industry has welcomed their many advantages over traditional pipe-joining techniques such as welding or brazing. Installation is simple, less costly, and does not rely on high levels of operator skill. The replacement of couplings and hydraulic lines is straightforward, and the possibility of annealing and damaging the hydraulic lines as in welding or brazing is eliminated (2).

Frangibolt® Release Bolts. Shape-memory bolts were developed by the TiNi Alloy Company to replace conventional exploding bolt devices in aerospace release mechanisms. The bolts are used to attach spacecraft accessories during launch and to release them after launch by using an activated heating element (17). A martensitic, shape-memory cylinder is compressed and assembled to a notched bolt. When activated by an electrical heater, the cylinder increases in length and delivers a force greater than 22 kN (5000 lbs) to fracture the bolt at its notch (18). These release bolts were used successfully aboard the spacecraft Clementine in 1994, and have improved upon designs for conventional explosive mechanisms by eliminating the risks of off-gassing, accidental activation during shipment, and potential spacecraft damage during explosions.

Mars Sojourner Rover Actuator. An SMA wire was used to actuate a glass plate above a small solar cell on the Rover unit during the recent Pathfinder/Sojourner mission to Mars. A material adhesion experiment performed during the mission used the actuator to replace large, heavy motors and solenoids. A small, simple length of Ni–Ti wire heated and contracted when the Rover applied power and pulled a glass plate away from the solar cell to allow comparison of sunlight intensity with and without the plate. The rate of dust collection was then determined, and the resulting data will be used to design cleaning methods for future missions to Mars (19).

Self-Erectable Antenna. A prototype space antenna was constructed by Goodyear Aerospace Corporation. Designed to fold compactly at room temperature, the device would unfold into a large, extended antenna shape when heated by solar energy (2). Although this did not become a commercial success, the concept is feasible, and the prototype has served as a model for similar designs pursued within the aerospace industry.

Smart Airplane Wings. Composite structures that have SMA wires embedded can be used to change the shape of an airplane wing. The embedded wires may be activated

Figure 8. Shape memory devices. *Clockwise from top left:* memory card ejector mechanism for laptop computers; Cryofit[®] hydraulic pipe couplings; Cryocon[®] electrical connector; fire safety lid release for public garbage receptacles (courtesy of Shape Memory Applications, Inc.).

to constrict and improve the vibrational characteristics of the wing, heated to change their effective modulus to reduce vibration, or activated to alter the shape of the wing for optimal aerodynamics. All of these properties can be used to produce an adaptive airplane wing that alters as environmental conditions change to improve efficiency and reduce noise.

Space System Vibrational Damper. Vibrational dampers comprised of composite materials using pre-strained, embedded SMA wire or ribbons can reduce unwanted motion in various space systems. A sensor detects vibration in the system and sends a signal to activate the embedded composite, which then alters the structural dynamics to damp or cancel the existing vibration (1).

Consumer Products

SMA devices and components have been used in high-volume consumer products for more than 20 years. Although many consumers who use these products are unaware of their SMA components, there is a growing public

awareness of SMAs due to recently marketed items that advertise their merits.

Flexon[®] Optical Frames. Superelastic eyeglass frames marketed by Marchon Eyewear, Inc., are one of the most widely known uses for SMAs. They are frequently advertised in television commercials and can be found at most optical frame retailers. The components of eyeglass frames that are most susceptible to bending, the bridge and temples, are wire forms of Ni-Ti, the remainder of the frame is comprised of conventional materials for adjusting purposes and cost savings. Due to the high strain recovery capability of Ni-Ti, these frames are highly deformation- and kink-resistant (Fig. 4). Marchon is aware of the high strain and high cycle fatigue limitations of Ni-Ti materials, as demonstrated by the marketing brochures that appropriately suggest bending and twisting limits that are within the design guidelines for the material.

Portable Phone Antennae. The growing demand for portable phones has resulted in a high-volume application for superelastic Ni-Ti material because most cell

phone antennae produced today are Ni–Ti wires coated with polyurethane. The superelasticity resists permanent kinking and withstands the abuses of user handling during the lifetime of portable phones.

Greenhouse Window Opener. An SMA that has a small temperature hysteresis is used as an actuator to open and close greenhouse windows at predetermined temperatures for automatic temperature control. The opener is a spring-loaded hinge that has a Cu–Zn–Al shape-memory spring and a conventional metal biasing spring. The SMA spring is compressed by the biasing spring at temperatures below 18°C, and the window is closed. The SMA spring activates around 25°C, overcomes the force of the bias spring, and opens the window (21). This actuator design relies on reduced thermal hysteresis using a biasing force. As the SMA spring cools to 18°C, although not sufficiently cool to completely transform to its softer martensitic phase, it is transformed enough to accommodate deformation via stress-induced martensite.

Recorder Pen Mechanism. A shape-memory pen driver was designed by The Foxboro Company in the early 1970s to replace conventional pen-drive mechanisms, which used a galvanometer to actuate a pen arm. The replacement used Ni–Ti wires pretensioned in a driver unit and actuated by heat from an induction coil in response to input signals. The new design reduced the number of moving parts, improved reliability, and decreased costs. The new recorder pen units were first introduced in 1972; by 1980 more than 500,000 units were produced (16,21).

Nicklaus Golf Clubs. Superelastic SMA golf club inserts were developed by Memry Corporation for a line of Jack Nicklaus golf clubs. The damping properties of the inserts hold the golf ball on the club face longer and provide more spin and greater control for golfers (22).

Brassiere Underwires. Superelastic Ni–Ti shapes that conform to the user's body are ideal for underwire applications, because they are unaffected by the temperatures and external forces from repeated washings. Wires are shaped in predetermined configurations, using either round wire or flat ribbon. The product is a commercial success in Asia, but the increased cost compared to that of conventional underwires has prevented the product from entering markets in North America and Europe.

Residential Thermostatic Radiator Valve. SMA actuators have been used to regulate the temperature of residential radiators. An actuator expands when the room temperature increases, overcomes a biasing spring force, and closes a radiator hot water valve. Assisted by the biasing spring, the SMA temperature hysteresis can be as low as 1.2°C (21). The thermostatic valve can be adjusted via a knob that alters the compression of the biasing spring—the more compression it exerts, the higher the temperature required for the SMA actuator coil to activate and close the hot water valve (16).

Rice Cooker Valve. SMA valve mechanisms have been successfully employed to improve the performance of rice cookers. The mechanism, comprised of an SMA spring and a bias spring, is inserted into the top lid of a rice cooker. The valve is open while rice cooks and steam is generated, but when the rice is finished cooking, the SMA spring cools and the bias spring closes the valve to keep the rice warm. A Ni–Ti–Cu alloy is used for the SMA spring because of its low strain, high cycle fatigue properties. Although its recovery force decreases due to repeated cycling, this application has demonstrated repeatability for more than 30,000 cycles, which corresponds to several daily operations for 10 years (23).

Robotic Doll. SMA actuator wires were designed to move the arms and legs of a doll to display human characteristics. The application is technically feasible, and prototypes were successful; however, the power required to activate the wires was too great. The battery changes required were sufficiently frequent to limit market acceptance of the product.

Miscellaneous Products. Furukawa Electric Co. Ltd. of Japan produced SMA-actuating air-conditioning louvers to deflect air up or down, depending on temperature. They also manufactured coffee makers that use temperature-control valves to initiate the brewing process when water starts to boil (24). Other products include superelastic fishing lures, superelastic SONY Eggo™ headphones for the minidisk Walkman®, and novelty items, such as a magic teaspoon that has a memory. The teaspoon is given to someone to stir a hot drink, and when the spoon is exposed to the hot liquid, it is immediately transformed to a bent position.

Commercial/Industrial Safety

Many safety devices for temperature sensing and actuation have been successfully used in actual operation. The following examples have all been sold in consumer or industrial markets.

Antiscald MemrySafe® Valve. An SMA valve was designed to shut off a faucet's hot water source when water temperatures become too high (above 50°C). The valve reopens when the water cools to safer temperatures and protects the user from scalding water. ShowerGard®, BathGard®, and Flow-Gard® are similar products, and all have been marketed in retail hardware stores.

Firechek® Valve. A safety device that employs an SMA actuator is often used in industrial process lines to shut off a gas supply in the event of fire. Exposure to high temperatures activates a valve and cuts off the pneumatic pressure that controls flammable gas cylinders and process line valves (25).

Circuit Breakers. SMAs have been used in circuit breakers to replace conventional bimetals. Due to the high forces required in large circuit breakers, a series of levers must be employed to amplify the forces available from bimetals. Cu–Al–Ni alloys have been used in this application

for their high temperature activation and low hysteresis. Simple cantilever beam designs increase force and stroke and eliminate the need for levers.

Proteus[®] Safety Link Device. A chain link has been fabricated from Cu–Zn–Al to change shape at high temperatures and act as a release mechanism. The release may activate sprinkler systems or trigger fire doors to close, depending on the application (26).

Telecommunication Line Fuses. Cu–Zn–Al shunts are coupled with high-sensitivity fuses throughout Europe to protect communication systems from lightning strikes. During normal operation, the fuse heats up more rapidly than the SMA, and the shunt remains inactive. Under heavy usage, however, the shunt increases in temperature and activates to bypass the fuse and protect it from a critical burnout temperature (26).

Safety Trash Lid Mechanism. An SMA device has been designed to smother accidental fires in public trash receptacles. The device holds a trash lid in the open position at normal operating (ambient) temperatures, but when heated by a fire within the trash can, the shape-memory component releases a latch and the lid drops to extinguish the fire (Fig. 8).

Medical

The medical industry is rapidly accepting the use of SMAs in a wide variety of applications. From simple pointed needles to complex components implanted in the bloodstream, Ni–Ti has been adopted by the industry for its ability to offer unique and ideal solutions to traditional medical challenges. Well known for its excellent biocompatibility and corrosion resistance, Ni–Ti has been used in many successful medical devices and is now widely accepted throughout the medical industry.

The majority of SMA medical applications use the superelastic property of Ni–Ti, and many of them are in the expanding field of minimally invasive surgery. Due to the high strain recovery of Ni–Ti, components can withstand extreme shape changes for minimal profiles during delivery and then expand to larger devices within the body. Many of these SMA devices have eliminated the need for open heart surgery and thereby reduce patient risk and decrease hospital recovery periods.

Orthodontic Dental Arch Wires. Dental arch wires, one of the first medical applications that used SMAs, were first introduced in 1977 to replace stainless steel arch wires for straightening teeth. The wires were initially used in the martensitic condition, cold worked, and deformed around the teeth. They exhibited sufficient springback properties for this application, although later superelastic (austenitic) forms of Ni–Ti wire were introduced to improve product performance. The superelastic arch wire is now designed to exploit the plateau region of SMA's stress–strain curve, which provides nearly-constant stress on the teeth as the wire recovers its shape and straightens the teeth.

Mitek Homer Mammalok[®]. Mitek Surgical Products, Inc., introduced a superelastic needle wire localizer in 1985 which is used to locate and mark breast tumors to make surgical removal less invasive. The needle is used as a probe to pinpoint the location of a breast tumor first identified by mammography. Surgeons find it difficult to discern the tumor from surrounding tissue, so the probe highlights the correct location for the surgical procedure (27).

Mitek Suture Anchors. Mitek anchors, fabricated from a titanium or NiTi body that has two or more arcs of superelastic NiTi wire, are secure, stable suture holders used to reattach tendons, ligaments, and soft tissues to bone. The anchors are placed in a hole drilled into a patient's bone and are locked in place by Ni–Ti arcs. In 1989, Mitek Surgical Products, Inc., introduced these anchors for use in shoulder surgery to fasten sutures to bone. Since then, the firm has expanded its product line for use in many other orthopedic applications, such as ligament anchors used for reattaching the anterior cruciate ligament (ACL) of the knee (28).

Guidewire Cores. Ni–Ti wires are snaked through the tortuous pathways of the human body to guide and deliver other tools and devices for interventional procedures. These superelastic guidewires are optimal for use in minimally invasive surgery where procedures are performed through a small portal in a major artery, and offer superior flexibility, kink resistance, and torquability for optimal steering and ease of operation (29).

Stents. SMA stents are becoming increasingly popular in the medical industry. These structural, cylindrical components, designed to prop open and support human blood vessel walls, ducts, and other human passageways, are implanted to prevent collapse or blockage and to patch lesions. Ni–Ti materials are used in place of more conventional metals for coronary artery stenting but are most often used in a peripheral location such as the carotid artery, esophagus, or bile duct. Several shapes and forms of Ni–Ti stents are displayed in Fig. 9.

Stents currently on the market and in development use various functional properties of SMAs: the superelasticity of austenite, the thermal shape memory, and the low effective modulus of martensite. Many of these SMA stents use a combination of superelastic and shape-memory properties. For example, a stent may be chilled in ice water for transformation to martensite, compressed in the martensitic state, covered with a protective sheath for a minimal profile, and then delivered into the body through a small portal. When in place, the sheath is retracted, and the stent warms to body temperature to recover its original shape. Once recovered, or transformed to austenite, the superelastic properties of the stent result in gentle and constant radial forces on the vessel wall. Stents that are martensitic at room and body temperature must be compressed on a delivery balloon for expansion once delivered into the body. The Paragon Coronary Stent developed by Vascular Therapies is an example of a martensitic stent that is marketed for its even, symmetrical expansion and its flexibility during delivery.

Figure 9. Nitinol stents. *Left to right:* Superelastic stent (5 mm OD \times 40 mm long), laser-cut from Ni-Ti tubing; Ni-Ti ribbon set in a coil configuration; Ultraflex™ esophageal knitted stent with fabric covering (courtesy of Shape Memory Applications, Inc.).

Simon Nitinol Filter®. An SMA vena cava blood clot filter was invented by Dr. Morris Simon of Nitinol Medical Technologies, Inc. The design is a Ni-Ti wire form shaped like an umbrella frame or wire basket. For delivery in the body, the filter is chilled below its transformation temperature and collapsed into a small insertion tube. The filter is cooled by a flow of cold saline solution while inserted into the patient and then expands when exposed to body temperature. Its recovered, umbrella-shaped form is designed to catch blood clots in the patient's bloodstream to prevent a pulmonary embolism (30).

AMPLATZER® Septal Occluder. Occlusion devices are designed to serve as Band-Aids to cover and heal holes in the heart without requiring open heart surgery and are typically fabricated from traditional materials. The AMPLATZER Occluder is an SMA device, comprised of a Ni-Ti wire frame that is woven and shaped into two flat caps connected by a short tubular section. The device is deployed through a portal in the femoral artery of a patient and placed at the center of the hole to be patched. A sheath is then retracted, and the two flat caps spring to shape and clamp on either side of the

hole, thus closing the hole and providing a tight seal (31).

Orthopedic Devices. SMA materials are used for their superelasticity and shape-memory properties in a variety of orthopedic devices designed to accelerate bone and cartilage formation under constant compressive stresses. Pre-strained SMA plates are used to treat bone fractures; when attached on both sides of a fracture and screwed together, they provide a compressive force to heal the fracture area. Staples are used to heal fractures as well. A Ni-Ti staple in the martensitic state is positioned so that its legs can be driven into bone sections across the fractured area to be closed. When heated, the legs of the staple bend inward and pull the bone sections together, creating a compressive force (32). Ni-Ti spacers are also used to assist spinal reinforcement in surgical procedures. In this procedure, a spacer is inserted as a compressed ring and then is heated to expand and force open a gap in the vertebrae. Bone chips are placed in the gap and fusion occurs over time to create solid bone. SMAs in solid rod form have been used to treat spinal curvature. Martensitic rods are pre-deformed to conform to a patient's original spinal curvature, wired to the spine, and then gradually recovered to move the spine to its corrected position (1).

Miscellaneous Instruments and Devices. Thousands of other medical devices have been developed to exploit the unique behavior of SMAs. A few additional, typical SMA products include catheters, endodontic files, aneurysm clips, retrieval baskets, surgical needles, and retractable grippers.

Automotive

SMA applications for the automotive industry are challenging for two primary reasons: the extreme range of operating temperatures expected during use and the market demand for low-cost components. Most automotive devices are expected to perform during exposure to the temperature extremes of climates throughout the world. The success of SMA automotive devices has been limited due to the deterioration of shape-memory properties over time caused by exposure to high temperatures (21). The successful SMA devices have exploited the benefits of lightweight, simple solutions. For example, SMA actuators are used as replacements for thermostatic bimetals and wax actuators and provide single metal components in place of complex systems. The simple SMA solutions further improve design performance by activating more quickly because they can be completely immersed in a gas or liquid flow (24).

Pressure Control Governor Valve. A shape-memory governor valve developed by Raychem Corporation and Mercedes-Benz AG was introduced in 1989 Mercedes cars to improve the rough cold weather shifting of automatic transmissions. The valves employ Ni-Ti coil springs to counteract the effects of increased oil viscosity. A Ni-Ti coil is immersed in the transmission fluid. At low temperatures, it is martensitic and is forced by a steel bias spring to move a piston. This activates a mechanism to reduce pressure and ease shifting. At higher temperatures, the NiTi spring is much stronger and pushes the bias spring in the opposite direction to optimize shifting pressure at the warmer temperatures (24).

Due to the ideal performance parameters of the application this governor valve design is one of the few technical and economic successes in the automotive industry. Operating temperatures are within the limits of the material, required force output is low, and expected life is less than 20,000 cycles. These conditions reduce the possibility of fatigue and degradation of SMA properties during the life of the product (33).

Toyota Shape-Memory Washer. Ni-Ti Belleville-type washers were developed by Toyota Motor Corporation and were used in Sprinter/Carib cars to reduce vibration and rattling noise at elevated temperatures. Automotive assemblies such as gearboxes are often combinations of many dissimilar metals. During the temperature increase in standard operation, a difference in the thermal expansion rates of the metals causes assemblies to loosen and rattle.

The washers were designed to change shape at high temperatures using forces up to 1,000 N (225 lb), which is sufficient to tighten the assembly and reduce the undesired rattling noise (24).

Shock Absorber Washer. This component, an application similar to the governor valve, is also designed to counteract the high viscosity of oil at colder temperatures. SMA washers are placed in shock absorber valves to alter their performance effectively in cold and hot temperatures (24).

Automotive Clutch Fan. An SMA device, developed as a selective switching mechanism for air cooled engines, requires the activation of a Cu-based SMA coil to control the operation of a clutch fan. The coil is activated at a temperature close to 50°C and engages a clutch to power the engine fan. The fan speeds up to cool the engine until the temperature is reduced, at which point the SMA coil is forced to disengage the clutch via a set of four steel leaf springs that serve as a biasing force. The device is designed to reduce engine noise and fuel consumption when the car is idle (21).

Industrial/Civil Engineering

Many SMA solutions have been designed and implemented to satisfy some of the rigorous, large-scale demands of civil engineering projects and miscellaneous industrial applications. Although the constraints of SMA properties often restrict use in industrial applications (the limited acceptable temperature range of operation, for example), many creative SMA solutions and design alternatives have successfully improved or replaced traditional industrial designs and devices.

Pipe Couplings. Cryogenic couplings developed by Raychem Corporation for the aerospace industry have been adapted for use in deep sea operations and are also used in the chemical and petroleum industries. The advancement of a Ni-Ti-Nb alloy for its wide hysteresis has helped to expand the use of these shape-memory couplings. When the components are machined at room temperature and then chilled in liquid nitrogen for expansion, they will not recover their shape until temperatures reach approximately 150°C. This allows storing and transporting expanded couplings without using liquid nitrogen. Once applied to the piping and heated to transform to austenite, they maintain their strength at temperatures colder than -20°C (33).

Structural Elements. Superelastic SMA materials can be used to increase strength and energy dissipation in a building. A project is currently underway to reinforce the Basilica of St. Francis in Assisi, Italy, after severe damage

during earthquakes in 1997. SMA wires will be placed in series with horizontal conventional steel ties to connect the walls to the Basilica's roof. The superelastic behavior of the wires will allow ductile, high strain motion to occur without breakage during an earthquake and will recover the strain by using a gentler, lower force stroke (exploiting the lower plateau of the stress-strain curve). It has been estimated that the SMA structural design will withstand an earthquake at least 50% stronger than if the Basilica were reinforced with conventional steel bars (34).

Rock Breakers. SMAs are used to replace explosives in demolition, which is similar in function to the Frangibolt[®] release mechanisms used in the aerospace industry. A prestrained SMA cylinder is placed within a crevice of a structure, electrically heated to expand, and the recovery forces produced are sufficient to destroy rocks and cement structures. This concept has been employed in Russia to yield demolition forces greater than 100 tons of force (1). Rock breakers comprised of Ni-Ti rods are also used in Japan. Nishimatsu Construction Co., Ltd. uses rods 29 mm long and 15 mm in diameter, which are compressed and inserted into boreholes in rock using an assembly of wedge-shaped platens. The NiTi rods are heated by attached electric heaters, causing them to expand and break the rock apart. Tests have demonstrated forces as high as 14 tons when they are heated to 120°C (23).

Power Line Sag Control. SMA materials are often used to prevent a sag or droop in overhead power lines. Using thermal shape-memory alloys, sag control in power lines has been successfully tested in Canada, the Ukraine, and Russia (35). When temperatures increase because of ambient temperatures or high load along the power lines, the lines tend to sag. Nitinol wires are attached to the lines and deform at the colder, high tension state, but contract when warm and remove the slack from the lines.

Steam Pipe Sag Control. Similar to the power line application, pipe hangers made from Ni-Ti are used to reduce the sagging of large steam pipes heated by the steam. This reduces the load variation in the system, rather than counteracting the shifts in geometry, as in power lines (35).

Transformer Core Compression. SMAs assist in compressing transformer cores, a critical aspect of transformer design. Ni-Ti bolts are prestrained axially to couple core sheets in large transformers, then heated to contract and provide high compressive forces on the sheets. This SMA solution improves on traditional techniques of tightening with nuts and bolts, where core sheets are placed in a vacuum to withdraw air from between sheets, then removed from the vacuum to install the bolts. Although technically a design improvement, the Ni-Ti solution requires 2-3 inch diameter bolts, which is larger than ideal for SMA products (35). The cost to process and machine the bolts may offset the benefits gained in the assembly process.

Multiwire Tension Device. SMA devices are used to increase piping integrity. They prevent crack initiation and propagation by compressing areas of a pipe using the

concept of multiwire tension (MWT) developed by the ABB Nuclear Division in Sweden. A split-sleeve coupling is wrapped with pretensioned SMA wire, the wire ends are fixed, and the coupling is placed over a weld point on a pipe. Then, the assembly is heated so that the wire contracts and the coupling then clamps to a tight fit. MWT techniques are used to improve stress in welded areas, preventing stress corrosion cracking and connecting the ends of the pipe should the weld point fail and break (35).

Indicator Tags. SMAs can be used to indicate high temperature points in a system. Wires used as tags are bent manually at typical operating temperatures, and the tags straighten when temperatures reach a critical level (the material's A_f temperature). Operators note the site of the high-temperature source and can fix the problem (35).

Sentinel[®] Temperature Monitoring System. SMAs are used on the low-voltage side of step-down transformers to indicate maximum temperatures and to close a switch at critical temperatures. This SMA mechanism is used to provide information for monitoring, so that operators can prevent overheating (35).

Injection Molding Mandrels. Centerless ground Ni-Ti round bar and wire are often used to replace conventional, deformation-prone mandrels. Plastics are molded in the shape of a superelastic Ni-Ti mandrel, and during rough handling as the mandrel is withdrawn from the cured polymer, the superelastic material recovers its original shape.

Heat Engines. SMA elements are used in heat engine designs to convert thermal energy to mechanical energy via thermal shape-memory behavior. Thermodynamic analyses of ideal, theoretical SMA heat engines have resulted in a wide range of calculated efficiencies, although the most thorough calculations yield maximum thermal efficiencies of only 2-4% (36). A great number of prototype engines has been constructed using SMA elements that change shape when they pass between hot and cold reservoirs. However, due to loss factors, such as friction, hysteretic effects inherent in the material, and energy input required to maintain a reservoir temperature differential, the practical efficiencies of these heat engines are much too low to serve as low-cost, high-volume energy converters.

The pursuit of a revolutionary SMA heat engine typifies a common occurrence in SMA application design. Intrigued by the potential of SMAs to provide unique and dramatic design solutions, inventors often pursue creative solutions before completing cost/benefit analyses. Although suitable for small-scale demonstrations, many SMA applications (as in heat engines) do not provide the necessary efficiencies—cost or energy—to warrant replacing conventional designs.

Electronics

The electronics industry has adopted SMA materials primarily for connection mechanisms. Applications in nearly all industries use the electronic activation capability of SMA materials to exploit thermal shape-memory behavior

Figure 10. Schematic diagram of a zero insertion force connector. Reprinted with permission from J.F. Krumme, *Electrically Actuated ZIF Connectors Use Shape Memory Alloys, Connection Technology*. Copyright 1987, Lake Publishing Corporation.

(including robotics); however, a few examples are highly specific and unique to the electronics industry.

Cryocon® Electrical Connector. An SMA connector has been designed to attach the braid sheathing of an electrical cable to a terminal plug. The connector is a shape-memory ring sheath on a split-walled, collet-shaped tube whose diameter expands when chilled due to the radial forces of the tube. When warmed to room temperature, the ring recovers its smaller diameter shape and clamps the tubing collet prongs together to form a tight electrical connection (3,37).

ZIF Connector. A Zero insertion force electrical connector was designed by Beta Phase, Inc., to simplify the installation and increase the quality of circuit board connections (Fig. 10). A U-shaped strip of Ni-Ti is martensitic at operating temperatures and is forced to grip the boards via the bias force of a conventional closing spring. When heated by electrical current, the Ni-Ti strip overcomes the force of the closing spring and opens the radius of its U shape, allowing insertion or removal of the boards without force. This combines installation simplicity and maintains optimal, high force electrical contact between mother and daughter circuit boards (38).

Microactuators

SMAs have been successfully processed as thin film actuators for microactuating devices such as tiny valves, switches, and microelectromechanical systems (MEMS) (39). Ni-Ti films are sputter deposited on silicon substrates, and actuators are fabricated by chemical milling and lithographic processes. Devices one millimeter in

diameter and three microns thick have been fabricated, resulting in tiny actuators such as microvalves for fluid and pneumatic control. The Ni-Ti film actuators can provide up to 3% strain recovery (40).

FUTURE TRENDS

SMA applications continue to gain acceptance in a variety of industries throughout the world. SMAs are introduced to an increasing number of students who study engineering and metallurgy and to the general public via the growing number of SMA products available to consumers. Although property values and design techniques for SMAs are not as readily available or as thoroughly standardized as those of conventional materials, current trends indicate a steady course toward complete characterization of SMA materials. The medical industry has already prompted the standardization of material production, testing, and mechanical behavior; current efforts include the formation of an ASTM standard for using Ni-Ti in medical devices. Spearheaded by supplier representatives of both the medical device and SMA material supply industries, the standard is scheduled to be completed and approved before this article is published. This new standard represents a significant milestone in the continual effort to demystify shape-memory alloys and augment their use in engineering and design.

SHAPE-MEMORY ALLOYS, MAGNETICALLY ACTIVATED FERROMAGNETIC SHAPE-MEMORY MATERIALS

R.C. O'HANDLEY

INTRODUCTION

For years it was speculated that the large strains associated with the thermoelastic shape-memory effect, such as in NiTi alloys, could be captured by application of a magnetic field in certain martensites that are also ferromagnetic (1–3); see Fig 1(a). Ferromagnetic shape-memory alloys (FSMAs) moved from a hypothetical new class of active materials, to join piezoelectric and magnetostrictive materials, upon observation of a 0.2% magnetic field induced strain in a single crystal of Ni₂MnGa in 1996 (4). Figure 1(b) shows the field-induced strain measured at 265 K in the martensitic phase of a Ni₂MnGa single crystal. The crystal contracts in the direction of the applied field. The strain components conserve volume and are of even symmetry in the field. There is some hysteresis in the strain with change in sweep direction of the field, and there is some unrecovered strain after the first field cycle. By way of comparison, piezoelectrics show strains of order 0.1% (5) and the leading magnetostrictive material, Terfenol-D (Tb_{0.33}Dy_{0.67}Fe₂), shows a field-induced strain of about 0.24% (6,7).

The strain-versus-temperature (ϵ - T) curves of thermoelastic martensite, Fig. 1(a), bear little resemblance to the ϵ - H curves of Fig. 1(b). The former typically show a

SHAPE-MEMORY ALLOYS, MAGNETICALLY ACTIVATED FERROMAGNETIC SHAPE-MEMORY MATERIALS

R.C. O'HANDLEY
 SAMUEL M. ALLEN
 Massachusetts Institute of Technology
 Cambridge, MA

INTRODUCTION

For years it was speculated that the large strains associated with the thermoelastic shape-memory effect, such as in NiTi alloys, could be captured by application of a magnetic field in certain martensites that are also ferromagnetic (1–3); see Fig 1(a). Ferromagnetic shape-memory alloys (FSMAs) moved from a hypothetical new class of active materials, to join piezoelectric and magnetostrictive materials, upon observation of a 0.2% magnetic field induced strain in a single crystal of Ni₂MnGa in 1996 (4). Figure 1(b) shows the field-induced strain measured at 265 K in the martensitic phase of a Ni₂MnGa single crystal. The crystal contracts in the direction of the applied field. The strain components conserve volume and are of even symmetry in the field. There is some hysteresis in the strain with change in sweep direction of the field, and there is some unrecovered strain after the first field cycle. By way of comparison, piezoelectrics show strains of order 0.1% (5) and the leading magnetostrictive material, Terfenol-D (Tb_{0.33}Dy_{0.67}Fe₂), shows a field-induced strain of about 0.24% (6,7).

The strain-versus-temperature (ϵ - T) curves of thermoelastic martensite, Fig. 1(a), bear little resemblance to the ϵ - H curves of Fig. 1(b). The former typically show a

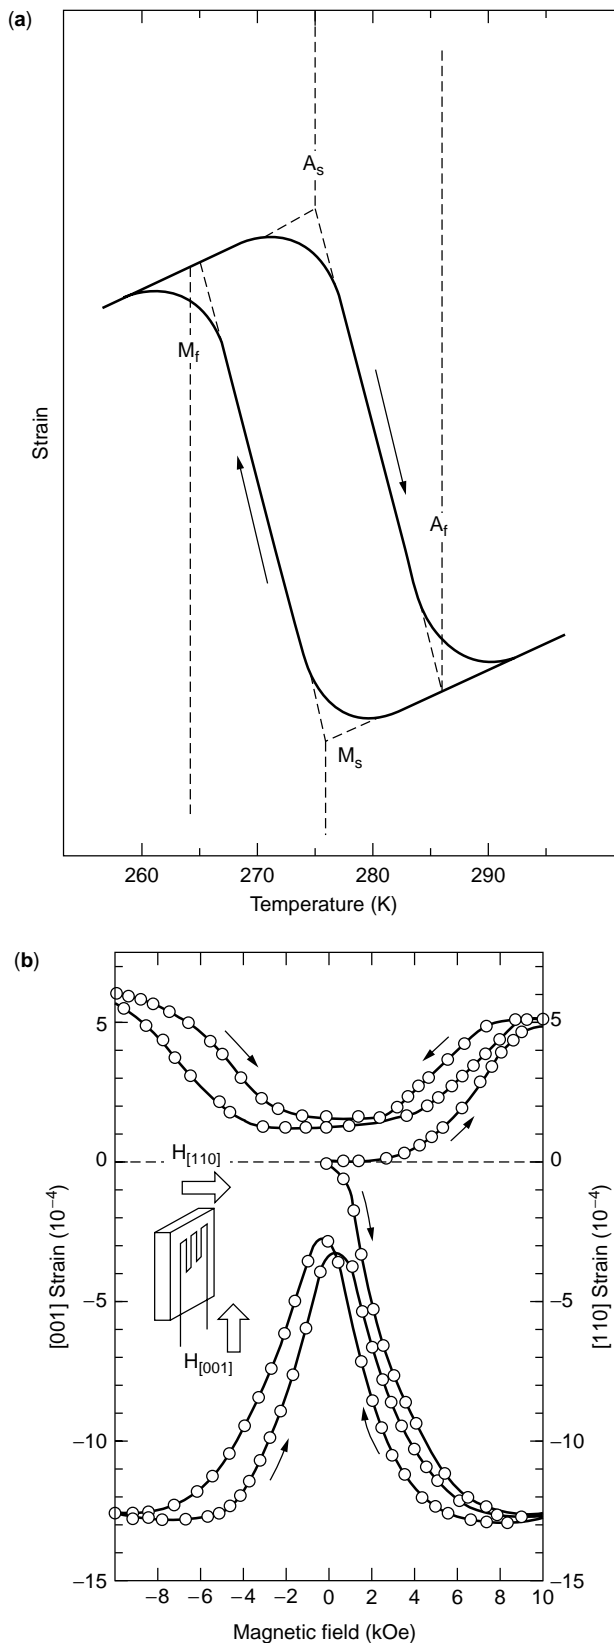

Figure 1. Contrast between (a) the thermally induced strain in the shape memory alloy, NiTi and (b) the magnetic-field-induced strain in a ferromagnetic shape memory alloy. Here, strain versus applied field is measured at 265 K in the martensitic phase of Ni_2MnGa . Inset: Relative orientation of sample, strain gauge, and applied field (4).

large thermal hysteresis, with martensite and austenite start and finish temperatures defined by the sharply curved points of the ε - T curves; the change in sample strain through the thermoelastic hysteresis can be several percent. The ε - H curves of Fig. 1(b) bear some resemblance to those of a negative magnetostriction material: the strain is of even symmetry in the applied magnetic field and increases superlinearly in H before saturating. However, the FSMA strain effect differs in many ways from magnetostriction as will be shown in detail later. The strain shown in Fig. 1(b) represents only a small fraction of the 6% or 7% transformation strain expected to be accessible by field-induced twin selection in Ni-Mn-Ga FSMAs. In fact, FSMAs have recently exhibited the full field-induced strain associated with their crystallographic distortion by application of a field of 320 kA/m (4 kOe) to a single-variant sample of an off-stoichiometry crystal of Ni-Mn-Ga (8).

The mode of actuation shown in Fig. 1(b), namely field-induced strain within the fully martensitic state, is to be contrasted with application of a magnetic field to the austenitic (A) phase of an FSMA to induce the transformation to the single-variant martensitic (M) phase, Fig. 2(a). Here the A-M phase boundary is shown as a surface in H - σ - T space. As is the case with most martensites, a *shear* stress applied to the A phase at a temperature just above the M-start temperature can initiate the A \rightarrow M transformation; see vertical path ε - σ in Fig. 2(a) (1,9,10). The A \rightarrow M transformation is accompanied by the release of a heat of transformation measured to be $Q = 40 \text{ MJ/m}^3$ (288 cal/mole) (11) and $Q = 98 \text{ MJ/m}^3$ (706 cal/mole) (12). Kanomata et al. (13) find that *hydrostatic* pressure stabilizes the A phase (the transformation temperature *decreases* with increasing *hydrostatic* pressure). This occurs despite the smaller volume of the martensitic phase: $a_A = 0.582 \text{ nm}$, $a_M = 0.592 \text{ nm}$, and $c_M = 0.557 \text{ nm}$. In contrast, a shear stress stabilizes the M phase (14). The M phase should also be stabilized by application of a magnetic field to an FSMA; see the horizontal ε - H path in Fig. 2 (a) (15). However, the Clausius-Clapeyron equation indicates that a magnetic field of order 10^7 A/m ($B = 12 \text{ T}$) would be needed to induce the transformation in a sample held about 1°C above the martensite start temperature (14). Experiments on $\text{Ni}_{2.19}\text{Mn}_{0.81}\text{Ga}$ bear this out (16). The field required for transformation could be reduced by simultaneous application of an appropriate stress. Such a field-induced phase transformation would release the full transformation strain accompanied by a stress comparable to the yield stress of the detwinned martensite. Stress-assisted, field-induced transformations have been investigated by Vasil'ev et al. (17). On transforming back to A, the heat of transformation is absorbed by the material (11). Such field-induced and stress-induced transformations can show significant hysteresis because phase boundary motion is involved.

The present article focuses on the application of a magnetic field to a twinned M phase that is ferromagnetic, Fig. 2(b). It is necessary that the magnetic anisotropy of the M phase be large compared to the energy required for twin boundary motion and, further, that the preferred direction of magnetization changes across the twin boundary. When this is the case, application of a magnetic field results in a difference in Zeeman energy, $\Delta(\mu_0 \mathbf{M}_s \cdot \mathbf{H})$,

Figure 2. (a) Magnetic field-induced transformation of an austenitic sample to a single-variant martensitic structure. The A-M phase boundary is shown below in field-stress-temperature space; the arrow indicates how an increasing field can induce the transformation (horizontal ε - H path). This process may be assisted by application of a suitable stress (vertical path ε - σ path). (b) A field may be able to move twin boundaries in a twinned martensitic FSMA, changing the state of strain of the martensite. Compare the strain-versus-temperature hysteresis loop in lower panel with Fig. 1(a). The added field axis shows how application of a field in the martensitic state (bold line on ε - T loop) can alter the state of strain of the sample.

across the twin boundary. This energy difference exerts a pressure on the twin boundary so as to grow the twin variants having the more favorably oriented magnetization. The resulting field-induced twin-boundary motion produces a large strain, fully within the martensitic state of an FSMA.

This article describes the crystallography and magnetism of Ni-Mn-Ga in order to explain the very large strains produced by field-induced twin-boundary motion in martensite. Examples of field-induced strain by twin boundary motion in Ni-Mn-Ga FSMA samples having different twin structures are given. Martensitic Fe₇₀Pd₃₀ has also shown field-induced strains of 0.5% (18), and efforts are under way to develop other iron-base FSMA (19–21). These other materials will not be covered in depth. The state of theoretical modeling of strain and magnetization in FSMA is reviewed. FSMA field-induced strains are compared and contrasted with the thermoelastic shape-memory effect and magnetostriction.

FIELD-INDUCED STRAIN IN FSMA

Crystallography and Mechanical Properties

The chemically ordered austenitic phase of Ni₂MnGa has the $L2_1$ Heulser structure ($Fm\bar{3}m$) with room temperature lattice constant $a = 0.582$ nm (22). Figure 3(a) shows the chemical ordering favored below 800°C, and the {101} slip planes are shaded in. The eight Ni atoms are located

at the center of each of the eight cubic sub-units; Ni orders to these sites in the high-temperature cubic phase near or above the melting temperature. The Mn and Ga atoms order on the remaining sites (as shown by the two sizes of spheres in Fig. 3a) below 800°C (23). In the martensitic state, this structure is tetragonally distorted with $a = b = 0.592$ nm, $c = 0.557$ nm. The c axis contraction is $c/a = 0.94$. The appropriate unit cell of the tetragonal martensite ($I4/mmm$, having $c' = c$ and $a' = b' = a/2$) is shown in Fig. 3(b). The twin plane identified in the structure at left as {101} has Miller indexes (112) when referred to the tetragonal unit cell axes. The c'/a' ratio in the unit cell has the magnitude $\sqrt{2} \cdot c/a \approx 1.33$.

In this article, discussions are referenced to the structure at left ({101} twin planes) rather than the true body-centered unit cell, in order to bring out the fact that the martensitic phase of Ni₂MnGa is contracted along its preferred direction of magnetization, relative to the austenitic phase.

The off-stoichiometry phases of Ni-Mn-Ga generally used in engineering studies may have more complex structures. The most useful phase is a five-layered, tetragonal martensite (22). Slight variations in composition near stoichiometry can result in different tetragonal structures having very different magnetic anisotropy, c/a ratios and responses to applied magnetic fields. For example, Sozinov et al. (24) report that while Ni_{49.2}Mn_{29.6}Ga_{21.2} is an easy axis ($M \parallel c$ -axis), tetragonal five-layered martensite with $c/a = 0.94$, and field-induced strains of several

Figure 3. (a) Model of the cubic Heusler, $L2_1$, structure of austenitic Ni_2MnGa . In the martensitic state this structure contracts along its c -axis ($c/a < 1$), and it may twin along $\{101\}$ planes. (b) The $14/mmm$, body-centered tetragonal ($c'/a' > 1$) martensitic unit cell is shown with the same twinning planes, now identified as $\{112\}$.

percent, $Ni_{52.1}Mn_{27.3}Ga_{20.6}$ is an easy plane ($M \perp c$ -axis), tetragonal martensite with $c/a = 1.2$, and negligible field-induced strain. Some Ni–Mn–Ga samples (both polycrystalline) show orthorhombic structures (16,25). While orthorhombic structures have more possible twin-plane orientations than tetragonal structure, the models described below for the field-induced strain still seem to apply.

The mechanical properties of FSMAs in the martensitic phase are similar to those of conventional SMAs (Fig. 4). With increasing stress, the material first shows a modulus, C_0 , characteristic of the single-variant state. Above a critical stress, σ_0 , at which deformation by twin-boundary motion initiates, the modulus decreases to C_{tb} and the material may strain to its full transformation strain, ε_0 , after which it is mechanically detwinned. The transformation

Figure 4. Schematic of the stress–strain behavior of martensite. Above a critical stress, σ_0 , the modulus drops to C_{tb} as the mode of deformation becomes twin-boundary motion. Depending on the twin-variant structure at σ_0 the material may deform as much as ε_0 , the transformation strain, before it is detwinned and reverts to the stiffness of the single-variant state, C_0 .

strain is the crystallographic distortion in a martensitic transformation: $\varepsilon_0 = 1 - c/a$ referred to the austenitic unit cell. For still larger stresses, the modulus reverts to its single-variant value.

Values of the parameters in Fig. 4 measured for Ni_2MnGa crystals are typically of order $\sigma_0 = 1 - 10$ MPa, $C_0 = 2$ GPa, $\varepsilon_0 = 0.06$, and $C_{tb} = 18 - 30$ MPa (26,27). The small value for C_0 relative to the stiffness of the parent phase, which is of order 70 GPa, probably reflects a small degree of twin-boundary motion in the martensite before the initiation of abundant twin-boundary motion at σ_0 . Hence 70 GPa should be regarded as more typical of the martensitic stiffness at constant strain.

Magnetization

Ni_2MnGa shows a saturation magnetization at 265 K (in the martensitic phase) of $M_s = 484$ kA/m (484 emu/cm³) (4). Given its mass density of 8.3 g/cm³, this translates to a saturation flux density of $B_s = 0.6$ T ($4\pi M_s = 6$ kG). The Curie temperature is about 350 K. This is greater than the martensite transformation temperature, which varies strongly with composition and stress and is typically about 273 K (1,11,27). The strength of the uniaxial anisotropy of tetragonal Ni_2MnGa has been measured from single-crystal magnetization curves and found to be about 1.2×10^5 J/m³ at -8°C , favoring magnetization parallel to the c axis (4). Tickle and James (29) made measurements on single crystals of a $Ni_{51.3}Mn_{24.0}Ga_{24.7}$ constrained to be in the single-variant state during magnetization. They find $K_u = 2.45 \times 10^5$ J/m³ at -17°C . The samples cited in this article, close in composition to $Ni_{50}Mn_{28}Ga_{22}$, show a magnetic anisotropy in the single-variant constrained M phase at room temperature that ranges from 1.6 to

Figure 5. $\mu_0 M$ - H measured on a sample of $\text{Ni}_{49.8}\text{Mn}_{28.5}\text{Ga}_{21.7}$ constrained to be in the single-variant state. The two curves are measured with the field parallel (square loop) and perpendicular (linear M - H process) to the c -axis of the variant. (27).

$1.9 \times 10^5 \text{ J/m}^3$ (27). Figure 5 shows M - H loops taken on a small crystal constrained to be in a single-variant state at room temperature. Loops are shown for field-applied parallel (\parallel) and perpendicular (\perp) to the c -axis of the variant (shape effects have been removed from both M - H loops). The coercivity of the H_{\parallel} loop suggests that the parallel magnetization process takes place by magnetic domain-wall motion. The zero-coercivity, linear H_{\perp} loop indicates magnetization by a rotation of the moment from the c axis to the field direction. The area between the H_{\parallel} and H_{\perp} curves, $1.6 \times 10^5 \text{ J/m}^3$, is the strength of the uniaxial magnetocrystalline anisotropy, K_u . A key factor that allows FSMAs to be deformed by application of a magnetic field is the relatively large field required to rotate the magnetization from the c -axis.

Field-Induced Twin Rearrangement

The magnetic driving force behind field-induced twin boundary motion is well illustrated by considering a NiMnGa sample showing large twins. Figure 6 shows an off-stoichiometry single-crystal sample, $\text{Ni}_{49.4}\text{Mn}_{29.7}\text{Ga}_{20.9}$, in the single-variant state and with a sharp kink (bend) at the position of a twin boundary introduced by application of a field at room temperature (30). The kink at the twin boundary spanning the cross section of the material can be moved along the sample length by varying the field strength and direction. In this mode of operation, the material always expresses its full transformation shear strain, γ_0 , across a twin boundary. The shear strain across the twin boundary is given by $\gamma_0 = (a/2c)(1 - c^2/a^2)$. Thus, for $c/a = 0.93, 0.94, \text{ and } 0.95$, $\gamma_0 = 7.3\%, 6.2\%, \text{ and } 5.1\%$, respectively.

When a single-variant sample, cut as that in Fig. 6(a), is placed in a magnetic field, the long sample axis does not align with the field as magnetostatic considerations alone would dictate. Instead, it aligns at about 45° to the field and is stable for only one orientation about its shape

Figure 6. a) Photo of single-variant sample of $\text{Ni}_{49.4}\text{Mn}_{29.7}\text{Ga}_{20.9}$ at room temperature in zero external field. b) The same sample with a 6° kink at a twin boundary introduced by application of a field of 320 kA/m (4 kOe). This kink defines a 5% shear strain relative to the unchanged variant at the left end of the sample (30).

axis. The same orientation is stable if the field is reversed. This indicates that this sample is characterized by a uniaxial magnetic anisotropy with the easy axis of magnetization oriented at about 45° to the sample length. X-ray diffraction shows this magnetic easy axis to lie along the crystallographic c -axis.

Given this orientation of the crystal structure, Fig. 7 illustrates how the crystal shown in Fig. 6 can be cut to optimize axial strain. The orientation of the twin boundary observed in Fig. 6 and sketched in Fig. 7(b), coincides with a $\{101\}$ plane (a $\{112\}$ plane in the unit cell of Fig. 3b). Note that the orientation of the c axis changes across the twin boundary.

Because the c -axis changes direction across the twin boundary, the preferred direction of magnetization also changes. The directions of magnetization shown in Fig. 7(b) have been confirmed by scanning the four long sample surfaces with a small Hall probe (30). The field normal to the sample surface, arising from the component of its magnetization perpendicular to the surface, was found to map very closely with the twin structure, changing sign across the twin boundary and from the front to the back

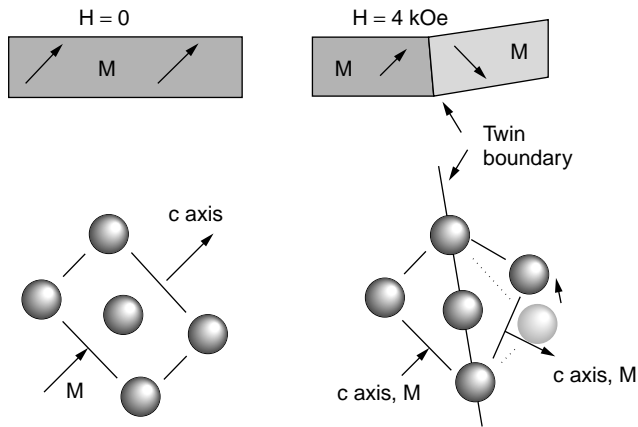

Figure 7. At the top are shown schematic views of the sample in Fig. 6 with the directions of magnetization shown for each variant. Below is sketched the orientation of the martensitic crystal structure, left, and the twinned martensite, right. The atomic displacements increase further to the right of the twin boundary shown, maintaining a constant shear angle.

of the sample. This change in the preferred direction of magnetization provides the mechanism for field-induced motion of the atoms that constitutes twin-boundary motion.

Application of a field orthogonal to the magnetization of a single-variant sample may cause a new variant to nucleate (perhaps at a surface defect) and grow. The twin boundary in Fig. 6(b) can be moved along the sample length by sliding the sample over the edge of a suitably oriented permanent magnet (30). The field at the corner of the magnet is approximately 320 kA/m (4 kOe). The magnetic field exerts a pressure on the twin boundary largely by virtue of the difference in Zeeman energy, $\Delta\mu_0\mathbf{M}_s\cdot\mathbf{H}$, between the two variants. For this pressure to exist, it is necessary that the anisotropy energy density, $K_u = 1.8 \times 10^5 \text{ J/m}^3$, be comparable to or greater than the Zeeman energy density difference, $K_u > \mu_0\mathbf{M}_s\mathbf{H}$. (If, on the other hand, the Zeeman energy is much greater than the anisotropy energy, the magnetization vectors in the two variants align with the field, and the Zeeman energy difference vanishes.) If the magnetic pressure on the twin boundary is greater than the energy density u_{tb} associated with twin-boundary motion, $\mu_0\mathbf{M}_s\mathbf{H} > u_{tb}$, then field-induced twin-boundary motion may result. The energy u_{tb} can be estimated from the stress-strain data such as that depicted in Fig. 4. A critical mechanical stress σ_0 is needed to initiate twin-boundary motion in martensite (30,31). Martynov and Kokorin (26) show that σ_0 can be as small as a few MPa. Using $\varepsilon_0 \approx 0.06$ at this critical strain, $u_{tb} \approx \varepsilon_0\sigma_0$ is of order 10^5 J/m^3 . The detailed interplay of these comparable energy densities, K_u , $\mu_0\mathbf{M}_s\mathbf{H}$, and u_{tb} , as well as the magnetostatic energy (which is a strong function of sample shape and is of order 10^4 to 10^5 J/m^3 for Ni_2MnGa) is best understood using quantitative models. These are described in the next section.

Because the strain across a twin boundary is a pure shear strain, samples having the active twin planes at 45° to the sample end faces can show extensional strain under twin boundary motion (as observed in Fig. 1). When the

active twin planes are at 45° to the sample surfaces, the FSMA behaves more like a magnetostrictive material such as Terfenol-D, $[(\text{Tb}_{0.3}\text{Dy}_{0.7})\text{Fe}_2]$ or a piezoelectric; it extends or contracts in the field direction and conserves volume to first order.

QUANTITATIVE MODELS OF TWIN-BOUNDARY MOTION

Three of the models describing the field-induced motion of twin boundaries in FSMA are reviewed. They are the numerical micromagnetic model (2,18), and the analytic, thermodynamic models of O'Handley (32) and Likhachev and Ullakko (31,33,34). Thermodynamic models developed by Vasil'ev et al. (17) to describe the composition dependence of T_C and T_m and by Lvov et al. (35) to describe the magnetization versus temperature behavior through the martensitic transformation are not described. A thermodynamic model of the relative stability of limiting states in a twinned FSMA (36) will be discussed later.

These models generally include the Zeeman energy, magnetic anisotropy energy, and an external stress. They may also include a magnetostatic energy (which tends to restore \mathbf{M} to zero when the field vanishes), an internal elastic energy (which tends to restore the field-induced strain to zero when the field is removed), and energies associated with the parameters σ_0 and C_{tb} shown in Fig. 4. The action of the external stress depends on its orientation relative to the field-induced deformation. Here, the stress is assumed to be oriented to oppose the field-induced strain. When the anisotropy is very large, the models generally predict a stress-strain product that increases linearly with applied field times the saturation magnetization. (If the external stress is increased, less strain-per-unit-field results.) When the anisotropy is not sufficiently strong to keep the magnetization along the crystallographic easy axis in the unfavorably oriented twins (i.e., those variants in which \mathbf{M} is perpendicular to \mathbf{H}), the Zeeman energy difference across the twin boundary is decreased by application of a field and the achievable strain is limited.

Micromagnetics

James and Wuttig (2) adapted for FSMA a numerical micromagnetic theory originally developed to describe the magnetostriction of Terfenol-D (37). Their model includes Zeeman energy, external stress, and magnetostatic energy in a twinned sample at the micromagnetic level:

$$g(\langle\varepsilon\rangle, \langle\mathbf{H}\rangle) = -\mu_0 H_0 \langle\mathbf{M}\rangle - \sigma_0 \langle\varepsilon\rangle + \left(\frac{\mu_0}{2}\right) \langle\mathbf{M}\rangle \mathbf{D} \langle\mathbf{M}\rangle. \quad (1)$$

The strain $\varepsilon(\mathbf{x})$ and magnetization $\mathbf{M}(\mathbf{x})$ are position dependent, and the energy density is calculated from their average values in each twin variant or domain, respectively. The external magnetic field and stress are given by H_0 and σ_0 , respectively. \mathbf{D} is the demagnetization tensor of the twin or domain. This energy is minimized subject to the constraint that the strains be determined by the allowed twin systems in the martensite. In addition to predicting linear ε - H_0 characteristics (18), detailed magnetization

Figure 8. Crystallography and variant magnetization directions calculated for martensitic Ni₂MnGa from Eq. (1). Increasing applied field (vertical in this figure) stabilizes variants having smaller lattice constant in the magnetization direction (38).

distributions in the twins can be plotted. Figure 8 shows the results of numerical minimization of Eq. (1) with the field applied orthogonal to the initial single-variant magnetization direction. The variant magnetization prefers to lie along the tetragonal c -axis. Increasing the field strength results in stabilization of new twin variants having magnetization more closely aligned with the field direction. Note the mirror symmetry in the crystal structure across the twin boundaries. In addition to a net contraction of the material in the direction of the applied field, the surfaces become ridged at the twin boundaries.

When $\mu_0 M_s H \approx K_u$, the external field can cause the moment in unfavorably oriented variants (M nearly horizontal in Fig. 8) to rotate away from the local c -axis. As the magnetization vectors in two adjacent variants become parallel to each other, the Zeeman energy difference across the twin boundary decreases and the field-induced twin boundary motion is diminished. When magnetocrystalline anisotropy is included in the micromagnetic model (39), the rotation of the domain magnetization by the external field can be mapped from variant to variant as an applied field alters the variant distribution. Plots similar to those

in Fig. 8 have been used to interpret the rich twin/domain images observed by magnetic force microscopy in NiMnGa samples (40).

These numerical micromagnetic models can include micromagnetic effects not tractable in analytic models. However, numerical models do not offer some of the insights afforded by analytic models.

Analytic models

O'Handley (32) wrote a free energy expression for an FSMA comprised of two twin variants separated by a single mobile twin boundary. Zeeman energy, $\mu_0 \mathbf{M}_s \cdot \mathbf{H}$, magnetic anisotropy energy, $K_u \sin^2 \theta$, and an internal restoring elastic energy, $C_{\text{eff}} \varepsilon_0^2 / 2$, were included initially; an external stress-induced energy, $\sigma \cdot \mathbf{e}$, was added later (8,41):

$$g_i = -\mu_0 \mathbf{M}_i \cdot \mathbf{H} + K_u \sin^2 \theta_i + \left(\frac{1}{2} \right) C_{\text{eff}} e^2 + \sigma \cdot \varepsilon. \quad (2)$$

The subscript i corresponds to variant 1 or 2 and the directions of the c axis and the local magnetic moment define the angle θ_i as in Fig. 9. The elastic energy density expresses energy stored in unresponsive variants; C_{eff} is the stiffness of the martensite in the presence of mobile twin boundaries (Fig. 4). The two-dimensional representation is justified because the deformation and magnetization changes occur only in the plane defined by the c -axes of adjacent variants. It applies to multivariant samples having more than two c -axis directions only with modifications (33).

The field-dependent strain is expressed purely as a function of the volume fraction, f_i , of each variant: $\varepsilon(H) = \varepsilon_0 \delta f(H)$, where ε_0 is the transformation strain and $\delta f = f_1 - \frac{1}{2}$ is defined in Fig. 9. The equivariant state, $f_1 = f_2 = \frac{1}{2}$, is defined here as $\varepsilon = 0$. In contrast, the expression for magnetization includes contributions from both twin-boundary motion and magnetization rotation within the twin variants (32).

In the strong anisotropy limit, the sample is magnetized only by twin-boundary motion rather than magnetization

Figure 9. Two-dimensional representation of field-induced twin-boundary motion. The parameters f_i ($i = 1, 2$) are the volume fractions of variants 1 and 2 and $\delta f = f_1 - \frac{1}{2}$ describes the displacement of the twin boundary from $\varepsilon = 0$ as shown at the far right.

rotation. The external stress is applied in a direction that opposes the action of the field; for Ni_2MnGa , that would be a compressive stress parallel to the c -axis of the twin variant that is unfavorably oriented with respect to the field. The total energy density in Eq. (1) can be minimized with respect to the twin-boundary displacement, δf , as well as with respect to the angles θ_i . In the special case $H \parallel M_1$, $\theta_1 = 0$ and only the θ_2 minimization need be done. The latter minimization gives $h = \sin \theta_2$, where $h = \mu_0 M_s H / (2K_u)$, and the two minimizations combine to give

$$\begin{aligned} \varepsilon(H) = \varepsilon_0 \delta f &= \frac{\mu_0 M_s H (1 - h) + K_u h^2 - \sigma \varepsilon_0}{C_{\text{eff}} \varepsilon_0} \\ &= \frac{2K_u h (1 - h/2) - \sigma \varepsilon_0}{C_{\text{eff}} \varepsilon_0}. \end{aligned} \quad (3)$$

For large K_u (small h), Eq. (3) indicates that $\varepsilon(H) = (\mu_0 M_s H - \sigma \varepsilon_0) / C_{\text{eff}} \varepsilon_0$. That is, the low-field strain response of the system is governed by the balance between the Zeeman energy and the external stress. This equation describing strain by twin variant rearrangement as positive *linear* in H is to be compared with the *quadratic* form for conventional magnetostrictive strain in an elastically isotropic, magnetically uniaxial material, $\varepsilon = (3/2) \lambda_s (x^2 - 1/3)$ where $x = \cos \theta = M/M_s = H/H_a$ for a hard-axis magnetization process (42). The field-induced strain in Eq. (3) can be shifted rigidly toward negative values by an external compressive stress. Further, the strain scales inversely with the internal elastic restorative stress, $C_{\text{eff}} \varepsilon_0$, due to the noncompliant parts of the sample. If this restorative stress is small (i.e., the twin boundaries move easily), a twinned sample strains easily ($d\varepsilon/dH$ approaches infinity), and even for large K_u , it magnetizes easily (dM/dH

approaches infinity) once the critical field for twin-boundary motion is exceeded.

On approaching rotational magnetic saturation ($h = 1$), $\varepsilon(H)$ scales with $(K_u - \sigma \varepsilon_0) / C_{\text{eff}} \varepsilon_0$ and is no longer linear in H . That is, the maximum field-induced strain is limited by the balance between the anisotropy and the external stress. The FSMA can show positive or negative strain depending on the relative magnitudes of anisotropy and applied stress.

These conclusions are plotted numerically in Fig. 10 for six different combinations of anisotropy-energy density and internal strain energy (32). At the upper left, for large anisotropy ($K_u = 3 \times 10^6 \text{ J/m}^3$) and small internal stress-induced energy ($0.5 C_{\text{eff}} \varepsilon_0^2 = 2 \times 10^5 \text{ J/m}^3$), the sample can be magnetized only by twin-boundary motion, not by magnetization rotation. Thus, the reduced magnetization, m , and the reduced strain, ε_y , increase together, linearly in applied field. They reach their saturation values in relatively small fields. Moving across the top row of panels, the anisotropy remains strong, but the internal restoring stress increases. The field dependence of m and ε remain correlated and close to linear even up to $\mu_0 H = 1 \text{ T}$ but the magnetic and strain response achieved in these fields are reduced because twin-boundary motion faces greater internal elastic opposition. The lower row of panels begins with both weak anisotropy and weak internal restoring force. The weak anisotropy allows the field to rotate the magnetization in the unfavorably oriented variant, increasing m . However, the rotation of the magnetization reduces the Zeeman pressure on the twin boundary. As a result, the magnetization can increase (by rotation into the field direction) while the strain lags behind because it depends only on twin-boundary motion. Further, the

Figure 10. Graphs of reduced magnetization, $m = M/M_S$, and reduced strain, $\varepsilon_y = \varepsilon/\varepsilon_0$ from Eq. (3) with $\sigma = 0$ in the intermediate anisotropy case, $h \approx 1$ for $\mu_0 M_S = 1.25 \text{ T}$ ($M_S = 1000 \text{ emu/cm}^3$). The twin geometry and field orientation are chosen to be as shown in Fig. 9. Curves are plotted for six combinations of magnetic anisotropy and internal elastic energy densities given by the bold ticks on the outer coordinate axes. Note that in all cases the remanence is 0.5 because of the geometry chosen. A nonzero applied stress would simply shift the strain values negative, including the value at $H = 0$ (32).

field-induced strain gained by twin-boundary motion at weak fields may be reclaimed by the material (depending on the irreversibility of the twin-boundary motion) as the Zeeman pressure on the twin boundaries decreases with increasing field, allowing the internal stored stress to relax. These effects become even more pronounced on moving to stronger internal stress as shown in the bottom row of inset figures. The magnetization curves calculated here differ from the hard-axis, magnetization-rotation process shown in Fig. 5 because these are the result of twin boundary motion as well as magnetization rotation; that in Fig. 5 is for magnetization rotation only as the sample there is constrained to the single-variant state. It should be noted that when M_2 rotates toward H in the weak anisotropy limit, the Zeeman energy difference decreases like $\sin \theta_2$ and the anisotropy energy difference increases like $\sin^2 \theta_2$. The net magnetic pressure reaches a maximum value of K_u when $h = 1$.

This model also indicates that the field component responsible for driving twin-boundary motion is that parallel to the twin plane. The data of Fig. 1(b), as well as $M(H)$ for that sample, are well described by this model with $\sigma = 0$, $K_u = 2.2 \times 10^5 \text{ J/m}^3$, and $C_{\text{eff}\varepsilon_0} = 2.6 \text{ MPa}$ (32).

The consequences of the parameters σ_0 and C_{tb} (Fig. 4) are to increase the irreversibility of the strain-versus-field loops. The twin boundary yield stress, σ_0 , adds a term to the applied field in Eq. (3) with a sign that always opposes the applied field: $H \rightarrow H \pm \sigma_0 \varepsilon_0 / \mu_0 M_s$. This addition to the applied field is a twin-boundary coercivity, the field needed to initiate twin-boundary motion. If one were to take account of the threshold field needed to initiate twin-boundary motion, the curves in Fig. 10 would be shifted on the field axis to show hysteresis with the increasing-field (decreasing-field) curves displaced to the right (left) by H_c .

Likhachev and Ullakko (31,33,34) have taken a more general analytic approach to the problem in three dimensions. They integrate the Maxwell relation

$$\frac{\partial \sigma}{\partial m} = -\frac{\partial h}{\partial \varepsilon} \quad (4)$$

to arrive at the field-dependent strain:

$$\varepsilon(H) = \left(\frac{\partial \sigma}{\partial \varepsilon} \right)_{\varepsilon=0}^{-1} \left[\frac{\partial}{\partial \varepsilon} \int_0^H \mu_0 M dH \right]_{\varepsilon=0}. \quad (5)$$

They assumed that from the equivariant state, one-third of the material is easily magnetized (the variant fraction that has its c -axis parallel to the field); H_{\parallel} is the anisotropy field for such *axial* variants. H_{\parallel} should be the shape anisotropy of the sample; about 0.1 MA/m in Fig. 5). Also, two-thirds of the material (those variants with c perpendicular to H) will have to be magnetized in their hard direction with a transverse anisotropy field, $H_{\perp} > H_{\parallel}$ (compare Fig. 5). As the equivariant state is upset by twin-boundary motion under the application of a field, the magnetization and strain can be expressed as functions of x , the volume fraction of axial variants, which plays a role similar to δf in the 2-D model (Fig. 9). The parameter x is eliminated between

the expressions for $\varepsilon^{\text{FSMA}}(H, x)$ and $M(H, x)$, giving

$$\varepsilon^{\text{FSMA}} = \frac{2}{3} \left(\varepsilon_0 \frac{d\sigma}{d\varepsilon} \right)_{\varepsilon=0}^{-1} \int_0^H \mu_0 \{M_{\parallel}(H) - M_{\perp}(H)\} dH. \quad (6)$$

This result indicates that the field-induced strain depends inversely on $\varepsilon_0 d\sigma/d\varepsilon = C_{\text{tb}}\varepsilon_0$. Further, the strain varies linearly with the magnetic field energy stored in the material because the integral in Eq. (6) is the anisotropy energy (the area between the two $M(H)$ curves in Fig. 5) that must be overcome by the applied field in order to saturate the material. Experimental $M(H)$ and $\sigma(\varepsilon)$ data are used as input to Eq. (6) to allow prediction of $\varepsilon(H, \sigma)$ (31). At saturation Eq. (6) reduces to

$$\varepsilon_{\text{Sal}}^{\text{FSMA}} = \frac{1}{3} \left(\varepsilon_0 \frac{d\sigma_0}{d\varepsilon} \right)_{\varepsilon=0}^{-1} (H_{\parallel} - H_{\perp}) \mu_0 M_s \approx \frac{\mu_0 M_s \Delta H}{3 C_{\text{tb}} \varepsilon_0}. \quad (7)$$

The term $\mu_0 M_s H (\Delta H/H)$ expresses succinctly and elegantly the dual importance of both the Zeeman energy, $\mu_0 M_s H$, and the anisotropy, $\Delta H/H$, which make up the energy difference across a twin boundary. This interplay of both Zeeman and anisotropy energy is represented by the first two terms in the numerator of Eq. (3). The model of Likhachev and Ullakko suggests that the field-induced strain is limited by the internal stress, $\sigma_0 = C_{\text{tb}}\varepsilon_0$, needed to nucleate and move mobile twin boundaries in the martensitic phase. This term has a different meaning than $C_{\text{eff}\varepsilon_0}$ in Eq. (3) although the magnitude of both terms is similar. In both models, a value for σ_0 of order a few MPa provides a good fit to data in Fig. 1.

The analytic models suggest that large values of the difference $H_{\perp} - H_{\parallel}$ (or large K_u), large saturation magnetization, and low-threshold stress, σ_0 , are critical parameters for achieving large field-induced strain by twin-boundary motion.

Finally, it is important to be able to extend the results of these single-crystal models to polycrystalline materials that may be used in some applications. Bhattacharya and Kohn (43) have given a Taylor (*lower*) bound to the strain that can be achieved in a random polycrystalline shape memory material. They find that for cubic-to-tetragonal martensites, the lower bound to the strain is zero. However, for lower symmetries, some fraction of the transformation strain can be induced by stress because in lower symmetry structures there are more planes along which the system can twin to accommodate an external stress.

Marioni et al. (44) have taken FSMA twin variants, described in a model similar to that in O'Handley (32), and assembled them with various textures to simulate noninteracting grains in a polycrystalline sample. This model gives an *upper* bound for the maximum field-induced strain because grain-to-grain elastic interactions are treated only in a mean-field way by the parameter $C_{\text{eff}\varepsilon_0}$. They find that for tetragonal FSMA, a random polycrystalline sample could give a field-induced strain up to 20% of ε_0 . For a texture in which twin plane normals are distributed about the field direction at a common angle (a texture which may be achieved by uniaxial compression), the field-induced strain can be as much as 34% of ε_0 . In addition, this model predicts a threshold field below which there is little strain

Figure 11. Above left: Orientation of M , H , and σ relative to the twinned sample. High-speed video frames (a), (b), and (c) show the sample in the initial vertically compressed ($\sigma \approx 1$ MPa) state ($H = 0$), in an intermediate state, and in the final magnetically saturated (and fully strained vertically by 6%) state, respectively. Below: Selected field-induced strain curves at various external opposing stresses at room temperature for a $\text{Ni}_{49.7}\text{Mn}_{28.5}\text{Ga}_{21.7}$ single crystal (8).

response because the component of the applied field parallel to the twin planes of a given orientation is less than the twin-motion coercivity. For fields above this threshold, the strain increases rapidly toward the linear value predicted by the thermodynamic models. The physical origin of this threshold field in polycrystalline samples is different from that associated with σ_0 and the initiation of twin-boundary motion.

FIELD-INDUCED STRAIN UNDER LOAD

With the background developed so far, it is now possible to describe and analyze in more detail the measurements of field-induced strain under load that form the basis for use of FSMAs as actuator materials.

dc Actuation under Static Stress

Figure 11 shows the results of field-induced strain measurements in a $\text{Ni}_{49.8}\text{Mn}_{28.5}\text{Ga}_{21.7}$ single crystal at room temperature for various axial external stresses that oppose the field-induced strain. The sketch at the upper left shows

the orientation of the magnetization, magnetic field, and external stress relative to the twinned sample. The three photographs are frames from a high-speed (1200 frames/s) video taken on the sample close to the initially stressed state (approximately 1 MPa) at $H = 0$ (frame a), at about 15 ms into the actuation (frame b), and at saturation after about 23 ms (frame c). The structure in frame (a) is dominated by the dark twin bands (M parallel to stress). In frame (b) the lighter twin bands (M parallel to H) fill more than half the area on the front surface. In frame (c) the sample is essentially filled by the light-colored twin bands (except for the thin twin band that apparently remains pinned).

The graph in Fig. 11 shows the ϵ - H loops with fairly abrupt strain changes of several percent, occurring over a narrow field range. On returning the field to zero, significant hysteresis is evident. With increasing external stress, the threshold field for strain actuation increases and the strain at saturation decreases. At low external stress, the field-induced strain does not reset to $\epsilon = 0$ upon removal of the field. This suggests that C_{eff} is small in this case. At strain levels in excess of 0.7 MPa, the sample resets

Table 1. Mechanical and Magnetic Parameters measured for Single-Crystal Ni-Mn-Ga and Used in Eq. 3 in the Model Results of Fig. 12

Parameter	Range of Measured Values	Values used in Fig. 12
σ_0 (MPa)	0.8–1.5	1.0
C_0 (GPa)	70	—
C_{tb} (MPa)	15–25	18
ε_0 (%)	5.7–6.1	5.7
$\mu_0 M_s$ (T)	0.60–0.63	0.60
K_u (MJ/m ³)	0.16–0.19	0.18
H_c (MA/m)	0.1–0.16	0.093

to condition a) when $H = 0$. The hysteresis appears non-monotonic in applied stress. Nearly the full transformation strain is achieved in this sample for stresses less than 0.5 MPa. Some samples have shown strains of 6.1% at saturation (8,45).

The data of Fig. 11 can be modeled with Eq. 3 using the measured Ni-Mn-Ga parameters (see Table 1). The hysteresis is accounted for in an ad-hoc manner by adding to the applied field a coercive (offset) field $H_c = \pm \sigma_0 \varepsilon_0 / (\mu_0 M_s) = 93.3$ kA/m (1.17 kOe). The model results displayed in Fig. 12(a) and (b) show that these parameters give a reasonable reproduction of the major trends in the experimental data, namely the shape of $\varepsilon(H)$, as well as the increase in threshold field and decrease in strain with increasing external stress. The model does not account for the observed change in coercivity with external stress. The predicted decrease in saturation strain with increasing stress, Fig. 12 (b), is consistent with observations.

The limitations of the model in fitting the data may be the result of neglecting magnetostatic effects in the model. It is not the result of a stress-induced anisotropy ($3\sigma\lambda/2$) adding to K_u as external stress is increased. Based on the measured magnetostriction of the martensitic phase, $\lambda_s = -145 \times 10^{-6}$ (28), the magnetoelastic anisotropy at $\sigma = 2$ MPa is more than two orders of magnitude smaller than K_u .

Alternating-Field Actuation under Dynamic Load

The quasi-static, field-induced strain measurements shown in Fig. 11 have also been carried out at actuation frequencies up to 330 Hz. To perform these measurements, the static load was replaced with a spring against which the sample extends under a transverse field (Fig. 13).

Figure 14 shows a set of field-induced strain curves taken at 1 Hz drive, 2 Hz actuation in the system shown in Fig. 13 (46). The sample is a single crystal of Ni-Mn-Ga measuring $1 \times 5 \times 7$ mm, with the field applied normal to the 1×7 mm face and the strain measured along the 7 mm direction. The saturation strain at any given stress level increases with increasing stress, reaching a maximum value near 1.4 MPa. Note the much smaller hysteresis in this case compared to the quasi-static situation shown in Fig. 11. For larger stresses, the saturation strain decreases, and the hysteresis as well as the threshold field for actuation increase.

When the sample is driven to higher frequencies than in Fig. 14, the saturation strain is unchanged up to an

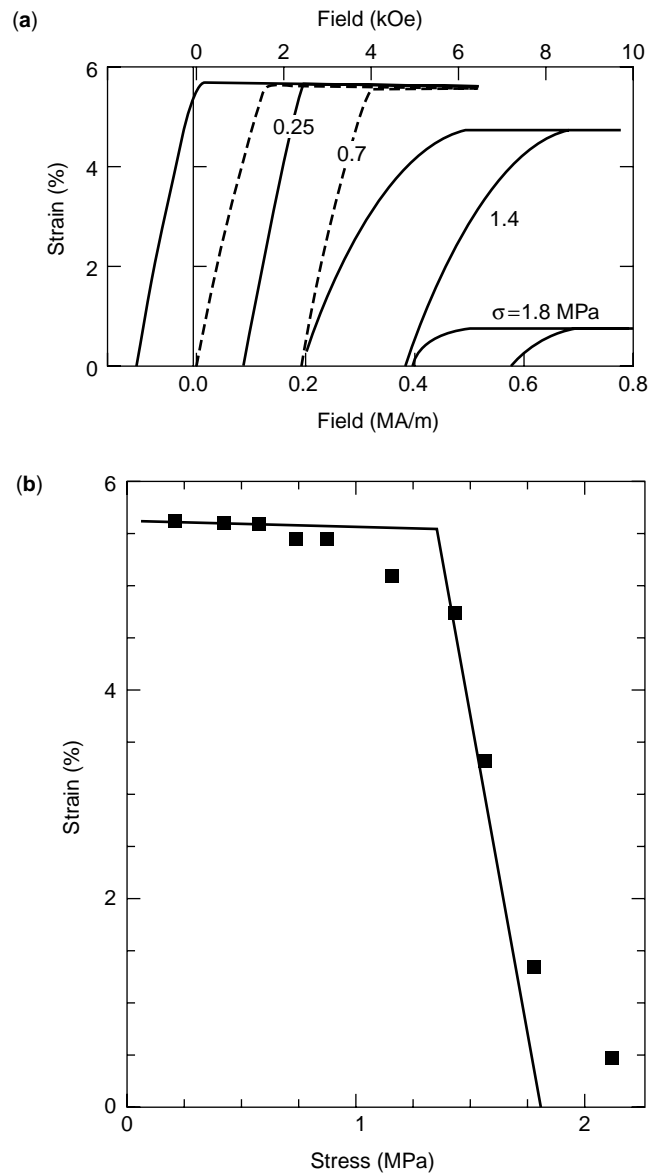

Figure 12. a) Calculated strain versus applied field curves from Eq. (3). b) Calculated strain at peak field versus stress with overlaid experimental points from the full set of data depicted in Fig. 11 (8).

actuation frequency of about 100 Hz. Beyond that value, the peak output strain drops off sharply. However, it is clear from the data in Fig. 15 that the drop-off in response is due to the reduction in the applied field. Above a drive frequency of about 50 Hz, the inductive reactance of the field coils becomes sufficiently large that the power supply can no longer deliver the current needed to generate a field sufficient to saturate the strain. Power supplies must be designed to match the impedance of the load over the operating bandwidth. Pulsed-magnetic-field measurements with a drive-field rise time of 1 ms indicate that single-crystal samples of Ni-Mn-Ga can strain at a rate that keeps up with the rise time of the pulse (47). This implies a bandwidth of at least 1 kHz for these materials.

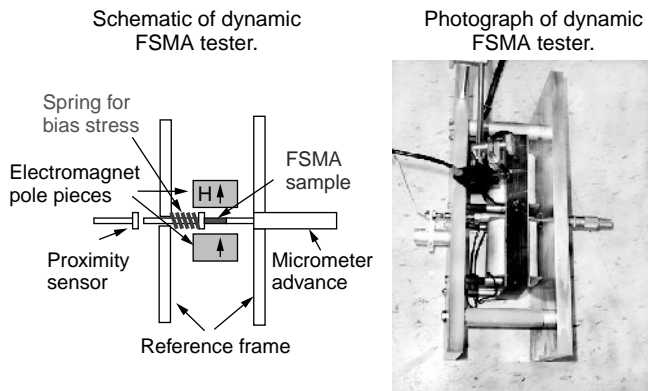

Figure 13. Test system, schematic (left) and photograph (right) The FSMA sample is subjected to a bias stress along one axis and an ac magnetic field along an orthogonal axis. A micrometer advances the sample into the spring to establish the desired bias stress level. The sample elongation under applied field is measured with an eddy-current proximity sensor. The apparatus measures approximately $12 \times 15 \times 30$ cm (46).

DISCUSSION

Engineering Parameters

James and Wuttig (18) have observed the rearrangement of twin boundaries in martensitic $\text{Fe}_{70}\text{Pd}_{30}$ accompanying a field-induced 0.5% extensional strain. Similarly, Ni–Mn–Ga crystals show extensional strains under quasistatic excitation of $\varepsilon > 4\%$ at room temperature (8,45). AC strains in excess of 3% in Ni–Mn–Ga crystals at room temperature have been reported (46). The response of active magnetic materials is generally described by the magnetostrictivity defined as $\mathbf{d}_{ij} = \partial \varepsilon_i / \partial H_j$, where the subscripts refer to directions in Cartesian coordinates. Magnetostrictive materials such as Terfenol-D are often operated under field bias. In the case of the FSMA data shown in Fig. 14, application of a bias field of about 2 kOe and an ac field of ± 1 kOe about that bias, would result in actuation at the drive frequency with an output strain of about 2% peak-to-peak. The value of \mathbf{d}_{31} under such actuation is about 1% per kOe or 12.5×10^{-8} m/A. This value compares

Figure 14. Field-induced strain data for several values of applied stress at an actuation frequency of 2 Hz. The sample elongates against the spring for both positive and negative field cycles, giving an actuation frequency twice the drive frequency.

Figure 15. Frequency dependence of peak field generated in the system shown in Fig. 13 (upper curve) and the strain at peak field. The decrease in actuation strain above a drive frequency of 50 Hz has been identified as due to the decrease in field applied to the sample (46).

favorably with the value of \mathbf{d}_{33} for Terfenol-D in Table 2. Table 2 compares the magnetostrictivities, \mathbf{d}_{ij} , for two active FSMAs and the leading magnetostrictive material, Terfenol-D, $\text{Fe}_2(\text{Tb}_{0.3}\text{Dy}_{0.7})$.

The negative (positive) sign of \mathbf{d}_{33} (\mathbf{d}_{31}) for Ni–Mn–Ga reflects the fact that it contracts along the axis in which the magnetization increases and expands along the original axis of \mathbf{M} . The magnetomechanical coupling coefficient, k , is defined for a magnetically driven actuator by the ratio of the output mechanical energy to the total input energy (magnetic plus mechanical). For purposes of determining the coupling coefficient, the following relations based on clamped and free permeabilities or free and clamped elastic moduli, can be derived: $\mu^\varepsilon = (1 - k^2)\mu^0$ or $C^H = (1 - k^2)C^M$ (6). From Fig. 4 and the data in Table 1, the latter relation suggests that k approaches unity for these materials, that is, they couple magnetic energy to a mechanical load with near-perfect efficiency (48). (The free modulus, C^H is taken as C_{tb} in Table 1 and the clamped modulus, C^M is given by C_0 in Table 1.)

Stress Dependence of $\varepsilon(H)$

The introduction of an external stress in the thermodynamic model when $C_{\text{eff}} \neq 0$ predicts a strain that decreases linearly with applied stress, Eq. (3), and Fig. 16(a).

Table 2. Comparison of Currently Achieved Field-Induced Strain and Magnetoelastic Coupling Coefficients \mathbf{d}_{33} and \mathbf{d}_{31} in FePd and Ni–Mn–Ga FSMAs with the Magnetostrictive Material, Terfenol-D

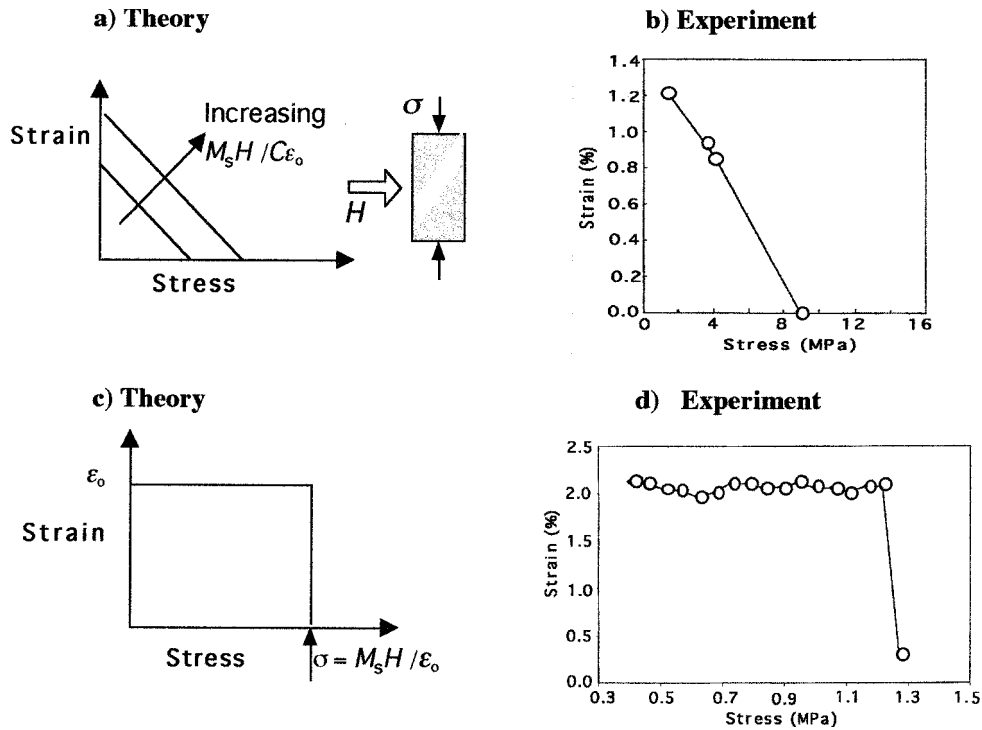

Figure 16. (a) Field-induced strain versus stress predicted by single-variant thermodynamic model (32) (b) Field-induced strain versus stress observed in Ni_2MnGa at -15°C (38). (c) Field-induced strain versus stress calculated with no restoring force (30). (d) Field-induced strain versus stress observed in Ni-Mn-Ga at room temperature (36).

Figure 16(b) shows one set of strain versus stress data for Ni_2MnGa at -15°C and $H=12\text{ T}$ (29). The saturation strain achieved here is less than ε_0 , suggesting that many of the twin variants are not responding to the applied magnetic field. These unresponsive twins may present an elastic resistance ($C_{\text{eff}} \neq 0$) to the deformation caused by motion of the active twin boundaries. The observed blocking stress of 9.2 MPa (σ at which $\varepsilon = 0$) is calculated from Eq. (3) to be 5 MPa (using $K_{\text{u}} = 2.45 \times 10^5 \text{ J/m}^3$ and $\varepsilon_0 = 0.05$). In contrast, Murray et al. (36) have noted that different Ni-Mn-Ga crystals may respond to an applied field with little or no restoring force, namely $C_{\text{eff}} \approx 0$. When the stored elastic energy is omitted from Eq. (2), the free energy cannot be minimized for $|\delta f| < 0.5$. Instead, an instability arises in which the twin boundary moves completely ($\delta f = \pm 0.5$) in the direction favored by the field if $\mu_0 M_s H > \sigma \varepsilon_0$ and in the opposite direction if $\mu_0 M_s H < \sigma \varepsilon_0$. There is no internal elastic opposition to this motion when there are no unfavorably oriented twin planes. In such situations, the strain under load does not decrease linearly with stress but rather maintains a constant value until a critical stress is reached, $\sigma_c = \mu_0 M_s H / \varepsilon_0$, at which point the strain vanishes abruptly as in Fig. 16(c). Recent data on Ni-Mn-Ga at room temperature, Fig. 16(d), support this instability model (36). In addition, the field-induced strain in these FSMAs is more bistable (like a Barkhausen jump), whereas the FSMAs whose response is shown in Fig. 16 (b) show smoother, more reversible $\varepsilon(H)$ as depicted in Fig. 1 (36). Likhachev et al. (49) have recently shown data for the strain dependence of $\text{Ni}_{48}\text{Mn}_{30}\text{Ga}_{22}$ that

fall between these two limits and are well described by their model.

It thus appears that a range of $e(H, \sigma)$ responses may be able to be achieved with FSMAs. Smaller output strain with larger blocking stress may be achieved in some crystals, Fig. 16 (b), or larger output strain with smaller blocking stress may be observed in other crystals, Fig. 16 (d). The reasons behind these different types of response are not yet well understood. In the present case, the different temperatures and compositions (and hence different magnetic anisotropies, magnetizations, and mechanical properties) may be factors. Another difference between the two samples contrasted in Fig. 16 is that the one in panel (b) shows a much finer twin structure (measured in tens of microns) with multiple twin systems present. The sample represented in panel (d) shows a much coarser twin structure (twin spacing of order 0.5 – 1 mm), and only one family of twin boundaries is present. It may be possible that some of the variously oriented twin systems in the former sample may not respond to the applied field and hence provide a mechanism for storing energy elastically ($0.5C_{\text{eff}}\varepsilon_0^2$) as the active twins respond to the field.

Comparison with Shape-Memory Effects

Here, we compare the field-induced strain observed in FSMAs with (1) the thermoelastic shape memory effect (pseudoplasticity) and (2) stress-assisted martensitic transformations (superelasticity).

First, in the thermoelastic shape memory effect, a *twinned, martensitic* material is macroscopically deformed in a manner that appears to be plastic. In fact, the deformation is not the result of dislocation formation and motion, but rather twin-variant rearrangement (twin-boundary motion). Upon heating to the austenitic phase, the macroscopic deformation is erased by the structural transformation of the martensite to austenite. This is the one-way shape memory effect if cooling back to the martensitic state does not restore the macroscopic deformation. In some cases, cooling back to the martensitic state can restore the macroscopic deformation. This is called the “two-way shape-memory effect.”

This thermoelastic shape-memory effect achieves a shape change by structural transformation of the material between a twinned phase and a different untwinned phase. By contrast, the shape changes so far observed in FSMA are induced by a magnetic field fully within the martensitic state. It involves the field-induced motion of twin boundaries. Thus, the effect in FSMA may be faster and more efficient compared to the thermoelastic shape-memory effect where the need for heat transfer limits the kinetics.

Second, when a material showing the shape-memory effect is subjected to a stress at a temperature just above the martensite start temperature, the stress can facilitate the transformation to the martensitic phase. Once twinned martensite is formed, the stress can result in a large (several percent) macroscopic deformation of the material (superelasticity). Upon removal of the stress, the material re-transforms to the austenitic phase and the large deformation is erased. This effect can be much faster than thermally induced shape changes associated with the martensitic transformation.

FSMA have been shown to exhibit stress-induced martensite that then responds to a magnetic field with an additional strain (19). When the external stress is removed, the material reverts to the austenitic phase and the large field-induced strain decreases to the smaller value typical of the austenitic phase.

Comparison with Magnetostriction

The field-induced strain observed in FSMA is similar in some ways to the magnetostriction generally observed in ferromagnetic materials.

1. In both cases, the strains conserve volume to first order. Thus, the strain measured from the demagnetized or equi-twin-variant state in a direction perpendicular to the field will be $\varepsilon_{\perp} \approx -\varepsilon_{\parallel}/2$, where ε_{\parallel} is the field-induced strain parallel to the field. Non-uniform initial distributions of domain magnetizations or twin variants can upset this relation (as in field-biased or pre-stressed samples such as that shown in Fig. 11 where $\varepsilon_{\perp} \approx -\varepsilon_{\parallel}$).
2. The bending effect across the twin boundary (which is also a 90° domain wall), shown in Fig. 6 for Ni–Mn–Ga, would also occur in an appropriately cut ferromagnetic crystal such as Fe ($\langle 100 \rangle$ at 45° to bar axis) if a single 90° domain wall could be

isolated. (Because the magnetostriction coefficient of Fe in the $[100]$ direction, λ_{100} , is positive, the domain magnetization would be orthogonal to those pictured in Fig. 6 or the bending would be in the other direction.) However, in Fe the bend angle across the 90° domain wall would be only 0.002° corresponding to a shear strain of 2×10^{-5} .

The differences in field-induced-strain between FSMA and magnetostrictive materials are more important than the similarities.

1. Field-induced strain in FSMA is due to twin-boundary motion, which brings with it a change in the direction of magnetization. The FSMA strain is tied to the crystallography, not to the direction of \mathbf{M} . That is, it is possible to rotate \mathbf{M} with no FSMA strain, only conventional magnetostriction, in FSMA that are characterized by relatively weak anisotropy. In magnetostrictive materials, on the other hand, field-induced strain is a result of magnetization rotation relative to the crystallography; the strain is tied to \mathbf{M} , and not to the crystallographic orientation.
2. In the ferromagnetic martensitic phase, the increased magnetocrystalline anisotropy relative to austenite means that saturation of the magnetization requires stronger magnetic fields than in austenite. If $T_C > T_{\text{mart}}$, there is no large FSMA field-induced strain between T_{mart} and T_C because the material is in the austenitic phase and twins are not present. The FSMA strain shows a peak on heating through T_{mart} (28,49). If $T_C < T_{\text{mart}}$, there is a static strain in each variant of the martensitic phase above T_C , but it cannot be controlled by a field because $\mathbf{M} = 0$. It can be controlled by an applied stress. Magnetostrictive strain becomes possible below T_C with a *second-order magnetic* transformation; it has a temperature dependence governed by $[M(T)/M(0)]^{l(l+1)/2}$ (51). (Here, l defines the symmetry of the lowest-order crystal field term: $l = 2$ is uniaxial and $l = 4$ is cubic.) The crystal strain in an FSMA, on the other hand, appears in the martensitic phase by a *first-order structural* transformation below T_{mart} [James and Wuttig (2)].
3. Field-induced strains in FSMA decrease as the strength of the magnetocrystalline anisotropy of the martensitic phase decreases below $\mu_0 M_s H$. For weak anisotropy martensite, the field may rotate \mathbf{M} without moving the twin boundaries, and there is no change in macroscopic strain. The field-dependence of strain in FSMA—that do not show discontinuous $\varepsilon(H)$ versus σ behavior in Fig. 16(b) and (d)—is predicted to be linear in H below saturation in the strong anisotropy limit (18,32). Reduced anisotropy can introduce strong nonlinearities in $\varepsilon(H)$ (18,31–34). On the other hand, the magnetostrictive strain accessible in a given field $H < H_a$ will be greater, the smaller the anisotropy. The field dependence of magnetostrictive strains in a hard-axis magnetization process is quadratic in H or M below saturation (42).

SUMMARY

Ferromagnetic shape-memory alloys have shown field-induced strains at room temperature greater than those of any magnetostrictive, piezoelectric, or electrostrictive material. This strain is due to the motion of twin boundaries in the martensitic phase. A variety of $\varepsilon(H, \sigma)$ characteristics appears to be possible in FSMAs. Some samples tend to show abrupt twin-boundary motion as the sign of the quantity $2K_u h(1 - h/2) - \sigma \varepsilon_0$ changes. In the other limit of FSMA behavior, twin-boundary motion appears to be opposed by an internal elastic restoring energy, possibly associated with unfavorably oriented twin boundaries. In the latter case, the field-induced strain is smaller and more linear in the applied field for $h < 1$, and the blocking stresses can be greater.

Micromagnetic and analytic thermodynamic models are able to describe the main features of the magnetization patterns in the twinned FSMAs and the forms of $\varepsilon(H, \sigma)$, and $M(H)$ in single-crystal FSMAs, respectively. Field-induced strains in FSMAs show some incidental similarities to magnetostrictive strains but are essentially different, arising from the field-induced motion of twin boundaries in a martensitic phase that is strongly distorted by a first-order transformation not connected to T_C . The field-induced strains occur at smaller fields as the stress required to nucleate twin boundary motion, σ_o , decreases. Decreased magnetocrystalline anisotropy or increased external stress limits the magnitude of the field-induced strains. Unlike the thermoelastic shape-memory effect, large magnetic-field-induced strain in FSMAs so far is observed fully within the martensitic state.

ACKNOWLEDGMENTS

The authors acknowledge fruitful discussions with R.D. James and M. Wuttig. The work at MIT, described in this review was carried out largely by S.J. Murray, M. Marioni, and C.P. Henry. It has been supported by the Finnish Ministry of Science and Technology (TEKES) with a consortium of Finnish companies, by a subcontract from Boeing Corporation on a DARPA contract, by grants from the Lord Corporation, Midé Technologies, and the Office of Naval Research, as well as by contracts from DARPA, ACX Corporation, and Midé Technologies. The crystals used in our study were grown by Dr. V.V. Kokorin, Institute of Metallurgy, Kiev (Fig. 1) and by Dr. Tom Lograsso of Ames Laboratory, Department of Energy (Figs. 6, 11, and 14).

SHAPE-MEMORY ALLOY SYSTEMS

Many systems exhibit martensitic transformation. Generally, they are subdivided into ferrous and nonferrous martensites. A classification of the nonferrous martensites was first given by Delaey et al. (1) (Table 1), and ferrous alloys that exhibit a shape-memory effect were first reviewed by Maki and Tamura (2) (Table 2).

Of the systems mentioned in both tables, only one system became industrially successful: Ni-Ti(X,Y) in which X,Y are elements that replace Ni or Ti. Besides the Ni-Ti system, a lot of attention had been given in earlier times to Cu-based alloys (3) and to Fe-Mn-Si alloys (4). Furthermore, in recent years, special attention has been given to high-temperature shape-memory alloys (HTSMA) (5).

The aim of this article is mainly an introduction to industrially applicable shape-memory alloys; the following alloy systems will be reviewed:

- Fe-based alloys
- Cu-based alloys
- Ni-Ti alloys
- HTSMA
- other systems

Fe-Based Alloys (2,4,6)

The austenite (fcc- γ phase) in ferrous alloys can be transformed to these three kinds of martensites, depending on composition or stress: γ - α' (bcc), $\gamma \rightarrow \varepsilon$ (hcp) and $\gamma \rightarrow$ fct martensite.

Although a shape-memory effect has been observed in all three types of transformation, most attention in developing a commercial alloy has been given to the alloys that have a $\gamma \rightarrow \varepsilon$ transformation. These alloys have a low stacking fault energy in austenite (Fe-Cr-Ni, Fe-high Mn alloys). The austenite to ε -martensite transformation proceeds by the a/6 [112] Schockley partial dislocations that trail a stacking fault ribbon on every {111} austenite plane and change the crystal structure to martensite. The shape-memory effect, which is of the one-way type, results mainly from reverse motion of the Schockley partial dislocations during heating.

A complete shape-memory effect has been reached in both single-crystal (7,8) and polycrystalline Fe-Mn-Si alloys (9,10) that contain suitable amounts of Mn and Si. A 9% shape-memory strain in single crystals (8) and 5% in polycrystals (9) have been reported.

Any factors that impede the reversibility of the motion of partial dislocations lead to incomplete recovery and in turn a poor shape-memory effect.

Table 1. Classification of Nonferrous Martensites^a

Group	Alloy System
1. Terminal solid solutions based on an element that has allotropic phases	1. Cobalt and its alloys 2. Rare-earth metals and their alloys 3. Titanium, zirconium, and their alloys 4. Alkali metals and their alloys and thallium 5. Others such as Pu, Ur, Hg, and alloys
2. Intermetallic solid solutions that have a bcc-parent phase	1. β -Hume-Rothery phases of Cu-, Ag-, and Au-based alloys 2. β -Ni-Al alloys 3. Ni-Ti-X alloys
3. Alloys that show cubic to tetragonal trans. (incl. Quasi-martensite)	1. Indium-based alloys 2. Manganese-based alloys (paramagn. \leftrightarrow antiferromagn.) 3. A15 compounds 4. Others: Ru-Ta, Ru-Nb, Y-Cu, LaCd, LaAg _x -In _{1-x}

	28~33%Mn–4~6%Si	hcp (ϵ)	Non-T.E.

^a Ref. 2.^bT.E.: Thermoelastic martensite, non-T.E.: Nonthermoelastic martensite.

The internal factors that hamper recovery include alloy composition, Néel temperature, transformation temperature, and lattice defects. External factors are applied stress and strain, deformation, recovery annealing temperature, and thermomechanical treatment.

For example, Murakami et al. (11) showed that Fe–Mn–Si alloys that contained 28–33% Mn and 4–6% Si exhibit a nearly perfect shape-memory effect. But alloys whose Mn content is less than 20% have also been developed successfully. Cr (less than 20%) and Ni are added to improve the corrosion resistance of commercial Fe-based alloys.

So far, Fe-based alloys are not successful SMA. They exhibit only a (limited) one-way shape-memory effect after a labor-intensive thermomechanical treatment. No significant two-way effect or pseudoelastic properties have been reported, whereas only moderate damping capacity might have some interest. Therefore the only reported successful applications of these Fe-based alloys are couplings. This type of application is based on the one-way effect. The recovery stresses are moderate but sufficient (12).

Cu-Based Alloys [(1,3,13–16)]

Copper-based shape-memory alloys are derived from Cu–Zn, Cu–Al, and Cu–Sn systems. The composition range of these alloys corresponds to that of the well-known β -Hume–Rothery phase. In most shape-memory alloys, this phase has a disordered bcc structure at high temperatures but orders to a B2, D0₃, or L2₁ form at lower temperatures. The shear elastic constant of the β phase exhibits anomalous behavior as temperature decreases, that is, it is lowered till the lattice instability with respect to $\{110\} \langle 1\bar{1}0 \rangle$ shears at some temperature and transforms β to martensite. The temperature of the transformation to martensite, M_s , varies with the alloy composition. The elastic anisotropy of the β phase is much higher compared to normal metals and alloys and increases further as the martensitic transformation is approached.

Cu–Zn and Cu–Al martensites are of three types α' , β' or γ' : the subscript 1, 2, or 3 is added to indicate the ordering schemes in β , namely, B2 (2) or D0₃ (1) or L2₁ (3). Some conversion from one martensitic structure to another, for example $\beta' \rightarrow \gamma'$, may also take place. The net result is a coalescence of plates within a self-accommodating group and even coalescence of groups. Heating this deformed martensitic microstructure transforms it to the β phase,

and the shape-memory effect accompanies the structural change.

Copper-based shape-memory alloys presently used are derived from Cu–Zn and Cu–Al systems, and elements are added for various metallurgical reasons. The working martensite in these alloys is only or predominantly the $\beta'_{1,2 \text{ or } 3}$, type where γ' martensite is the minor constituent in the latter case. Alloys that have α' martensites have so far not been used. Therefore, alloys of $\beta'_{1,2 \text{ or } 3}$ martensite are the subject in this part.

Two criteria should be taken into account when selecting an alloy composition to obtain a complete β microstructure that transforms to martensite: (1) The β phase must be stable across as wide a temperature range as possible. The less wide this temperature range, the faster the cooling rate required to retain the β phase without diffusional decomposition. (2) Transformation temperatures must fall within a range that satisfies the requirement for the shape-memory application (–150 to 200°C). The three alloy systems in Table 3 satisfy these criteria. They are used nowadays, but in limited amounts. Apart from composition, transformation temperatures are also strongly influenced by other factors.

The Influence of Chemical Factors on the Transformation Temperature

The Influence of Composition. Several authors have attempted to quantify the M_s –composition relationship for several Cu-based alloys. An overview is given in (3). Different authors weight the same element differently. The main reason for this discrepancy might be that the samples measured have different thermomechanical histories, that is, one has probably not measured “identical samples.” Indeed, composition is not the only chemical factor that affects the M_s temperature. The type and degree of order of the β and the martensite lattice also affect the M_s . Thermal treatments can, therefore, influence the transformation, as discussed in the following sections.

Quenching and the Order State of the β Phase. The transformation temperatures of Cu-based alloys are very sensitive to minute changes of the degree of order in the β phase. Such changes are easily brought about by quenching from intermediate and high temperatures in the form of dilute disorder in an otherwise well-ordered material. The effect is noticeable in both Cu–Zn–Al (17,18) and

Table 3. Industrial Cu-based Alloys

Base Alloy	Composition (wt%)	M_s (°C)	Hyst. (°C)	Other Alloying Elements in Solution (%)	Current Grain Refining Elements Producing Precipitates	Remarks on the Base Alloy
Cu–Zn–Al	5–30 Zn 4–8 Al	–190 to +100	10 (β')	Ni (5%) Mn (12%)	Co (CoAl); B (AlB ₂); Zr (?); B, Cr (Cr _x B _y)	Good ductility and reproducibility; prone to martensitic stabilization; poor β stability ($T > 200^\circ\text{C}$)
Cu–Al–Ni	11–14.5 Al 3–5 Ni	–140 to +200	10 (β') 40 (γ')	Mn (5%)	Ti [(Cu, Ni) ₂ TiAl]; B (AlB ₁₂); Zr (?)	Low ductility; low martensitic stabilization; good β -stability
Cu–Al–Be	9–12 Al 0.4–1 Be	–80 to +80	6 (β')	Ni (5%)	B (AlB ₂ or AlB ₁₂) Ti (Cu ₂ TiAl)	Poor reproducibility; excellent β stability ($T > 200^\circ\text{C}$)

Cu–Al–Ni (19,20) alloys and manifests as a suppression of the transformation temperatures thereby stabilizing the β phase relative to the martensitic. The suppression is temporary, but it is easily recoverable in Cu–Zn–Al alloys by aging in the β condition at as low a temperature as room temperature. However, the recovery of Cu–Al–Ni alloys tends to be more sluggish and requires higher aging temperatures. For example, Cu–Al–Ni alloys aged at 300°C for 1 hour can have transformation temperatures up to 60°C higher than the as-quenched alloys.

Aging and the Order State of Martensite. Aging a Cu–Zn–Al alloy in the martensitic condition can appreciably shift the reverse transformation temperatures of the martensite to the β phase (21). This shift to higher temperatures stabilizes the martensitic relative to the β phase. This stabilization is brought about by a thermally activated diffusional process and, as it is presumed, alters the ordered state inherited by the martensite from the β to a relatively disordered state (21,22). The effect is more pronounced in the presence of excess vacancies retained after a prior quench from higher temperatures. A quench to a temperature above the M_s followed by a hold at the same temperature (step quenching) to rid the alloy of excess vacancies reduces the problem considerably (21). But even then, stabilization of martensite can recur during subsequent aging, and the effect is worse, the higher the aging temperature in the martensitic condition.

Manganese or nickel addition to Cu–Zn–Al, it has been shown, too lessens the problem of stabilization. This happens possibly through a slowing of diffusion in the martensite in the presence of the added elements. More interestingly, the effects it has been shown are inhibited, even in the absence of these elements, by dislocations introduced into the β phase during hot rolling (23) or through transformation cycling (24). Further understanding of the role of these dislocations in such inhibition might provide the information needed to improve the stability of these alloys for use at higher temperatures. Stabilization of Cu–Al–Ni martensite is much slower compared to Cu–Zn–Al (19,25). The former alloys thus are more thermally stable than Cu–Zn–Al and are more suited for use at higher temperatures.

Influence of Other Factors on the Transformation Temperature. Besides the chemical factors such as composition and order; certain nonchemical factors may also influence the M_s temperature. Among the latter are contributions from defects such as vacancies, dislocations, grain boundaries, and precipitates.

Influence of Nonequilibrium Precipitates. Precipitates like the γ phase can be formed in Cu–Zn–Al by flash heating to an intermediate temperature after prior dissolution followed by quenching (17). These precipitates may shift the transformation temperatures with respect to their nominal values and also may produce variations in the transformation temperature range and the hysteresis that accompanies the transformation. The exact changes depend on the coherency, size, and distribution of the precipitates. The variations are brought about by an alteration in the chemical, stored, elastic, and frictional energies of the transformation because of the presence of the additional phase. Stored elastic energy plays a dominant role when the precipitates are small and coherent and when their presence does not appreciably change the composition of the matrix. This usually leads to a suppression of the M_s and to minor changes in the hysteresis, providing the precipitates are deformed in the transformation. Larger semi- or incoherent precipitates that substantially alter the composition of the matrix and impede the growth of martensitic plates lead to changes in the M_s that depend on the partitioning of the elements and an enlarged hysteresis (26).

Precipitation and concomitant changes in transformation temperatures can be disadvantageous if they are produced inadvertently during service, but they can be incorporated in the heat treatment schedule to fine-tune the transformation temperatures or when wider hysteresis is required.

The Influence of Grain-Refining Elements that Form Precipitates. Copper-based shape-memory alloys exhibit rapid grain growth at higher dissolution temperatures. When grain sizes are of the order of millimeters and the elastic anisotropy in the β phase is high, they suffer

intergranular cracking and plastic deformation during quenching. The problem has been solved by adding grain refining elements to the two shape-memory alloys. Zr (0.4–1.2 wt%), Co (0.4–0.8%), Ti (0.5–1.0 wt%), and B (0.4–0.2 wt%), have been added to Cu–Zn–Al alloys to reduce the grain size to the 100- μm level. Titanium is also effective in refining the grain size in Cu–Al–Ni alloys to the 50–100 μm range (27,28).

Refining is brought about by the formation of insoluble particles that aid nucleation of the grains or retard their growth. These grain refining elements have four direct or indirect effects on transformation temperatures: (1) By forming intermetallics, they deplete the original β lattice of alloying elements that change the transformation temperatures. (2) Part of these elements remain in solution within the β matrix. Depending on the atom size, this can give rise to solid-solution hardening that decreases the M_s and eventually the other transformation temperatures (29). (3) They can also have a chemical contribution, which means that the global composition determines the transformation temperatures on a purely thermodynamic basis. (4) The precipitates limit grain growth during annealing, which influences the transformation temperatures, as discussed in the next section.

The Influence of Grain Size. Several authors have shown that small grain size results in stabilizing the parent phase and depressing the transformation temperatures up to 40°C (30,31). This effect is observed in alloys with and without the special addition of grain-refining elements, which indicates the restraining effect of grain size itself on the transformation. Lowering of transformation temperatures is attributed to the increasing grain restraint as grain size decreases. This is the conclusion of most authors (32,33) and is also consistent with Hornbogen's argument that the increase in yield stress σ_y is proportional to the stress required to start the transformation (20). Hornbogen's important assumption is that matrix strengthening increases the undercooling $\Delta T (= T_0 - M_s)$ but does not influence necessarily the T_0 temperatures. T_0 is the temperature at which the free energy of the β phase is equal to the free energy of the martensitic phase.

Adnyana (30) and Jianxin (33) found a linear relationship between the M_s temperature and the yield stress derived via the classic Hall–Petch relationship for Cu–Zn–Al alloys. The restraining effect of grain size is, however, also influenced by the grain size (gs) to thickness (t) ratio. At high gs/t ratios, the contribution of the free surface becomes important and M_s no longer changes linearly with gs, as observed by Wood (34). This is consistent with the conclusion of Mukunthan and Brown (35) who showed that the flow stress in all specimens decreases as specimen thickness decreases when the value of t/d becomes smaller than a critical value. These authors showed further that this critical value of t/d increases as both grain size and stacking fault energy decrease. These elements that contribute to high stacking fault energy have an effect similar to a small grain size.

Influence of Defects. Often it is not only the effect of the grain size or the grain size thickness ratio that

accounts for changes in transformation temperatures. Annealing a sample at higher temperatures can give rise to grain growth but will also reduce the amount of defects and thus the nucleation sites. In Cu-based alloys, the situation is again complicated by the quenched-in vacancies and the size of the antiphase domains, which can also be regarded as strengthening the matrix. An increase in the energy of the β phase due to a higher defect concentration such as foreign elements in solid solution, precipitates, internal strain fields (e.g., coherency strains) causes a lowering of M_s (32). Moreover, if the defect density is proportional to that of the nucleation sites, a higher defect density gives rise to much smaller martensitic plates. A Hall–Petch type relationship is also found between martensitic plate thickness and fracture stress (36).

Specific defect configurations can be introduced by thermal cycling and also by two-way memory training. The influence of such defects, notably dislocations, has been discussed in some recent literature. It has been suggested that the changing character of the same dislocation in the β and martensitic phases alters the relative phase stability of the two phases.

Ni–Ti Alloys

Ni₅₀–Ti₅₀ and near equiatomic Ni–Ti alloys are the best explored system of all shape-memory alloys and occupy almost the whole SMA market. Ni₅₀–Ti₅₀ is an intermetallic phase that has some solubility at higher temperature.

The science and technology of Ni–Ti is overwhelmingly documented. The influence of composition and thermomechanical processing on functional properties is well understood and described in the literature. Therefore, we refer to some very interesting and relevant publications such as (37–41).

The basic concept of processing Ni–Ti alloys is that the martensitic and β phases have to be strengthened to avoid plastic deformation during shape-memory or pseudoelastic loading. This occurs by classic methods: strain hardening and during cold deformation, solution hardening, and precipitation hardening. Ni–Ti alloys have the significant advantage that these techniques can be easily applied due to excellent ductility and a very interesting but complicated precipitation process (42).

The compositions of Ni–Ti SMA are approximately between 48 and 52 at% Ni and the transformation temperatures of the B2 structure to the martensitic phase that has a monoclinic B19' structure are very sensitive to the nickel content (a decrease of about 150°C for an increase of 1 at% Ni). Transformation temperatures can be chosen between –40 and +100°C.

Ni–Ti alloys have the best shape-memory behavior of all SMA. Even in the polycrystalline state, 8% shape recovery is possible, 8% pseudoelastic strain is completely reversible above A_f , and the recovery stress is of the order of 800 MPa.

In some cases, the martensitic transformation is preceded by the so-called R-phase transition. The R transition is a B2 \leftrightarrow rhombohedral transformation that also has second-order characteristics (43).

The most specific characteristics of this R-phase transition are that it shows clear one- and two-way memory

effects of the order of 1% recoverable strain and that the hysteresis of the transformation is very small, only a few degrees which creates possibilities for accurately regulating devices.

Note that further cooling transforms the R phase into B19' martensite. During heating, generally only the reverse martensitic transformation is observed. It has been shown that the appearance of the R phase depends on composition, alloying elements, and thermomechanical processing (39). The major common point is that all effects that depress the martensitic forward transformation below room temperature favor the appearance of the R-phase transition that is quite stable near 30°C.

Ternary Ni-Ti Alloy Systems

Adding third elements opens even more possibilities for adapting binary Ni-Ti alloys to more specific needs of applications. Adding a third element implies a relative replacement of Ni and/or Ti. Therefore, it must be always very well indicated which metal, Ni or Ti or both, is replaced by the third element.

Alloying third elements influences the transformation temperatures and also affects hysteresis, strength, ductility, shape-memory characteristics, and the B2→(R)→B19' sequence. The influence of several elements has been described in (44–48).

Although more application oriented, one can distinguish four purposes to add third elements:

1. to decrease (Cu) or increase (Nb) hysteresis,
2. to lower transformation temperatures (Fe, Cr, Co, Al),
3. to increase transformation temperatures (Hf, Zr, Pd, Pt, Au), and
4. to strengthen the matrix (Mo, W, O, C).

Some ternary alloys have been developed for large-scale applications. We will summarize only the two most well developed: Ni-Ti-Cu and Ni-Ti-Nb.

Ti-Ni-Cu. Ternary Ti-Ni-Cu alloys in which mainly Ni is substituted by Cu are certainly as important as binary Ti-Ni. Increasing the Cu content decreases the deformation stress in the martensitic state and also decreases the pseudoelastic hysteresis without affecting the M_s temperature significantly (49). However, addition of more than 10% Cu embrittles the alloys and hampers formability.

It should also be remembered that Ti-Ni transforms from a B2 into a monoclinic phase, but Ti-Ni-Cu that contains more than 15 at% Cu transforms from a B2 into an orthorhombic phase. Ti-Ni-Cu that has less than 15 at% Cu transforms in two stages (37).

A disadvantage of most Ti-Ni-Cu alloys is that the transformation temperatures do not decrease below room temperature. Cr or Fe can be alloyed to obtain pseudoelastic alloys at room temperature that have small hystereses. An $Ni_{39.8}-Ti_{49.8}Cu_{10}Cr_{0.4}$ alloy was developed that has small hysteresis (130 Mpa), one-fourth compared with $Ni_{50}-Ti_{50}$, and an M_s below room temperature (50).

Ti-Ni-Nb (51,52). The inherent transformation hysteresis of Ni-Ti-Nb is larger than that of binary Ni-Ti alloys. By using a large dispersed volume fraction of deformable β -Nb particles, the hysteresis can be further widened by an overdeformation of stress-induced martensite, generally between M_s and M_d . Originally, Ni-Ti-Nb (more specifically $Ni_{47}-Ti_{94}-Nb_9$) was developed by Raychem Corp. for clamping devices. The large shift of reverse transformation temperatures from below to above room temperature by deformation, allows room temperature of storage open couplings.

Recently, pseudoelastic Ni-Ti-Nb alloys have also been developed that have three significant differences from binary alloys (52):

1. Stress rate is much lower.
2. σ^{P-M} stresses are much higher.
3. The superelastic window is much larger.

High-Temperature Shape-Memory Alloys (5)

Actual shape memory alloys (SMA) are limited to maximal A_f temperatures of 120°C: M_s is generally below 100°C. However, because market demands for SMA have expanded greatly, the need for SMA that transform at higher temperatures than presently available is increasing. The main application areas of interest are actuators in the automobile and oil industries and in safety devices.

There is also an interest in robotics because shape-memory alloys that have high transformation temperatures allow faster cooling, which would significantly increase the bandwidth in which the robot can operate.

Although many alloy systems have high transformation temperatures, no large-scale applications have been developed. A major breakthrough has not been reported yet mainly due to the following problems: (much) lower performance than the successful Ni-Ti alloys, stabilization of martensite, decomposition of the martensitic or parent phase, and brittleness due to high elastic anisotropy or due to the presence of brittle phases or precipitates.

Another condition for a good shape-memory effect is that the stress to induce martensite or the stress to reorient martensite is (much) lower than the critical stress for normal slip. Because the critical stress for slip generally decreases as temperature increases, this condition is quite difficult to fulfil, especially at high temperatures. Thus, a HTSMA should be designed at such a composition and/or thermomechanical treatment that strengthening mechanisms are incorporated to increase the critical stress for slip.

Table 4 summarizes the systems under investigation. For references to this table, see (5).

OTHER TYPES OF SHAPE MEMORY ALLOYS

β -Ti Alloys

In spite of the good biocompatibility of NiTi-alloys, doubts remain on the long-term stability or on the danger of bad surface treatment leading to Ni leaching. Since Ni is

Table 4. High-Temperature Shape-Memory Alloys^a

Base System	Type of Martensite	Other Alloying Elements		$A_s \leq$
		Name	Reason	
Fe–Mn–Si	Nonthermoelastic $\gamma \leftrightarrow \varepsilon$	Co, Ni, Cr	To improve corrosion resistance	150–200°C
Cu–Al–Ni	Thermoelastic $\beta 1 \leftrightarrow 18 R (2H)$	Mn, Ti, B, Zn	To improve machinability, control of transformation temperatures; Grain refinement to improve ductility.	100–200°C
(Ni–X)–Ti	Thermoelastic $\beta_2 \leftrightarrow B19', B19$	X = Pt, Pd, Au, Rh	Based on B2–Ti–X intermetallic compounds that have martensitic transformation at very high temperatures	150–500°C
		B	To reduce the grain size and improve the strength	
Ni–(Ti–X)	Thermoelastic $\beta_2 \leftrightarrow B19', B19$	X = Hf, Zr	Based on Ni–X intermetallic compounds that form a pseudobinary with Ni–Ti.	120–350°C
Ni–Al	Thermoelastic $B_2 \leftrightarrow 3R (7R) (L1_0 \text{ structure})$	Cu, Co, Ag	To increase transformation temperatures	100–600°C
Ni–Mn	Thermoelastic (?) $B2 \leftrightarrow \theta (L1_0 \text{ structure})$	Fe, Co, Mn, B Al, Ti, Cu for Ni	To improve ductility To decrease M_s and to improve shape-memory characteristics	500–750°C
Zr-based intermetallics	B19' monoclinic	Mg, Al, Si, Ti, V, Sn, Cr, Co, Fe, Mo for Mn Ti, Ni	To increase M_s and to improve shape-memory characteristics To improve ductility	200–900°C
Cu–Zr	Nonthermoelastic			
Zr ₂ –Cu–Ni	Nonthermoelastic			
Zr ₂ –Cu–Co	Thermoelastic			

^aRef. 5.

known for his high allergic reaction, Ni-less shape memory alloys could be attractive. Such alloys might be developed based on the allotropic transformation in Ti, a highly biocompatible material. Pure titanium shows an allotropic transformation from β (bcc) to α (hexagonal) phase at 1155 K. Transition elements (TM) stabilise the β -phase. Thus the temperature of the $(\alpha + \beta)/\beta$ transition decreases with increasing concentration of the alloying element.

β -phase Ti alloys can be martensitically transformed if they are quenched from the stable β -phase. Two types of martensite, respectively α' and α'' can be formed, depending on the composition and the solution treatment conditions (53).

The α' -martensite is hexagonal, while α'' has an orthorhombic structure (54). It is the α'' -martensite that shows the shape memory effect. The shape memory effect was first studied in detail by Baker in a Ti-35 wt% Nb alloy (127). Since then several observations of SME especially in Ti-Mo base alloys have been reported (57,58, 59,60,61). A systematic work on the influence of different alloying elements on the shape memory effect can be found in (62), a patent deposited J. Albrecht, T. Duerig and D. Richter.

The authors come to the conclusion that α'' -martensite can be obtained when the following condition is fulfilled:

$$-1100 \leq \varepsilon(A_i X_i + B_i X_i^2) \leq -700$$

where X_i is the atomic percentage for each element, A_i and

B_i are constants given in the patent for each element (V, Al, Fe, Ni, Co, Mn, Cr, Mo, Zr, Nb, Sn, Cu). Ta was not claimed although it also offers its contribution to SME as described in (61).

Generally, a shape recovery in the order of 3% can be obtained based on strain-induced martensite and recovery stresses up to 170 MPa have been reported (60). The disadvantage is that those alloys are very prone to stabilisation and decomposition due to the fact that the β -phase is retained after quenching in its metastable state and competes with ω -phase during quenching. Also spinodal decomposition of α'' -martensite in Ti-Mo and Ti-Nb has been observed (53). The sensitivity to decomposition at moderate temperatures is less, if not, important at room temperature. Therefore pseudoelastic β -Ti alloys could offer an interesting alternative to Ni-Ti alloys for example for orthodontic wires. Such an alloy has recently been developed by Lei et al. (63). Ti-11Mo-3Al-2V-4Nb was selected for optimization. Good pseudoelasticity of the order of 3% was obtained after cold working and heat treatment.

Magnetic-Field-Induced Martensitic Transformation

T. Kakeshita et al. (64) defined a magnetoelastic martensitic transformation: when a magnetic field is applied (above A_F) to an alloy that exhibits a thermoelastic martensitic transformation, martensite variants may be induced while a magnetic field is applied and revert to the parent phase when the magnetic field is removed. This has been observed in Fe_{31.9}-Ni_{9.8}-Co_{4.1}-Ti (at%) (64,65). Apart from

Fe-based alloys, Ni–Mn–Ga near the Ni₂MnGa compound, which is a ferromagnetic Heusler ordered alloy, is one of the candidates (66,67).

Besides their very interesting fundamental properties, these alloys might act much faster than classic SMA-based actuators that are thermally driven. The bandwidth of the latter is limited to a few hertz (for very thin wires) due to cooling restrictions. In magnetoelastic martensitic transformations, bandwidths of some orders larger can be obtained.

FUNCTIONAL PROPERTIES OF SHAPE-MEMORY ALLOYS

Shape-memory alloys have different shape-memory effects and can be used in different ways. These effects and ways of use are described in general terms here. As explained before, binary and ternary Ni–Ti alloys are probably used for more than 90% of new SMA applications. Therefore, quantitative data refer to Ni–Ti alloys, unless otherwise stated.

One-Way Shape-Memory Effect

A shape memory element can be deformed in its martensitic state to almost any “cold shape.” The basic restriction is that the deformations may not exceed a certain limit, typically 8%. These apparent plastic deformations can be recovered completely during heating when the reverse transformation occurs and results in the original “hot shape.” This strain and shape recovery during heating is called the *one-way shape-memory effect* because only the hot shape is memorized (Fig. 1).

The physical basis for this *one-way effect* is a reverse martensitic transformation from a preferentially oriented martensitic phase and shape to the original high-temperature phase and shape, as explained more in detail earlier and in many review papers on shape-memory alloys. The preferential orientation of the martensitic variants originates from the application of stress either below M_f that causes martensitic reorientation, or during the forward transformation that causes preferential oriented formation of martensite. Thus, the apparent plastic strain is caused by the preferential orientation of martensite.

Figure 1. The one-way memory effect. The sample is deformed (A→B) and unloaded (B→C) at a temperature below M_f . The apparent plastic deformation is restored during heating to a temperature above A_f (C→D). Length change, load, and temperature are indicated, respectively, by L , F , and T [from (69)].

Figure 2. The two-way memory effect. A spontaneous shape change occurs during cooling to a temperature below M_f (A→B). This shape change is recovered during subsequent heating to a temperature above A_f (B→C) [from (69)].

Therefore, the reverse transformation to the parent phase during heating is accompanied by a strain and shape recovery. The one-way shape-memory effect is thus a property *inherent* in the reversible, thermoelastic martensitic transformation.

Thermoelasticity was observed as early as 1938 by Greninger and Mooradian (70). Since then, thermoelasticity and the one-way memory effect have been found in many different alloy systems (71). In 1962, the one-way shape-memory effect was also found in Ni–Ti (72).

Two-Way Shape-Memory Effect and Training

The two-way memory effect involves memorization of two shapes. Figure 2 shows that a cold shape is obtained spontaneously during cooling. Different from the one-way memory effect, no external forces are required to obtain the “memorized” cold shape. During subsequent heating, the original hot shape is restored. The maximum strains are in general substantially smaller than those of the one-way memory effect. A strain limit of about 2% has been mentioned (73), although higher TWME strains have been found in specific cases.

In 1972, Tas et al. proposed the term “two-way memory effect” (abbreviated to TWME) to refer to this spontaneous, reversible shape change between a “hot” shape linked to the parent phase and an acquired “cold” shape linked to the martensitic phase (74). This spontaneous shape change was observed only after particular thermomechanical procedures. Since that time, many papers have been published on the TWME, the thermomechanical procedures and the mechanisms of the TWME, especially for Cu-based SMAs (73,75–83). There have not been many systematic studies of Ni–Ti shape-memory alloys, however, to investigate the TWME and the effects of the thermomechanical procedures (77,78).

The essential difference from the one-way effect is the macro stress-free shape change during the forward transformation or, in physical terms, the spontaneous formation of preferentially oriented martensitic variants. Thus, the TWME requires some sort of asymmetry in the microstructure of the parent phase, such as retained martensite or dislocation structures (76,82). The microstructural asymmetry and the resulting TWME are not inherent characteristics of shape memory alloys, as is the one-way effect, and can be induced only after particular thermomechanical procedures. These thermomechanical procedures are in

general based on the repetition of thermomechanical cycles through the transformation region (73,76,79), that consists of transformation cycles from the parent phase to preferentially oriented martensite. The goal of these repetitive procedures is to acquire the cold shape; therefore, these procedures are referred to as “training.” Some examples of such training procedures are temperature cycling at a constant strain or at a constant stress and superelastic cycling. It can be easily understood that many combinations and variants of these procedures can also be applied. As a result, new procedures have been regularly reported in the literature. In most of these publications, the new aspects of the procedures are emphasized, but almost no attention is paid to the points of similarity to previously described procedures (81).

It is important to note that the training results in concomitant effects, such as changes of the transformation temperatures and heats and residual deformations of the austenitic shape (75,76,81,84). In general, these characteristics become insensitive to cycling as the number of training cycles increases. So, the repetitive procedures to induce the TWME can also be used merely to stabilize the shape-memory behavior. The term training is also generally used to indicate such stabilization treatments, though the TWME can be negligible and should in this case be considered a side effect of the stabilization treatment. It is generally agreed that cyclic training procedures generate some kind of microstructural asymmetry in the parent phase, so that preferential martensitic variants are formed in subsequent thermal cycles, thus causing the TWME (76,82). Basically, three mechanisms for the TWME have been proposed in the literature. It has been observed that training cycling results in generating complex dislocation arrays (76,79,80). Based on this observation, the TWME has been attributed to the residual stress fields of these dislocation arrays (75,76). It was proposed that these residual stress fields favor the nucleation and the beginning of the growth of some preferentially oriented variants, and at the same time, the residual stresses are relaxed by the accompanying shape change. During further cooling, these preferential variants grow without any assistance and result in the TWME.

A second proposed mechanism is based on local stabilization of remnants of preferential martensitic variants that are retained above the original A_f temperature. During cooling, these small martensitic plates would grow and influence the subsequent positioning of other variants, thus causing the TWME (76,79). However, specific experimental observations obtained on Cu-based alloys invalidate these two proposed TWME mechanisms (82). A third mechanism became widely accepted in the past years. Based on a thermodynamic analysis of specific experimental results, it was shown that the defect energy of the complex dislocation arrays generated during training is minimal in the trained variants, that is, in the preferentially oriented variants that have been repeatedly induced during training cycling (82,85). From thermodynamic considerations, it follows that the growth of these trained variants are also favored during subsequent thermal cycling, which explains the TWME. This thermodynamic analysis has also allowed us to explain many other phenomena

related to the TWME (83,86). Because the TWME is closely related to the “trained” dislocation arrays, the TWME can be removed by annealing at moderate temperatures (75).

Next to the cyclic training procedures, the following one-time procedures to induce the TWME have been reported. Remnants of preferentially oriented variants can be stabilized by holding a constrained or stressed sample at temperatures above the nominal A_f for a sufficiently long time. The TWME obtained by this procedure is attributed to the growth of those remnants (76). Aging of a sample at sufficiently high temperatures and stresses can also result in a reversible shape effect (73,76,87,88). Precipitates are formed during the aging. The observed reversible effect is attributed to the residual stress field generated by these precipitates and to the interaction between martensitic formation and the preferentially oriented precipitates. A TWME of small magnitude can also be obtained by a single, sufficiently high plastic deformation of the martensitic phase (73). However, the disadvantages of these one-time procedures are numerous, including large deformations of the hot shape; large shifts of the transformation temperatures; and strong dependence on the stabilization or aging temperatures, stresses, and times (76).

Superelasticity

The shape-memory effects described before require temperature changes. In contrast, the superelastic effect, also called the pseudoelastic effect, is isothermal (89,90). The two-dimensional graph of Fig. 3 shows that a superelastic specimen exhibits normal elastic behavior until a critical stress is reached. Under further stressing, the specimen elongates substantially, as if it were plastically deformed. However when the stress is removed, the specimen contracts to its original dimensions, and the apparent plastic strain is recovered.

Superelasticity can be considered the mechanical analog of the thermal shape-memory effect. Isothermal loading at a temperature above A_f results in a stress-induced martensitic transformation that starts at a critical stress

Figure 3. Superelastic behavior at constant temperature due to stress-induced transformation and retransformation.

σ_{M_s} . Further straining occurs at a nearly constant stress level until the transformation finishes at σ_{M_f} . Thus, the apparent plastic strain is caused by the shape strain that accompanies the stress-induced formation of preferentially oriented martensite. During subsequent unloading, the reverse transformation occurs at a lower stress level between σ_{A_s} and σ_{A_f} , and the apparent plastic strains are recovered. Large reversible deformations up to 10% can be obtained, compared to 0.2–0.5% elastic strain in most other metallic alloys. Further straining at stress levels above σ_{M_f} results in elastic straining of the stress-induced martensite, followed at σ_y by plastic yielding of the martensite.

The stress-induced transformation exhibits stress hysteresis that is revealed by the different stress levels for the forward and reverse transformations. This hysteresis is typically 150–300 MPa in Ni–Ti and results in dissipating of energy during superelastic cycling. The energy dissipated per cycle is given by the area enclosed between the upper and lower curves in Fig. 3. Superelasticity also involves the storage of potential energy, given by the area under the unloading curve in Fig. 3. The capacity of this elastic energy storage can be as high as 10 J/g. All of the previously mentioned superelastic characteristics are strongly affected by processing and composition (91,92).

The critical transformation stresses (σ_{M_s} , σ_{M_f} , σ_{A_s} , and σ_{A_f}) increase, in a first approximation, linearly as temperature changes starting from zero at the corresponding transformation temperature, as described by the Clausius–Clapeyron equation. It follows that at a temperature, denoted as M_d , the stress for plastic yielding becomes equal to the stress for martensitic formation. Thus, superelasticity occurs only across a relatively narrow temperature window between the temperatures A_f and M_d . This temperature range of typically 50–100 K is too small for applications in most industrial and consumer fields. The strong temperature dependence of mechanical behavior, described by the Clausius–Clapeyron equation, is a further impediment to the general use of superelasticity (93).

The temperature dependence and small temperature range are no barrier to use in mammalian bodies, where temperature is constant. Moreover, the superelastic effect

results in a unique combination of deduced properties. No other material or technology can offer the combination of high strength, high stiffness, high pliability, and high kink resistance. Ni–Ti has excellent biocompatibility after proper surface treatment. The concept of a metallic material that has extreme elasticity and nearly constant stress levels across a large strain area is something that can be tackled more easily by designers than the concepts related to temperature-activated shape-memory effects (94). Accordingly, the largest commercial successes of SMAs in recent years are linked to using superelasticity in biomedical applications (93–95). Other advantages related to superelasticity and relevant for medical applications have been described in detail by Duerig et al. (93).

It must be mentioned also that Ni–Ti alloys in their as-cold worked state can exhibit nearly linear elastic behavior across an extremely broad strain range. This linear behavior that has a low elastic modulus of typically 30 GPa is called linear superelasticity (96,97). Reversible deformations as high as 4% can be induced that have a very small hysteresis between the loading and unloading curve. Clearly different from the superelastic effect described before, stress-induced martensitic transformation is not the controlling mechanism of linear superelasticity. As a result, temperature and composition have only a minor effect on this behavior.

Generation of Recovery Stresses

If an external constraint prevents an SMA element from returning to its hot shape when heated, high recovery stresses are gradually generated during heating, as illustrated in Fig. 4. Stresses up to 800 MPa can be obtained (99).

Four parameters have to be introduced to describe this shape-memory property (100): the contact strain e_c , the contact temperature T_c , the recovery stress σ_r , and the stress rate $d\sigma_r/dT$. Similar to the one-way and two-way memory effects, the generation of recovery stresses starts from a macroscopic deformation in the martensitic state. During subsequent heating, free recovery occurs until a

Figure 4. The generation of recovery stresses is shown in three two-dimensional figures: (a) stress–strain, (b) strain–temperature, and (c) stress–temperature. A deformation is imposed at a temperature T_d in the martensitic state. Shape recovery is impeded at a contact strain e_c . From the corresponding contact temperature T_c , recovery stress σ_r are generated at a stress rate $d\sigma_r/dT$ [from (69,98)].

temperature T_c at which an external mechanical obstacle is contacted. The recovery of the remaining deformation, characterized by the contact strain e_c , is impeded by this obstacle. Therefore, from the temperature T_c , recovery stresses are generated at a nearly constant stress rate $d\sigma_r/dT$, often described by a Clausius–Clapeyron equation. This shape-memory property is the basis of some very successful shape-memory applications, especially in earlier years (100,101). However, compared to the number of papers on superelasticity and the one- and two-way memory effects, the number of publications on generating recovery stresses is rather limited (99–114). Moreover, most of these publications focus on engineering applications. Also important to note is that these applications are based mostly on the stresses generated during the first heating after the initial predeformation. Therefore, cyclic generation of recovery stresses was not investigated in earlier papers.

The recent substantial efforts in developing hybrid composites that have embedded shape-memory elements have resulted in an increasing interest in understanding the generation of recovery stresses (99,113–115). In these smart composites, thin SMA wires or other SMA elements are embedded in advanced structural materials without losing the structural integrity of the matrix material. Most functional properties of such adaptive composites are directly related to the following mechanism on the level of the SMA elements. During heating, prestrained martensitic SMA elements operate against the elastic stiffness of the host matrix, and bias the strain recovery and the reverse transformation of the SMA elements. The result is that recovery stresses are generated gradually by the SMA elements in the composite during heating, and the strain recovery and reverse transformation of the SMA elements are delayed. After overcoming temperature hysteresis, the reverse process occurs during cooling. A crucial difference from earlier applications that use the generation of recovery stresses is that these hybrid composites are activated repeatedly, that is, recovery stresses are generated cyclically.

A remarkably common feature of several papers on recovery stress generation is that elementary principles of thermoelastic martensitic transformation are frequently violated. Although review publications can give the impression that the generation of recovery stresses is well understood, careful analysis has shown that the scientific understanding of this property in many papers is still limited (69,86). The limited understanding can be partly explained by the lack of experimental results. In addition, the majority of the published experimental results are questionable because a hard tensile machine was used in most studies. In that case, the thermal dilatations of the crosshead arms can have such a dominating effect that the measured results are unreliable (81,100).

As a result of the lack of data, many papers refer to an old NASA report, published in 1972, for quantitative data on recovery stress generation (102). However, the data in that report refer to the first heating after predeformation in isostrain conditions. This would correspond to a biasing element that has no thermal dilatation and infinite rigidity.

Figure 5. Recovery stress versus temperature for a constant prestrain of 2%. (b) Recovery stress versus temperature for a variable prestrain. The prestrain e is a function of temperature, given by $e = 2\% + \alpha x (T - 55)$, where T is the temperature in $^{\circ}C$. More details can be found in (114).

Yet, in most practical cases, the conditions are quite different. Only recently, the first results for more complex constraining conditions and for cyclic activation appeared in the literature. An example evidencing some important features is shown in Fig. 5.

The figure shows clearly that the stress–temperature path during the first heating can be quite different from the second heating path. Second and subsequent heating and cooling paths coincide. This difference between the first and second heating path can be caused by a difference in hysteresis paths (99) or by one-time shifts of the reverse transformation temperatures that result from the initial predeformation (116).

It can be also seen that the temperature hysteresis between the heating and cooling paths can be extremely small in isostrain conditions (Fig. 5a) but can increase significantly for nonisostrain conditions (Fig. 5b). This can be simply explained. The fraction of martensite transforming in the isostrain conditions of Fig. 5a is much smaller than the transformed fraction in Fig. 5b. The temperature hysteresis is, in a first approximation, proportional to the transformed fraction, which explains directly the small temperature hysteresis in Fig. 5a (99). An

important conclusion is that for most practical constraining conditions, only a small fraction of martensite is actually transforming during the constrained heating and cooling. Therefore, the observed hysteresis is much smaller than the overall hysteresis, typically below 10 K for Ni–Ti, below 5K for Ni–Ti–Cu, and below 2K for the R-phase transformation (99,114).

As stated before, it is often assumed that stress changes linearly as temperature changes. Moreover, the stress rate $d\sigma_r/dT$ is often considered a material constant directly derived from a Clausius–Clapeyron equation. Such descriptions should be considered very elementary simplifications. The results in Fig. 5 show clearly that the stress rate decreases during constrained heating. It has been also found that the stress is affected by many other parameters, including the thermomechanical history and the prestrain (69,86).

Depending on the magnitude of the prestrain, either a plastic upper limit or an elastic upper limit to σ_r exists. At lower prestrains, the stress increases during heating until the reverse transformation is completed. The upper stress limit in this case is given by the strain divided by Young's modulus. When the prestrain is sufficiently high, the stress increases during heating until plastic yield occurs at a temperature M_d . So, the upper stress limit in this case is the plastic yield stress σ_y . Evidently, in cyclic actuation, the maximum temperature should be kept below M_d .

In all cases discussed, a constraint prevents the SMA element from returning to the hot shape when heated. Thus, a more specific name would be “hot shape” recovery stress. It has been found in trained Cu-based SMA-elements that stresses can also be generated when the TWME is impeded during cooling (69,83). Because the constraint in this case prevents the sample from returning to the cold shape when cooled, the generated stress was called “cold shape” recovery stress to contrast with “hot shape” recovery stress. Practical applications have not been reported so far.

Quantitative comprehension of recovery stress generation presented in the literature is far below the comprehension of the other functional properties of shape-memory alloys. Therefore, recovery stress generation was discussed a bit more extensively than other functional properties. Considering the substantial research efforts in developing hybrid composites that have embedded shape-memory elements, substantial progress in quantitatively understanding recovery stress generation can be expected in the near future.

Work Output

One- and two-way memory effects can be used for free recovery applications in which the single function of the SMA element is to cause motions without any biasing stress. Under constant strains, shape-memory elements can generate substantial recovery stresses. Between these two extremes of free recovery and completely constrained recovery, shape-memory components can yield a wide variety of combinations of strains and stresses. As shown in

Figure 6. The work output. The sample is deformed at a temperature at a below M_f (A→B), followed by unloading (B→C) and loading again using a bias weight W (C→D). Shape recovery occurs under an opposing force W during heating to a temperature above A_f (D→E). So work is done [from (69)].

Fig. 6, a shape-memory element can be deformed by low force in the martensitic condition or during the forward transformation and can exert a substantially higher force as it reverts to the hot shape when heated. So, work up to 5 J/g is done during heating. This concept can be used in thermal actuators in which the SMA element is activated by an increase in the environmental temperature, or in electrical actuators in which the SMA element is in general activated by direct Joule heating. The work needed to deform the SMA element is much lower than the work that can be obtained during heating. This has been the basis of many prototypes of heat engines that convert heat into useful work [see (117)].

SMA actuators offer distinct advantages compared other types of actuators (118). The main advantage is that by far SMA actuators offer the highest work and power-to-weight ratios of all available actuating technologies at low levels of weight (119). These high-work and high-power densities enable a whole class of applications (e.g., in the field of micro actuation) that are impossible to realize by using other actuating technologies (120–123). SMA actuators can be reduced mostly to a single SMA element without auxiliary parts, resulting in simple compact and reliable devices.

Several important drawbacks that limit the use of SMA actuators to specific niches should also be considered. The conversion of heat into mechanical energy via SMA actuators was studied extensively 15 to 25 years ago. Simple thermodynamic calculations showed that the maximum theoretical efficiency of an SMA actuator is less than 10% (124). In practice, the conversion of heat into mechanical work is less efficient, and the result is that real efficiency is even one order of magnitude smaller than the theoretical value. Another drawback is that the SMA actuator has to be heated and cooled. The low cooling rate, especially limits the use of SMA actuators to relatively low-frequency applications. It was discussed before that stresses in trained Cu-based SMA elements can also be generated when the

TWME is impeded during cooling. Similarly, it has been shown that these trained SMA elements can do a small amount of work during cooling (82,83).

High Damping Capacity

SMA elements have high damping capacity in the austenitic and martensitic conditions. Shape-memory alloys show strong amplitude-dependent internal friction in the martensitic condition. For impact loads, the specific damping capacity can be as high as 90%. Starting from the austenitic condition, energy is dissipated during superelastic cycling as a result of stress hysteresis between superelastic loading and unloading, as explained before. A detailed analysis can be found in (125,126).

INTRODUCTION

An understanding of shape-memory behavior requires knowledge of various physical processes that operate on different length scales. The crystallographic shifts that are responsible for shape-memory behavior take place in unit cells of atomic dimension. Here, however, these microscopic length scales are not the focus, rather, this article considers the macroscopic scale modeling that allows for the engineering assessment of thermomechanical response (stress–strain–temperature) and energy balances (including damping) for devices such as connectors, actuators, vibration absorbers, and biomedical stents. The macro scale is useful for primary design evaluation such as predicting triggering forces and determining range of motion. Since the shape-memory material is typically incorporated into a larger engineered device or structure, there is also a need for detailed computational simulation of the system as a whole.

BASIC MATERIAL BEHAVIOR AND MODELING ISSUES

The term *shape-memory material* (SMM) is meant to encompass a wide class of metallic alloys with the common feature that they exhibit, at the macroscopic scale, some peculiar and useful functional properties such as pseudoelasticity and shape memory. Nickel-titanium (NiTi) is perhaps the best known and most widely used such material. SMM functional properties derive from transformations between two different solid phases: austenite (**A**) and martensite (**M**). Aspects of the **A** ↔ **M** phase transformation are essential for model development and implementation. In addition, certain intermediate phases may also occur, but these are neglected here because their effect on the macroscopic response is small in comparison.

The **A** ↔ **M** transformation can be induced by a variety of energy inputs (mechanical, thermal, magnetic, ultrasonic, etc.), and it is influenced by grain boundaries, dislocations, inclusions, and other material defects. This article considers the standard thermomechanical setting, namely the **A** ↔ **M** transformation that is induced by temperature T and stress σ . In general, austenite is favored at high temperatures and low stress, whereas martensite is favored at low temperatures and high stress. We will use a boldface σ (and ϵ) to denote a general stress and strain tensors with components σ_{ij} (and ϵ_{ij}). Models involving only a single stress component σ will be developed more than those involving the tensor σ .

Austenite is of higher crystallographic symmetry and so can transform into one or more martensite variants that differ mainly by their orientation relation to the austenite

Figure 1. A phase diagram defines the zones of the (σ, T) -plane where the various phase transformations can occur. Each curve represents the (σ, T) -points at which a transformation can either be activated or else completed. Hence there are two curves (start and finish) for each transformation. The figure shows a sketch of a phase diagram that can arise when the SMM is modeled as a mixture of austenite **A** and two martensite variants **M+**, **M-**. Such a diagram can be viewed as an unfolding of a conventional phase diagram triple point so as to include the effects of phase mixing and transformational hysteresis.

parent. By contrast, all martensite variants tend to transform into a single common austenite crystal structure. The transformation from the **A** structure to that of a particular **M** variant is characterized by a crystallographic transformation strain. Typically, an **A** material region transforms into a martensitic microstructure with several variants that combine in complicated twin arrangements and plate morphologies. These microstructures provide a *local transformation strain* γ^* . This in turn gives a *macroscopic transformation strain* ε^* at the engineering scale. This ε^* gives a potentially large strain in stress-induced **A** \rightarrow **M** transformations. It is negligible in cooling-induced **A** \rightarrow **M** transformations because the resulting microstructures involve so-called self-accommodated martensite with local strains γ^* that cancel each other.

Since the phase transformations can be activated under very different conditions to obtain different effects, to have a picture of SMMs behavior, it is necessary to see how stress and temperature differ with respect to **A** \leftrightarrow **M** transformation. Figure 1 shows a stress and temperature phase diagram of a single austenite phase **A** and two families of martensite variants **M+** and **M-**. The curves in this diagram show the relation between stress and temperature levels at which various phase transformations begin and end. This partitions the (σ, T) -plane into three single phase regions, three double phase regions, and a triple phase region.

Purely Thermal Transformation

In the absence of stress, austenite is stable at high temperatures, and martensite is stable at low temperatures. Stress-free cooling of austenite gives **A** \rightarrow **M** conversion beginning and concluding at temperatures M_s and M_f , respectively ($M_f < M_s$). The resulting microstructure is an *unbiased martensite* with a fine-scale arrangement of variant twins with opposing local transformation strains γ^* .

This produces a negligible engineering scale transformation strain $\varepsilon^* = 0$. Similarly, a temperature increase causes **M** \rightarrow **A** conversion, the start and finish temperatures being A_s and A_f , with $A_f > A_s$. The transformation temperatures M_f , M_s , A_s , and A_f are the basic material parameters for purely thermal transformations. They are highly sensitive to the alloy concentrations and to the granular and defect structure as determined by heat treatment and cold work. Once the material is ready for service, these temperatures are easily determined by various means including resistivity and calorimetry testing.

Low-Temperature Martensite Reorientation

Austenite is not present at temperatures below M_f . Nonzero stress at these low temperatures causes certain martensite variants to be relatively more favored. This favoritism correlates with the value of the transformation work $\sigma \cdot \gamma^* = \sigma_{ij} \gamma_{ij}^*$. In the important special case of uniaxial tension/compression, the variants favored in tension are those for which γ^* projects onto the tensile axis as a positive quantity. It is convenient to group all of the variants favored in tension into an **M+** variant family, and all variants favored in compression into an **M-** variant family. Unbiased martensite involves a mixture of both **M+** and **M-**. Sufficiently high tensile loading at temperatures below M_f causes movement of the internal boundaries separating the martensite plates, which can be viewed as a conversion from the **M-** family into the **M+** family. This **M-** \rightarrow **M+** transformation yields *biased martensite*, namely $\varepsilon^* \neq 0$. Unloading does not cause the reverse transformation (**M+** \rightarrow **M-**) so long as the load does not become compressive. Hence the transformation strain ε^* is like a conventional plastic strain upon unloading (Fig. 2). The **M-** \leftrightarrow **M+** transformation is referred to as *reorientation*. As a result, a plasticlike *reorientation plateau* is observed on the isothermal stress-strain curve, with the tensile reorientation beginning and concluding at stresses σ_s^+ and σ_f^+ ($\sigma_f^+ > \sigma_s^+ > 0$). These reorientation stresses are relatively insensitive to temperature changes (there may be a mild increase in σ_s^+ and σ_f^+ with a temperature

Figure 2. Sketch of the macroscopic effects of the various phase transformations in the stress-strain-temperature $(\sigma-\varepsilon-T)$ space (left). Effect of the loading rate on the pseudoelastic behavior: faster loads give rise to greater hardening and temperature variations (right, where t denotes time).

decrease). Similar reorientation processes occur in compressive loading due to the $\mathbf{M}^+ \rightarrow \mathbf{M}^-$ transformation, with the start and finish of the reorientation plateau described by stresses $-\sigma_s^-$ and $-\sigma_f^- (-\sigma_f^- < -\sigma_s^- < 0)$.

Pseudoelasticity

Austenite can be present at temperatures above M_f . Such austenite is converted to biased martensite upon application of sufficiently high stress, either tensile (activating $\mathbf{A} \rightarrow \mathbf{M}^+$) or compressive (activating $\mathbf{A} \rightarrow \mathbf{M}^-$).

Consider the tensile case. A stress increase gives the $\mathbf{A} \rightarrow \mathbf{M}^+$ transformation, which again generates a plateau on the stress–strain diagram. This is referred to as a *pseudoelastic* plateau so as to distinguish it from the reorientation plateau observed at the lower temperatures. For $T > A_f$, the start and finish stresses for pseudoelasticity are greater than the $\mathbf{M}^- \rightarrow \mathbf{M}^+$ reorientation stresses σ_s^+ and σ_f^+ . They are also highly temperature sensitive, increasing with temperature at an approximately constant rate. However, if the temperature is close to M_f , then little distinction can be made between pseudoelasticity and reorientation because the loading plateau stresses match the reorientation values σ_s^+ and σ_f^+ . Unloading activates the $\mathbf{M}^+ \rightarrow \mathbf{A}$ transformation if $T > A_s$, resulting in an unloading plateau below the $\mathbf{A} \rightarrow \mathbf{M}^+$ loading plateau. The unloading plateau rejoins the loading curve if $\mathbf{M}^+ \rightarrow \mathbf{A}$ goes to completion ($T > A_f$), and so defines a hysteresis loop (Fig. 2). At temperatures $A_s < T < A_f$, the $\mathbf{M}^+ \rightarrow \mathbf{A}$ unloading conversion does not go to completion and the unloading plateau intersects the strain axis before reaching the origin of the stress–strain diagram. If $T < A_s$, then the $\mathbf{M}^+ \rightarrow \mathbf{A}$ transformation is not even activated upon unloading. Thus, in all cases where $T < A_f$, there is some residual strain due to the presence of \mathbf{M}^+ martensite when unloading is complete.

Shape-Memory Effect

At all temperatures, where $T < A_f$, after sufficiently high load causing either $\mathbf{A} \rightarrow \mathbf{M}^+$ or $\mathbf{M}^- \rightarrow \mathbf{M}^+$ transformation, residual strain is present after unloading due to the presence of biased martensite. Unlike conventional plastic flow in metals (generated by dislocations) the SMM plasticlike residual strain is recovered by heating above A_f , because this converts martensite to austenite. Since this austenite converts to unbiased martensite upon any later stress-free cooling, the residual plastic strain does not return (unless there is further loading/unloading). This heating/cooling elimination of an apparently “plastic” strain due to previous loading/unloading is the *shape-memory effect*.

While the preceding discussion has covered the basic aspects of the material behavior that macroscopic models should reproduce, SMM is often employed in situations involving further effects that are important objectives for useful modeling. The most important of these are briefly described next.

Response to Complex Loading Paths

At constant temperature, loading reversals that interrupt $\mathbf{A} \rightarrow \mathbf{M}$ and $\mathbf{M} \rightarrow \mathbf{A}$ before completion lead to internal

subloops within the major stress–strain hysteresis loop associated with complete transformation. Load paths involving simultaneous change in T and σ generally augment or diminish transformation that would occur under either T or σ alone. This is critical for modeling the rate effect that is described next.

Rate Dependency due to Transformational Heating

If mechanical loads producing phase transformation are not applied in a quasi-static way, then temperature variation occurs in the sample and a rate-dependent response is observed. This is due to the exothermic and endothermic nature of the $\mathbf{A} \rightarrow \mathbf{M}$ and $\mathbf{M} \rightarrow \mathbf{A}$ transformations, respectively. During $\mathbf{A} \rightarrow \mathbf{M}$ the material self-heats and the temperature rise works against the transformation (conversely during $\mathbf{M} \rightarrow \mathbf{A}$ the sample self-cools). This might involve a number of consequences: different onset stresses for transformation plateaus, plateau steepening, and variation in the shape of internal loops (Fig. 2). The extent of this effect is governed by the heat exchange with the environment: high rates of loading can cause significant departure from isothermal behavior. High rates of loading can occur in both actuator and damping shape-memory devices.

Tension/Compression Asymmetries

In uniaxial loading, significant differences in the stress–strain behavior have been observed between tension and compression. This is due to the different microstructures that are formed. In particular, the behavior of the \mathbf{M}^+ variant family in tension is not the symmetric image of the behavior of the \mathbf{M}^- variant family in compression. Such a phenomenon is modeled by a phase diagram that is asymmetric with respects to σ .

Three-Dimensional States

In the three-dimensional case involving tensor σ rather than scalar σ , the experimental behavior is less well understood, and complex multivariant structures are to be expected in most cases. A key issue in three-dimensional modeling is the proper constitutive description of an appropriate local transformation strain that transcends the lack of information about the actual multivariant microstructure. In view of the correlation of variant favoritism with the transformation work $\sigma \cdot \gamma^* = \sigma_{ij} \gamma_{ij}^*$, some sort of coaxiality relations between stress and transformation strain are conjectured at modeling scales appropriate to a multivariant microstructure. These difficulties are compounded under nonproportional loading, since the transformation strain then evolves as a consequence of both pseudoelastic $\mathbf{A} \leftrightarrow \mathbf{M}$ processes and $\mathbf{M} \leftrightarrow \mathbf{M}$ reorientation of existing variants.

STATE OF THE ART AND HISTORICAL DEVELOPMENTS

Modeling of the macroscopic behavior of SMM has been the subject of much activity since the beginning of the 1980s, attracting the interest of engineers, applied mathematicians, and materials scientists. This section surveys the state of the art on the basis of the huge literature

available on the subject. The survey is restricted to models that directly relate to macroscopic modeling and does not delve into the voluminous literature on metal physics and purely microstructural development, even though much of this literature provides enormous insight. While an effort has been made to be rather comprehensive, the survey is still far from complete. We have attempted to give careful bibliographic references by selecting one representative paper for each approach. Each of these models then typically gives rise to refinements, generalizations, verification studies, and implementation strategies. For the sake of conciseness, complete bibliographic references cannot be given for all of these modeling extensions.

The discussion of the previous section makes clear that the behavior of SMM observable at the macroscopic scale is the effect of several complex microstructural phenomena. This section is organized, as in the list below, with respect to contributions that include an explicit model for such microstructural phenomena and others that do not. Although certain models that will be discussed can be viewed as spanning more than one such approach, the classification given below aids in organizing the numerous modeling approaches that have been proposed.

Approaches modeling one or more microstructural phenomena	<i>Lattice cell mechanics</i> <i>Interface nucleation and propagation</i> <i>Micromechanics</i>
Approaches modeling directly the macroscopic behavior	<i>Models without internal variables</i> <i>Hysteresis models</i> <i>Models with internal variables</i>

Approaches Modeling One or More Microstructural Phenomena

Models included in this group are grounded in theories that analyze the material at a scale in which the multiphase nature of the material is rendered explicit and one or more effects of phase transformations can be described by some direct microstructural model. Macroscopic behavior is then recovered by some kind of averaging procedure. In a continuum setting, this implies that each point belongs to one phase and the first spatial derivatives of the displacement and temperature fields can be discontinuous.

Lattice Cell Mechanics. In this approach, the macroscopic response of the material is determined by studying the behavior of a collection of lattice cells that can be in a particular phase or phase variant. In response to loads and temperature changes at the system boundary, cell transitions between different phases can take place. Two approaches for the transition kinetics can be broadly identified: *statistical mechanics* and *strain energy minimization*.

The statistical mechanics approach has roots in Muller and Wilmanski (1) and has been further developed by Achenbach (2). The cellular array is grouped as a stack of layered aggregates of cells that can be found in one of the

Figure 3. The three-well energy function of the Muller-Achenbach model without (*left*) or with (*right*) mechanical load. Each minimum corresponds to a phase with different structure (austenite **A** and two martensite variants **M₊**, **M₋**). The differences among the ordinates of the various minima represent the energy barriers that cells have to overcome to undergo phase transformations. The right graph shows the effect of a mechanical load P that lowers the right minimum and causes the **M₊** phase to be the energetical favorite.

three phases: austenite **A** and two martensite variants **M₊**, **M₋**; each characterized by a different cell length. Cells are in random thermal motion, and thermal fluctuations permit them to transform from one phase to another. Such transitions lead to variations in the stack composition that are monitored by the phase fractions ξ_A , ξ_+ , and ξ_- . A three-well potential energy ϕ whose minima are each associated with one phase is the basic constitutive ingredient from which all material parameters are derived by statistical arguments (Fig. 3). Macroscopic strain and temperature are obtained respectively from the normalized length of the whole layer aggregate and from a measure of the thermal fluctuation. The phase fraction evolution is governed by a system of ordinary differential equations expressing the transition rate balance between layers on the basis of the probability of overcoming the energy barriers that separate the minima of ϕ . This finally provides a complete model for uniaxial stress pseudoelasticity and reorientation.

A second approach for the description of the transitions between lattice cells is based on strain energy minimization. A model developed by Morris and his collaborators (3) involves a multidimensional lattice of cells with corresponding multidimensional transformation strains for each cell. The total free energy is the sum of a temperature-dependent chemical free energy and a strain-dependent elastic strain energy. The strain energy contribution is highly dependent on cell location and choice of transformation variant, due to the constraint of surrounding cells. The computation is based on isotropic elasticity, and the underlying mathematical technique developed by Khachaturyan requires equality of elastic constants in all phases. For a given change in temperature, the overall transformation process is simulated by a stepwise energy minimization. At each step, the particular cell that transforms is selected as the one that most lowers the energy, and such transformations continue so long as the overall energy is lowered. Complex microstructures and internal stress states occur. These complex states are the main focus of such modeling, as opposed to providing a macroscopic model for overall stress-strain-temperature behavior.

Interface Nucleation and Propagation. Large deformation theories of continuum mechanics have also been used to treat martensitic phase transformation. These treatments stem from analysis by Ericksen of a uniaxial continuum with a nonconvex elastic strain energy density (4). These energies give rise to nonmonotone stress–strain curves. Fundamental thermodynamic arguments harking back to Gibbs and Maxwell indicate that strains on the descending branches of these stress–strain curves are unstable in that they cannot be part of a deformation field that minimizes energy. Energy minimization naturally gives rise to distinct material regions, each involving continuous strain, that are separated from each other by interfaces across which the strain is discontinuous so as to avoid unstable branches. The connection to stress-induced phase transformation follows by placing the distinct stable branches of the stress–strain curve into correspondence with distinct material phases. Avoidance of the unstable branches is then formally similar to spinodal decomposition. One outgrowth of this work has focused on putting the crystallographic theory of martensite on a rigorous mathematical foundation so as to predict microstructure without invoking the approximations inherent in the linear theory of elasticity (5–7).

The fundamental nature of much of the work cited immediately above renders it outside the scope of this modeling survey. However, under suitable interpretation, certain treatments of this type do provide a macroscopic model for the thermomechanical behavior of shape-memory materials. In particular, SMM uniaxial response follows from a thermoelastic free-energy density with either two or three minima that each define a distinct phase. Boundary value problems give solutions in which the continuum is subdivided via phase boundary interfaces into different phase regions. Phase transformation proceeds from the nucleation of new interfaces or from the propagation of the existing ones (8). The jump in the Gibbs free energy across the interface follows from the Eshelby energy-momentum tensor in the form of a generally nonzero driving traction. Phase boundary movement gives either energy dissipation or energy accumulation as determined by the direction of interface motion. Standard boundary value problems do not have a unique solution when phase boundaries are present unless the constitutive theory is augmented with both interface nucleation criteria and interface kinetic motion criteria. These typically depend on the driving traction, and they can be formulated so that the overall load–displacement–temperature relation reproduces pseudoelastic and reorientation behavior. Kinetic criteria can be derived, for example, similarly to that of Achenbach and Muller, so as to involve a probability of overcoming the energy barriers between phases on the basis of thermal fluctuation. Quasi-static and fully dynamic treatments follow for isothermal, adiabatic, and heat conducting cases. The kinetic motion criteria can be extracted from more refined theories in which the phase boundaries are regarded as transition zones exhibiting additional physical effects (9).

Micromechanics. In the models of this group each macroscopic point is put in correspondence with a representative volume element (RVE) of a multiphase material in

Figure 4. Macroscopic versus microscopic scale modeling. Each macroscopic point P corresponds to a microscopic region Ω where the multiphase nature of the alloy (A , M) can be appreciated explicitly. At the macroscopic scale the features of Ω are synthetically described by the internal variables α .

which some regions are subjected to local transformation strains due to the different crystal structure of the phases (Fig. 4).

Under proper boundary conditions, a boundary value problem on the RVE that models the effects of the phase transformations is obtained. Local quantities are volume averaged over the RVE, giving macroscopic quantities that generally retain a dependence on the microstructural features through some overall descriptor α (usually the phase fractions ξ). The resulting equations for the macroscopic behavior fit into the framework of internal variable models, as described later in this section. Constitutive ingredients are a macroscopic free-energy function Φ and a set of kinetic rate equations for the microstructural descriptors α . The free energy provides, via partial differentiation with respect to stress (or strain), equations for strain (or stress) while derivatives with respect to α give generalized forces that drive the phase transformations. The free-energy functions are structured as the sum of an elastic strain energy and a chemical free energy. While the chemical contribution is specified mainly by standard thermodynamic expressions, the elastic term varies considerably among such models as it follows from different micromechanics assumptions on the accommodation process due to phase interaction (10). Kinetic equations are derived from phase transformation criteria stating that the transformations occur when the generalized driving forces meet experimentally determined threshold values.

Patoor, Eberhardt, and Berveiller initiated such an approach in 1987 by combining ideas from transformation plasticity, continuum micromechanics, and crystallographic theories of martensitic transformation (11). In its recent formulation, their model considers, at the single-crystal level, a linear elastic RVE consisting of an austenite matrix with inclusions of 24 martensite variants, each exhibiting a local transformation strain computable from the lattice parameters. Each variant is assumed to grow, mixed with austenite, in a well-defined cluster. The interaction energy describing the accommodation between pairs of variants is then computed using the interfacial operator method of Hill. The minimization of this interaction energy determines the cluster orientation and the overall free energy finally depends only on the variant fractions. At the polycrystalline level, a second RVE consisting of nontextured assemblies of spherical grains is considered and a self-consistent approach is used to derive the

final macroscopic constitutive equations. Large numerical simulations involving the representation of each grain are required. Comparisons with experimental data are given, mainly for uniaxial stress, and show good agreement even in the prediction of tension–compression asymmetry. Recent developments also include the consideration of non-isothermal behavior. Promising applications of this model have been proposed by Gall and Sehitoglu (1999) who used experimentally determined grain orientation distribution functions to simulate the effect of texture.

In 1993, Sun and Hwang proposed to treat the problem focusing directly on the polycrystals with an RVE consisting of grains that are each wholly in the austenite or martensite phase. The phase interaction energy is computed using Mori-Tanaka theory by considering martensite grains as randomly dispersed spherical inclusions within the matrix of austenite grains. While martensite is considered as a single phase without explicitly accounting for the different variant orientations, neglect of the multivariant structure is overcome by proposing a direct relation between the local transformation strain and the average stress in the matrix so as to simulate the biasing effect of stress in the variant selection process. The local transformation strain is therefore not strictly crystallographic, and the resulting description is in terms of an equivalent transformation strain. Reorientation effects are taken into account by introducing a second martensite fraction. Issues related to nonproportional loading are also discussed (12).

Starting in the early 1990s, Levitas developed models from a somewhat different viewpoint (13). The SMM is modeled as a dissipative material already at the microscale where, due to the phase transformations, relevant field quantities vary between two values reflecting an underlying two-phase model for the microstructure. A first-averaging procedure is performed over an internal time scale representative of the transformation duration in order to obtain an average dissipation rate and driving force. Different energetic transformation criteria are given: an overall nucleation criterion results after integration over the RVE while a criterion for interface propagation is given after integration over the propagating interface. An extremum principle with respect to the variation of the RVE boundary conditions is invoked to determine the evolution of the microstructural parameters.

Goo and Lexcellent (14) proposed a model for single crystals based on a free-energy function and a dissipation rate function. The free-energy function is derived by a self-consistent evaluation of internal stresses among the phases. The model allows for nonisothermal behavior, reorientation, and two-way shape-memory effect. The influence of the interaction energy on the macroscopic modeling is examined, and the comparisons with experimental data under uniaxial stress show good agreement with the modeling prediction.

The analysis of Lu and Weng (15) treats each grain as a mixture of austenite and a single martensite variant whose local transformation strain is computed from lattice parameters. The particular variant is selected in analogy with the Patel-Cohen criterion on maximum transformation work. Polycrystals are then modeled by an assembly of

nontextured spherical grains, and a self-consistent method is used to compute the macroscopic response. As with the Patoor-Eberhardt-Berveiller model, this requires large numerical simulations involving the representation of each grain.

Huang and Brinson (16) propose a different microstructural model at the single-crystal level. An austenite matrix with martensite inclusions made of groups of self-accommodating variants, each exhibiting the local crystallographic transformation strain, is arranged in a way reminiscent of the experimentally observed wedgelike microstructure. Free energy is then computed by assuming a random distribution of such inclusions that are taken to be of spherical shape. This idealization is shown to be useful in modeling thermally activated transformations and low-temperature reorientation. The model captures also the tension/compression asymmetry and the different response observed experimentally when the loading direction varies with respect to crystal axes. The model has been extended to cover penny-shaped inclusions and polycrystalline behavior by studying an assembly of nontextured spherical grains homogenized by a self-consistent method.

Summarizing, micromechanic approaches incorporate several features into the modeling, including the effect of a multiple-variant microstructure and the effect of its polycrystalline texture. This permits explanations for most macroscopically observed behaviors, though certain detailed issues remain under discussion. Such issues include the determination of the number of variants and the modeling of their arrangement (17), as well as the modeling of nonproportional multi-axial loading; for recent experimental studies, see (18,19).

Approaches Modeling Directly the Macroscopic Behavior

Direct modeling will be understood as including theories where each point of the material, instead of being in an identifiably distinct phase, is representative of a phase mixture whose microstructural features are described by one or more descriptive variables. In a continuum setting, the associated strain and temperature gradient fields are continuous.

Models without Internal Variables. In such models the material behavior is described by strain, stress, temperature, and entropy without the introduction of quantities representing the phase mixture. Constitutive information is provided by a free-energy function whose partial derivatives provide constitutive equations for strain (or stress) and entropy.

In 1980, Falk proposed a Landau-Devonshire type of free-energy function based on the analogy between SMM uniaxial stress–strain curves and the electric field–magnetization curves of ferromagnetic materials (20). Nonmonotone stress–strain curves are obtained, and the unstable negative slope part is interpreted as the occurrence of the phase transition. The actual pattern followed during transformation is assumed to proceed at constant stress. The particular form of the Landau-Devonshire free-energy accounts for the temperature dependence of the

Figure 5. Nonmonotone stress–strain curves. The negative slope part is unstable and the dashed lines represent an assumed transformation path.

isothermal stress–strain behavior. Hysteresis arises as consequence of the different stress levels of the extremal points of the unstable region, as indicated in Fig. 5.

Under suitable interpretation, many aspects of this model correspond to aspects of Ericksen’s treatment and its subsequent extensions. In particular, although the time evolution of a phase transformation is not treated directly, such information can be inferred by associating the extent of the transformation with the strain distance on the constant stress transitions.

Hysteresis Models. Hysteresis models seek to reproduce experimentally observed curves that involve high nonlinearity and complex looping. They have been widely used in several fields, with that of magnetic materials being most developed. In this approach, constitutive equations are proposed directly on the basis of their mathematical properties, often without explicit focus on their link with the physical phenomena of interest. Reliability and the robustness of the model are favorably matched to experiments, and the resulting algorithm allows for the treatment of arbitrarily complex driving input.

Two main algorithm classes have received special attention in the context of SMM phase transformation. The first one is based on tracking subdomain conversion/reversion and lead to integral based algorithms. The most common of these is known as the Preisach algorithm and it has been used to describe uniaxial isothermal pseudoelastic stress–strain SMM response (21,22).

The second algorithm class involves differential equations with separate forms for driving input increase and driving input decrease. Differential equations of Duhem-Madelung form have been used to model SMM phase fraction evolution during thermally induced transformation (23,24). This gives phase fraction subloops for temperature histories obeying $M_f < T(t) < A_f$. Under sustained thermal cycling, these subloops collapse onto a final limiting subloop, with the resulting shakedown behavior registering the fading influence of the initial phase-fraction state. By being formulated so as to link the internal variable of phase fraction to the driving force variable of temperature, such algorithms lend themselves to a wider internal variable framework as is described next.

Models with Internal Variables. The key feature of this approach is to introduce one or more *internal variables*

(*order parameters*) α describing the internal structure of the material (see again Fig. 4). A general thermodynamical treatment then proceeds by providing equations for the evolution of these internal variables (23,26). The first application of such an approach to SMM seems to be due to Tanaka and Nagaki (27) where internal variables are employed to describe the development of the underlying phase mixture. The internal variables α , along with a set of mechanical and thermal *control variables*, then define a collection of *state variables* \mathbf{s} . Typical mechanical control variables are either strain ε or stress σ . Typical thermal control variables are either temperature T or entropy η . The internal variables α typically include one or more phase fractions ξ and/or macroscopic transformation strains. For example,

$$\mathbf{s} = \{\sigma, T, \alpha\}. \quad (1)$$

The temperature gradient ∇T must also be incorporated into \mathbf{s} if heat conduction is considered. The theory is composed of the *physical laws*, the *constitutive equations* that characterize the features typical of each material, and *material behavior requirements* that ensure thermodynamical process restrictions.

Constitutive information is specified by two kinds of relations:

1. *State equations* for the entities that are conjugate to the control variables. These can be formulated directly or else obtained as partial derivatives of a suitable free energy function after enforcing the Clausius-Duhem inequality for every process. The Gibbs free-energy G is appropriate for Eq. (1) and gives

$$\begin{cases} \varepsilon = \widehat{\varepsilon}(\mathbf{s}) \\ \eta = \widehat{\eta}(\mathbf{s}) \end{cases} \quad \text{with} \quad \begin{cases} \varepsilon = -\frac{\partial G(\mathbf{s})}{\partial \sigma} \\ \eta = -\frac{\partial G(\mathbf{s})}{\partial T} \end{cases}. \quad (2)$$

If heat conduction is to be included, then a constitutive equation relating temperature gradient ∇T and heat flux \mathbf{q} (usually the Fourier equation) is also required. The relation between microscale phenomena and the structure of the macroscale free-energy functions is discussed in (10).

2. A set of *kinetic equations* for the internal variables α . In view of phase transformation hysteresis, these equations generally depend on the past history of the material. Standard practice in most internal variable models is to specify this dependence through equations relating the rates of the internal variables to the state and its time derivatives. The internal state then follows from the solution of differential equations in time:

$$\widehat{\mathbf{F}}(\mathbf{s}, \dot{\mathbf{s}}) = \mathbf{0} \quad \text{typically giving } \dot{\alpha} = \widehat{\mathbf{f}}(\mathbf{s}, \dot{\sigma}, \dot{T}), \quad (3)$$

and often linear in $\dot{\sigma}$ and \dot{T} as well. The superposed dot in Eq. (3) denotes time differentiation.

The full thermomechanical behavior of a system involving SMM is then described by a complete “initial value problem”: *given an initial state, an initial time, and an arbitrary loading history, predict the state reached by the system at subsequent times.* This initial value problem is governed by the preceding constitutive equations together with appropriate initial and boundary conditions and with the physical laws of:

Energy conservation (first law of thermodynamics)

$$\dot{e} = \sigma \cdot \dot{\varepsilon} + \dot{Q}, \quad (4)$$

Conservation of linear momentum (equation of motion)

$$\text{div } \sigma = \rho \ddot{\mathbf{u}} - \mathbf{b}, \quad (5)$$

Entropy balance and Clausius-Duhem inequality (second law of thermodynamics)

$$\Gamma = \dot{\eta} - \frac{\dot{Q}}{T} \quad \text{and} \quad \Gamma \geq 0, \quad (6)$$

where e is the internal energy, ρ the mass density, \dot{Q} the rate of heat exchange with the environment (positive if absorbed by the SMM), \mathbf{u} the displacement, \mathbf{b} the body force density, and Γ the internal entropy density production rate. The Gibbs free energy is $G = e - T\eta - \sigma \cdot \varepsilon$.

Although sometimes employing formalisms that are quite different, several models fitting into this basic framework have been proposed to describe SMM behavior. Irrespective of their derivation, they involve a constitutive description prescribed via state equations and kinetic equations. Differences involve the choice and interpretation of the internal variables α and the form of the kinetic equations. The following survey proceeds in chronological order, using a common notation that may depart from that of the original work.

One of the first explicit macroscopic models for SMM has been given by Tanaka and his coworkers for uniaxial isothermal pseudoelasticity (28). This model for $\mathbf{A} \leftrightarrow \mathbf{M}$ transformation employs one scalar internal variable, the martensite fraction ξ_M , together with strain and temperature as control variables so that $\alpha = \{\xi_M\}$ and $\mathbf{s} = \{\varepsilon, T, \xi_M\}$. The constitutive equation for stress is given as $\sigma = L(\varepsilon - \varepsilon^*)$, where the overall transformation strain is $\varepsilon^* = \gamma^* \xi_M$. Here L is the elastic modulus and γ^* the local transformation strain, both of which are regarded as material parameters. The kinetic equation for the martensite fraction ξ_M is derived from a dissipation potential resulting in a form analogous to the exponential Koistinen-Marburger relation used in metallurgy. The kinetic equation is especially simple and so enables closed form integration to give

$$\xi_M = \begin{cases} 1 - e^{\beta_F} & (\mathbf{A} \rightarrow \mathbf{M}) \\ e^{\beta_R} & (\mathbf{M} \rightarrow \mathbf{A}) \end{cases} \quad \text{with} \quad \begin{cases} \beta_F = a_M(M_s - T) + b_M \sigma, \\ \beta_R = a_A(A_s - T) + b_A \sigma, \end{cases}$$

where a_M, b_M, a_A and b_A are material constants.

In 1987 Frémond proposed a three-dimensional model based on the following state description:

$$\mathbf{s} = \{\varepsilon, T, \xi_A, \xi_+, \xi_-, \nabla \xi_A, \nabla \xi_+, \nabla \xi_-\},$$

where ξ_A, ξ_+, ξ_- are the fractions of austenite and two martensite variants and ∇ denotes gradient (29). The free energy is the sum of the pure phase energies weighted by the respective fractions plus a term aimed to enforce the constraint $\xi_A + \xi_+ + \xi_- = 1$. The evolution equations are derived from a dissipation potential. The balance equations governing the model are derived on the basis of the principle of virtual power taking into account explicitly the contribution of the internal variables. The model performances are discussed within simplified constitutive assumptions, and show the ability of the model to capture the main qualitative features of pseudoelasticity and low temperature reorientation.

In 1988 Bondaryev and Wayman developed a multi-surface plasticity theory for SMM to account for three-dimensional isothermal pseudoelasticity and reorientation (30). This yields a three-dimensional framework that would allow for the generalization of many of the uniaxial stress models that are the major focus of this article. The macroscopic transformation strain tensor ε^* is treated as an internal variable on its own so that $\mathbf{s} = \{\sigma, T, \varepsilon^*\}$. Free energies are given for the austenite phase and for a general martensite phase in which the transformation strain is of arbitrary orientation. The free-energy difference among the phases initiates the transformation activity when resistive the thresholds are met. This defines temperature-dependent threshold surfaces in stress space, which are analogous to traditional yield surfaces. These surfaces, govern transformation strain accumulation ($\mathbf{A} \rightarrow \mathbf{M}$), reduction ($\mathbf{M} \rightarrow \mathbf{A}$), and reorientation ($\mathbf{M} \rightarrow \mathbf{M}$). The change in transformation strain proceeds according to a normality condition with respect to these threshold surfaces and so determines the orientation of a transformation strain increment. This gives:

- $\mathbf{A} \rightarrow \mathbf{M}$: Transformation strain increment $d\varepsilon^*$ coaxial with the stress deviator
- $\mathbf{M} \rightarrow \mathbf{A}$: Transformation strain annihilated without regard to stress orientation
- $\mathbf{M} \rightarrow \mathbf{M}$: $d\varepsilon^*$ oriented according to the difference between the current stress deviator orientation and the current ε^* orientation

The magnitude of the transformation strain increment follows by analogy to traditional yield surface plasticity. Under hardening, continued plastic straining requires a sustained increase in stress. A consistency condition for remaining on the evolving yield surface then determines the magnitude of the plastic strain increment. In the absence of hardening, the yield surface is fixed so that continued plastic straining can be sustained under constant stress. The magnitude of the plastic strain increment is then determined from boundary conditions. Bondaryev-Wayman initially present $\mathbf{A} \rightarrow \mathbf{M}$ and $\mathbf{M} \rightarrow \mathbf{A}$ thresholds that do not harden (corresponding to $M_s = M_f$ for $\mathbf{A} \rightarrow \mathbf{M}$ and $A_s = A_f$

for $\mathbf{M} \rightarrow \mathbf{A}$). In contrast, the $\mathbf{M} \rightarrow \mathbf{M}$ reorientation threshold is naturally dependent on the current ε^* and so exhibits a changing form analogous to hardening. At any instant of time there may be (1) no transformation, (2) a single transformation from among $\mathbf{A} \rightarrow \mathbf{M}$, $\mathbf{M} \rightarrow \mathbf{A}$, $\mathbf{M} \rightarrow \mathbf{M}$, or (3) a multiple transformation consisting of $\mathbf{M} \rightarrow \mathbf{M}$ in concert with one of $\mathbf{M} \rightarrow \mathbf{A}$, $\mathbf{A} \rightarrow \mathbf{M}$. Case 3 requires the determination of a transformation strain incremental multiplier for each simultaneous process. Modifications are then presented for $\mathbf{A} \rightarrow \mathbf{M}$ and $\mathbf{M} \rightarrow \mathbf{A}$ threshold hardening ($M_s > M_f$ and $A_s < A_f$). The few model predictions that are presented confirm the correct qualitative features of this approach, but a detailed discussion of the full range of model predictions is not given.

Muller and his coworkers (31) proposed one of the first models for stress–strain curve sublooping when phase transformations do not go to completion. The main constitutive ingredient of the theory is an overall Helmholtz free energy of the form

$$\Phi(\varepsilon_A, \varepsilon_M, T, \xi_M) = (1 - \xi_M) \phi_A(\varepsilon_A, T) + \xi_M \phi_M(\varepsilon_M, T) + \Omega \xi_M (1 - \xi_M),$$

where ϕ_A , ϕ_M , ε_A , ε_M are the free energies and strains of the pure phases and ξ_M is the martensite fraction internal variable. The last term is a phase interaction energy, with Ω being a material parameter. The overall strain is $\varepsilon = (1 - \xi_M)\varepsilon_A + \xi_M\varepsilon_M$. Values of ξ_M , ε_A , and ε_M are determined by minimizing Φ under strain constraint. As in the models of Ericksen (4) and Falk (20), the resulting uniaxial stress–strain response is nonmonotone with the negative slope part being unstable. Constant stress lines from the maxima and minima define a stress–strain outer envelope loop associated with complete transformations. The unstable negative slope portion of the stress–strain response then provides a triggering threshold for phase transformations within the interior of the stress–strain envelope (Fig. 6). The associated model for internal sublooping determines the evolution of ξ_M and so, roughly speaking, plays a similar role to the kinetic evolution equations in other internal variable models.

Ortin and planes have developed a detailed thermodynamic framework for SMM materials (32) that provides a basis for thermomechanical modeling and the experimental determination of material characterization parameters. They develop a model uniaxial stress, describing the state as $\mathbf{s} = \{\sigma, T, \xi_M\}$. Energy balance during phase transformation generates a transformation kinetic in which the free-energy differential during transformation is balanced by the sum of an elastic energy storage rate differential and an energy dissipation rate differential. The evolution of σ and T then determines the evolution of ξ_M once the dissipation rate is given a constitutive prescription. Dissipation functions can be constructed so as to ensure known qualitative aspects of phase transformation hysteresis, including fine sublooping features. Experimental data fitting with reference to purely thermal transformation allows for explicit functional forms. Full stress–strain–temperature dependence for uniaxial $\mathbf{A} \leftrightarrow \mathbf{M}$ transformation then follows.

In 1990, Liang and Rogers proposed a modification of the Tanaka $\mathbf{A} \leftrightarrow \mathbf{M}$ transformation model so as to account

for the effect of phase fraction values at the beginning of the transformation in the event of an initial phase mixture (33). This allows for the treatment of internal subloops. They also replaced the exponential Koistinen-Marburger kinetic equation with a trigonometric expression, giving

$$\xi_M = \begin{cases} \frac{1 - \xi_0}{2} \cos \beta_F + \frac{1 + \xi_0}{2}, & (\mathbf{A} \rightarrow \mathbf{M}), \\ \frac{\xi_0}{2} \cos \beta_R + 1, & (\mathbf{M} \rightarrow \mathbf{A}), \end{cases}$$

where ξ_0 is the value of ξ_M when the transformation process is first activated and β_F, β_R are as given previously.

In 1992, Raniecki, Tanaka, and Lexcellent proposed a model for three-dimensional pseudoelasticity based on the martensite fraction as internal variable so that $\mathbf{s} = \{\varepsilon, T, \xi_M\}$ (34). They proposed a Helmholtz free-energy function in the form

$$\Phi(\mathbf{s}) = \frac{1}{2}(\varepsilon - \varepsilon^*) \cdot \mathbf{L}(\varepsilon - \varepsilon^*) - (T - T_0) \mathbf{m} \cdot \mathbf{L}(\varepsilon - \varepsilon^*) + E^{ch}(T) + \Omega(T)\xi_M(1 - \xi_M),$$

where \mathbf{m} provides thermal expansion coefficients, E^{ch} is the chemical free energy and the last term is the phase interaction energy. The overall transformation strain tensor is given as $\varepsilon^* = \gamma^* \xi_M$. The local transformation strain tensor γ^* is assumed to be traceless and coaxial with the strain deviator. In this context the phase equilibrium corresponds to the vanishing of the quantity $\Pi = \partial \Phi / \partial \xi_M$, which is identified as the driving force for $\mathbf{A} \leftrightarrow \mathbf{M}$ phase transformation. The condition $\Pi = 0$ gives rise to a stress–strain curve with a descending branch which, as in Muller’s model, triggers the activation of certain transformations (Fig. 6). Here, however, the transformation evolution is described by a kinetic equation for ξ_M . A generalized expression for such a kinetic equation is proposed and includes the exponential form of Tanaka as a special case. Subsequent development of the model includes the incorporation of micromechanical considerations into the derivation of the free energy and the proposal of a modified relation between γ^* and the state

Figure 6. Modeling of subloops in a model of Muller (31). The upper and lower constant stress lines arise as in Fig. 5 and bound an internal region in stress–strain space where subloops can occur. If a transformation associated with these bounding lines is interrupted before completion due to load reversal, then the stress–strain path enters the internal region. The reverse transformation is only activated if the internal path encounters the negatively sloped line associated with unstable stress–strain response.

variables so as to capture an optimal variant arrangement on the assumption that the actual value of γ^* minimizes the free energy.

In 1993, Brinson proposed a further extension of the Tanaka-Liang-Rogers model in order to distinguish between stress-induced (oriented) martensite and thermally induced (unbiased) martensite (35). Accordingly, $\xi_M = \xi_s + \xi_T$ where ξ_s is the fraction of stress-induced martensite resulting in a local transformation strain γ^* and ξ_T is the fraction of thermally induced self-accommodated martensite resulting in a zero transformation strain. Hence $\alpha = \{\xi_s, \xi_T\}$, and the resulting model gives a true shape-memory capability, formally absent in the earlier Tanaka-Liang-Rogers model, in that transformation strain at zero stress is annihilated on heating without reappearing on cooling. Kinetic equations for ξ_s and ξ_T then model both $\mathbf{A} \leftrightarrow \mathbf{M}$ pseudoelasticity and low-temperature conversion of thermally induced martensite to oriented martensite under isothermal uniaxial stress. Subsequent development explicitly correlates the kinetic equations to the (σ, T) -phase diagram, with the resulting model permitting both analytical and numerical treatment of initial value problems for uniaxial response (36).

In 1994, Ivshin and Pence proposed a model for uniaxial pseudoelasticity based on $\mathbf{s} = \{\sigma, T, \xi_A\}$, where $\xi_A = 1 - \xi_M$ is the austenite phase fraction (24,37). State equations are given for strain and entropy by assuming that the pure phases are subject to a common overall stress. Kinetic equations are given in terms of the Duhem-Madelung hysteresis algorithm. Both stress and temperature-induced $\mathbf{A} \leftrightarrow \mathbf{M}$ transformation are treated in a unifying thermodynamic framework by the identification of the proper driving input via the Clausius-Clapeyron equation. This allows for a straightforward treatment of arbitrary thermomechanical loading paths in (σT) -space under uniaxial tension. Load-cycling behavior and the resulting shakedown response are then easily determined. Unlike earlier treatments, rate effects due to heating and cooling intrinsic in the $\mathbf{A} \leftrightarrow \mathbf{M}$ transformation are systematically investigated. To treat uniaxial compression in the same framework, Wu and Pence (38) decompose the martensite phase into two martensite variant families \mathbf{M}_+ and \mathbf{M}_- each characterized by its own transformation strain and, respectively, favored under tension (\mathbf{M}_+) or compression (\mathbf{M}_-). Accordingly, $\xi_M = \xi_+ + \xi_-$, leading to $\mathbf{s} = \{\sigma, T, \xi_+, \xi_-\}$. In this setting, unbiased (thermally induced) martensite is the specific mixture of the two variant families giving zero overall transformation strain. While maintaining all of the features of the Ivshin-Pence formulation, the Wu-Pence model provides a complete uniaxial description for SMM not only at temperatures near A_f but also at temperatures well below M_f where reorientation applies.

In Lubliner and Auricchio (39), a three-dimensional model for isothermal pseudoelasticity is proposed on the basis of $\mathbf{s} = \{\sigma, T, \xi_M, \mathbf{v}\}$, where \mathbf{v} defines the orientation of ε^* via $\varepsilon^* = \gamma^* \mathbf{v}$ and γ^* is a material parameter. Kinetic equations for \mathbf{v} and ξ_M are given by normality conditions to proper loading functions specified for each type of transformation. A Drucker-Prager form is taken for \mathbf{v} so as to treat the dependence of phase transformation on hydrostatic stress. Pseudoelasticity and high-temperature

reorientation as induced by nonproportional loads are considered. In the uniaxial setting, the Brinson decomposition $\xi_M = \xi_s + \xi_T$ is introduced to account for low-temperature reorientation. The extension to finite kinematics is developed. Numerical implementation is given in the context of finite elements.

Boyd and Lagoudas (40) present a three-dimensional model for SMM behavior based on $\mathbf{s} = \{\sigma, T, \xi_M, \varepsilon^*\}$. A free energy with a structure similar to that of Muller is generalized so that the phase interaction term is specified by a series expansion whose coefficients are left to experimental identification. The macroscopic transformation strain rate is decomposed into the sum of a pseudoelastic and a reorientation contribution, $\dot{\varepsilon}^* = \dot{\varepsilon}^{pe} + \dot{\varepsilon}^{re}$. Similar to Tanaka et al. (28), dissipation potentials are used to derive kinetic equations for $\dot{\xi}_M, \dot{\varepsilon}^{re}$, while $\dot{\varepsilon}^{pe}$ is related to the martensite fraction rate via $\dot{\varepsilon}^{pe} = \Lambda \dot{\xi}_M$. The orientation tensor Λ is assumed as coaxial with a modified stress deviator for $\mathbf{A} \rightarrow \mathbf{M}$ transformation, whereas it is aligned with the ε^* deviator for $\mathbf{M} \rightarrow \mathbf{A}$ transformation. Various aspects of the model, such as sublooping, connection with micromechanics, and numerical implementation, have been developed in subsequent papers.

Rajagopal and Srinivasa (41) apply the concept of materials with multiple natural configurations to uniaxial pseudoelasticity with the martensite fraction ξ_M acting as an internal variable. The Green-Naghdi approach to balance and constitutive equations is used together with a principle of maximum dissipation. This elegant treatment accounts for nonisothermal behavior and finite deformations within a rigorous and innovative framework of continuum thermomechanics.

Sittner, Stalmans, and Tokuda (18) have developed a hysteretic model for uniaxial pseudoelasticity based on a martensite fraction that is governed by an evolution equation with a driving force that involves the concept of an effective equilibrium temperature. This effective equilibrium temperature, which generally differs from the actual material temperature, is formally dependent on the martensite volume fraction. Unlike other models, the macroscopic transformation strain is assumed in the form $\varepsilon^* = \chi \gamma^* \xi_M$, where $\chi = \chi(\sigma)$ is a nonlinear stress-dependent function. The model is able to capture a wide variety of sublooping behavior including a notion of return point memory.

Within the setting of finite kinematics Govindjee and Hall (42) present a model based on two martensite variants \mathbf{M}_+ and \mathbf{M}_- . A phase diagram approach is used, and the transformation kinetics are derived by arguments reminiscent to those of Muller-Achenbach and Abeyaratne-Knowles. The resulting model allows for both pseudoelasticity and reorientation. Algorithmic issues specific to finite element implementation are carefully considered, and civil engineering scale applications are presented.

A COMPREHENSIVE MODEL FOR UNIAXIAL STRESS

As seen from the previous section, SMM uniaxial behavior is well understood. This covers a wide range of applications including several kinds of actuators, vibration absorbers,

and applications exploiting the material in the form of wires. Models available for this setting treat reorientation, shape memory, and pseudoelasticity under arbitrary temperature-stress paths so as to reproduce nonisothermal behavior, transformational heating/cooling, and internal subloops. Accordingly, this section summarizes a practical and complete one stress-component material model. It synthesizes aspects of the previous section's discussion with a focus on the complementary roles of state equations and kinetic equations in generating a well-posed and complete model. The development is framed in the context of tensile and compressive loading, although it also applies to other choices of stress component, such as a particular shear stress component. The equations that are presented in the final implementation follow those of Ivshin and Pence (24,37) and Wu and Pence (38), although the discussion is framed so as to permit alternative implementations.

The SMM is treated as subject to *mechanical loads* specified by histories of prescribed stress $\sigma(t)$ or strain $\varepsilon(t)$ or a combination of both (e.g., representing bias springs in actuators among elastic restraints) and *thermal loads* specified by histories of prescribed temperature or heat rate. Alternatively, under mechanical loads, the temperature can be determined as a consequence of the heat exchange with a known environmental temperature T_E .

The state in Eq. (1) is given by $\mathbf{s} = \{\sigma, T, \alpha\}$ with $\alpha = \{\xi_A, \xi_+, \xi_-\}$ subject to

$$\xi_A + \xi_+ + \xi_- = 1, \quad 0 \leq \xi_A \leq 1, \quad 0 \leq \xi_+ \leq 1, \quad 0 \leq \xi_- \leq 1. \quad (7)$$

The \mathbf{M}_+ family has an associated scalar transformation strain $\gamma_+^* > 0$, representing the maximum positive macroscopic transformation strain when an \mathbf{M}_+ microstructure is maximally oriented with the tensile stress. Similarly, the \mathbf{M}_- family has an associated scalar transformation strain $-\gamma_-^* < 0$. The positive constants γ_+^*, γ_-^* are basic material parameters.

State Equations for Strain and Entropy

The first group of constitutive equations are obtained from a Gibbs free energy that is taken as

$$G(s) = \xi_A g_A(\sigma_A, T) + \xi_+ g_+(\sigma_+, T) + \xi_- g_-(\sigma_-, T), \quad (8)$$

where g_A, g_+, g_- and $\sigma_A, \sigma_+, \sigma_-$ are the free energies and the stresses relative to the pure phase. The phase stresses depend on the microstructural phase arrangement. This arrangement is henceforth regarded as giving

$$\sigma_A = \sigma_+ = \sigma_- = \sigma. \quad (9)$$

In conditions different from Eq. (9), an additional term expressing the interaction energy between the phases would otherwise arise (10). In the present model, hysteresis properties that would be influenced by such an interaction energy are instead modeled with the aid of envelope functions introduced below. This permits easy specification of desired thermal hysteresis properties.

Standard forms for the pure phase free energies are

$$\begin{aligned} g_A &= -\frac{1}{2} \frac{\sigma^2}{E_A} - m_A \sigma (T - T^*) + C_A \left(T - T^* + T \ln \frac{T}{T^*} \right) \\ &\quad - \eta_{A0} (T - T^*) + g_{A0}, \\ g_+ &= -\frac{1}{2} \frac{\sigma^2}{E_+} - \gamma_+^* \sigma - m_+ \sigma (T - T^*) + C_+ \left(T - T^* + T \ln \frac{T}{T^*} \right) \\ &\quad - \eta_{+0} (T - T^*) + g_{+0}, \\ g_- &= -\frac{1}{2} \frac{\sigma^2}{E_-} + \gamma_-^* \sigma - m_- \sigma (T - T^*) + C_- \left(T - T^* + T \ln \frac{T}{T^*} \right) \\ &\quad - \eta_{-0} (T - T^*) + g_{-0}. \end{aligned} \quad (10)$$

Here E_A, E_+, E_- are the elastic moduli; m_A, m_+, m_- are the coefficients of thermal expansion, and C_A, C_+, C_- are the specific heats at constant stress of the various phases. The expressions (10) make use of a stress-temperature reference state $(\sigma, T) = (0, T^*)$, which is regarded as at the center of the multiphase region of Fig. 1 by taking T^* as the average of the four transformation temperatures. The constants $\eta_{A0}, \eta_{+0}, \eta_{-0}$ and g_{A0}, g_{+0}, g_{-0} are the single-phase entropies and single-phase free energies at this reference state. Additional simplification follows by assuming the following:

- A common specific heat C in martensite and austenite.
- A common reference state entropy η_{M0} in all martensite variants.
- Negligible thermal expansion.
- Negligible slip plasticity.

None of these simplifications is essential, and the associated generalizations are easily made. According to the general formulation, the macroscopic strain and entropy follow from Eq. (2) as

$$\varepsilon = -\frac{\partial G}{\partial \sigma} = \bar{D}\sigma + \varepsilon^*, \quad \eta = -\frac{\partial G}{\partial T} = C \ln \frac{T}{T^*} + \bar{\eta}_0, \quad (11)$$

where

$$\begin{aligned} \bar{D}(\xi) &= \frac{\xi_-}{E_-} + \frac{\xi_A}{E_A} + \frac{\xi_+}{E_+}, \quad \varepsilon^*(\xi) = \xi_+ \gamma_+^* - \xi_- \gamma_-^* \\ \bar{\eta}_0(\xi) &= (\xi_+ + \xi_-) \eta_{M0} + \xi_A \eta_{A0}. \end{aligned} \quad (12)$$

Here $\varepsilon^*(\xi)$ is again the transformation strain, and $\bar{D}(\xi)$ is the Reuss estimate of the effective compliance. Introduce $\Delta \eta_0 = \eta_{A0} - \eta_{M0}$, whereupon $\bar{\eta}_0(\xi) = \eta_{M0} + \xi_A \Delta \eta_0$. Other than the baseline value of η in Eq. (11), the model dependence on η_{M0} and η_{A0} is only via the basic material parameter $\Delta \eta_0 > 0$. It is given by $\Delta \eta_0 = \Delta H / T^*$ where ΔH is the latent heat of the $\mathbf{M} \rightarrow \mathbf{A}$ transformation as measured from calorimetry.

These considerations account for the following essential material parameters: $M_f, M_s, A_s, A_f, \Delta \eta_0$ (or ΔH), $E_A, E_+, E_-, \gamma_+^*, \gamma_-^*, C$. These eleven parameters are sufficient for modeling the basic SMM behavior with the exception of $\mathbf{M} \leftrightarrow \mathbf{M}_+$ reorientation. As will be explained in what follows, reorientation is modeled by including four

additional material parameters $\sigma_s^+, \sigma_f^+, \sigma_s^-, \sigma_f^-$. All 15 material parameters are taken to be positive by definition.

Phase Transformation Kinetics

The second group of constitutive equations give the phase transformation kinetics. The model derives such equations from two constitutive ingredients that are, in principle, both experimentally measurable:

- The *phase diagram* that defines the loci of the points in the stress-temperature plane in which the various phase transformations can be activated (an example of which is reported in Fig. 1).
- The *envelope functions* $\zeta_{M \rightarrow A}(T)$ and $\zeta_{A \rightarrow M}(T)$ that, as explained below, determine the equations for the internal variables thus describing how the phase transformations evolve once activated.

Here, $\zeta_{A \rightarrow M}(T)$ is the value of ξ_A associated with $\sigma = 0$ and T decreasing from above A_f to below M_f . Similarly, $\zeta_{M \rightarrow A}(T)$ is the value of ξ_A associated with $\sigma = 0$ and T increasing from below M_f to above A_f . Each function has a graph that monotonically increases from zero to one as T increases over an appropriate interval: $M_f < T < M_s$ for $\zeta_{A \rightarrow M}(T)$; $A_s < T < A_f$ for $\zeta_{M \rightarrow A}(T)$. In the absence of detailed experimental data, these functions can be approximated on their transition interval. The simplest approximation is a linear function of T , but this gives a slope change at the associated start and finish temperatures. Such slope changes give rise to sharp corners on the model stress-strain curves at the beginning and end of the transformation plateaus. Smoother forms, which eliminate such corners, involve hyperbolic or trigonometric functions. A simple and useful representation is the Liang-Rogers trigonometric form:

$$\begin{aligned}\zeta_{M \rightarrow A}(T) &= \frac{1}{2} \left\{ 1 - \cos \left(\left(\frac{T - A_s}{A_f - A_s} \right) \pi \right) \right\}, \\ \zeta_{A \rightarrow M}(T) &= \frac{1}{2} \left\{ 1 - \cos \left(\left(\frac{T - M_f}{M_s - M_f} \right) \pi \right) \right\}\end{aligned}\quad (13)$$

on the transition intervals with

$$\zeta_{M \rightarrow A} = \begin{cases} 0 & \text{if } T \leq A_s, \\ 1 & \text{if } T \geq A_f, \end{cases} \quad \zeta_{A \rightarrow M} = \begin{cases} 0 & \text{if } T \leq M_f, \\ 1 & \text{if } T \geq M_s. \end{cases}$$

For the sake of clarity of exposition, it is useful to discuss the features of the phase transformation kinetics with reference first to purely thermal transformation and then to combined stress and thermally induced transformation.

Purely Thermal Transformation. In this case the driving input is the temperature history $T(t)$. Times t of temperature reversal are *switching instants*. The martensite is then unbiased in that it involves \mathbf{M}_+ and \mathbf{M}_- in the ratio γ_+^* to γ_-^* so as to give $\varepsilon^* = 0$. Thus $\xi_+ = \lambda_+ \xi_M$ and $\xi_- = \lambda_- \xi_M$, where the constants λ_+ and λ_- are given by

$$\lambda_+ = \frac{\gamma_-^*}{\gamma_+^* + \gamma_-^*}, \quad \lambda_- = \frac{\gamma_+^*}{\gamma_+^* + \gamma_-^*}, \quad (14)$$

and $\xi_M = \xi_+ + \xi_- = 1 - \xi_A$ is the overall martensite fraction. The transformation kinetic reduces to the determination of ξ_A as T changes. The graph of ξ_A versus T will generally involve complicated sublooping if there are numerous switching instants obeying $M_f < T < A_f$ that prevent the $\mathbf{M} \rightarrow \mathbf{A}$ and $\mathbf{A} \rightarrow \mathbf{M}$ transformations from going to completion. However, no matter how complicated, this graph will be contained between the two envelope functions so that $\zeta_{M \rightarrow A}(T) \leq \xi_A \leq \zeta_{A \rightarrow M}(T)$.

The phase transformation kinetic is now proposed by means of a Duhem-Madelung (D-M) differential equation of the form:

$$\begin{aligned}\dot{\xi}_M &= H_{A \rightarrow M}(\xi_A, T) \dot{T} \quad \text{if } \dot{T} \leq 0 \quad (\mathbf{A} \rightarrow \mathbf{M}), \\ \dot{\xi}_M &= H_{M \rightarrow A}(\xi_M, T) \dot{T} \quad \text{if } \dot{T} \geq 0 \quad (\mathbf{M} \rightarrow \mathbf{A}).\end{aligned}\quad (15)$$

These equations, in conjunction with the conservation condition $\xi_A + \xi_M = 1$, determines ξ_A, ξ_M from the prevailing conditions at the last switching instant. Each D-M equation in (15) can be given a time independent form, such as $d\xi_M/dT = H_{A \rightarrow M}(\xi_A, T)$ for $\mathbf{A} \rightarrow \mathbf{M}$. The centerpieces of Eq. (15) are the *governing functions* $H_{M \rightarrow A}$ and $H_{A \rightarrow M}$, which must be formulated so that the phase fraction obeys the envelope containment condition $\zeta_{M \rightarrow A}(T) \leq \xi_A \leq \zeta_{A \rightarrow M}(T)$. Envelope coincidence must occur for transformations that begin from a pure \mathbf{M} or a pure \mathbf{A} state so long as temperature reversal is avoided. The following general form for the governing functions ensures these properties:

$$\begin{aligned}H_{A \rightarrow M}(\xi_A, T) &= - \left(\frac{\xi_A}{\zeta_{A \rightarrow M}(T)} \right)^n \frac{d\zeta_{A \rightarrow M}(T)}{dT}, \\ H_{M \rightarrow A}(\xi_M, T) &= - \left(\frac{\xi_M}{1 - \zeta_{M \rightarrow A}(T)} \right)^n \frac{d\zeta_{M \rightarrow A}(T)}{dT},\end{aligned}\quad (16)$$

where $n > 0$ is a constant. Larger values of n give flatter internal subloops. The choice $n = 1$ gives a standard D-M model for shape-memory materials (24). Experimental magnetic susceptibility measurements (43) indicate that enhanced experimental correlation is obtained for n near $n = 3$. Further refinements and modifications can be invoked, and certain sublooping situations that are difficult to describe with a D-M equation have been noted (44). Some examples of (T, ξ_A) -trajectories within the bounding envelope functions are shown in Fig. 7.

The purely thermal process involves simultaneous $\mathbf{A} \rightarrow \mathbf{M}_+$ and $\mathbf{A} \rightarrow \mathbf{M}_-$ transformation for temperature decrease, and simultaneous $\mathbf{M}_+ \rightarrow \mathbf{A}$ and $\mathbf{M}_- \rightarrow \mathbf{A}$ transformation for temperature increase, always with $\xi_+ = \lambda_+ \xi_M$ and $\xi_- = \lambda_- \xi_M$. It follows that ξ_M can be eliminated from Eq. (15) by rewriting them as

$$\begin{aligned}\dot{\xi}_+ &= \lambda_+ H_{A \rightarrow M}(\xi_A, T) \dot{T} \quad \text{if } \dot{T} \leq 0 \quad (\mathbf{A} \rightarrow \mathbf{M}_+), \\ \dot{\xi}_+ &= \lambda_+ H_{M \rightarrow A} \left(\frac{\xi_+}{\lambda_+}, T \right) \dot{T} \quad \text{if } \dot{T} \geq 0 \quad (\mathbf{M}_+ \rightarrow \mathbf{A}),\end{aligned}\quad (17)$$

and

$$\begin{aligned}\dot{\xi}_- &= \lambda_- H_{A \rightarrow M}(\xi_A, T) \dot{T} \quad \text{if } \dot{T} \leq 0 \quad (\mathbf{A} \rightarrow \mathbf{M}_-), \\ \dot{\xi}_- &= \lambda_- H_{M \rightarrow A} \left(\frac{\xi_-}{\lambda_-}, T \right) \dot{T} \quad \text{if } \dot{T} \geq 0 \quad (\mathbf{M}_- \rightarrow \mathbf{A}).\end{aligned}\quad (18)$$

Figure 7. Magnetic susceptibility versus T under purely thermal loading for a NiTi thin film as determined by measurement (*above*). Magnetic susceptibility correlates directly with austenite phase fraction. Both the outer hysteresis loops for cooling (upper envelope) and heating (lower envelope) are shown. The internal curves leave the upper envelope if T is increased before $\mathbf{A} \rightarrow \mathbf{M}$ transformation is complete. This behavior is modeled (*below*) on the basis of Eq. (15), with a hyperbolic tangent envelope form and $H_{M \rightarrow A}$ governing function with $n = 3$.

These equations, in conjunction with Eq. (7), determine the evolution of the phase fraction variables ξ_A, ξ_+, ξ_- for purely thermal transformation. Although unwieldy compared to Eq. (15), the alternative formulations (17) and (18) recast the phase transformation kinetic in terms of the internal variables $\alpha = \{\xi_A, \xi_+, \xi_-\}$.

Pseudoelasticity. While temperature is the driving input in the purely thermal case, under simultaneous change in temperature and stress, the functions

$$\begin{aligned} \Pi_{+A}(\sigma, T) &:= \frac{\partial G}{\partial \xi_+} - \frac{\partial G}{\partial \xi_A} = -\gamma_+^* \sigma + \Delta \eta_0 (T - T^*) \\ &\quad - \frac{1}{2} \left(\frac{1}{E_+} - \frac{1}{E_A} \right) \sigma^2, \\ \Pi_{-+}(\sigma, T) &:= \frac{\partial G}{\partial \xi_-} - \frac{\partial G}{\partial \xi_+} = (\gamma_+^* + \gamma_-^*) \sigma - \frac{1}{2} \left(\frac{1}{E_-} - \frac{1}{E_+} \right) \sigma^2, \\ \Pi_{-A}(\sigma, T) &:= \frac{\partial G}{\partial \xi_-} - \frac{\partial G}{\partial \xi_A} = \gamma_-^* \sigma + \Delta \eta_0 (T - T^*) \\ &\quad - \frac{1}{2} \left(\frac{1}{E_-} - \frac{1}{E_A} \right) \sigma^2, \end{aligned} \quad (19)$$

are the more generalized driving forces for the respective transformations $\mathbf{M}_+ \leftrightarrow \mathbf{A}$, $\mathbf{M}_- \leftrightarrow \mathbf{M}_+$, and $\mathbf{M}_- \leftrightarrow \mathbf{A}$. Changes in (σ, T) that cause Π_{+A} , Π_{-+} , and Π_{-A} to increase favor $\mathbf{M}_+ \rightarrow \mathbf{A}$, $\mathbf{M}_- \rightarrow \mathbf{M}_+$, and $\mathbf{M}_- \rightarrow \mathbf{A}$, respectively.

Conversely, the decrease favors transformation in the opposite direction. The associated transformation is activated only if the current value of (σ, T) is also within the corresponding transformation zone of the (σ, T) -phase diagram (e.g., see Fig. 1).

The $\mathbf{M}_- \leftrightarrow \mathbf{M}_+$ transformation zone does not extend into $T \geq A_f$, in which case only transformations $\mathbf{M}_+ \leftrightarrow \mathbf{A}$ and $\mathbf{M}_- \leftrightarrow \mathbf{A}$ can occur. Accordingly, for $T \geq A_f$ attention is focused on Π_{+A} and Π_{-A} which are renormalized as follows:

$$\begin{aligned} \beta^+(\sigma, T) &:= \frac{\Pi_{+A}(\sigma, T)}{\Delta \eta_0} + T^* = T - k_1^+ \sigma - k_2^+ \sigma^2, \\ \beta^-(\sigma, T) &:= \frac{\Pi_{-A}(\sigma, T)}{\Delta \eta_0} + T^* = T + k_1^- \sigma - k_2^- \sigma^2, \end{aligned} \quad (20)$$

where $k_1^+ = \gamma_+^* / \Delta \eta_0 > 0$, $k_1^- = \gamma_-^* / \Delta \eta_0 > 0$, $k_2^+ = (E_A - E_+) / (2E_A E_+ \Delta \eta_0) \geq 0$, and $k_2^- = (E_A - E_-) / (2E_A E_- \Delta \eta_0) \geq 0$. The inequalities follow from $\Delta \eta_0 > 0$, $\gamma_+^* > 0$, $\gamma_-^* > 0$, $E_A \geq E_+$, and $E_A \geq E_-$. Under this renormalization $\beta^+(0, T) = T$. For $\sigma \neq 0$, the function $\beta^+(\sigma, T)$ behaves like a “stress-adjusted temperature” that governs the $\mathbf{M}_+ \leftrightarrow \mathbf{A}$ transformation for general changes in (σ, T) . The function $\beta^-(\sigma, T)$ plays a corresponding role with respect to $\mathbf{M}_- \leftrightarrow \mathbf{A}$ transformation.

Extending the purely thermal algorithm with driving input $T(t)$ to the case where the driving input is given by $\sigma(t)$ in conjunction with $T(t) \geq A_f$ amounts to replacing $T(t)$ in Eq. (17) with $\beta^+(\sigma(t), T(t))$ and to replacing $T(t)$ in Eq. (18) with $\beta^-(\sigma(t), T(t))$. This gives

$$\begin{aligned} \dot{\xi}_+ &= \lambda_+ H_{A \rightarrow M}(\xi_A, \beta^+(\sigma, T)) \dot{\beta}^+ \quad \text{if } \dot{\beta}^+ \leq 0, \\ \dot{\xi}_+ &= \lambda_+ H_{M \rightarrow A} \left(\frac{\xi_+}{\lambda_+}, \beta^+(\sigma, T) \right) \dot{\beta}^+ \quad \text{if } \dot{\beta}^+ \geq 0, \end{aligned} \quad (21)$$

and

$$\begin{aligned} \dot{\xi}_- &= \lambda_- H_{A \rightarrow M}(\xi_A, \beta^-(\sigma, T)) \dot{\beta}^- \quad \text{if } \dot{\beta}^- \leq 0, \\ \dot{\xi}_- &= \lambda_- H_{M \rightarrow A} \left(\frac{\xi_-}{\lambda_-}, \beta^-(\sigma, T) \right) \dot{\beta}^- \quad \text{if } \dot{\beta}^- \geq 0. \end{aligned} \quad (22)$$

The switching instants are now times when either $\dot{\beta}^+$ or $\dot{\beta}^-$ changes sign. Note, for example, that

$$\dot{\beta}^+ = \frac{\partial \beta^+}{\partial \sigma} \dot{\sigma} + \frac{\partial \beta^+}{\partial T} \dot{T} = (-k_1^+ - 2k_2^+ \sigma) \dot{\sigma} + \dot{T}.$$

Kinetic Eqs. (21), (22), with the balance condition Eq. (7), determine the evolution of the phase fraction variables ξ_A, ξ_+, ξ_- . According to the structure assumed for $H_{A \rightarrow M}$, $H_{M \rightarrow A}$ and $\zeta_{A \rightarrow M}$, $\zeta_{M \rightarrow A}$, it follows that the $\mathbf{A} \rightarrow \mathbf{M}_+$ and $\mathbf{M}_+ \rightarrow \mathbf{A}$ transformations are activated and completed for those values of (σ, T) such that $\beta^+ = M_s$, $\beta^+ = M_f$, $\beta^+ = A_s$, $\beta^+ = A_f$, respectively. Along with Eq. (20), they define the boundaries of the relevant zones of the (σ, T) phase diagram. A similar remark applies to the transformations $\mathbf{A} \rightarrow \mathbf{M}_-$ and $\mathbf{M}_- \rightarrow \mathbf{A}$ vis-à-vis the function $\beta^-(\sigma, T)$. The strain and entropy follow from Eqs. (11) and (12). The resulting model for $T \geq A_f$ faithfully predicts general

tension/compression asymmetry, pseudoelastic transformation, and pseudoelastic sublooping.

Low-Temperature Reorientation. If the temperature is below A_f , then two additional phenomena have to be taken into account: The $\mathbf{M}_- \leftrightarrow \mathbf{M}_+$ reorientation transformation and the possibility of multiple transformations. An example of the latter is provided in the purely thermal case when $\mathbf{A} \leftrightarrow \mathbf{M}_-$ and $\mathbf{A} \leftrightarrow \mathbf{M}_+$ take place simultaneously. The model can be extended to cover such situations provided a phase diagram is available that describes the activation and the completion of all possible transformations. Equations (21), (22) can then model the additional transformation possibilities provided that the functions $\beta^+(\sigma, T)$ and $\beta^-(\sigma, T)$ are modified from the specification (20) so as to account for the change in zonal geometry of the (σ, T) -phase diagram when $T < A_f$. A modification that accomplishes this purpose and so establishes such a phase diagram is given by

$$\begin{aligned} \beta^+(\sigma, T) &= T - k_1^+ \sigma - k_2^+ \sigma^2 \quad \text{if } \sigma \geq 0, \\ \beta^+(\sigma, T) &= \frac{(A_f - A_s)T - (A_f k_s^+ - A_s k_f^+) \sigma}{A_f - A_s - (k_s^+ - k_f^+) \sigma} \quad \text{if both } \sigma \leq 0 \\ &\quad \text{and } T \geq M_f - k_1^- \sigma + k_2^- \sigma^2, \\ \beta^+(\sigma, T) &= \frac{(A_f - A_s)(M_f - k_1^- \sigma + k_2^- \sigma^2) - (A_f k_s^+ - A_s k_f^+) \sigma}{A_f - A_s - (k_s^+ - k_f^+) \sigma} \\ &\quad \text{if both } \sigma \leq 0 \text{ and } T \leq M_f - k_1^- \sigma + k_2^- \sigma^2, \quad (23) \end{aligned}$$

and

$$\begin{aligned} \beta^-(\sigma, T) &= T + k_1^- \sigma - k_2^- \sigma^2 \quad \text{if } \sigma \leq 0, \\ \beta^-(\sigma, T) &= \frac{(A_f - A_s)T + (A_f k_s^- - A_s k_f^-) \sigma}{A_f - A_s + (k_s^- - k_f^-) \sigma} \quad \text{if both } \sigma \geq 0 \\ &\quad \text{and } T \geq M_f + k_1^+ \sigma + k_2^+ \sigma^2, \\ \beta^-(\sigma, T) &= \frac{(A_f - A_s)(M_f + k_1^+ \sigma + k_2^+ \sigma^2) + (A_f k_s^- - A_s k_f^-) \sigma}{A_f - A_s + (k_s^- - k_f^-) \sigma} \\ &\quad \text{if both } \sigma \geq 0 \text{ and } T \leq M_f + k_1^+ \sigma + k_2^+ \sigma^2. \quad (24) \end{aligned}$$

Again $k_1^+, k_2^+, k_1^-, k_2^-$ are defined after Eq. (20). The new constants: $k_s^+, k_f^+, k_s^-, k_f^-$ are

$$\begin{aligned} k_s^+ &= \frac{A_s - M_f - k_1^- \sigma_s^- - k_2^- (\sigma_s^-)^2}{\sigma_s^-}, \\ k_f^+ &= \frac{A_f - M_f - k_1^- \sigma_f^- - k_2^- (\sigma_f^-)^2}{\sigma_f^-}, \\ k_s^- &= \frac{A_s - M_f - k_1^+ \sigma_s^+ - k_2^+ (\sigma_s^+)^2}{\sigma_s^+}, \\ k_f^- &= \frac{A_f - M_f - k_1^+ \sigma_f^+ - k_2^+ (\sigma_f^+)^2}{\sigma_f^+}. \quad (25) \end{aligned}$$

Contours of constant β^+ and constant β^- give continuous curves on the phase diagram, although each such curve will have up to two sharp corners by virtue of the abrupt

formula changes in Eqs. (23) and (24). Smooth contours more resembling those in Fig. 1 can be obtained by a more complicated redefinition of β^+, β^- .

Note that the phase diagram of Fig. 1 is defined by six continuous curves. The present treatment provides similar such curves. The four curves that continue into $T < M_f$ as approximately constant stress curves parallel to the T -axis are defined by $\beta^+ = A_s$, $\beta^+ = A_f$, $\beta^- = A_s$, and $\beta^- = A_f$. The zone $A_s < \beta^+ < A_f$ bounded by two of these curves, $\beta^+ = A_s$ and $\beta^+ = A_f$, is associated with transformations that deplete \mathbf{M}_+ . This depletion gives $\mathbf{M}_+ \rightarrow \mathbf{A}$ for $\sigma > 0$. For $\sigma < 0$, this depletion gives $\mathbf{M}_+ \rightarrow \mathbf{M}_-$ reorientation provided that T is sufficiently low. The low-temperature threshold for such pure reorientation is given by $T = M_f - k_1^- \sigma + k_2^- \sigma^2$ as specified in Eq. (23). In particular, this $\mathbf{M}_+ \rightarrow \mathbf{M}_-$ reorientation is activated in compression, beginning at $\sigma = -\sigma_s^-$ and finishing at $\sigma = -\sigma_f^-$. The portion of the zone $A_s < \beta^+ < A_f$ that is near the central region of the phase diagram is characterized by $\sigma < 0$ and $T > M_f - k_1^- \sigma + k_2^- \sigma^2$. Here \mathbf{M}_+ transforms into a mixture of \mathbf{A} and \mathbf{M}_- . Similar comments hold with respect to the zone $A_s < \beta^- < A_f$ provided that the roles of \mathbf{M}_+ and \mathbf{M}_- are interchanged. Note that neither zone is specifically associated with depletion of \mathbf{A} . The zone of \mathbf{A} depletion is bounded by the remaining two curves on the phase diagram. These two curves pass through $T = M_s$ and $T = M_f$ on the T -axis and are given by $\beta^+ = M_s$ and $\beta^+ = M_f$ on $\sigma > 0$ and by $\beta^- = M_s$ and $\beta^- = M_f$ on $\sigma < 0$. The austenite depletion is via $\mathbf{A} \rightarrow \mathbf{M}_+$ if σ is sufficiently tensile, and is via $\mathbf{A} \rightarrow \mathbf{M}_-$ if σ is sufficiently compressive. For σ near zero, the depletion of \mathbf{A} is into a mixture of \mathbf{M}_+ and \mathbf{M}_- , as in the case of thermally induced martensite.

In summary, Eqs. (7), (21), and (22) with (23) and (24) now describe general $\mathbf{A} \leftrightarrow \mathbf{M}_+$, $\mathbf{A} \leftrightarrow \mathbf{M}_-$, $\mathbf{M}_- \leftrightarrow \mathbf{M}_+$ transformation throughout the full extent of the (σ, T) -phase diagram. A more detailed discussion is given in Wu and Pence (38) for the special case of symmetric tension/compression behavior. Equations (23), (24) also give the proper tension/compression asymmetry if any of the equalities $\gamma_+^* = \gamma_-^*$, $\sigma_s^+ = \sigma_s^-$, $\sigma_f^+ = \sigma_f^-$, or $E_+ = E_-$ do not hold. As discussed above, this model gives multiple concurrent transformations in the core region of the phase diagram. Low-temperature reorientation involves passing through an unexpressed unstable austenite intermediary (45). Algorithm (15) is recovered under purely thermal transformation. At temperatures $T < A_f$, isothermal tension followed by compression generates open stress-strain curves that are sometimes referred to as ferroelastic response.

Operative Equations for Various Driving Conditions

The set of equations required for the actual computation of SMM response are summarized in the following. This set may be different depending on the conditions in which the material is used and the way that the loading input specified.

If T and σ in the material are prescribed, then the determination of ξ_A, ξ_+, ξ_- proceeds directly on the basis of Eqs. (7), (21), and (22). In this case the strain ε as provided by Eq. (11) decouples from the kinetics.

If T in the material is prescribed, but σ in the material is not, then the first of Eqs. (11) must be solved in conjunction with Eqs. (7), (21), (22). This includes cases where ε is prescribed (various hard constraint situations) or when σ is related to ε by external constraint (e.g., a bias spring).

If T in the material is not prescribed directly, then the complete thermomechanical behavior requires consideration of the material thermal balance and heat exchange with the environment. The heating rate \dot{Q} can be written

$$\dot{Q} = \dot{Q}_{\text{rev}} + \dot{Q}_{\text{irrev}} \quad (26)$$

where, in view of Eq. (6), the reversible contribution is

$$\dot{Q}_{\text{rev}} = T\dot{\eta}. \quad (27)$$

The irreversible contribution $\dot{Q}_{\text{irrev}} = -T\Gamma$ includes dissipative effects that are intrinsic with the phase transformation, and by Eqs. (2), (4), (8), (26), and (27), it can be expressed as

$$\dot{Q}_{\text{irrev}} = \frac{\partial G}{\partial \xi_A} \dot{\xi}_A + \frac{\partial G}{\partial \xi_+} \dot{\xi}_+ + \frac{\partial G}{\partial \xi_-} \dot{\xi}_-. \quad (28)$$

According to Ortin and Planes (46), \dot{Q}_{irrev} can be neglected in a first approximation. More generally,

$$C\dot{T} + T\Delta\eta_0\dot{\xi}_A + \left(\frac{\partial G}{\partial \xi_A} \dot{\xi}_A + \frac{\partial G}{\partial \xi_+} \dot{\xi}_+ + \frac{\partial G}{\partial \xi_-} \dot{\xi}_- \right) = \dot{Q}. \quad (29)$$

Here \dot{Q} provides the heat exchange with the environment and requires additional description to this effect. Important situations in which T is not prescribed include adiabatic conditions and conditions of convective heat transfer to an ambient temperature T_E . The adiabatic case is $\dot{Q} = 0$, and involves no heat exchange with the environment. It is an appropriate model under sustained and rapid mechanical loading. The case of convective heat transfer may often be described by

$$\dot{Q} = \kappa(T_E - T), \quad (30)$$

where $\kappa > 0$ is a known parameter. Here $\kappa \rightarrow 0$ gives the adiabatic limit, while $\kappa \rightarrow \infty$ enforces $T(t) = T_E(t)$. If T is in fact prescribed, then Eqs. (29) and (30) determine either the heat exchange \dot{Q} or the fluid/atmospheric media temperature T_E that is necessary to sustain the prescription. Table 1 summarizes the equations one uses for the determination of ξ_A , ξ_+ , ξ_- .

Table 1. Modeling Equation Summary

Prescribed Quantities		Equations
Stress σ	Temperature T	(7), (21), (22)
Strain ε	Temperature T	(7), (11) ₁ , (21), (22)
Stress σ	Heat rate \dot{Q}	(7), (21), (22), (29)
Strain ε	Heat rate \dot{Q}	(7), (11) ₁ , (21), (22), (29)

Discussion

Some features of the model can be shown explicitly by the presentation of a few representative numerical simulations and experimental validations for a NiTi alloy. The results are given in this section with reference to governing functions (16), with $n = 1$ and tension/compression symmetry, which implies that $\gamma_+^* = \gamma_-^* = \gamma^*$, $\sigma_s^+ = \sigma_s^- = \sigma_s$, $\sigma_f^+ = \sigma_f^- = \sigma_f$, and $E_+ = E_- = E_M$. Under these circumstances, typical values of the full set of material parameters needed by the model are given in Table 2.

Subloops. The subloop model provides internal stress-strain subloops within the fuller stress-strain curve that is associated with complete transformation. Repeated cycling between either fixed stresses or fixed strains causes the subloops to converge onto a final limiting response. This allows for the prediction of shakedown behavior associated with either repeated stress cycling or repeated strain cycling (Fig. 8).

Pseudoelasticity and Reorientation. For $T > A_f$, combined tension/compression loading gives transformation behavior that alternates: $\mathbf{A} \rightarrow \mathbf{M}_+ \rightarrow \mathbf{A} \rightarrow \mathbf{M}_- \rightarrow \mathbf{A} \rightarrow \mathbf{M}_+ \rightarrow \dots$. As the temperature is lowered, the model gives isothermal stress-strain behavior with plateau stresses that decrease with temperature in the correct way. Once the temperature is lowered below A_f , the isothermal stress-strain behavior under tension/compression begins to involve $\mathbf{A} \leftrightarrow \mathbf{M}$ transformation in conjunction with direct $\mathbf{M}_- \leftrightarrow \mathbf{M}_+$ reorientation. The model Eqs. (7), (21), (22) track this multiple transformation activity. The model also retrieves pure $\mathbf{M}_- \leftrightarrow \mathbf{M}_+$ reorientation with temperature-independent plateau stresses when $T < M_f$. For $T < A_f$, isothermal tension/compression loading excursions

Figure 8. Stress cycling between 150 MPa and 400 MPa is modeled at $T = 315 \text{ K} > A_f$ using the trigonometric envelope functions (13) and D-M governing functions (16) with $n = 1$. Each new loop is richer in \mathbf{M}_+ and leaner in \mathbf{A} than the previous loop. After about five transient loops, the response has converged to a repeating loop that stabilizes the cycling between \mathbf{A} and \mathbf{M}_+ .

Figure 9. Stress cycling between -150 MPa and 150 MPa is modeled at $T = 235$ K $> M_f$ using the same envelope and governing functions as in Fig. 8. Here $\sigma_s^+ = -\sigma_s^- = 120$ MPa and $\sigma_f^+ = -\sigma_f^- = 210$ MPa. Since $120 < 150 < 210$ MPa, the cycling generates a sequence of transformations: $\mathbf{M}_- \rightarrow \mathbf{M}_+ \rightarrow \mathbf{M}_- \rightarrow \mathbf{M}_+ \rightarrow \dots$, all of which are incomplete. The convergent stable loop is symmetric, because the particular material parameter choice represents a tension/compression symmetric material.

generate open stress–strain curves (ferroelasticity). As is the case for high-temperature behavior, loop convergence takes place under repeated cycling. The convergence is immediate after the first cycle if the stress or strain magnitude is sufficient to complete all of the transformations. If, however, the cycling magnitudes do not cause complete transformation, then the curves again shake down to their limiting response (Fig. 9).

Nonisothermal Pseudoelasticity. Rate dependency follows from this model under the common condition of convective heat transfer as described by Eqs. (29), (30). For fixed κ , faster loading gives less phase transformation because convection inefficiency gives heat retention that works against the $\mathbf{A} \leftrightarrow \mathbf{M}$ transformation. The adiabatic limit is approached under very rapid loading. The opposite limit of isothermal transformation occurs under very slow loading. Figure 10 shows the connection among isothermal, convective, and adiabatic loading as predicted by this modeling.

Experimental Validation. As an example of validation of the model, we report a comparison of the model predictions with experimental data. Figure 11 shows the results of mechanical loading tests with temperature measurements performed on 1 mm near equiatomic commercial grade NiTi wires (47) and the corresponding prediction of the model after straightforward material parameter identification. The comparison gives excellent agreement in predicting sublooping behavior and temperature change under the combined conditions of cyclic loading, transformational heating/cooling, and convective heat transfer.

Further features of the model that also follow but are not obvious from the previous figures include temperature-dependent stress–strain curves due to the change in pseudoelastic yield stress with temperature, stress-free strain upon unloading due to the presence of stress-induced martensite, and the shape-memory effect.

Figure 10. Three stress–strain simulations beginning at $T = 323$ K $> A_f$ (above). This simulation uses a hyperbolic tangent envelope function and slightly changed material parameters suggestive of a different NiTi material microstructure (e.g., $A_f = 315$ K, $E_M = 20000$ MPa). The extended stress–strain curve is the isothermal response. The curve on the far left is the adiabatic response, and the middle curve models heat transfer to $T_E = 323$ K over 20 s loading and unloading intervals. Nonisothermal loading gives heating since $\mathbf{A} \rightarrow \mathbf{M}_+$ is exothermic. Nonisothermal unloading gives cooling since $\mathbf{M}_+ \rightarrow \mathbf{A}$ is endothermic. Under adiabatic conditions, the cooling returns the material temperature back to $T = 323$ K at the conclusion of unloading. Under convective conditions, there is temperature undershoot on unloading (below) because of net heat transfer to the generally cooler ambient.

SUMMARY AND CONCLUSIONS

The thermomechanical stress–strain–temperature behavior of SMM can be modeled so as to predict shape memory, pseudoelasticity, and martensite reorientation. In order to achieve broad engineering utility, it is also necessary to predict sublooping, shakedown, and nonisothermal behavior. Current models can reliably capture these effects under

Figure 11. Comparison of this modeling (red) to measured response (black) in a NiTi wire at a loading rate for which convection is important.

simple states of stress such as uniaxial tension or simple shear. These settings cover a rather wide range of applications such as actuators, vibrations absorbers and other devices. Models for multi-axial loads are not yet as thoroughly validated with experiment, especially with regard to reorientation under nonproportional loading. As was indicated by the literature surveyed above, these models differ principally in how refined a description of the microstructure is implicit in their framework. Some models explicitly treat interactions between microstructural entities, whereas others treat the effect of microstructural evolution in a thermodynamic framework with consolidated internal variables.

A brief description of a generally useful internal variable model for uniaxial stress and a variety of heating effects was also presented. The internal variables describe the microstructure in terms of local phase fractions for austenite \mathbf{A} and two variants of martensite \mathbf{M}_+ and \mathbf{M}_- with transformation strains of opposite orientation. The internal variables evolve with temperature and stress according to kinetic equations (7), (21), (22). Strain and entropy follow from Eqs. (11) in a way that is consistent with their status as thermodynamic conjugates to stress and temperature. Equations (29), (30) treat the effect of transformational heating/cooling and heat transfer, which naturally provides a rate effect to the stress-strain behavior. The examples presented here have not addressed the effect of inhomogeneous deformation or nonuniform temperature within the SMM material. These issues can be treated for this and similar models with appropriate field equations, such as Eqs. (4) to (6), and Fourier's law. This approach in turn allows for computational simulation of SMM components within larger systems.

SHIP HEALTH MONITORING

JASON S. KIDDY
 PETER C. CHEN
 PAUL ROSS
 Alexandria, VA

INTRODUCTION

Although ships have been sailing for hundreds of years, the field of ship health monitoring is relatively new. Two main forces have spurred the rise in the popularity and importance of ship health monitoring systems. First, reduced budgets and reduced manpower have resulted in smaller crew sizes and less routine maintenance. This reduced maintenance has brought into question the health of many ships, their components, and the ability to detect a problem quickly. Clearly, a failure aboard any vessel will bring a loss of revenue and productivity, if not worse. The second driver behind the growth of ship health monitoring systems is the decrease in the expense of computers and sensors coupled with an increase in their capabilities and the associated data processing algorithms. Until recently, an automated health monitoring system was either impossible to achieve or prohibitively expensive to install and maintain. Today, ship health monitoring systems are becoming increasingly more common as their capabilities are further demonstrated and understood by the maritime community. Nevertheless, many issues remain to be settled as technology improves, resulting in continuously expanding requirements.

OVERVIEW OF SHIP HEALTH MONITORING

Modern ships, both commercial and military, are extremely complicated machines, so that the aspects of the ship to which a ship health monitoring system can be applied are numerous. To date, efforts have focused primarily on the global hull response and diagnostic monitoring of the propulsion system. Although these two applications have the greatest potential for financial and safety improvements, other areas, such as local hull stresses and cargo tanks, can benefit from monitoring (1). In military applications, many specialized monitoring applications can be envisioned, such as weapon systems or ordinance monitoring and battle damage estimates (2).

Potential Benefits

Ship health monitoring systems can be employed for many reasons. In almost all cases (except research vessels), the primary reason is to reduce the overall cost of ship operations. In isolated cases, other reasons have dictated the use and development of monitoring systems. Another readily apparent benefit of an installed system is failure prevention. Although this is rarely the primary factor for ship monitoring, the safety benefit gained from avoiding a catastrophic failure is a strong motivator for using a system. Finally, because of the advanced technology and recent emergence of ship health monitoring systems, many

systems have been installed for research. The research has focused on the capabilities, benefits, and logistics of long-term ship health monitoring system use.

Financial. Ultimately, for the field of ship health monitoring to be viable, installed systems must decrease the overall costs of operating a ship and/or provide a substantial performance benefit. In both cases, a financial impetus will exist for installing and using a ship monitoring system. In general, cost savings will come from three sources: a reduction in maintenance labor-hours, reduced equipment costs, and increased readiness and uptime. Unfortunately, of these three, only the cost savings from the reduction in maintenance labor-hours can be easily calculated. If a ship health monitoring system is operating properly, many equipment failures are likely to be detected earlier before they become disastrous. Early detection will in turn help prevent one failure from affecting other components and lower the costs to fix a failure, resulting in a reduction in equipment costs that is hard to quantify. Furthermore, unscheduled maintenance will be reduced, resulting in an increase in ship availability. The increased availability will then create higher revenues for the entire system.

Safety. An additional benefit of ship health monitoring is the inherent safety provided by such a system. If the physical health of critical areas is constantly monitored, catastrophic failures are less likely to occur. Most critical regions of the ship can be monitored for stress overloads. Should a stress overload occur, the monitoring system quickly informs the bridge and provides pertinent information to the crew to lessen the amount of damage caused by the overload. If a failure has occurred, this information will also be passed to the bridge. In this case, although the system was unable to prevent a major failure, it will give the crew additional time and information to deal with the problem. For military vessels, the safety of the crew can be protected by the provision of real-time, accurate battle damage estimates. Again, this information will allow for a rapid damage assessment that could easily save lives onboard a crippled vessel.

Potential Dangers to Ships

Ocean and seagoing ships are subject to many potential hazards. The following sections describe some of the operational hazards in detail. In general, these hazards are caused by wind and waves, ice, and material (cargo) handling/storage. In addition to the hazards faced by commercial vessels, military vessels face the obvious threats from enemy actions. However, this section discusses only hazards that are encountered during typical ship operations.

Wind and Waves. Waves, both large and small, are an ever-present hazard to shipping. Waves stress a ship through several different phenomena that are adapted from (3) and described here.

Quasi-Static Hull Girder Stress (Global Stress). Hull girder shears and moments are caused by the cyclic buoyancy of a wave that is superimposed on the ship's geometry in a quasi-static balance with the ship accelerations. The

moment values depend more on the projected wave length superimposed on the hull (wave length/cosine of the heading angle) than on the encounter frequency. However, the pitch and heave resonance (a function of the encounter frequency versus the motion natural frequency) can increase the hull girder moments.

Hull Girder Whipping (Global Stress). When a structure is impacted, much of the impact energy is absorbed by the structure as vibrational energy. This vibration generally forms as motion of the structure at its first natural frequency. When a ship is impacted, such as during a slam, the ship hull vibrates in its fundamental bending modes (vertical and lateral). This is termed hull girder whipping. Slams can occur on the bottom and on the flare of the ship's bow. Bottom slams occur when the forefoot of the ship is lifted clear of the sea by severe ship and wave motions during rough seas. A slam occurs as the ship reenters the sea and the bow impacts the water. Flare slamming may occur as the result of relative motion between the vessel and the sea, even without bow emergence, but can also occur when there is little motion between the vessel and the sea, if the wave is steep enough. Bottom slams tend to have shorter lengths and higher loading frequencies than flare slams. The dominant slam type depends on the ship type. High-speed containerships that have finer forward lines and a flaring bow experience greater stresses from a flare slam, but the opposite is true for full-form tankers that have little flare. Measurements on an aircraft carrier have shown that the whipping moments are of the same magnitude as the quasi-static moments during flare slam (1). Although the whipping vibrations and energy dissipation mechanisms are not well understood for large complex vessels, they are generally less severe in flexible (i.e., high L/D ratio) ships (4). The whipping moment components are usually small compared to the quasi-static moment, but the whipping moments occur at higher frequencies. Recent investigations suggest that whipping may increase fatigue damage by 20% to 30% (5).

Springing (Global Stress). When a ship impacts waves at a frequency that is at or close to the primary hull resonant frequency (the two-noded, vertical bending mode), springing may occur. Springing is steady-state resonance of the ship at its natural frequency. Although this is also a low-frequency event, springing frequencies are of an order of magnitude higher than quasi-static hull girder stresses. The resulting moment, especially when superimposed on the quasi-static stresses, may be significant in long-term fatigue damage. Ships can experience springing in small and moderate seas, as long as the encounter frequency approaches the ship's natural frequency.

Wave Refraction (Local Stress). Hull girder stresses are generally caused by larger waves of the order of the ship's length. But the lower stresses created by smaller waves impacting on the sides of the ship can cause localized long-term fatigue damage and may lead to cracks and crack propagation. This effect is intensified by wave reflection in beam seas. Localized fatigue cracking has been a problem on some Trans Alaska Pipeline System (TAPS) trade tankers where the local waves generally strike the starboard side during the southern voyages and the port side on the northerly routes.

Slamming (Local Stress). The damage from forefoot slamming has been mentioned previously as a cause of whipping. In addition, the locally high stresses can cause damage to the bow structure. Bottom slamming in ships often results in dishing of the bottom shell plate, and flare slamming results in dishing of the side shell and possibly the loss of the flare strake.

Ice. In addition to the stresses caused by sea loading, ice represents a significant danger to shipping. The danger from ice comes primarily from localized impact loading on the hull. However, global stresses can also become a factor due to hull girder whipping.

Ice Transit (Local Stress). Because ship speed, heading, and ice conditions can vary greatly, local ice loads on the ship's structure are complex. The danger from ice depends more on local stresses than on the global hull forces. Shipboard measurements have shown that typical hull girder stresses induced by ice transit are less than those induced by open-water waves (3). The pressures and forces encountered during ship-ice impacts are random and follow log-normal type probability distributions (6). Ice loads are nonuniform, and high loads are applied to small areas of the hull (e.g., 0.5 m²). In addition, these loads occur at many locations along the hull, predominately on the bow. The instantaneous area of the hull that is most highly loaded depends on the type of operation (ramming, turning, etc.) and the geometry and strength of the hull structure. Ice loads are more difficult to measure than slamming loads because of their high frequencies and random distributions. Studies indicate that strain rates for ice loading in the local structure are similar to those for the global response and that neither of these is significantly different from those experienced from sea loading (3).

Hull Girder Whipping (Global Stress). Hull girder whipping caused by slamming is described in the previous section. Because whipping is the vibration of the ship's primary bending modes due to impulsive loading, ice ramming can also induce hull girder whipping. This effect is usually felt during initial ice impact and less during steady ice transit.

Cargo. As for ice, cargo and material handling can also add additional stresses to a ship's hull. Cargo loads can be categorized into two forms.

Quasi-Static Hull Girder Stress (Global Stress). Quasi-static hull girder stress was mentioned previously when caused by long length waves superimposed on the geometry of the ship, causing high moment and stress values. For cargo, quasi-static girder stresses are caused by differences in the loading distribution curve and the ship's buoyancy curve along the length of the ship. Care must be taken during cargo loading and unloading so that the maximum allowable stress values are not exceeded.

Cargo Loads (Local Stress). Cargo loading anomalies can often result in localized regions of high stress. Two examples of loading anomalies are uneven loading in bulk ships (this, it has been hypothesized, is the cause for a number of bulk ship failures) and unequal hydrostatic pressure heads

across tank boundaries. The American Bureau of Shipping (ABS) SafeHull code specifically considers a checkerboard loading pattern in cargo and ballast tanks as a worst case scenario. Hence, the loading sequence can result in excessively high global and local stresses.

Different Ship Types and Requirements

Ship Types. Specific ship designs are susceptible to various hull responses. Table 1, taken from (3), shows the typical monitoring requirements for several common ship types.

Operating Environment. Ships are designed for many functions and operate in a wide variety of conditions. The size, type, and operating environment of a ship greatly influence the requirements placed on a health monitoring system. For example, because container ships that operate in calm, smooth waters in the tropical zones are rarely subjected to icy conditions or severe storms, whipping and other wave/ice-induced fatigue stresses are not critical factors. Therefore, a proper health monitoring system should concentrate on cargo-induced loads and maximizing operational efficiency.

On the other hand, TAPS trade tankers are constantly subjected to severe storms, high waves, and very directional sea states (7). As cargo runs are made to the south, waves primarily strike the starboard side of the ship. On the return trip to the north, waves strike the port side primarily. This pattern has resulted in localized fatigue problems and requires a high density of local stress sensors to detect the onset of cracking. In the North Sea, hull girder bending, slamming, and green water are present because of

the very steep waves and require sensors similar to those for the TAPS trade tankers to detect any potential problems. Bulk ships operating on the Great Lakes are susceptible to springing because of their high L/D ratios and require global hull bending sensors. Ice breakers are subject to high localized stresses, especially around the bow, but the global bending stresses are typically lower than those experienced by other oceangoing vessels.

These basic generalizations apply only to small groups of ships that continuously operate in a given environment. Many ships are not easy to classify; their health monitoring considerations must include all of the potential operating conditions for a specific vessel. Most military vessels are prime examples of ships that are commonly operated with no fixed route and that experience many types of sea states throughout a voyage.

Additional Capabilities

Industry has realized that ship operators expect a ship health monitoring system to do more than simply measure the state of stress throughout the ship and monitor machinery health. As mentioned previously, ship health monitoring systems must be financially attractive to be commercially acceptable. It is clear that preventing the loss of a ship or increasing the useful life of a ship by structural monitoring are financial benefits. However, additional benefits can be gained by incorporating external (non-ship-based) sensor readings into a comprehensive monitoring system. These external readings are currently composed of two primary types: weather avoidance/planning and route monitoring.

Weather Reports. Current weather reports are available to ships from a variety of environmental sensor platforms, including fixed land sensors, ocean buoys, other ships, aircraft, and satellites. Collectively, these platforms can provide the necessary information to a ship to help prepare an optimal route to increase the efficiency of the route and to lessen any damage that may be caused by ice or poor weather.

Fixed Land Sensors. Fixed land sensors are primarily used to measure basic meteorological conditions such as wind speed and direction, temperature, and precipitation.

Ocean Buoys. The National Data Buoy Center (NDBC) operates the Ocean Data Acquisition System (ODAS), which is a network of more than 60 buoys that are anchored in deep ocean areas off of North America. These buoys send satellite transmissions to the National Weather Service (NWS) that provide weather and oceanographic data from their stations in the Atlantic, Pacific, Gulf of Mexico, and the Great Lakes. The wind speed and direction data, once processed by NDBC, is reportedly accurate to within $\pm 10^\circ$ and ± 1 m/s.

Ships. NWS receives weather reports every 3 hours from ships that participate in the U.S. and World Meteorological Organization (WMO) Voluntary Observing Ship Program (VOS). These reports include basic meteorological conditions and best estimates of the current sea state, ice, and visibility. These programs include 49 participating countries and approximately 7000 ships that provide about

Table 1. Monitoring Requirements by Ship Type

Ship Type	Typical Hull Response
Passenger ship	Ship motion (roll) Bow flare slam
Tanker/products carrier	Midship hull girder stress Bow/amidships shell stiffeners Forefoot slam Explosive environment
Bulk ships	Cargo loading hull girder stresses Cargo hold frame stresses Stress concentrations at hatch corners Forefoot slam
Container ships	Stress concentrations at hatch corners Hull girder torsion Bow flare slam Green water Whipping/cargo accelerations
LNG/internal tank	Forefoot slam Temperature/explosive environment Sloshing
Barges/platforms	Towline/mooring tension Motions and inertial forces Lateral motion
Naval combatant	Bow flare slam Fire control plane deflections

1000 reports a day. The U.S. program has existed as a descendant of the U.S. Coast Guard Ocean Weather Station ships for several decades. The data provided by the VOS is commonly used for weather forecasting and is distributed by the National Ocean Weather Service through the Global Telecommunications System.

Aircraft. Aircraft are most commonly used to track hurricanes in the Atlantic Ocean. But they have also been experimentally used to track ice conditions in the polar regions (8) and have been used to provide Synthetic Aperture Radar (SAR) readings to estimate local sea states.

Satellites. In general, satellites provide a great deal of information to weather forecasters. Due to the advent of modern satellite imaging technology, forecasters can accurately predict the weather many days in advance. In addition to the basic weather forecasting functions, several satellite instruments have been used to aid in ship navigation.

Advanced High-Resolution Radiation (AVHRR) sensors are used to sense ocean temperatures and map sea currents. Flown by NOAA since 1978, AVHRR sensors detect infrared radiation to measure the sea surface temperature. This data is critical to helping oceanographers track ocean currents. Generally, two AVHRR satellites are in polar orbit on 24-hour cycles phased 12 hours apart to give both day and night readings. Although clouds interfere with AVHRR readings, this interference has not significantly affected their usefulness.

Radar altimetry has been used to measure the distance between a satellite and the ocean waves to estimate the sea state. Although the technology was first demonstrated onboard the GEOS-3 in the 1970s, suitable accuracy was not obtained until the recent launch of the TOPEX/Poseidon in 1992. However, until additional satellites become operational, this technology will be used primarily for research.

A final sensor technology is scatterometry. Scatterometry measures the scatter within a return pulse from a radar altimeter to determine the roughness of the seas. Calm seas give a clear, concise radar reflection, whereas rough seas tend to distort the return. The sea state is then related to the local wind speed through an empirical correlation. Again, scatterometry is a new technology that is currently in the development stages and that will hopefully be available to health monitoring systems in the future.

Route Monitoring/Planning. Adding the capability of monitoring weather conditions to a ship health monitoring system can improve the crew's ability to plan an optimal course through the weather. Ideally, though, the monitored weather conditions would be integrated with a route planning system to provide an optimal route to the crew automatically. By integrating the local health monitoring system with a real-time routing system, the ship's handling can also be adjusted to minimize danger to the ship. Using this type of system, it is possible to plan the best route to reach a given destination while reducing time and fuel consumption from unwanted ship responses. Several technologies needed for such a system are already in existence, including weather forecasting, the predicted ship responses, and the local sensors to determine the actual ship response. However, an intelligent software product for

performing the optimization at real-time speeds has not been fully realized.

The benefits of route planning were demonstrated in 1993 by ARCO Marine (9). Two sister TAPS trade tankers traveled from San Francisco, California to Valdez, Alaska with the same ballast condition. One ship contained a voyage planning system based on the predicted wave heights and directions; the other did not. The ships remained within a narrow corridor and varied only the timing and speed. The ship that used route planning arrived approximately 18 hours earlier than the sister ship, and the sister ship suffered \$400,000 in wave-induced damage.

ENVIRONMENTAL ISSUES

For a ship health monitoring unit to be acceptable, it should not adversely affect the operation of the ship or its crew. Furthermore, the system must be reliable and require very low maintenance. A primary driving benefit of a ship health monitoring system is a reduction in crew workload. If the system is constantly in need of repairs, this benefit does not materialize. Unfortunately, the maritime environment is very harsh and unforgiving. Every component of a health monitoring system must be considered for reliability and maintenance. The primary factor that reduces the life of ship components is the highly corrosive marine environment. Many other sensor location-specific factors may also contribute to component failures. These include explosive environments, inadvertent physical damage by the crew, and operational overloads.

Corrosive Marine Environment

The marine environment is tremendously harsh and corrosive. This environment quickly affects most exposed metals and many other materials. Therefore, a ship's health monitoring system components must either be protected from this environment or constructed of materials that are not subject to marine corrosion. Although any material will eventually corrode, corrosion in the marine environment is more severe for several reasons. First, most metals corrode slowly at ambient temperatures and low humidity. Increasing the humidity provides water, which is necessary as an electrolyte for charge transfer. In addition to the ever-present water, the saline environment of ocean water further increases corrosion by speeding up the localized breakdown of oxide films. The chloride also increases the conductivity of seawater compared to freshwater, again increasing the corrosion of many metals. A final contributor to corrosion is the low acidity of seawater. The pH of seawater is usually 8.1 to 8.3.

Other

In addition to the highly corrosive marine environment, ship health monitoring sensors are placed in other types of extreme environments. Many modern ships are designed for and dedicated to transporting large quantities of oil or natural gas. For these ships, it is desirable to measure the health of the fuel storage tanks. This environment places additional safety requirements on the sensor

and any associated electronics due to the explosive nature of the cargo. A few sensors are intrinsically safe in an explosive environment, but most sensors must be encapsulated or encased in an explosion-proof container, which can substantially increase the cost and complexity of the sensor.

Another concern is to protect the health monitoring system's components from physical harm. It is often necessary to place sensors or wiring in locations that are susceptible to physical damage. Examples include deck-mounted components that can be damaged by the crew's activities or forefoot-mounted pressure sensors that must be designed to handle the high forces experienced during slams or ice-breaking duties. In some early systems, pressure sensors failed most frequently of all equipment (3). Without the proper protection, these sensors fail quickly.

SENSOR TECHNOLOGY

The sensor network is crucial to providing real-time, accurate information from the ship health monitoring unit to the ship's crew. It is the distributed sensors that directly measure the motions and health of the ship. To provide a detailed picture of the entire ship, these sensors must comprise many different types and must be placed throughout the vessel. Therefore, current and future health monitoring systems will incorporate a wide variety of sensor types that measure a diverse number of physical parameters. Figure 1 illustrates a possible ship health monitoring sensor arrangement. In addition to choosing the physical parameters that must be measured, where they are to be measured, and the type of sensor to be used, one must make decisions concerning the cost, reliability, and safety of the specific sensor. Current state-of-the-art sensors can meet these objectives, but novel sensor designs are continuously being developed and must be considered as possible improvements over existing designs.

Measurands and Potential Sensors

As mentioned, a wide variety of parameters must be measured to obtain an adequate picture of a ship's motions and health. The following sections describe many of these measurands and the potential sensors that are currently available for the measurement.

Pressure. Pressure gauges are most often used in a ship health monitoring system to measure slamming pressures, forefoot emergence, and in-tank hydrostatic pressures. Multiple pressure gauges are often located longitudinally along the forefoot to detect the extent of emergence and to determine the magnitude and extent of bottom impact pressures (10). To facilitate maintenance, it is important to ensure that any sensors, especially forefoot pressure sensors, can be replaced or repaired without entering dry-dock.

There are two primary types of pressure transducers: diaphragm and piezoelectric types. Both types are commonly available commercially at about the same cost, but each has certain advantages and disadvantages.

Diaphragm-Type Pressure Transducers. There are two types of diaphragm style pressure transducers: one has a clamped circular plate, and the other employs a hollow cylinder. However, the clamped plate design is more suited for the pressure ranges of ship health monitoring, and only they are discussed in this section. The strain distribution on a clamped circular plate of constant thickness has been solved analytically and has been experimentally validated. Based on these results, a special purpose diaphragm strain gauge has been designed to take advantage of this strain distribution. Using this type of strain gauge arrangement, one finds that the pressure is proportional to the measured strain. Typical strain gauge instrumentation can be used to sample the data.

Piezoelectric-Type Pressure Transducer. This type of pressure transducer uses a piezoelectric crystal as both the diaphragm and sensor. In general, the piezoelectric crystal

Figure 1. Potential ship health monitoring sensor arrangement.

Figure 2. Long-base strain gauge.

(most commonly quartz) is placed inside a hollow cylinder. Because of the piezoelectric effect, an applied pressure generates an electrostatic charge that is proportional to the pressure. The piezoelectric crystal has a high output impedance. Therefore, a charge amplifier is commonly employed to convert the charge into an amplified voltage that is read by a standard voltage recorder. The low-frequency response of the transducer depends on the time constant of the amplifying circuit but can be designed to use frequencies that are low enough for ship health monitoring. The primary disadvantage of this type of transducer is that the charge amplifier electronics make the system less intrinsically safe than diaphragm-type pressure transducers.

Global Strain. Global strain is most commonly measured using long-baseline strain gauges. Long-baseline strain gauges normally consist of a long rod (approximately 2 meters long) rigidly attached at one end to the hull. The second end is allowed to move freely through a set of guides that ensure only axial movement. The extent of movement of the free end, as measured from a set “zero” strain locations, divided by the length of the rod gives the average strain in the deck across a region of the hull that is the length of the rod. Figure 2 is an illustrative example of a long-base strain gauge.

Although the basic mechanism is simple and robust, these devices are commonly placed on the deck of a ship and must be appropriately protected from both physical damage and the environment. Three common techniques are currently available for measuring the displacement of the free end.

Linear Potentiometer. Linear potentiometers are simple resistors that have a varying resistance that is proportional to the displacement. The displacement is measured by sending a low voltage and current through the potentiometer and measuring the resistance. This method is very inexpensive, and recent advances have made precision linear potentiometers as accurate and repeatable as other technologies. One disadvantage is that the resistor’s life is limited and it must be protected from the environment.

Linear Variable Differential Transformers (LVDT). LVDTs are the most popular variable-inductance sensor used for displacement measurements. In an LVDT, a magnetic core

moves through an insulated bobbin without physical contact. Three symmetrically spaced coils are wound around the bobbin. The position of the magnetic core controls the mutual inductance between the center primary coil and the two outer secondary coils. When a voltage is applied to the primary coil, a voltage is set up in the two secondary coils. The secondary coils are wired 180° out of phase with each other. Therefore, when the core is centered within the bobbin, the secondary voltages are of equal magnitude and cancel out. However, a small movement of the core results in a larger voltage in one of the secondary coils and hence a sensor reading. Because there is no contact between surfaces, LVDTs are free from friction and have very long lives. The response is also free from hysteresis. The resolution of an LVDT is partially determined by the voltage recorder, which give LVDTs superb resolution and accuracy. The two primary disadvantages of LVDTs are their higher cost compared to linear potentiometers and the relatively high voltage (5 to 15 volts) that must be supplied to the primary coil.

Linear Displacement Transducer. A linear displacement transducer is a magnetostrictive sensor that measures the time between an interrogating magnetic pulse and a return pulse that is generated by a magnet connected to the free end of the rod. As for an LVDT, this type of device has no contacts and a long service life. It is also intrinsically safe for hazardous environments but is much higher in cost than either of the other two options.

Local Strain. Local strain measurements are often used in ship health monitoring systems. They are applicable to detecting a wide variety of potential hazards. They are most commonly used along the bow, in cargo and ballast tanks, and along any other critical internal structures. Local strain gauges are also ideal for detecting cracking around certain areas such as hatch corners and highly stressed welds. In general, the number of local strain gauges is limited by the cost of installation and data acquisition as opposed to the cost of the gauges or the desire to measure more parameters. Ideally, almost any failure can be detected by a local strain gauge if it is installed in the right location.

By far the most common method of measuring local strains is to use a resistance foil strain gauge. Details of

the performance and use of resistance strain gauges can be found in many texts. The strain gauge operates by detecting a change in resistance of metal wire as it is stretched. The change in resistance is caused by a decrease in the conductive cross-sectional area due to Poisson's ratio. To amplify the change in resistance, one employs thin metal-foil grids to maximize the amount of conductor within a given region. Because the change in resistance is very slight, a Wheatstone bridge is usually used to convert the changing resistance to a variable voltage. Resistance strain gauges can be purchased in a wide variety of sizes, sensitivities, and geometries. It is also possible to purchase strain gauge rosettes that permit measuring all three surface stress components simultaneously. Because strain gauge readings depend on measuring a changing resistance, they can be made safe by using very low voltages.

An important consideration is the temperature sensitivity of strain gauges. As a material is heated or cooled, the material expands or contracts, depending on the material's coefficient of thermal expansion. If the strain gauge does not similarly expand or contract, an apparent strain will be seen by the strain gauge. Two methods exist for eliminating this apparent strain. The first method is ensuring that the coefficient of expansion is identical for both the structure and gauge. Therefore, both expand at the same rate, and no apparent strain is seen. For this reason, commercial vendors sell strain gauges made from a wide variety of materials. The second approach is not as attractive for practical applications. In this approach, a second gauge/material combination is bonded together but is placed in a region that is completely free of stress. Through this technique, the amount of apparent temperature-induced strain can be calculated from the second gauge and can be subtracted from the active gauge to provide the final mechanical strain reading. However, finding a suitable location for the dummy gauge is not generally possible.

The installation of strain gauges is also a well-documented field that has a myriad of options. The most common techniques include adhesive bonding and welding, but other methods are also available for packaged sensors. Generally, it is preferable to protect the strain gauge after installation. Again, this is done by using a variety of protective coatings and encapsulation techniques. Many strain gauges sold have the gauge itself prepackaged into an encapsulated enclosure for protection.

Motion. Ships' motions are possible in all six degrees of freedom. The three translational degrees of freedom are surge (longitudinal), sway (lateral), and heave (vertical). Roll, pitch, and yaw are the three rotational degrees of freedom. Roll, pitch, and heave are generally considered the three most important degrees of freedom for the following reasons:

Roll. Roll generally affects the crew and cargo loads. In addition to crew and passenger discomfort, rolling creates lateral cargo loads that must be resisted by horizontal restraints. In fluid tanks, rolling may increase the hydrostatic pressure head or induce sloshing. A ship's master usually turns the ship into waves to reduce rolling, but this increases hull girder stresses.

Pitch. Pitching has the same effect on fluid-filled cargo tanks as rolling and results in an increased hydrostatic pressure head and sloshing. In addition, the length of the ship increases the distance between the ends of the ships and the pitch axis, resulting in high pitch accelerations that may in turn result in slamming.

Heave. Heave is more pronounced than surge or sway because of wave motions and the coupling with pitch motions. Heave causes effects similar to roll and pitch in fluid-filled tanks. In addition, the vertical accelerations require vertical cargo restraints.

Ship motions are commonly measured by a variety of sensor types. The most common devices are accelerometers and gyros, although there are many variations of both. Table 2 lists the current state of the art in ship motion sensors (11).

Shaft Speed, Power, and Thrust. The ship's performance parameters (shaft speed, power, and thrust) can provide measurements of the propulsive efficiency relative to the current environmental conditions. These measurements can also provide an indication of the health of the propulsion equipment. Most ships are currently configured with equipment to measure these parameters directly from the propeller shaft. In general, this information is already passed into the engine control room and can be further routed to the ship health monitoring system.

Global Positioning. Similar to the propulsion system measurements, ships usually already have an installed Global Positioning Systems (GPS). As a rule, GPS units output a serial signal dictating the ship's position (latitude and longitude), heading, and speed on a regular basis. Therefore, the ship health monitoring unit only needs to read this information from the preexisting unit.

Advanced Sensors

Fiber-Optic Strain Gauges. One promising new technology is fiber optic strain gauges. There are two primary types of fiber-optic strain gauges, Fabry-Perot and fiber Bragg grating sensors (12). Both types offer a number of advantages over traditional resistance strain gauges. Because fiber-optic strain gauges use light as the sensing and transmitting element, they are intrinsically safe and pose no fire or explosive hazards. Furthermore, fiber optics are very resistant to corrosive elements because they have no metallic components and are covered by protective hermetically sealed coatings. A final common advantage is that fiber optics are immune to electromagnetic interference. Therefore, they can be placed in regions of high electric or magnetic fields without any degradation of performance. Both types of fiber-optic strain gauges are also capable of strain resolutions equal to or greater than that of resistance strain gauges.

Fabry-Perot Fiber-Optic Strain Gauges. Fabry-Perot strain gauges are manufactured by placing a small air gap (or an internal mirror) within a fiber, followed by a reflective surface, which can be either a micromirror or more optical fiber. A broadband light wave is transmitted down the length of the fiber. At the first junction between the

Table 2. Ship Motion Sensor Technology

Motion	Sensor Type	Advantages	Potential Problems
Roll and pitch	Vertical gyro	Reliable, may be able to use existing ship unit	Drift, cost, power
	Magnetometer	Moderate cost	Calibration on steel ships
	Solid-state gyro	Low cost and power, units packaged with integral rates and displacements	Sensitive to external vibrations
	“Watson meter”	Reliable, accurate for pendulum-based design	Moderate cost
Yaw (heading)	Bubble/simple pendulum	Low cost	Inaccurate when not at the center of motion
	Gyrocompass	Current state of the art	Expensive, frequently needs service
	Solid-state gyro (KVH)	Low-cost combination of rate gyro and flux gate compass	Unproven, unknown life and reliability
	Solid-state gyro (fiber optic)	New laser ring technology, no moving parts	Expensive, not yet commercialized for ship use
	Flux gate compass	Good for small ships once compensated for, low cost	Difficult to use effectively unless able to swing the ship for compensation
	Magnetometer	Moderate cost	Calibration on steel ships
	Piezoelectric accelerometer	Good for machinery vibrational measurements	Unsuitable for ship response frequencies
Surge Sway Heave	Piezoresistive accelerometer	Low cost, good for short-term ship motions	Subject to temperature cross-axis errors
	Servo-accelerometer	Excellent stability, accuracy, and reliability	Expensive
	Capacitive accelerometer	Moderate cost, performance nearing that of a servo-accelerometer	Cross-axis sensitivity higher than that of servoaccelerometers

fiber and the air gap (or mirror), some of the light is reflected back to the source, and some of the light is transmitted into the gap. At the mirror or second air/fiber interface, light is again reflected and transmitted. Now, two separate light sources are reflecting light back along the length of the fiber. The length of the air gap dictates the phase difference between the two waves. Allowing this air gap to expand or contract, based on the local strain, creates a strain sensor. Hence, a measurement of the phase offset can be correlated to a strain measurement. There are extrinsic Fabry–Perot sensors, intrinsic Fabry–Perot sensors, and in-line fiber etalon (ILFE) sensors. All three are based on the same principle, the differences lie in the choice of the reflective medium. Although intrinsic Fabry–Perot sensors are sensitive to strain and temperature, extrinsic Fabry–Perot sensors and ILFEs have very low thermal sensitivity. One disadvantage of Fabry–Perot sensors, compared to fiber Bragg grating sensors, is the difficulty in multiplexing many sensors along a single fiber.

Fiber Bragg Grating Strain Gauges. Fiber Bragg gratings are based on the photorefractive effect. Bare fiber is exposed to a hydrogen environment and then imprinted using an ultraviolet laser. The imprinting is done by one of several methods, and it leaves a series of equally spaced lines along a region of the fiber. This series of lines is called a Bragg grating; the lines are actually very small regions that have a slightly different index of refraction. Bragg gratings can be fabricated through an interferometric (holographic) method or by using phase masks. In a fiber that has a Bragg grating, transmitted broadband light is

reflected back toward the source at a specific frequency that corresponds to the grating wavelength. All other frequencies of light pass unaffected through the Bragg grating.

Because the frequency of the reflected light is proportional to the spacing of the Bragg grating, a change in the spacing will result in a change in the reflected wavelength. Hence, a strain gauge can be made by bonding a Bragg grating of a specific wavelength to a structure. As the structure is strained, the Bragg grating will expand or contract, thereby changing the wavelength of the reflected light. By measuring the wavelength of the reflected light, one can deduce the strain at the location of the grating (13).

One major advantage of using fiber Bragg gratings as local strain sensors is the capability of using wavelength and/or time division multiplexing to place many Bragg gratings (strain sensors) along a single optical fiber (14). When a broadband light source is used with a Bragg grating, every wavelength, except the wavelength corresponding to the grating, is transmitted through the grating. Therefore, a second Bragg grating, at a different wavelength, may be placed further along the fiber. This second Bragg grating will reflect a different wavelength back to the source. Now, two separate strain readings can be taken by monitoring the two reflected wavelengths. This process can be repeated many times along the length of the fiber, which allows making many distributed local strain readings within a single fiber-optic cable that also transmits all of the data back to the control computer. Similarly, time division multiplexing can be achieved by monitoring the time of return of the Bragg grating wavelengths, enabling interrogation of

multiple sensors along a fiber. One disadvantage of Bragg grating strain sensors is its strong thermal sensitivity. Numerous methods have been proposed to compensate for this thermal sensitivity, but none have yet been commercially successful.

Other Fiber-Optic Gauges. In addition to fiber-optic strain gauges, Fabry–Perot and Bragg grating strain sensors have been incorporated into other designs to enable detecting pressure, temperature, or even chemical content. In general, these sensors have many of the same advantages due to the nature of fiber optics as opposed to electrical components. But again, very few of these hybrid sensors are currently available commercially. These sensors will probably become more available and less expensive as the technology matures. Using Bragg grating-type sensors, it will also be possible to construct a series of varying sensors that are connected to the same fiber-optic transmission cable. For example, the fiber-optic cable from several forefoot pressure sensors could be run up to the cargo tanks where several Bragg grating strain sensors were located. Each of these sensors could be multiplexed together so that all of them are interrogated by a single fiber-optic cable running back to the control computer.

Sensor Power

Another consideration for ship health monitoring sensor systems is the source of the required power. Most common sensors, including strain gages and accelerometers, require a constant electrical input to operate. This power is usually provided by the control computer and is sent through installed wiring to the individual sensors. The disadvantage is that this approach often leads to additional bulky cabling. An alternative is to use the ship's existing power distribution network. This approach is, however, complicated because the existing power, especially near the bow, is limited and of poor quality, and high voltage spikes are common. The control computer and critical sensors must also be connected to an uninterruptable power supply (UPS) to maintain operation in the event of a power failure.

DATA

The wealth of information obtained from the remote and on-board sensors of a health monitoring system must be transmitted and processed into a form that is both useful and concise. It is widely accepted that a useful health monitoring system must have a bridge terminal to display all of the pertinent information to the ship's crew. This first step is to transmit the data to a central location, either on the bridge or nearby. After the data has been transmitted to a central location, it is input into a computer system that analyzes and formats it into easy-to-read displays. In addition to displaying the real-time data to the crew during the voyage, it is often desirable to store this data for future analysis. Each step in this process is an involved function, and each is described in the following sections.

Transmission

The first requirement is to transmit the data obtained from the various sensors that are located throughout the ship to a central location. This task is made difficult by several factors. First, the corrosive marine environment is extremely harsh to any exposed wiring. The distances onboard modern vessels also require that many signals be transmitted hundreds of feet before being amplified or received by the central computer. In general, there have been three main methods of transmitting the data: hard wiring, radio links, and fiber optics (3).

Hard Wiring. Hard wiring is the most common form of data transmission in currently installed health monitoring systems. In ships that have protected longitudinal passageways, shielded and grounded cables offer the route that has the lowest installation expense. However, many ships, including tankers and product carriers, do not have these passageways and require more extensive cable routing and cost. The use of armored cable is also recommended for any external cable routing to protect it from physical damage. In explosive environments, it is extremely important to ground all cables to reduce the risk of sparking; in fact this procedure is generally preferred in all applications to reduce noise.

Radio Links. Radio links between sensors and the control computer offer the advantage of simplicity of installation because no cables need to be run through the ship's hull. Nevertheless radio links have increased costs because of the transmitter and antenna. An additional advantage for explosive environments is that radio links eliminate the spark hazard found in hard wiring. This type of signal transmission becomes less attractive for large numbers of localized sensors. When wiring, one can lay a multitude of sensor cables at one time. For radio transmission, multiple transmitters are required for additional sensors. Although radio transmission does not degrade over the length of the ship, signal interference is possible and can corrupt the data with spurious signals.

Fiber-Optic Network. Fiber-optic networks represent a good alternative to hard wiring and many advantages but higher cost. As proved by the telecommunications industry, fiber optics can easily transmit many signals hundreds of feet without any signal degradation. Fiber optics are also inherently safe for explosive environments and do not suffer from electromagnetic interference. For many of these reasons, current naval vessels are being outfitted with wide area distributed fiber-optic networks (15). Similar to hard wiring, fiber-optic networks suffer the disadvantage of needing a fiber-optic cable from the sensors to the control computer. In addition, most standard analog electrical sensors require expensive signal converters and decoders to convert the data into a corresponding light signal and back to electrical signals at the control computer. However, for a ship that has a preexisting fiber optic network, this form of transmission is extremely attractive and will be attractive for other systems as the cost of fiber-optic components continues to drop.

Analysis

The analysis and display of the sensor data are the primary objectives of the standard ship health monitoring unit. It is the responsibility of the control computer to perform data acquisition from the individual sensors and to process this data to determine whether the ship has been damaged or faces any immediate danger. The most common method of analyzing the information is to monitor each sensor in terms of the absolute magnitude of the sensor reading. Although the algorithm is relatively simple, the crew should determine whether the ship has experienced a reading that approaches or exceeds the maximum allowable level. If an overload has occurred, the crew must know immediately, so that appropriate action may be taken. This may dictate a change in the ship's heading, an adjusted cargo loading pattern, or possibly a visual inspection of the sensor location.

More complicated analyses are also performed to determine the overall fatigue experienced by the ship and to locate any general trends in the data that might indicate a potential failure. These analyses include average sensor levels, standard deviations, and peak values. More complicated signal processing techniques have been developed for machinery health monitoring, but such techniques have not yet been used for ship health monitoring systems. Limited attempts have been made at this point to use ship health monitoring information to predict the remaining fatigue life of ship components.

Display

A key component of the ship health monitoring system is the bridge display. The information displayed on at the bridge is the primary interface between the monitoring system and the ship's crew. To be easily used by the crew, the information must meet many different requirements.

Information. The information given by the display is the most important function of the entire system. The crew requires simple displays that can quickly inform them of any potential dangers and the effect of various maneuvers on the state of the ship. Complicating the information display is the crew members' needs for different types and amounts of data. The information that is required during cargo loading is very different from the information needed when traveling through rough seas. Support personnel are interested in different types of information as they post-process the data. To meet these many demands simultaneously, it is common practice for the bridge display to consist of numerous (more than five) different screens.

Experience has also shown which data formats and types of information are the most helpful to bridge personnel. For example, the ABS requires displaying hull girder stresses over a relatively short period of time so that the effect of speed or heading changes on the measured stress levels can be evaluated. Experience has also shown that bridge crews want the stress information to be displayed as a percentage of the maximum allowable stress as opposed to actual stress or strain readings. The actual values are

important and are generally saved for later use, but the immediate needs do not require this information.

Alarms. Both audible and visual alarms are standard in all ship health monitoring systems. The alarms are needed to inform the crew quickly of any potential dangers. However, it is very important to set the alarm sensitivity levels high enough so that the crew does not become frustrated by the alarm system. Excessively sensitive alarms have resulted in disconnection of the alarm system in previous applications, especially because of ice-induced local stresses (3).

Color/Lighting. The graphical display of the ship health monitoring system must be capable of operating in two modes. During the daytime, it is desirable to have a bright screen with obvious color clues to inform the crew quickly of the ship's status. Standard danger colors such as red and yellow should be used to highlight high sensor levels or overloads. Similarly, cool colors should be used to indicate that the ship is operating normally. However, the display must not interfere with the crew's night vision during evening hours. Hence, the display must be able to switch to a second mode where lower intensity schemes can be used to maintain night vision. Intensity variations can then be used to signify danger as opposed to a color change.

Storage

After the information has been displayed to the crew, the sensor information must be stored for later retrieval and analysis. Using modern storage media, it is not difficult to store vast amounts of data in relatively little space. Nonetheless, a continuously operating ship health monitoring system can generate huge amounts of data. Several options exist for storing data, including magnetic disks and tapes and optical disks. The primary considerations for the storage medium are the cost and capacity of the device versus the frequency with which the medium needs to be changed by the ship's crew during a voyage.

COMMERCIAL SYSTEMS

To date, there are a few commercially available comprehensive ship health monitoring systems. In addition, several manufacturers commercially produce Hull Response Monitoring Systems (HRMS). Although these systems are not comprehensive health monitoring systems that encompass the entire vessel, they provide detailed and adequate monitoring of the vessel's hull structure and include many other associated monitoring functions. These systems will surely form the basis for a comprehensive ship health monitoring system. To regulate commercial HRMS, the ABS published, in 1995, classifications for Hull Condition Monitoring Systems. Although these guidelines are general, they do provide a minimum compliance level for all HRMS. These requirements are listed in Table 3.

Table 3. ABS HRMS Requirements

Measurement Device	Parameter	Sensitivity
Accelerometer	Range	None
	Accuracy	± 0.01 g's
	Frequency	$3 \times$ required response
Strain Gage	Range	Yield stress
	Accuracy	$\pm 5 \mu\epsilon$
	Frequency	5 Hz
Fatigue	Bin size	$50 \mu\epsilon$

Current Systems

Currently, there are approximately 10 commercial manufacturers of HRM systems. Although many of the systems focus on recording the same physical parameters, no two systems are identical and almost every manufacturer will specially design a system to the end user's needs. Nonetheless, it is helpful to give approximate capabilities of these individual systems. The values in Table 4 are given only as a reference; individual or all values may be higher or lower for any given manufacturer and system.

Future Enhancements

The future of HRMS and comprehensive ship health monitoring systems is both exciting and dynamic. As the cost of new vessels continues to rise, there is an increasing demand to maintain and extend the operational life of new and existing vessels. A ship health monitoring unit is uniquely capable of extending the life of a vessel by providing the optimal course to the crew to avoid severe storms and to limit the damage incurred by the ship. The health monitoring system may also allow aging ships to be kept in service for longer periods of time by accurately identifying any failures before they become catastrophic.

Almost every aspect of future systems is likely to be enhanced over the current state of the art within the next decade. These advancements include the following:

1. *Improved Sensors.* Almost every type of sensor will have more capabilities, reduced cost, and improved safety and reliability.
2. *Increased Sensor Density.* As the cost of individual sensors and data acquisition hardware decreases, the number of sensors installed in a typical system will increase. This will bring a greater density of sensors to a given region and will allow for more detailed measurements of local stresses.

Table 4. Typical HRMS Features

Parameter	Value
Input channels	16–64
Sample rate	10–50 Hz
Data storage capacity	1 GB
Real-time display	1 min
Average display length	5 min
No. of display screens	5–10

3. *Additional Monitoring Functions:* In addition to improving the ability to detect and locate any potential damage to the ship's hull, advancements will allow monitoring the health of additional regions of the ship or ship components. For example, researchers in related fields have demonstrated the capability of accurately detecting transmission faults before they become catastrophic. Faults such as cracked or broken gear teeth, damaged bearing raceways, or misaligned shafts have all been successfully detected before failure. These systems generally use accelerometers to measure the vibrations close to the gears, bearings, and shafts in many transmission systems. The measured vibrational signals can be analyzed by a wide variety of methods of varying complexity and computing power. Although the global parameters of power, speed, and torque are measured in current systems, they can only inform the crew of a transmission fault after it has occurred and has begun to affect the ship's operation. Therefore, this type of transmission health monitoring system is a logical addition to current ship health monitoring systems.
4. *Increased Computing Power:* The continued push for faster computers will enable health monitoring systems to perform more detailed analysis in real time. Such advances will lead to more sophisticated and sensitive algorithms that can inform the crew of a potential problem before it occurs. This is especially helpful in machinery diagnostics.
5. *Condition-Based Maintenance:* Currently, ship components are repaired or replaced based on one of two factors. Either the part is replaced on a time-dictated schedule, to prevent the part statistically from ever failing, or it is repaired/replaced after failing. Neither of the current methods is optimal. In the first case, healthy components are discarded only because they have been used for a set amount of time. In the latter case, the ship is potentially unavailable for service because of the required repairs. An alternative approach, which may be provided by an advanced ship health monitoring system, is condition-based maintenance (16–18). By monitoring the health of a structure, one can also monitor the remaining life of that component. For example, a crack may be detected, but the monitoring system may show that the part has an additional 6 months of life before failure. This monitoring capability will ensure that the ship's availability is not lost because of repairs or waiting for a component to become available, and healthy parts will not be inadvertently wasted.
6. *Increased Data Storage:* It is well known that the cost of data storage is continuously dropping. This trend will be very beneficial to ship health monitoring systems as increased amounts of raw data will be stored for possible retrieval and postprocessing.
7. *Improved Weather Forecasting and Route Planning:* Although weather forecasting is not a direct part of a ship health monitoring unit, the advances in weather forecasting will give the system greater confidence in

the predicted weather and will improve the effectiveness of route planning activities. This will be coupled to improved route planning algorithms that will be developed, as the relationships between the ship's response and weather conditions are more fully understood.

SMART PEROVSKITES

ZHONG L. WANG
Georgia Institute of Technology
Atlanta, GA

Perovskite and perovskite-related structures are a class of smart materials (1). Perovskite-structured materials have important applications in ferroelectricity, piezoelectricity, ferromagnetism, magnetoresistance, superconductivity, ionic conductivity, and dielectricity. Typical perovskite

materials of technological importance are piezoelectric $\text{Pb}(\text{Zr},\text{Ti})\text{O}_3$, electrostrictive $\text{Pb}(\text{Mg},\text{Nb})\text{O}_3$, magnetoresistant $(\text{La},\text{Ca})\text{MnO}_3$, and superconductive $\text{YBa}_2\text{Cu}_3\text{O}_7$. Perovskite-related materials are versatile matrices for generating transition- and rare-earth metal oxides that exhibit a broad spectrum of properties and functions (2) that are related to the following characteristics: (1) Nearly innumerable combinations of metal cations can be accommodated within perovskite-related structural systems. (2) By reduction / reoxidation processes, nonstoichiometry (i.e., controlled amounts of ordered oxygen vacancies) can be introduced into the structure. In turn, high oxygen ion mobility or modified electronic and magnetic features can be implemented, and (3) the design of composite structural systems containing perovskite building units (perovskite slabs of different thicknesses) allows fine-tuning electronic and magnetic properties.

From the viewpoint of crystal structure, the ABO_3 type structure, in which the cation A usually has valence 2+ and the cation B has valence 4+, is the fundamental perovskite. The perovskite family is created by doping other types of cations into the stoichiometry and/or introducing anion deficiency. Understanding the structures and the relationships among the abundant structures in the perovskites may lead to some insights into the intrinsic connection between structure and properties. This article focuses on the structure and structural evolution of perovskites and explores the intrinsic linkages among the members of the perovskite family. First, we introduce the "smart" properties of perovskites. Then, the intrinsic connection among the perovskites is explored. Finally, the analysis of mixed valences and oxygen deficiency is addressed.

THE FAMILY OF PEROVSKITE-STRUCTURED MATERIALS

Examples of Perovskite Structures

The most typical perovskite structure is BaTiO_3 (Fig. 1a). The Ba atoms appear at the corners of the unit cell and oxygen atoms at the face centers. Both the Ba and O make up a face-centered lattice structure. The octahedrally coordinated titanium ion is located at the center of the unit cell. This structure can be generically written as ABO_3 , which is the fundamental structural configuration of perovskites.

Materials that have perovskite-like structures are numerous. The most typical are ceramic high-temperature superconductors such as $\text{YBa}_2\text{Cu}_3\text{O}_7$ (Fig. 1b). The unit cell can be considered a stack of three perovskite units along the c-axis direction, where the cation lattice preserves that of the perovskite, and oxygen vacancies are introduced. The distortion in the oxygen lattice sites is due mainly to the vacancies. The long periodicity of the c axis (e.g., superstructure) is the result of alternate distribution of the Y and Ba cations and the ordered structure of oxygen vacancies.

A comparison of BaTiO_3 with $\text{YBa}_2\text{Cu}_3\text{O}_7$ indicates the following. In BaTiO_3 , the cations are screened by anions so that two cations are not directly face-to-face. In $\text{YBa}_2\text{Cu}_3\text{O}_7$, although the cation distribution is the same as that in BaTiO_3 , the Cu ions at the top layer of the

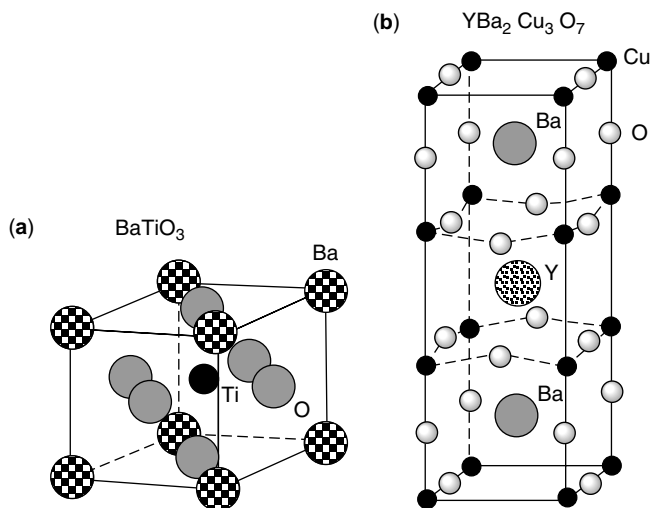

Figure 1. Atomic structural models of (a) BaTiO_3 and (b) $\text{YBa}_2\text{Cu}_3\text{O}_7$.

unit cell are face-to-face without the screening of anions, whereas the Cu cations next to Y are well coordinated. This structural configuration is possible only if Cu ions have different valence states at the two types of lattice sites. Therefore, perovskites have three major structural characteristics: cation substitution, ordered oxygen vacancies, and mixed valences of cations.

Perovskite-Like Structures

In the ABO_3 structure, the valences of the A (12-coordinated) and B (6-coordinated) cations are usually $2+$ and $4+$, respectively. The valence variation at the A cation position can cause distortion or displacement of the oxygen anion array, possibly resulting in distortion in the B-cation-centered octahedron. The B cation must have the flexibility to tolerate this effect, and the transition-metal elements are candidates for filling the B-cation position because of their multivalences and their special 3d and 4d electronic configurations. This is the reason that transition-metal oxides have perovskite-type structures (3). Perovskite-like structures can be sorted by the valence combination of the A and B cations as follows (4):

1. $\text{A}^{1+}\text{B}^{5+}\text{O}_3$ type, such as KNbO_3 , NaNbO_3 , LiNbO_3 and KTaO_3 .
2. $\text{A}^{2+}\text{B}^{4+}\text{O}_3$ type, in which the A^{2+} cations are alkaline-earth ions such as cadmium or lead, and the B^{4+} ions can be Ce, Fe, Pr, Pu, Sn, Th, Hf, Ti, Zr, Mo, and U. BaTiO_3 and PbTiO_3 are typical examples. These two compounds are well known for their remarkable ferroelectric properties (see later section).
3. $\text{A}^{3+}\text{B}^{3+}\text{O}_3$ type, such as GdFeO_3 , YAlO_3 , PrVO_3 , PrCrO_3 , NdGaO_3 and YScO_3 .
4. $\text{A}^{2+}(\text{B}^{3+}_{0.67}\text{B}^{6+}_{0.33})\text{O}_3$ type, such as $\text{Ba}(\text{Sc}_{0.67}\text{W}_{0.33})\text{O}_3$ and $\text{Sr}(\text{Cr}_{0.67}\text{Re}_{0.33})\text{O}_3$.
5. $\text{A}^{2+}(\text{B}^{2+}_{0.33}\text{B}^{5+}_{0.67})\text{O}_3$ type, for example $\text{Ba}(\text{Sr}_{0.33}\text{Ta}_{0.67})\text{O}_3$, and $\text{Pb}(\text{Mg}_{0.33}\text{Nb}_{0.67})\text{O}_3$.
6. $\text{A}^{2+}(\text{B}^{3+}_{0.5}\text{B}^{5+}_{0.5})\text{O}_3$, $\text{A}^{2+}(\text{B}^{2+}_{0.5}\text{B}^{6+}_{0.5})\text{O}_3$, $\text{A}^{2+}(\text{B}^{1+}_{0.5}\text{B}^{7+}_{0.5})\text{O}_3$, and $\text{A}^{3+}(\text{B}^{2+}_{0.5}\text{B}^{4+}_{0.5})\text{O}_3$ types, such as $\text{Ba}(\text{Sr}_{0.5}\text{W}_{0.5})\text{O}_3$, $\text{Pb}(\text{Sc}_{0.5}\text{Ta}_{0.5})\text{O}_3$ and $\text{Pb}(\text{Sc}_{0.5}\text{Nb}_{0.5})\text{O}_3$. The compounds, $\text{Pb}(\text{Mg}_{0.33}\text{Nb}_{0.67})\text{O}_3$, $\text{Pb}(\text{Sc}_{0.5}\text{Ta}_{0.5})\text{O}_3$ and $\text{Pb}(\text{Sc}_{0.5}\text{Nb}_{0.5})\text{O}_3$, are very important ferroelectric materials, and they are usually called “relaxors.”
7. $\text{A}^{2+}(\text{B}^{1+}_{0.25}\text{B}^{5+}_{0.75})\text{O}_3$ type, such as $\text{Ba}(\text{Na}_{0.25}\text{Ta}_{0.75})\text{O}_3$ and $\text{Sr}(\text{Na}_{0.25}\text{Ta}_{0.75})\text{O}_3$.
8. $\text{A}^{2+}(\text{B}^{2+}_{0.5}\text{B}^{5+}_{0.5})\text{O}_{2.75}$ and $\text{A}^{2+}(\text{B}^{3+}_{0.5}\text{B}^{4+}_{0.5})\text{O}_{2.75}$ that are anion deficient, such as $\text{Sr}(\text{Sr}_{0.5}\text{Ta}_{0.5})\text{O}_{2.75}$ and $\text{Ba}(\text{Fe}_{0.5}\text{Mo}_{0.5})\text{O}_{2.75}$.
9. $\text{A}^{2+}(\text{B}^{3+}_{0.5}\text{B}^{2+}_{0.5})\text{O}_{2.25}$.

It is apparent that the perovskite structures cover a large group of materials. Three questions are particularly interesting: What are the special properties of perovskites as far as smart materials are concerned? What is the relationship between these structures, for example, the structural evolution in perovskite, and what is the relationship between the cation valence and its coordination? The following analysis explores the answers to these questions.

STRUCTURES AND PROPERTIES

Ferroelectricity

Ferroelectric materials are candidates for robust non-volatile memories (5). Figure 2 gives a high-resolution transmission electron microscopy (TEM) image of BaTiO_3 oriented along [100] (or [001]), where the cations are in dark contrast and the contrast is directly related to the

Figure 2. High-resolution transmission electron microscopy image of BaTiO_3 oriented along [100], showing the cation (in dark contrast) distribution in the crystal. The atom types can be clearly identified. At the top of the film, surface steps of one unit cell height are seen, and the termination layer is Ba–O.

Figure 3. (a) Intrinsic spontaneous polarization in tetragonal BaTiO₃. (b) Displacements of the cations and anions in the tetragonal structure. (c) Schematic of a hysteretic loop for a ferroelectric material induced by an external electric field E , where P and E_c are the polarization and coercive fields, respectively. (d, e) 180° and 90° domain boundaries in BaTiO₃.

atomic number. The oxygen anions are not clearly resolved in the image because of its weak scattering power. At the top of the film, the last ending layer is the Ba–O layer, clearly indicating that the Ti atom strongly demands a complete octahedral coordination even at the boundary of the crystal. The octahedral coordination of Ti is at the root of ferroelectricity.

The Ti ion is surrounded by six oxygen ions in an octahedral configuration (Fig. 1a). BaTiO₃ has a cubic structure at $T > 120^\circ\text{C}$. For $5 < T < 120^\circ\text{C}$, it is tetragonal. In the low-temperature range of $-90 < T < 5^\circ\text{C}$, it has an orthorhombic structure, and for $T < -90^\circ\text{C}$, it is rhombohedral. Therefore, the structural transformation from centrosymmetric to noncentrosymmetric occurs at 120°C , and ferroelectricity occurs at $T < 120^\circ\text{C}$. Below the 120°C transition temperature, the oxygen and titanium ions are displaced to new positions (Fig. 3a,b), forming a tetragonal structure where $c/a = 1.01$ (3). A unilateral displacement of the Ti⁴⁺ ion against O²⁻ results in a dipole moment. When all of the dipoles of different domains point in the same direction, the material is *ferroelectric*. If the dipoles have equal strength but are aligned in an antiparallel configuration so that they cancel each other and the material does not exhibit a macroscopic dipole, it is *antiferroelectric*. If these dipoles cannot completely cancel each other, the residual dipoles add up, forming a macroscopic dipole, which is *ferroelectricity*.

The spontaneous alignment of dipoles that occurs at the onset of ferroelectricity is often associated with a

crystallographic phase change from a centrosymmetric, nonpolar lattice to a noncentrosymmetric polar lattice. If an external electric field is applied to the crystal, the population of the domains whose polarizations are parallel to the field increases, and those whose polarizations are antiparallel and not parallel to the field decrease. If the external electric field is removed, the domains cannot spontaneously compensate for each other again, and a remanent polarization P_r remains. To remove the remanent polarization, an oppositely oriented electric field whose field strength is E_c , called the *coercive field*, has to be applied to the crystal. The polarization hysteretic loop (Fig. 3c) is the basis of electric data storage using ferroelectric materials.

An increasing number of materials have been found that demonstrate spontaneous polarization. Lead titanate (PbTiO₃), which has the same perovskite structure as BaTiO₃, is ferroelectric. Other examples includes Rochelle salt (potassium sodium tartrate tetrahydrate), KH₂PO₄, KH₂AsO₄; perovskites NaCbO₃, KCbO₃, NaTaO₃, and KTaO₃; ilmenite structures, LiTaO₃ and LiCbO₃; and tungsten oxide, WO₃.

Domains and domain boundaries can be formed in ferroelectric materials. The spontaneous polarization of the Ti and oxygen ions creates an electrostatic polarization P along the c axis. This anisotropic structural configuration can form 90 and 180° domain boundaries defined with reference to the orientations of the c axes or the P vectors that belong to the two crystal domains (Fig. 3d,e). The 90° domain boundary is just a (101) [or (011)] twin boundary of

Figure 4. High-resolution transmission electron microscopy image of BaTiO_3 oriented along $[100]$, showing the presence of a (011) 90° domain boundary.

the tetragonal crystal (6). The \mathbf{P} polarization or c axis turns its direction by an angle $\alpha = \delta - 90^\circ$ across the twin or domain boundary, where δ is determined by the axial ratio of the tetragonal unit cell: $\delta = 2 \arctan(c/a)$; $\alpha = 0.57^\circ$ for $c/a = 1.01$.

Figure 4 is a high-resolution transmission electron microscopy image of a 90° domain boundary in BaTiO_3 . The domain boundary is parallel to the electron beam direction. A relative rotation α of the crystal lattice across the domain boundary (dark line) can be seen along the white lines traced along the rows of atoms. Domain structure, such as its sharpness, thickness, and size, is a key to many ferroelectric properties.

Another candidate for nonvolatile memories is $\text{SrBi}_2\text{Ta}_2\text{O}_9$ (Fig. 5). The structure is a c -axis stacking of perovskite units accommodated by bismuth oxide layers. The noncentr. symmetric structure produces the relative displacements of the cations and anions, for example, ferroelectricity.

Piezoelectricity

Piezoelectric Effect. *Piezoelectricity* is induced by a linear relationship between an electric field and mechanical strain. To illustrate piezoelectricity, consider a positively charged atom that is surrounded tetrahedrally by anions (Fig. 6). The center of gravity of the negative charges is at the center of the tetrahedron. By exerting pressure on the crystal along the cornering direction of the tetrahedron, the tetrahedron experiences distortion, the center of gravity of the negative charges and the position of the positive central atom no longer coincide, and an electric dipole is generated. If all of the tetrahedra in the crystal have the same orientation or some other mutual orientation that does not allow for cancellation among the dipoles, the crystal has a macroscopic dipole. The two opposite faces of the crystal have opposite electric charges. This is an electromechanical transducer that converts a mechanical force into an electric signal or vice versa.

Figure 5. Structure of ferroelectric $\text{SrBi}_2\text{Ta}_2\text{O}_9$.

$\text{Pb}(\text{Zr}_x\text{Ti}_{1-x})\text{O}_3$ (PZT) is the most typical piezoelectric material (Fig. 7) (7). PZT has the perovskite structure. When cooling from high temperature, the crystal structure of PZT undergoes a displacive phase transformation and atomic displacements of $\sim 0.1 \text{ \AA}$. For titanium-rich compositions, the point symmetry changes from $m3m$ to tetragonal $4mm$ at the Curie temperature. To maximize the polarization of the PZT phase, compositions near a second phase transition are chosen. At the Curie point (T_c), PZT converts from a paraelectric state that has the ideal cubic

Figure 6. Mechanism of the piezoelectric effect. External pressure causes the deformation of a coordination tetrahedron that results in a shift of the gravity centers of the electric charges and creates a local polarization dipole.

Figure 7. (a) Structural model of $\text{Pb}(\text{Zr}_x\text{Ti}_{1-x})\text{O}_3$ (PZT). (b) Phase diagram $\text{Pb}(\text{Zr}_x\text{Ti}_{1-x})\text{O}_3$ and the associated structural changes at the Curie temperature (T_c) and the morphotropic phase boundary (MPB). Compositions near MPB have 14 possible poling directions (six perpendicular to the planes and eight along the corners).

perovskite structure to a ferroelectric phase located near a morphotropic phase boundary (MPB) between the tetragonal and rhombohedral states. Very large piezoelectric coupling between electric and mechanical variables is attained near the MPB.

Parameters for Piezoelectric Ceramics. The proportional constants between the strain and the applied electric field are related by $\mathbf{x} = \mathbf{d}\cdot\mathbf{E}$, where \mathbf{d} is the *piezoelectric coefficient* tensor (8). The state of strain in the volume is fully described by a second-rank tensor, a “strain tensor,” and the state of stress by a stress tensor, again of second rank. Therefore, the relationships between the stress and strain tensors, that is, Young’s modulus or compliance, are fourth-rank tensors. The relationship between the electric field and electric displacement, the permittivity, is a second-rank tensor. In general, a vector (formally regarded as a first-rank tensor) has three components, a second-rank tensor has nine components, a third-rank tensor has 27 components, and a fourth-rank tensor has 81 components. However, not all of the tensor components are independent. The crystal symmetry and the choice of reference axes reduce the number of components. A poled ceramic has ∞ -fold symmetry in a plane normal to the poling direction. Therefore, the symmetry of a poled ceramic is described as ∞mm .

The convention is to define the poling direction as the 3 axis. The shear planes are indicated by the subscripts 4, 5, and 6 and are perpendicular to directions 1, 2, and 3, respectively (see Fig. 8). For example, d_{31} is the coefficient that relates the field along the polar axis to the strain perpendicular to it, and d_{33} is the corresponding coefficient for both strain and field along the polar axis. Shear can occur only when a field is applied at right angles to the polar axis so that there is only one coefficient, d_{15} . There are also piezoelectric coefficients corresponding to hydrostatic stress, for example, $d_h = d_{33} + 2d_{31}$.

Figure 8. Labeling of reference axes and planes for piezoceramics (note that the polarization direction is upward).

Both intrinsic and extrinsic factors contribute to piezoelectric coefficients. The intrinsic effects from the distortions of the crystal structure under mechanical stress appear in Fig. 9. Under mechanical stress parallel to the dipole moment, an enhancement of the spontaneous polarization P along x_3 is induced. When stress is applied perpendicularly to that dipole moment, electric charges develop transversely. These are the d_{33} and d_{31} effects, respectively. When the dipole is tilted by shear stress, charges appear on the side faces, the d_{15} coefficient. The extrinsic contribution to the piezoelectric coefficient comes mainly from domain-wall motion.

Piezoelectric properties are described in terms of these parameters: dielectric displacement (\mathbf{D}), electric field (\mathbf{E}), stress (\mathbf{X}), and strain (\mathbf{x}). The direct piezoelectric effect relates polarization to stress and is used in sensors. The converse effect relates strain to electric field and is used in actuators. If the piezoelectric coefficient \mathbf{d} is assumed constant, the direct and converse effect can be written as

$$\mathbf{D} = \mathbf{d}\cdot\mathbf{X} + \epsilon^{\mathbf{x}}\cdot\mathbf{E}, \quad (1)$$

Figure 9. Schematics showing the relationship between the intrinsic piezoelectric effect and the piezoelectric coefficients in polar lead titanate.

and

$$\mathbf{x} = \mathbf{s}^E \cdot \mathbf{X} + \mathbf{d} \cdot \mathbf{E}, \quad (2)$$

where \mathbf{s} is elastic compliance and the superscripts denote the parameters held constant. The crystal structure and its distortion determine the piezoelectric coefficients (Fig. 9). Table 1 gives typical values of the parameters for some piezoelectric materials. Piezoelectric ceramics are probably the most important actuating materials (9).

Electrostrictive Perovskites

Electrostriction describes a quadratic relationship between mechanical strain and the square of the electric polarization. $\text{Pb}(\text{Mg},\text{Nb})\text{O}_3$ (PMN) is the most typical electrostrictive perovskite (10). PMN is cubic at high temperatures, and when annealed, transforms to a partially

ordered state. When cooled further, PMN passes through a diffuse phase transformation at room temperature where it exhibits very large dielectric and electrostrictive coefficients. Just below room temperature, it transforms to a ferroelectric rhombohedral phase. The piezoelectric d_{33} coefficient is the slope of the strain–electric field curve when strain is measured in the same direction as the applied field. Its value for $\text{Pb}(\text{Mg}_{0.3}\text{Nb}_{0.6}\text{Ti}_{0.1})\text{O}_3$ is zero at zero field, but it increases to a maximum of 1300 pC/N, three times larger than that of PZT, under a bias field of 3.7 kV/cm. This means that the electromechanical coupling coefficient can be tuned across a wide range to convert the transducer from inactivity to extreme activity. The dielectric constant of PMN depends on the bias field. Polarization saturates at a high field and causes a decrease in the dielectric constant. Therefore, the electrical impedance can also be controlled. This tunable property has its roots in so-called compositional microdomains. Because the ionic radii of Sc^{2+} , Ta^{6+} , Mg^{2+} , and Nb^{6+} in perovskites are close to each other, the long-range order is not favorable, but the shorter range order is preferable. The ordered phase has a double size in each axis of the perovskite unit cell and a face-centered-cubic structure. They are reexpressed as the $\text{Pb}_2\text{MgNbO}_6$ -order domain and the PbNbO_3 -disorder domain if the original compound is $\text{Pb}(\text{Mg}_{0.33}\text{Nb}_{0.67})\text{O}_3$ in which the valence states of Nb, Mg, and Pb are 5+, 2+ and 2+, respectively. High-resolution TEM reveals that the domains are about 3 nm in diameter and the ordered regions are small islands separated by narrow walls of niobium-rich PMN (11). The ordered regions, $\text{Pb}_2\text{MgNbO}_6$, have a negative charge, but the disordered areas, PbNbO_3 , have a positive charge. The ordered regions have to be very small to minimize the coulombic energy, but the distortion of perovskite is so small that the interfacial energy is negligible. The compositions of the ordered and disordered regions are different; therefore, the domains may be called compositional domains. The negatively charged ordered islands are enclosed by positively charged disordered layers to make the system neutral on a local scale and minimize the electrostatic energy.

Electrostriction is a 6×6 matrix, that relates strain to the square of the electric polarization. For a cubic crystal, Q_{11} , Q_{12} , and Q_{44} are the coefficients normally used.

Table 1. Typical Properties of Some Piezoelectric Materials^a

^cPZT A and PZT B are two typical PZT materials that illustrate, in particular, the wide range of tunable properties.

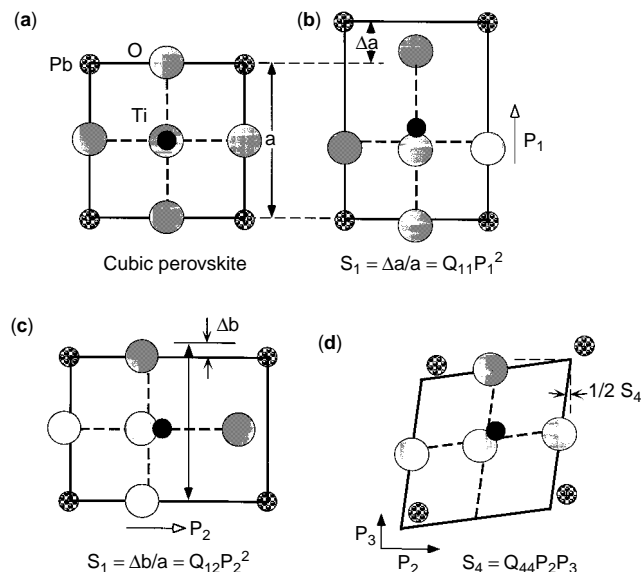

Figure 10. Electrostriction in cubic perovskite, showing the physical origin of electrostrictive coefficients Q_{11} , Q_{12} , and Q_{44} . The cross represents the lattice site of the atom.

Electrostrictive transducers rely on microregions that fluctuate in polarization. On average, the atoms reside in the ideal cubic sites but are continually shifting from these positions. Atomic scale descriptions of Q_{11} , Q_{12} , and Q_{44} are given in Fig. 10 (12).

Colossal Magnetoresistivity

Magnetoresistance is the change in electrical resistance R due to an external magnetic field. Positive or negative magnetoresistance refers to the increase or decrease of resistivity as the applied magnetic field changes. Two kinds of magnetoresistance are defined by the two possible orientations of the magnetic field H and the current J applied to the samples measured. $\Delta R_{//} = R_{//}(H) - R_{//}(0)$ when H is parallel to J , and $\Delta R_{\perp} = R_{\perp}(H) - R_{\perp}(0)$ when H is perpendicular to J . In ferromagnetic metals, magnetoresistance is anisotropic where $\Delta R_{//} > \Delta R_{\perp}$, positive $\Delta R_{//}$ and negative ΔR_{\perp} . They are saturated under a modest field (10 Oe for PermalloyTM), and the magnitude depends on the direction of the spontaneous magnetization. These materials are often referred to as anisotropic magnetoresistant materials. A typical value of $(R_{//} - R_{\perp})/R(0)$ for Permalloy TM is about 2% at room temperature.

Colossal magnetoresistance (CMR) has been observed in a perovskite-structured $(La,A)MnO_3$ ($A = Ca, Sr,$ or Ba) (13,14). A $(La,Ca)MnO_3$ epitaxial film prepared by laser ablation reportedly exhibited a CMR peak value of 127,000% at 77 K and 1300% at 260 K (13). Figure 11 gives a magnetoresistance curve of a new material, $La_{0.5}Ca_{0.23}MnO_{3-\delta}$, that displays CMR at room temperature (15). The resistance drops as the applied magnetic field increases, and it increases as the temperature increases. This property is very useful in sensor applications.

CMR magnetic oxides have a perovskite type crystal structure that has ferromagnetic ordering in the a,b plane

Figure 11. Magnetoresistance observed in an A site deficient $La_{0.5}Ca_{0.23}MnO_{3-\delta}$ around room temperature. The field was applied perpendicularly to the film.

and antiferromagnetic ordering along the c axis (Fig. 12b). The ferromagnetically ordered Mn–O layers of the a,b planes are isolated by a nonmagnetic La(A)–O monolayer. This spin-coupling structure is intrinsic. $La_{1-x}A_xMnO_3$ and $La_{1-x}A_xCoO_3$ compounds that have the extreme values $x = 0, 1$ are neither ferromagnetic nor good electrical conductors; they are semiconductors. Only compounds that have intermediate values of x are ferromagnetic, and the strongest ferromagnetism occurs in the range of $0.2 < x < 0.4$. Within this same range, the materials are electrically conductive.

Cation Doping-Induced Insulator-to-Conductor Transition

The electric conductivity of a perovskite, such as $LaMnO_3$, can be tuned by cation doping. We limit our discussion here to the case in which the dopants are distributed in a long-range order rather than as random impurities, as in conventional ceramics. The substitution of trivalent La^{3+} in $LaMnO_3$ by divalent A^{2+} is balanced by the conversion of Mn valence states between Mn^{3+} and Mn^{4+} and creation of oxygen vacancies as well. The following ionic structure of $La_{1-x}A_xMnO_3$ is proposed (16):

Whenever Mn^{3+} and Mn^{4+} are on neighboring Mn sites, the possibility exists of conductivity from electrons hopping from Mn^{3+} to the Mn^{4+} assisted by the oxygen anion. That this hopping current should be spin polarized is required for a process of two simultaneous electron hops (from Mn^{3+} onto O^{2-} and from O^{2-} onto Mn^{4+} , thus interchanging Mn^{3+} and Mn^{4+} ; this is called *double exchange* (17) (Fig. 13). The electron hopping away from the Mn^{3+} remembers the spin state that it has on the ion, as determined by *Hund's rule*, and the electron hopping onto Mn^{4+} must have the same spin state. This is only possible,

Figure 12. (a) Perovskite unit cell of $(\text{La,Ca})\text{MnO}_3$. (b) The newly introduced unit cell considering that the Jahn–Teller distortion results from magnetic ordering, so that the structure is orthorhombic and has space group $Pnma$. (c) High-resolution transmission electron microscopy image of $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ oriented along $[100]$.

without violating Hund's rule on Mn^{4+} , if the net ion spins of the neighboring Mn^{3+} and Mn^{4+} are in the same spin direction. Hopping is impossible if the spin directions of the two states are antiparallel. In fact, the likelihood of electron hopping between two magnetic ions turns out to depend on the spin or transformation (18,19), which is characterized by a transfer integral (analogous to the transfer probability)

$$t_{ij} = b_{ij} \cos(\theta_{ij}/2), \quad (4)$$

where b_{ij} is a constant depending on the isolation between the ions and θ_{ij} is the angle between the direction of the spin ions. Thus, the electric resistance of the material is a function of its intrinsic magnetic order.

Figure 13. Schematic illustration of the double-exchange effect for parallel, antiparallel, and general cases. This effect is responsible for the electric conductivity of a doped perovskite.

Cation doping in PZT usually preserves the standard ABO_3 structure, in which the B-atom site can be occupied by either Zr or Ti. Cation doping, in some cases, can create superstructures. Figure 14a shows a high-resolution TEM image of $\text{La}_{0.33}\text{Sr}_{0.67}\text{CoO}_3$ (20), where the cation positions and types can be identified from the image. The oxygen atoms are not seen in the image due to the limited resolution power of the TEM and its weak scattering power. This structure is the result of cation substitution in a perovskite, and its structural model of fully coordinated anions is given in Fig. 14b. If the structural model is projected along $[100]$, the cation positions match the positions of the white dots observed in the image.

From Eq. (3), it can be seen that charge ordering of Mn^{3+} and Mn^{4+} can also occur in CMR materials. The ordered arrays of Mn^{3+} and Mn^{4+} can produce long, periodic, structural modulations, and this structure is important for coordinating the intrinsic electron hopping effect.

Ionic conductivity

Compounds that have perovskite or perovskite-related structures usually can be used as oxygen ion conductors, such as LaMnO_3 , and fuel cells, such as $\text{Fe}_{1-x}\text{Sr}_x\text{CoO}_3$. The sizes of A cations should be similar to that of oxygen anions, for example, Ba^{2+} (0.135 nm), Pb^{2+} (0.119 nm), Sr^{2+} (0.118 nm), Ca^{2+} (0.1 nm), and O^{2-} (0.14 nm). In LaMnO_3 , the La cations are smaller than oxygen anions (about 24%). Thus, oxygen migration is possible but limited. For faster diffusion of oxygen anions, it is best to create oxygen vacancies. Increasing temperature, of course, could create oxygen vacancies, but for lower temperature diffusion, the substitution of La^{3+} by divalent cations, such as Sr^{2+} and Ca^{2+} , can create oxygen vacancies [see Eq. (3)]. In

Figure 14. High-resolution TEM image of $\text{La}_{0.33}\text{Sr}_{0.67}\text{CoO}_3$, viewed along [100], showing the superstructure induced by cation substitution. The inset is a Fourier transform of the image. The structural model of $\text{La}_{0.33}\text{Sr}_{0.67}\text{CoO}_3$ is also given.

$(\text{LaO}_3)^{3-}$ (111) stacking layers (as displayed in Fig. 17a), the oxygen anions are closely packed around the A cation; a missing oxygen anion (due to creation of a vacancy) will cause strong coulombic interaction between the A cations (Fig. 15). This repulsive force makes the distance between the two adjacent A cations larger, and the A cations attract the neighboring oxygen anions to move in. If this distortion is too large, it may introduce buckling of the $(\text{LaO}_3)^{3-}$ layers and change the Bravais

cell. In other words, oxygen diffusion may induce phase transition.

Aurivillius phases have the general formula $\text{Bi}_2\text{O}_2(\text{A}_{n-1}\text{B}_n\text{O}_{3n+1})$ and can be described as layered structures that consist of perovskite blocks sandwiched between fluorite-like $(\text{Bi}_2\text{O}_2)^{2+}$ sheets (see Fig. 5). $\text{Bi}_2\text{NaNb}_2\text{O}_{8.5}$ is an $n = 2$ defect Aurivillius phase that exhibits good oxide ion conductivity at high temperature because of a structural phase transition (21). CaTiO_3 , SrCeO_3 , and

Figure 15. Migration of oxygen vacancies in perovskite and an ionic conductor. (a) Creation of one oxygen vacancy may lead to the diffusion of another oxygen anion toward the vacancy site, thus (b) the vacancy site is shifted, resulting in some distortion near the new vacancy site in the (AO_3) (111) stacking layer.

BaCeO₃ can be good conductors of ions and electrons or protons by simply changing the valence of the B cations to mixed valency.

Superconductivity

Superconductivity is the phenomenon of vanishing electrical resistance below the superconducting transition temperature (T_c). Superconductivity has important applications in power transmission, nuclear magnetic resonance, extremely strong magnets, and high-speed computing. High-temperature superconductors, such as YBa₂Cu₃O₇, Bi₂Sr₂CaCu₂O_{8+d} and Tl₂Ba₂Ca₂Cu₃O_x, are the focus of today's research (22). Most ceramic superconductors are based on the perovskite structure. The structure of YBa₂Cu₃O₇ will be used as an example to show the construction of its structure from anion-deficient perovskites (see later section).

A superconductor is characterized by three physical quantities. The first is the *critical transition temperature* T_c , below which superconductivity appears. The second is the *critical magnetic field* H_c , below which a superconducting body exhibits perfect diamagnetism and excludes a magnetic field. If the applied magnetic field is higher than H_c , the materials revert to the normal state. H_c is temperature-dependent. The third is the *critical current density* J_c , above which superconductivity is destroyed and the superconductor reverts to the normal state. Polycrystalline superconducting materials are limited mainly by low J_c due to the weak link between grain boundaries. Improving J_c in the field is the essential task of current research in superconductivity.

THE FUNDAMENTAL STRUCTURAL CHARACTERISTICS OF ABO₃ PEROVSKITE

Perovskite and related structures cover a large portion of smart materials, and their crystal structures can vary to a large extent. The key questions are do the perovskite-type structures have smart properties and are there any intrinsic connections among the structures? The answers may be found in the following areas: (1) nonstoichiometry

of the cation and/or the anions; (2) distortion of the cation configuration; and (3) the mixed valence and the valence mixture electronic structure. From the viewpoint of crystal structure, each of these features can be introduced by doping a third type of cation into the stoichiometric phase of a base structure. It is important to understand how oxygen stoichiometry and lattice distortion are introduced as a result of doping another type of cation that has different valence states. First, we explore the fundamental perovskite structure (2).

Vertex Sharing of Oxygen Octahedra

In the ABO₃ type structure, the cation B whose valence is 4+ is usually a transition-metal element that prefers to form a six-coordinated octahedron with its neighboring oxygen anions, and itself is located at the center. The octahedron is the basic unit of these structures. The geometric configuration of the arrangement of the octahedra that has the lowest interactive energy is a linear 180° vertex-sharing connection. If the octahedra are connected to each other at every vertex, they form a 3-D network (Fig. 16a). Because the oxygen at every vertex is shared by adjacent octahedra, the composition of this configuration is BO₃, and the unit cell is a simple cubic, as given in Fig. 16a. This structure, however, cannot exist unless B has a valence of 6+ because the valence charges are not balanced. Thus, a cation of valence 2+ must be introduced into the structure to balance the local excess negative charge. A vertex-sharing octahedral network, on the other hand, has a large cavity in the center of the unit cell. A cation of valence 2+ can occupy this cavity. Then, the unit cell still preserves the simple cubic structure, and the composition is ABO₃, simply the basic model of the perovskite structure (Fig. 16b). It is clear, therefore, that six-coordinated octahedra are essential structural and compositional building blocks, and sharing of all of the vertexes is required for the stoichiometry and the structure of the perovskite. Based on this ideal, we can outline some characteristics of the perovskite structure:

1. Any cation, that prefers to have six coordination could occupy the B position even if its valence is

Figure 16. ABO₃ perovskite structure formed by corner-sharing octahedron chains. The corners of the Bravais cell are the B cations. (a) A postulated structure where the A cation is absent at the center, and (b) a structure that has the A cation. The anions shadowed by the octahedra are not shown for clarity. (c) ABO₃ perovskite structure drawn by setting the A cations as the corners of the Bravais cell, showing the BO₆ octahedron located in the A-cation cube.

- different from $4+$, but to balance the valence charges, the average valence at the B site usually equals $4+$.
- The A cation of valence $2+$ is expected to have a larger radius because, as a general rule, the valence increases as the radius of the cation decreases and vice versa. The coordination number of the A cation is 12. Elements that have a coordination number of more than six are likely to bond ionically. This is possible because the A cation in the perovskite structure is usually an alkaline-earth metal element. From this viewpoint, we may say that any cation, of higher ionicity or less polarity could occupy the position of the A cation, although its valence is different from $2+$. But to balance the charge, the average valence at this site is likely to be $2+$.
 - From 1 and 2, we can see that B cations have some degree of covalency, or in other words, they are easier polarize than A cations, and bonding between the B cation and the adjacent oxygen is stronger than that of the A cation. The octahedron of oxygen is the basic unit of the perovskite structure although it may be distorted, as is discussed later. Oxygen anions have significant influence on the cation valence if it can be changed. For example, a vacancy of oxygen can result in modifying the valence state of the B cation. The A cation may not be easily modified because it bonds ionically to the adjacent oxygen. However, if the A cation changes valence, the surrounding oxygen anions must be affected to balance the valence charges by creating vacancies. Because the oxygen anion cannot have a valence other than -2 , an oxygen deficiency must form to balance the local charge.

The roles of the A and B cations in the structural evolution of ABO_3 type perovskite can be understood as follows. *The A cation plays a key role in oxygen deficiency because of its stronger ionic interaction with oxygen anions.* We will see later that the A cation is closely packed together with oxygen. The B cation prefers six-coordination (i.e., an octahedron) although its valence can vary. The flexibility in the valences of the B cation makes the oxygen anion deficiency acceptable, and in a reverse process, the oxygen deficiency is autocontrolled by adjusting the valence of the B cation. This process makes the perovskite structure the most fascinating structural configuration for smart materials.

If the A cation changes its valence, for example, from $+2$ to $+3$, the oxygen anion must modify its occupancy to match the valence variation of the A cation and to balance the local charge, resulting in oxygen deficiency. But this change will feed back to the B cation, leading to disproportionation of the local valence state. The disproportionation of the B cation's oxidation state usually changes the electronic band structure of the perovskite compound, resulting in a transition from an insulator to a semiconductor, conductor, or even superconductor. CaMnO_3 is an insulator, but when the Ca (i.e., A^{2+} cation) is totally replaced by La($+3$), LaMnO_3 could be a conductor if the monovalence Mn^{4+} were replaced by mixed valent states of Mn^{3+} and Mn^{4+} . From the viewpoint of charge balance, if the valence of the Mn cations is $+3$ and $+4$, the relative content of the oxygen anions should be more than 3, in other words, its formula

should be LaMnO_{3+x} . Based on the crystallography of the perovskite structure illuminated discussed before, the excess oxygen anions have no place to locate because the existing oxygens have already been closely-packed in the structure. Therefore, if Mn^{3+} and Mn^{4+} must coexist in the system, the only choice is to change the A cation's valence state from La^{3+} to a mixture of La^{3+} and A^{2+} , a divalent cation. For example, if a small portion of La^{3+} is replaced by Ca^{2+} , the La^{3+} stoichiometry will change from 1 to $1-x$. Then we can have a perovskite type structure that has $+3$ and $+4$ mixed Mn cations at the B site.

Unit Cell by Taking the A Cation as the Origin

The perovskite structure has a simple cubic Bravais cell, in which the octahedra share corners and the origin of the Bravais cell is at the B cation, as shown in Fig. 16a. Alternatively, we can also take the A cation as the origin, and the unit cell is transformed into the form given in Fig. 16c. In this configuration, the A cations locate at the cubic vertices, and the oxygens occupy the face centers of the six faces to form an octahedron where the B cation is at the center. This geometric arrangement makes the oxygen form linear $\text{O}^{2-}-\text{B}^{4+}-\text{O}^{2-}$ triples parallel to the x , y , and z axes, and the oxygens are located at the centers of the squares formed by the A^{2+} cations. If an electric field is applied parallel to the z axis, for example, the $\text{O}^{2-}-\text{B}^{4+}-\text{O}^{2-}$ chain parallel to the z axis is polarized, but the $\text{O}^{2-}-\text{B}^{4+}-\text{O}^{2-}$ chains parallel to the x and y axes may not be disturbed, resulting in polarization of the crystal parallel to the z axis (ferroelectricity). Moreover, the displacement of the oxygen anions could cause a distortion in the configuration of the A cations, resulting in a change in the shape of the unit cell (the piezoelectric effect).

Oxygen Cubic Close Packing

Now, we reexamine the ABO_3 perovskite structure from a different viewpoint. We use the structural model of perovskite formed by the corner-sharing chains of octahedra, for example, the unit cell that has B cations as the origin, as shown in Figure 16b, in which the octahedron is sketched for clarity. The relationship between the oxygen anions and A cations in the $\{111\}$ stacking layers are revealed in Fig. 17a, where an A cation is surrounded by six oxygen anions and forms a closely packed structure. Note that three oxygen atoms form a triangular unit. Naturally, the A cations also form a hexagonal array, but are separated by the triangularly packed oxygen anions. The chemical composition of this layer is AO_3 . Because the charge of A is $2+$, the valence charge of the layer is $(\text{AO}_3)^{4-}$. To balance the local negative charge, a layer that has a charge of $4+$ must be introduced. Therefore, a B^{4+} cation layer (without oxygen anions) should be the next stacking layer (Fig. 17b). The A cation has three stacking positions, indicated by α , β , and γ , respectively, and the B cation has similar stacking. An A cation hexagon contains six apex-sharing oxygen triangles. This characteristic of the fundamental stacking layer $(\text{AO}_3)^{4-}$ determines the features of the perovskite structure. The $(\text{AO}_3)^{4-}$ and the B^{4+} layers are stacked together to form a combined layer, and the perovskite structure is obtained by stacking the new layers following a sequence of $\alpha \beta \gamma$ by translating the cation

Figure 17. (a) The fundamental $(\text{AO}_3)^{4-}$ (111) close-packing layer, and (b) the B^{4+} (111) close-packing layer in the perovskite structure. sites (similar to the stacking to form a face-centered-cubic lattice).

Anion Close Packing and Formation of Tetrahedra and Octahedra

The introduction of oxygen vacancies in the unit cell can create a wide range of perovskite structures. If one of the oxygen sublattices is vacant, the layer composition is $(\text{AO}_2)^{2-}$ (see Fig. 18b). If two of the oxygen sublattices are vacant, the layer composition is AO ; thus, the layers are neutral, provided the valence of cation A is 2+. There is no electrostatic force attracting the B^{4+} cation layers, and thus, the perovskite structure cannot be formed. If oxygen vacancies are partially formed in the $(\text{AO}_3)^{4-}$ layer, the close-packing layer should be $(\text{AO}_{3-x})^{(4-2x)-}$ (Fig. 18c,d where $x = 0.67$ and $x = 0.33$, respectively). Therefore, there are two choices to have oxygen vacancies in the three oxygen sublattices. If one oxygen vacancy is formed in the oxygen sublattice, it can locate in different layers and/or different sublattices of oxygen. The symmetry of oxygen triangles makes vacancies possible at different corners of the triangles that belong to alternate stacking layers. This creates the five- and four-coordinated oxygen polyhedra, shown in Fig. 19, where the structure of the B cations does not change, but their valence states may change to balance the local charge. The A cations in the

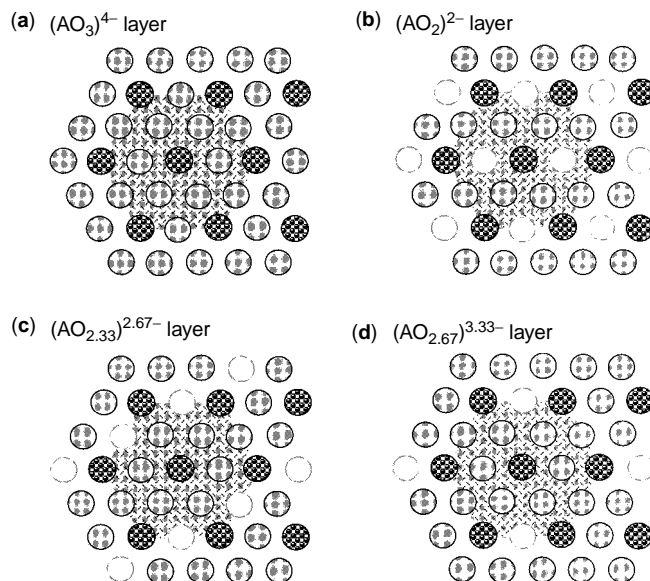

Figure 18. Two-dimensional oxygen sublattices in the $(\text{AO}_3)^{4-}$ layers (a) no vacancy [$(\text{AO}_3)^{4-}$], (b) one vacancy [$(\text{AO}_2)^{2-}$], and (c, d) partial vacancies.

$(\text{AO}_3)^{4-}$ layer may change their valence states and/or their total number in the layer (e.g., stoichiometry). Therefore, the substitution of the A cations by an element of different valence may be the optimum choice to induce oxygen deficiency and/or the mixed valence states of the B cations. This is the tailoring characteristic of the perovskite structure.

In the ABO_3 structure, the A cations are closely packed with the oxygen anions and are dominated by ionic bonding. The B cations may be regarded as the dependent subordinations that rely on the structure of the $(\text{AO}_3)^{4-}$ layer. Bonding of B cations with the surrounding oxygens may be ionic, covalent, or partially covalent. If the $(\text{AO}_3)^{4-}$ layer has defects, such as vacancies, stacking these layers will form distorted or deficient oxygen octahedra. Thus, the B cation must have the flexibility of modifying its valence state to balance the local charge. In other words, if we intend to modify the valence of the B cation, changing the structure surrounding the A cations via doping is recommended. This is an important principle for modifying the structure and properties of perovskites.

ANION-DEFICIENT PEROVSKITE STRUCTURAL UNITS—THE FUNDAMENTAL BUILDING BLOCKS FOR NEW STRUCTURES

Perovskite types of structures are the basis of many oxides, in which oxygen-deficient perovskites are a key group of materials that possess functionality. Anion-deficiency can change the coordination number of the B cation octahedra and the size and type of the Bravais unit cell of the compounds. It is important to elucidate the possible types of anion-deficient perovskite structures to enhance insight into fabricating new materials.

As shown in Fig. 18, there are three equivalent stacking positions for the layers parallel to the (111) plane. Figure 19a shows an $\alpha\beta$ stacking of the $(\text{AO}_3)^{4-}$ layers (the

Figure 19. The local oxygen vacancy arrangements and the stacking of the $(\text{AO}_3)^{4-}$ type layers (with vacancies). (a) Single and double oxygen vacancies in BO_6 octahedron, where 1, 2, and 3 represent the anions in the α , β , and γ layers, respectively. (b, c) Connections of the octahedra without, with one, and with two oxygen vacancies.

α , β , and γ positions are indicated in the left part of this figure). The octahedra are formed by superimposed oxygen triangles that belong to the α and β layers (this is most easily seen in Fig. 18). If an oxygen vacancy is created in the β layer, as indicated by V_2 , a five-coordinated polyhedron is formed. By the same token, oxygen vacancies can be created in the octahedra formed by the superposition of the β and γ layers, as shown in Fig. 19a,b, where the sequence numbers 1, 2, and 3 represent the anions in the α , β , and γ layers, respectively. As discussed before, any $(\text{AO}_3)^{4-}$ stacking layer can have oxygen vacancies. A five-coordinated polyhedron is formed if only one oxygen vacancy is created in the β layer, and the α layer is perfect. If two oxygen vacancies (V_1 and V_2) are created in the two adjacent layers within the same octahedron, a four-coordinated square is formed, as shown in Fig. 19a. It is impossible to have more than two vacancies in one octahedron because four apexes are the minimum to form a 3-D connection for the

perovskite type of frame. The geometric assemblies of the four-, five-, and six-coordinated A cations are given in Fig. 19c.

Figure 20a,b shows the BO_5 and BO_4 structures, respectively, in an octahedral sheet. The lack of one oxygen at a vertex forms a five-coordinated unit (Fig. 20a), and the lack of two oxygens located at two opposite vertices results in a four-coordinated square (Fig. 20b). The lack of three oxygens in one octahedron forces the unit to break its connections to other octahedra. Figure 20c shows a cluster constructed on the basis of the symmetrical distribution of two oxygen octahedra, resulting in four 5-coordinated polyhedra and two 4-coordinated squares. It has the composition AB_8O_{30} , and it demonstrates how the different coordinated polyhedra may be connected to each other in 3-D.

Figure 20d–n shows eight possible interconnecting configurations of the five- and four-coordinated polyhedra (2). Any of these types of anion-deficient perovskite-like

Figure 20. A total of 14 perovskite-type structural modules that have oxygen vacancies, where the oxygen anions are represented by different patterns to distinguish their stacking layers and V stands for vacancy. The combination of these modules can reproduce the crystal structures of many compounds (see text).

Figure 20. (Continued)

structural modules may be connected to the ideal perovskite structure's unit cells to form a new structure. The compound YBaCuFeO_5 (23), for example, has a structure that contains CuO_5 and FeO_5 units, corresponding to configuration (f) shown in Fig. 20. $\text{LaBa}_2\text{Cu}_2\text{TaO}_8$ (24) and $\text{Ba}_2\text{La}_2\text{Cu}_2\text{Sn}_2\text{O}_{11}$ (25) belong to the module shown in Fig. 20(l). The idealized structure of this compound contains TaO_6 or SnO_6 octahedra and five-coordinated CuO_5 . The structure of $\text{YBa}_2\text{Cu}_3\text{O}_7$ (26) is built by the unit in Fig. 20(l), and it contains five-coordinated CuO_5 and four-coordinated CuO_4 squares. The compound $\text{La}_2\text{Ni}_2\text{O}_5$ is constructed by the (h) type in Fig. 20, and it contains NiO_6 octahedra and NiO_4 four-coordinated squares. These types of anion-deficient perovskite-like units can be combined with tetrahedra, octahedra, or others including themselves to form a variety of different structures. The compound $\text{Ca}_2\text{Mn}_2\text{O}_5$ (27), for example, contains distorted MnO_5 units similar to the (m) type unit shown in Figure 20. The modules shown here are based the squares, tetrahedra, square-based pyramids (half-octahedra) and octahedra. These are the most fundamental "bricks" for constructing anion-deficient perovskite structures.

It must be pointed out that although the structural modules proposed in Fig. 20 assume that the atom sites are the same as in perfect perovskite structures, in practice, lattice relaxation/distortion is possible due to unbalanced anion coordination and oxygen vacancies. Fine-tuning of the structure must rely on quantitative fitting of X-ray or neutron diffraction data.

STRUCTURAL EVOLUTION IN THE FAMILY OF PEROVSKITES

High-Temperature Superconductors

In high T_c superconductors, the B cation is Cu that has +1, +2, and +3 valence states and coordination numbers 2, 3, and 4 for Cu(I) and 4 and 6 for Cu(II) and Cu(III). If the A and B cations in ABO_{3-x} have valences +3 and +2, respectively, the $(\text{AO}_3)^{4-}$ layers must be replaced by $(\text{AO}_{3-x})^{(3-2x)-}$. Because the Cu cation (the B cation) may have valence +1, +2, and +3, the perovskite-type cell that contains oxygen vacancies gives the Cu cation the possibility of disproportionating its valence from

+2 to +1 plus +3. Figure 21a gives the module shown previously in Fig. 20(l). The B cation in this module has two types of coordinations: BO_5 and BO_4 . If we flip this module over, as shown in Fig. 21b, and combine these two by superimposing the BO_4 units of the two, we obtain the new module given in Fig. 21c. This new module is the building block for the Y–Ba–Cu–O system of high T_c superconductors and introduces Ba cations between the modules. The structure of $\text{YBa}_2\text{Cu}_3\text{O}_7$ is given in Fig. 21d. Combining BO_4 units and the $\text{YBa}_2\text{Cu}_3\text{O}_7$ module (Fig. 21d) produces the structure of $\text{YBa}_2\text{Cu}_4\text{O}_8$ (Fig. 21f). Stacking $\text{YBa}_2\text{Cu}_3\text{O}_7$ and the $\text{YBa}_2\text{Cu}_4\text{O}_8$ modules creates the structure of $\text{Y}_2\text{Ba}_4\text{Cu}_7\text{O}_{15}$ (Fig. 21g).

Anion Deficiency-Induced Brownmillerite Structure

As we discussed before, the ABO_3 type perovskite has a fundamental stacking layer $(\text{AO}_3)^{4-}$ in which the A cations play a key role in creating oxygen vacancies. In general, the A cations have the valence +2 and an ionic character, which means that their coordination numbers are higher than six, for instance, 12. If the A cations have the valence +3 and an ionic character, the oxygen in the $(\text{AO}_3)^{4-}$ layers must be modified by creating oxygen vacancies. The charge of the layer is $(\text{AO}_3)^{3-}$; thus, the B cation layers must be modified to balance the local excess positive charge. The B cations usually have polarization or partial covalence, and they have favorable coordination numbers for reducing energy. If the valence of partial A cations is changed from +3 to +2, the negative charge of (AO_3) layers increases from -3 to $-(3+x)$, where x depends on the relative population of A^{2+} . Simultaneously, part of the B cations should modify their valence state from +3 to +4 to balance the local charge. The percentage of B cations whose valence is modified is related to the x value, as $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$. Mn^{3+} and Mn^{4+} cations are both favorable for six-coordinated octahedra, but the situation is different for Co cations. Both Co^{3+} and Co^{4+} can have six and four coordinations. Four-coordinated Co^{4+} requires the presence of oxygen vacancies; thus, the (AO_3) layer is replaced by $(\text{A}_{1-x}^{3+}\text{A}_x^{2+}\text{O}_{3-y})^{(3+x-2y)-}$.

On the other hand, if some B cations are reduced and their valence state is decreased from +3 to +2, the $(\text{AO}_3)^{3-}$ layers are required to compensate for the excess negative charge, resulting in oxygen vacancies and the change in

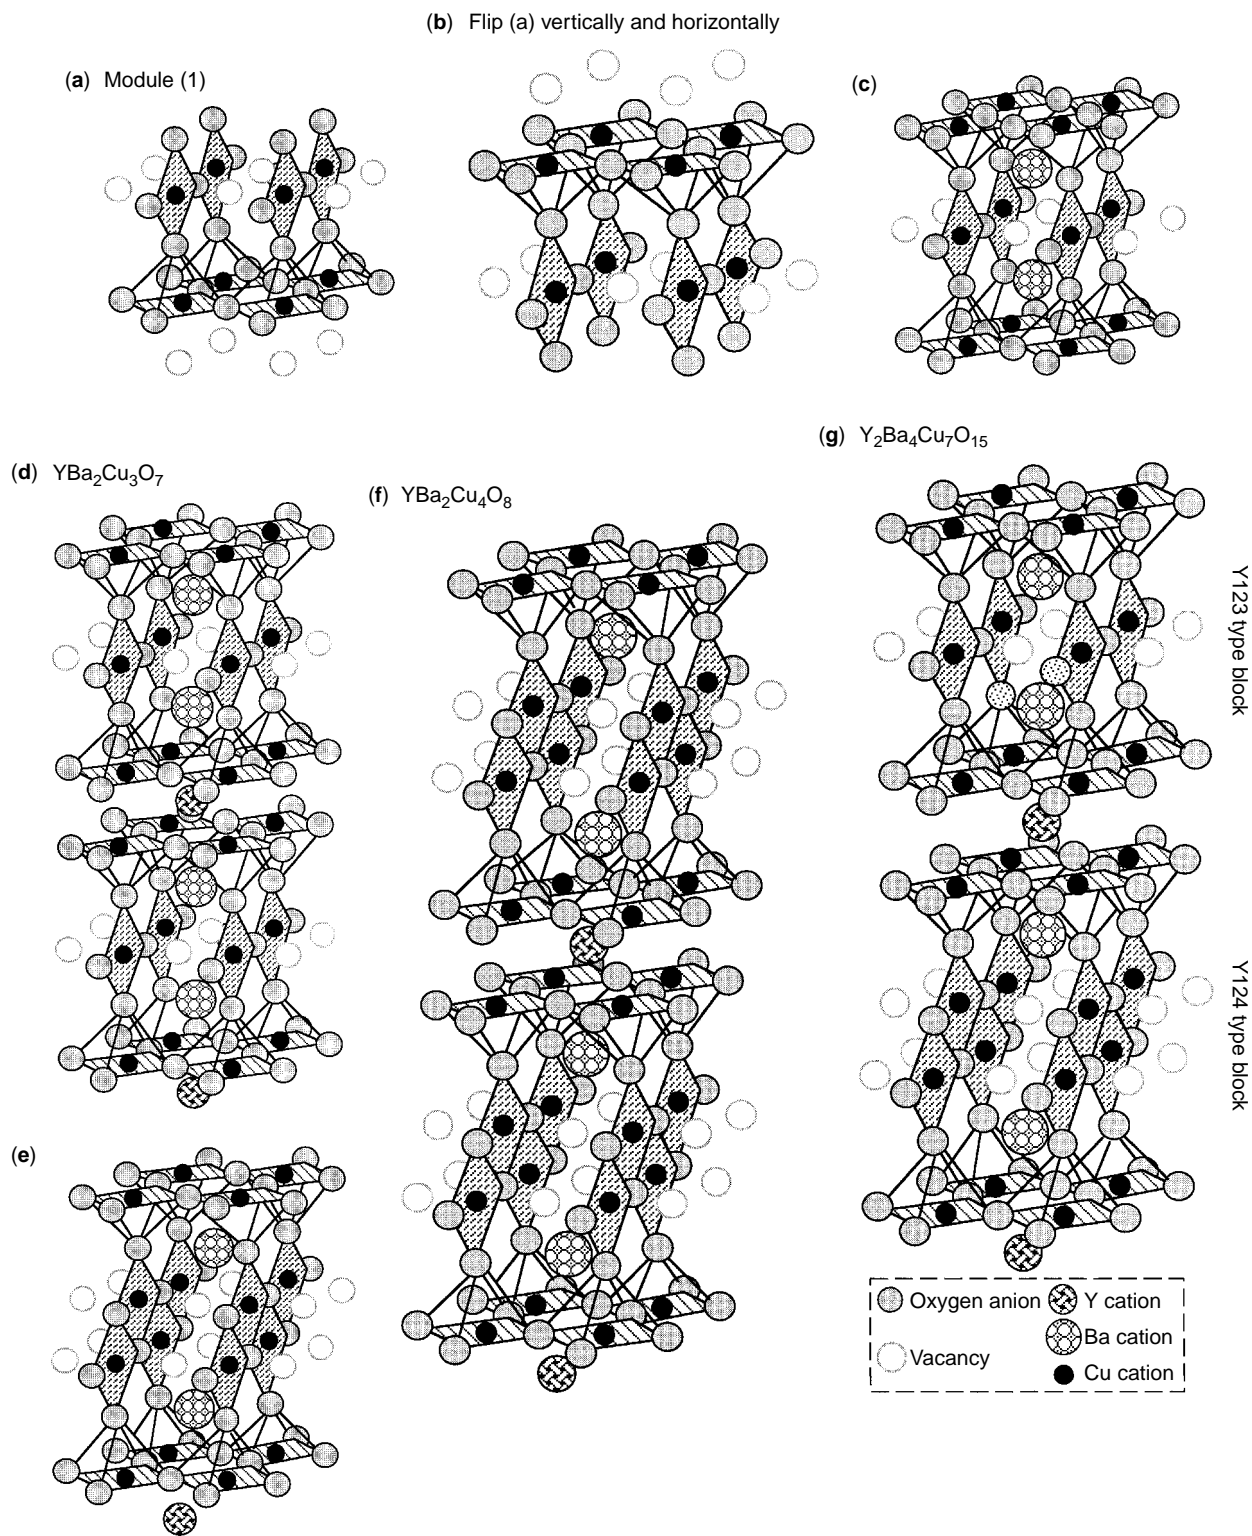

Figure 21. Evolution of the oxygen-deficient perovskite modules into the crystal structures of the Y–Ba–Cu–O system. (a) The module given in Fig. 20(l); (b) the module is flipped over vertically and horizontally. (c) The modules in (a) and (b) are combined by superimposing the BO_4 units to form a new module, which is the structural building block for $\text{YBa}_2\text{Cu}_3\text{O}_7$. (d) The structure of $\text{YBa}_2\text{Cu}_3\text{O}_7$. (e) A new module created by combining the two modules in (a) and (b) to share the edges of the BO_4 units. This new module is the building block of the structure of $\text{YBa}_2\text{Cu}_4\text{O}_8$. (f) The structure of $\text{YBa}_2\text{Cu}_4\text{O}_8$. (g) The structure of $\text{Y}_2\text{Ba}_4\text{Cu}_7\text{O}_{15}$ is a combination of the modules in (c) and (e).

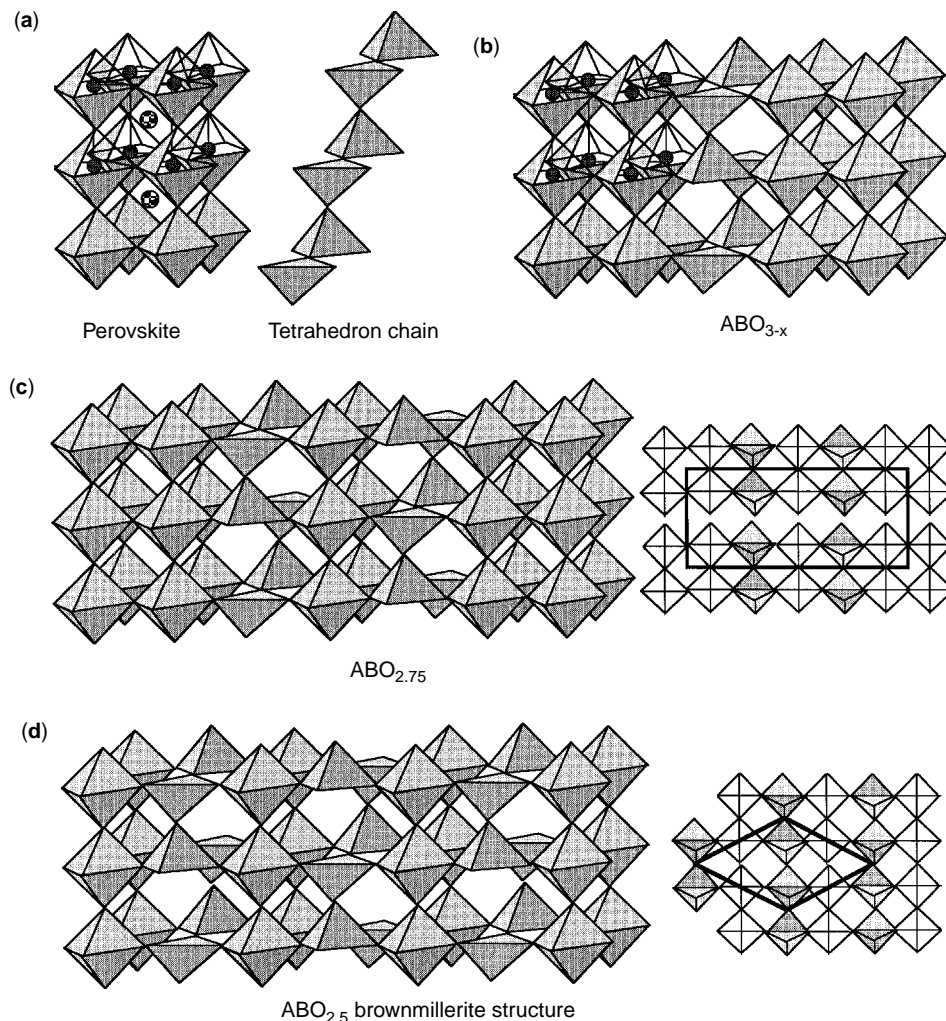

Figure 22. Structural evolution from perovskite and tetrahedron chains to form ABO_{3-x} , $ABO_{2.75}$, and $ABO_{2.5}$ (brownmillerite) structures owing to ordered anion deficiency. In all of these structures, the A and B cation lattice remains the same as that in standard perovskite, although for clarity they are not shown in the models; the only change is the introduction of anion vacancies.

the coordination number of the B cations. If the percentage of reduced B cations is small, the perovskite structure still holds. If the percentage of reduced B cations reaches an upper limit, the perovskite structure has to be changed to another structure that might be related to perovskite. The structural evolution from perovskite into the brownmillerite structure is an example.

$A\text{CoO}_3$ ($A = \text{La, Pr, Nd, Gd}$) perovskite is a typical example. Methane gas can be oxidized by LaCoO_3 above 1000°C . This means that LaCoO_3 can release lattice oxygen (28,29). Co^{2+} cations can have coordination numbers of six, five, and four. During the reduction process, Co^{3+} can be reduced to Co^{2+} and Co^0 . The coordination is changed from octahedral to tetrahedral. During the reduction process, the anion framework should hold, but it can have vacant sites. The perovskite unit and the possible corner-sharing tetrahedron chain are shown in Fig. 22a. When these chains are connected to neighboring octahedra, the remaining two corners of each tetrahedron are shared. If we randomly

insert these tetrahedra chains into the perovskite structure (Fig. 22b), the compound is ABO_{3-x} . As the number of tetrahedron chains increases and reaches a number at which two octahedron slabs (that have the thickness of the perovskite unit cell) and one corner-sharing octahedron slab are separated by a “slab” of the tetrahedron chains, as shown in Fig. 22c, the $ABO_{2.75}$ structure is formed. Ordered structures of $A^{2+}(B_{0.5}^{3+} B_{0.5}^{4+})O_{2.75}$ and $A^{2+}(B_{0.5}^{2+} B_{0.5}^{5+})O_{2.75}$ can be formed. If the octahedron slab and the slab of the tetrahedron chains are stacked alternately via corner-sharing, the brownmillerite structure $ABO_{2.5}$ is constructed (Fig. 22d). As the relative number of the tetrahedron chains increases, the interaction between A cations also increases. If the number of the tetrahedron slabs is more than that of the octahedron slabs, the system will be unstable. Then, LaCoO_{3-y} is likely to be reduced to two phases: La_2O_3 and CoO . In other words, all of the Co^{2+} will have tetrahedral coordination, and there is no octahedral-coordinated Co^{2+} .

Tailoring Perovskite-Related Structures

In general, compounds that have perovskite-like structures can be represented by the chemical formula $A_mB_mO_{3m-x}$. In this formula the $(AO_3)^{4-}$ and the B^{4+} layers are the basic stacking layers, and they are stacked alternately following the sequence $\alpha\beta\gamma$, respectively, as defined by the three positions shown in Fig. 17. If the compound contains m layers of $(AO_3)^{4-}$ and m layers of B^{4+} and they are stacked together in the sequence $\alpha\beta\gamma$, respectively, alternately, we can have $A_mB_mO_{3m}$, such as ABO_3 when $m = 1$, the perovskite structure. If oxygen vacancies are introduced, an $(AO_3)^{4-}$ layer may have one oxygen sublattice possessing a vacancy, and the layer $(AO_3)^{4-}$ is transformed into $(AO_2)^{2-}$. If these types of anion-deficient layers are mixed with the ideal $(AO_3)^{4-}$ layers, the new compounds should have the formula $A_mB_mO_{3m-n}$ (where $n \leq m$), in which n represents the number of the $(AO_2)^{2-}$ layers that contain sublattices that have oxygen vacancies. $Ca_2Mn_2O_5$ ($m = 2$ and $n = 1$), $YBa_2Cu_3O_6$ or $YBa_2Cu_3O_8$ ($m = 3$ and $n = 3$), $YBa_2Cu_3O_7$ ($m = 3$ and $n = 2$), $LaBa_2Cu_2TaO_8$ ($m = 3$, $n = 1$), and $Ba_2La_2Cu_2Sn_2O_{11}$ ($m = 4$ and $n = 1$) are typical examples.

Furthermore, if the $(AO_3)^{4-}$ layer lack only a portion of the oxygens, the composition and the charge of the layer becomes $(AO_{3-x})^{(4-2x)-}$. If n and m are the numbers of the $(AO_{3-x})^{(4-2x)-}$ type and the $(AO_3)^{4-}$ type layers, respectively, the compounds formed by stacking these layers and a total of $(m+n)$ B cation layers alternately, should be $A_{m+n}B_{m+n}O_{3(m+n)-xn}$. For example, when $n = m = 1$, it is $A_2B_2O_{6-x}$ ($x < 1$). These two types of oxygen-deficient perovskite compounds have been found. Compounds that have $(AO_{3-x})^{(4-2x)-}$ layers may be more stable than those that have $(AO_2)^{2-}$ layers. The high T_c superconductor is an example (21).

Compounds that have some $(AO_2)^{2-}$ layers may have an integral number of oxygens, but the compounds that have $(AO_{3-x})^{(4-2x)-}$ layers may have a nonintegral number of oxygens. As discussed before, the A cation can be substituted by cations that have different valences or by partial cation vacancies to satisfy the local electron orbital and charge balance requirements. These results may help us to understand the structure of oxide functional materials. Most of the useful compounds that have functionality contain anion-deficient perovskite-like structural units, especially those that contain $(AO_{3-x})^{(4-2x)-}$ layers. The 14 structural configurations shown in Fig. 10 are the fundamental building blocks for building these structures. The perovskite-related compounds that have A cation and/or oxygen anion deficiency may have the general formula

where $0 \leq x < 1$, $0 \leq y < 1$, $0 \leq n < m$, and n and m are integral numbers.

Although A or B cations can be partially substituted by another element, the average valences are usually close to +2 and +4 (see later), respectively. The A cation, for example, may be replaced by (A^+, A^{3+}) or (V^+, A^{3+}) , where V stands for a positively charged vacancy site, and B cation

Figure 23. High-magnification TEM images of $La_{0.5}Sr_{0.5}CoO_{2.25}$ recorded along [100], where the white spots correspond to the projected atom columns.

can be (B^{3+}, B^{5+}) or (B^{2+}, B^{6+}) . Substitution of these combinations can give a series of compounds that belong to the perovskite family. Cations of different valences usually have different sizes and electron configurations, and they tend to have a strong influence on the oxygen close packing, especially in the $(AO_3)^{4-}$ layers. A change in the valence of the A cation should have a much stronger effect because it is in the fundamental stacking layer.

Figure 23 shows a cross section of a TEM image of $La_{0.5}Sr_{0.5}CoO_{2.25}$ viewed along [100]. The La and Sr atoms are distributed in different (001) atomic planes and exhibit La–Co–Sr–Co–La–Co–Sr–Co–(001) layered structure (31). The crystal structure is based on a fundamental perovskite module of $LaSrCo_2O_6$ (or $La_{0.5}Sr_{0.5}CoO_3$) without anion deficiency, as shown in Fig. 24a, which is a combination of two perovskite unit cells of $LaCoO_3$ and $SrCoO_3$. The structure of $La_{0.5}Sr_{0.5}CoO_{2.25}$ is composed of eight of this type module that has ordered anion vacancies in each. Two anion-deficient modules of $LaSrCo_2O_{4.5}$ are derived from this stoichiometric module, denoted by M_1 and M_2 (Fig. 24b). A divalent Co is likely to be coordinated by one oxygen, on average, in the top and bottom layers. These modules are the building blocks for constructing the full unit cell of $La_{0.5}Sr_{0.5}CoO_{2.25}$ (Fig. 24c). The unit cell is orthorhombic. The 3-D atomic distribution in the full unit cell is given in Fig. 24d. The coordination numbers of La and Sr are nine, respectively, and those of Co are five and four (Fig. 24e); thus, the structure is chemically stable. The three-oxygen-coordinated cation is a tetrahedron, the four-oxygen-coordinated cation is a square sheet, and the five-oxygen-coordinated cation forms a half-octahedron (e.g., a square-based pyramid).

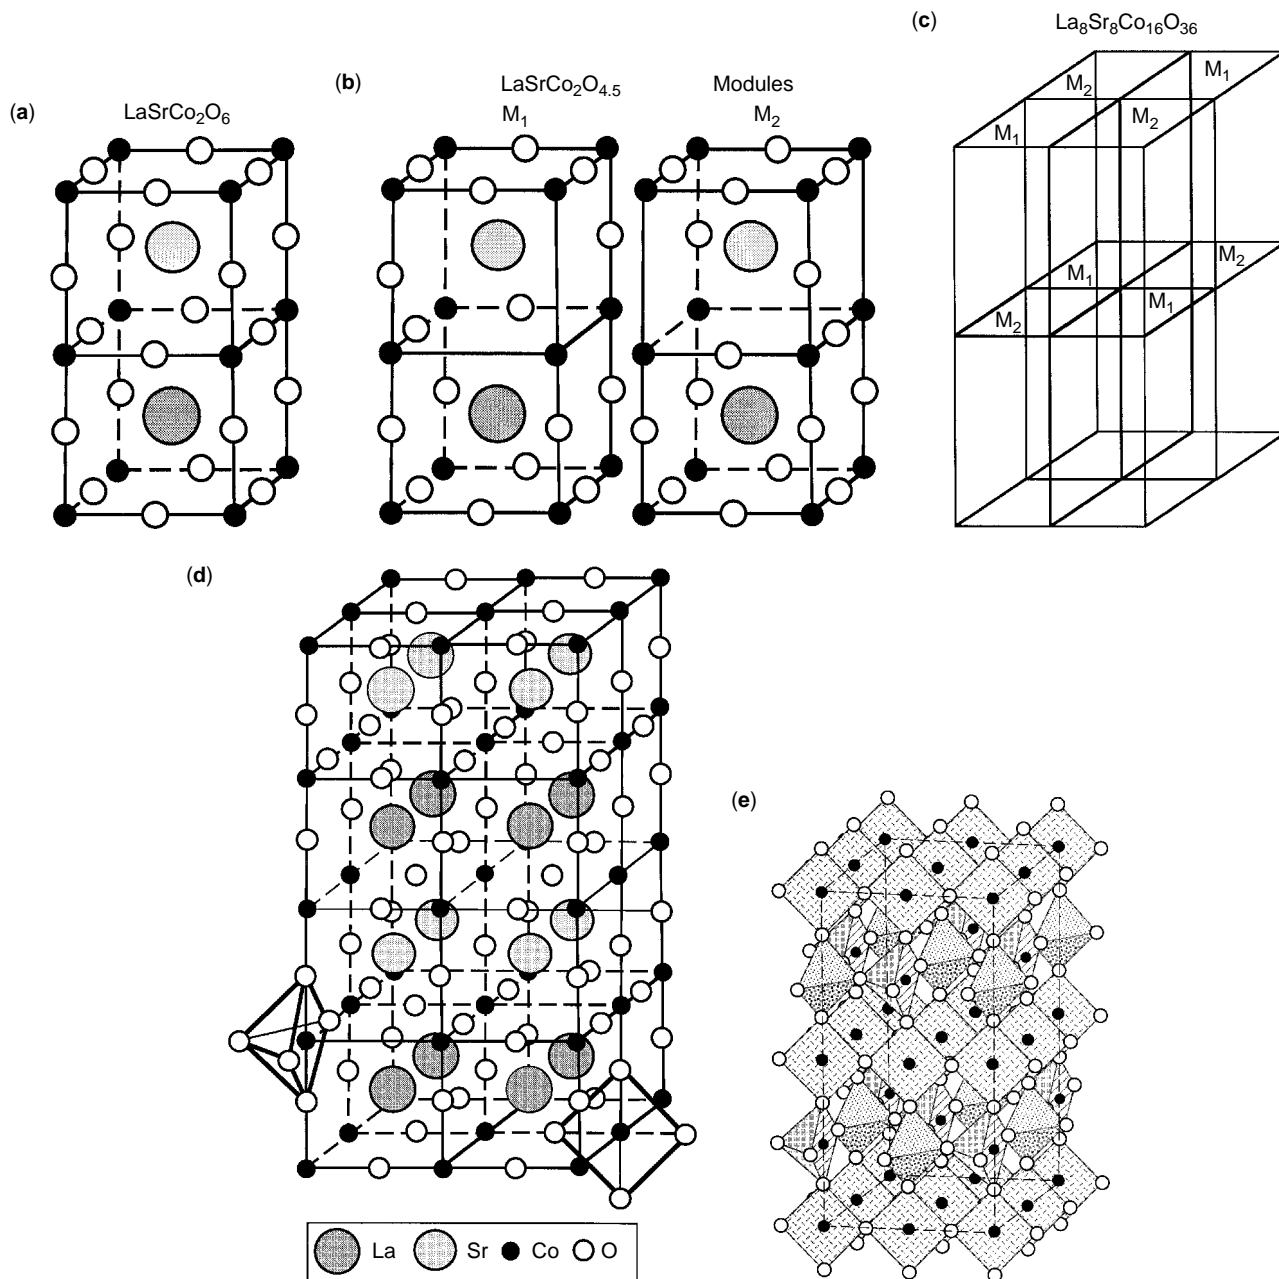

Figure 24. (a) Structural model of the $\text{LaSrCo}_2\text{O}_6$ module. (b) Two anion-deficient modules of $\text{LaSrCo}_2\text{O}_{4.5}$, and (c) the corresponding stacking to form a complete unit cell of $\text{La}_8\text{Sr}_8\text{Co}_{16}\text{O}_{36}$ (or $\text{La}_{0.5}\text{Sr}_{0.5}\text{CoO}_{2.25}$). (d) The 3-D model of the structure proposed for $\text{La}_8\text{Sr}_8\text{Co}_{16}\text{O}_{36}$. (e) A replot of (d) without showing the La and Sr cations for clarity, displaying the five and four coordinations of the Co atoms.

QUANTIFICATION OF MIXED VALENCES BY EELS

Transition- and rare-earth metal oxides are the fundamental ingredients of *mixed valences* in the structural unit (2). The valence states of metal cations in such materials can be chemically determined by using the redox titration, but it is inapplicable to nanophase or nanostructured materials such as thin films. The wet chemistry approaches usually do not provide any spatial resolution. X-ray photoelectron spectroscopy (XPS) can provide information on the average

distribution of cation valences for nanostructured materials that have certain spatial resolution, but the spatial resolution is nowhere near the desired nanometer scale, and the information provided is limited to a surface layer 2–5 nm thick.

Electron energy-loss spectroscopy (EELS), a powerful technique for materials characterization at nanometer spatial resolution, has been widely used in chemical microanalysis and studies of solid-state effects (32). In EELS, the L ionization edges of transition-metal and

rare-earth elements usually display sharp peaks at the near edge region, which are known as *white lines*. In transition metals that have unoccupied 3d states, the transition of an electron from the 2p state to the 3d levels leads to the formation of white lines. The L_3 and L_2 lines are the transitions from $2p^{3/2}$ to $3d^{3/2}3d^{5/2}$ and from $2p^{1/2}$ to $3d^{3/2}$, respectively, and their intensities are related to the unoccupied states in the 3d bands (33).

Numerous EELS experiments have shown that a change in the valence state of cations introduces a dramatic change in the ratio of the white lines, leading to the possibility of identifying the occupation number of the 3d orbital using EELS. The 3d and 4d occupations of transition-metal and rare-earth elements have been studied systematically (34,35). The oxidation states of Ce and Pr have been determined in an orthophosphate, in which the constituents of Ce and Pr are of the order of 100 ppm (36). It has been applied to quantifying the valence transition in Mn and Co oxides (37), determining the concentration of oxygen vacancies (38), refining the crystal structure of an anion-deficient perovskite (31), identifying the crystal structure of nanoparticles (CoO and Co_3O_4) (39), and determining magnetic ordering in spinel (40). The principle of this analysis is illustrated following.

Figure 25 shows an EELS spectrum of Co oxide. The EELS data must also be processed first to remove the gain variation introduced by the detector channels and to

Figure 25. An EELS spectrum acquired from a Co oxide that shows the O-K and Co-L ionization edges. The fine structures arise from the atomic and solid structure of the specimen. (b) The technique used to extract the intensities of the white lines.

Figure 26. Plots of the intensity ratios L_3/L_2 calculated from the spectra acquired from (a) Co compounds and (b) Mn compounds as a function of the cation valence. A nominal fit of the experimental data is shown by the solid curve.

remove the multiple-inelastic-scattering effect by a deconvolution technique. Consequently, the data presented here are the result of single inelastic scattering. The ratio of white line intensities is likely to be a reliable and sensitive approach. The calculated result for L_3/L_2 is rather stable and is not sensitive to the specimen thickness or the noise level in the spectrum.

EELS analysis of valence states is carried out by reference to the spectra acquired from standard specimens that have known cation valence states. Because the intensity ratio of L_3/L_2 is sensitive to the valence state of the corresponding element, if a series of EELS spectra is acquired from several standard specimens that have known valence states, an empirical plot of these data serves as the reference for determining the valence state of the element in a new compound. The L_3/L_2 ratios for a few standard Co compounds are plotted in Fig. 26a. EELS spectra of Co-L_{2,3} ionization edges were acquired from CoSi_2 (Co^{4+}), Co_3O_4 ($\text{Co}^{2.67+}$), CoCO_3 (Co^{2+}), and CoSO_4 (Co^{2+}). Figure 26b is a plot of the experimentally measured intensity ratios of white lines L_3/L_2 for Mn. The curves clearly show that the ratio L_3/L_2 is very sensitive to the valence state of Co and Mn. This is the basis of our experimental approach for measuring the valence states of Co and Mn in a new material.

To demonstrate the sensitivity and reliability of using white line intensity for determining valence states in

Figure 27. An overlapped plot of the white line intensity ratio of Co L₃/L₂ and the corresponding chemical composition of n_O/n_{Co} as a function of the *in situ* temperature of the Co₃O₄ specimen that shows the abrupt change in valence state and oxygen composition at 400°C. The error bars are determined from the errors introduced in background subtraction and data fluctuation among spectra.

mixed valence compounds (37), the *in situ* reduction of Co₃O₄ is examined first. Figure 27 shows the Co L₃/L₂ ratio and the relative composition of n_O/n_{Co} for the same crystal, as the specimen temperature was increased. The specimen composition was determined from the integrated intensities of the O–K and Co–L_{2,3} ionization edges by using ionization cross sections calculated from the SIGMAK and SIGMAL programs (32). The L₃/L₂ ratios corresponding to Co²⁺ determined from the EELS spectra of CoSO₄ and CoCO₃ at room temperature and Co^{2.67+} obtained from Co₃O₄ are marked by shadowed bands, whose widths represent experimental error and the variation among different compounds. The Co L₃/L₂ ratio and the composition, n_O/n_{Co}, simultaneously experience a sharp change at $T = 400^\circ\text{C}$. The chemical composition changes from O:Co = 1.33 ± 0.5 to O:Co = 0.95 ± 0.5 that accompanies the change of the average valence state of Co from +2.67 to +2 when the temperature is above 400°C. Electron diffraction has also confirmed the reduction process observed.

HIGH-SPATIAL-RESOLUTION MAPPING OF VALENCE STATES

Energy-filtered transmission electron microscopy (EF-TEM) (41) is a rapidly developing field for high spatial-resolution chemical imaging. Images (or diffraction patterns) formed by electrons that have specific energy losses can be obtained by using an energy filter. If the energy-selected electron image can be formed using the white lines described earlier (6), one can map the spatial distribution of the valence states (42). According to Fig. 25, an energy window 12 eV wide is required to isolate the L₃ from the L₂ white lines. A five-window technique is introduced

(see Fig. 25a): two images are acquired at the energy losses before the L ionization edges, and they are to be used to subtract the background for the characteristic L edge signals; two images are acquired from the L₃ and L₂ white lines, respectively, and the fifth image is recorded using the electrons right after the L₂ line that will be used to subtract the continuous background underneath the L₃ and L₂ lines. Then, a L₃/L₂ ratio image will be obtained, which reflects the distribution of valence state across the specimen. It must be pointed out that the thickness effect has been removed in the L₃/L₂ image.

A partially oxidized CoO specimen that contains a CoO and Co₃O₄ grain structure was chosen for this study (44). The CoO and Co₃O₄ phases are separated by clear boundaries, and it is an ideal specimen for testing the optimum resolution. Figure 28 shows a group of energy-filtered TEM images from a triple point in the CoO–Co₃O₄ specimen. The energy-filtered images using the L₂ and L₃ lines and the post-L₂ line region (Fig. 28b–d) show distinctly different contrast distributions due to differences in the relative white line intensities. From these three images, the L₃/L₂ ratio is calculated after subtracting the contribution from the continuous energy-loss region that is due to single atom scattering, the image clearly displays the distribution of cobalt oxides that have different valence states (Fig. 28e), where the diffraction contrast disappears. The region of lower oxidation state (Co²⁺) shows a stronger contrast, and those that have high oxidation states show darker contrast (see the L₃/L₂ ratio in Fig. 26a). The O/Co image (Fig. 28f) was calculated from the images recorded from the O–K edge and the L₃ + L₂ white lines for an energy window width of $\Delta = 24$ eV. Although the energy-filtered O–K edge image exhibits some diffraction contrast and the thickness effect, the O/Co compositional ratio image greatly reduces the effect. The high-intensity region in the O/Co image indicates a relatively high local concentration of oxygen (e.g., higher Co oxidation states); the low intensity region contains relatively less oxygen (e.g., a lower Co valence state), entirely consistent with the information provided by the L₃/L₂ image. A line scan across the valence state map clearly illustrates that a spatial resolution of 2 nm can be achieved (42). This is remarkable compared to any existing techniques.

SUMMARY

Perovskite is probably the most important structural type of smart materials. The properties of perovskites depend strongly on their structures. In this article, the characteristics of ABO₃ perovskites are analyzed to reveal the intrinsic connection among the A, B, and O elements and the roles of tetrahedrons and octahedrons in the structure. The (111) alternate stacking of the close-packed (AO₃)⁴⁻ and B⁴⁺ layers is responsible for the cation substitution and the creation of anion vacancies. Careful analysis of the possibilities of creating oxygen vacancies results in a total of 14 fundamental structural units, which are the building blocks for constructing the unit cells of complex functional materials, such as high T_c superconductors.

Figure 28. A group of images recorded from the same specimen region using signals of (a) electrons without energy loss, (b) the Co-L₂ edge, (c) the Co-L₃ edge, and (d) the post-Co-L₂ line. (e) The processed L₃/L₂ image that displays the distribution of valence states. (f) The atomic concentration ratio image of O/Co. The O/Co image is normalized with reference to the standard composition of CoO for the low portion of the image to eliminate the strong influence of the white lines on the ionization cross section. Each raw image was acquired using an energy window width of $\Delta = 12$ eV except for O-K at $\Delta = 24$ eV. (g) and (h) are line scan profiles from (e) and (f), respectively, proving the achievement of 2-nm spatial resolution.

ACKNOWLEDGMENT

SOIL-CERAMICS (EARTH), SELF-ADJUSTMENT OF HUMIDITY AND TEMPERATURE

EMILE H. ISHIDA
INAX Corporation
Minatomachi, Tokoname, Aichi, Japan

INTRODUCTION

Earth ceramics are hydrothermally solidified soil bodies that have been developed mainly for use as interior and exterior materials for housing. Generally, manufacture of industrial materials requires the use of refined raw materials. In the case of earth ceramics, a wide range of soils can be used for manufacture without extensive refining. Besides, since solidification is carried out at 150 to 200°C under saturated steam pressure, the energy required for solidification is relatively small. Therefore, the load imposed on the earth by the manufacturing of this material is kept very low. Earth ceramics possess excellent thermal insulation and self humidity control properties because the original nano-pores of the soil remain in the bodies after solidification. Because of these properties, earth ceramics are effective in controlling the interior climate in dwellings, particularly in monsoon regions like Japan. It has been reported that in dwellings where earth ceramics were actually used as the floor material, the humidity control properties of the material allows comfortable and healthy living with almost no necessity for the use of air conditioners throughout the year and that the amount of energy consumed for living is reduced significantly.

The necessity of a new concept of manufacturing goods based on due consideration for humans and the earth, and the thinking behind the development of earth ceramics based on investigations of this concept, are described below. Examples of actual use of earth ceramics are also outlined.

A NEW DEFINITION ON MATERIALS WITH CONSIDERATION FOR HUMANS AND THE EARTH

The Inevitability of a Recirculation-Based Society

The global environment has now begun to have great effects on our lives. Environmental issues such as global warming, desertization, depletion of the ozone layer, and acid rain stem mainly from global scale expansion of the economic activities of the industrially advanced nations and population expansion in the developing countries. These two problems are compelling enough for us to consider radical reforms of the global social structure.

In their book *Beyond the Limits* published in February 1992, Meadows and his co-authors (1) warned that unless countermeasures are taken, the world economy which may still expand until around the year 2020, will cease its growth after that because of various limiting factors, and that the world's social structure will have disintegrated completely by the year 2100. A number of similar reports supplementing these warnings were published (2,3) and created a great stir among material scientists.

The United Nations Conference on Environment and Development (Earth Summit) held in Brazil in June of the same year issued the Rio Declaration on Environment and Development, adopting Agenda 21 as the action plan of the summit. Out of all the activities carried out by humans, those that impose the largest load on the earth are the economic and industrial activities. These activities depend on a flow of materials and energy. To counter the danger of extinction of humankind and build a sustainable society, it is essential that we institute a recirculation-based society. A recirculation-based society is a rejection of the consumption-based economic structure of the industrialized countries. The idea is to construct a type of society not ever experienced in the past. What will the manufacture of goods be like in a recirculation-based society? Here, we need to redefine the basic notion of manufacturing.

Manufacturing of Goods with Awareness of a Recirculation-Based Society

A recirculation-based society can be expressed by a simple diagram as shown in Fig. 1. Since the dawn of civilization the human being has demarcated a border (system boundary) between the natural ecological system and the human life system (human ecological system).

Humans thought that they could not sustain their livelihood without exploiting nature. The amount of intake from nature and the resulting amount of release into nature he increased rapidly after the Industrial Revolution. These now far exceed what nature can offer without serious consequences for the preservation of humankind. A recirculation-based society is one that reduces much of the

Figure 1. Re-circulation based society.

input from nature (fossil energy, raw materials) as well as its output into nature's ecosystem (exhaust gases, exhaust heat, waste materials), and makes efforts to recirculate and regenerate the input from nature within the human ecosystem. In other words, when manufacturing goods for a recirculation-based society, it is very important to think about the total energy balance and the material balance. In practice, it is necessary to reduce the output by reducing the input, and in addition, synthesize new materials from materials and energy that have the possibility of producing fresh output. We must, therefore, change our attitude from recycling to recirculation.

Manufacturing of Goods with Consideration for the Earth

Although manufacturing of goods with an awareness of a recirculation-based society is unavoidable, it is doubtful whether goods manufactured based on such a concept would be accepted by the world. Let us consider an extreme example. An electric refrigerator not only consumes electricity but also the refrigerating agent, which is Freon gas and a burden to the earth's environment. In order to lower the input and output, should we then stop using electric refrigerators and return to the earlier era of ice-boxes for refrigeration? Most people would answer no. It is not easy to abandon a convenience once it has been experienced. Furthermore, denial of the existence of electric refrigerators means also denial of large businesses that sell refrigerated foods like department stores, supermarkets, and convenience stores. The invention of the electric refrigerator brought great changes to the social system. As long as irreversibility of life values exists, we cannot easily return to the "good old age." If we reach an ultimate state where there is no alternative but to return to the past such a reversal would probably be at the expense of unprecedented patience and great pain. Conversely, if it were easy to return to a former way of living, environmental problems

would not occur, there might not be the need to develop new materials. Our inability to return to a former, energy-efficient way of living is why we need to address the serious issue of environmental pollution and set guidelines for new materials:

Most important, the manufactures need to be made more conscious of the earth. The goods they develop should be useful, convenient, or improvements of existing goods that are necessary to people. Of course, as environmental problems become more severe, the balance between people and the earth will shift, and without doubt, more emphasis will start to be placed on earth friendly materials and manufacturing. Materials and goods produced without consideration of their value or usefulness to people would cease to exist. Taking this argument from a different perspective, no one could argue that the manufacturing of goods does not exploit something (input) from the earth and then discharge some waste to the earth (output) which is produced as the input from the earth is converted into goods with functions that have some value to people (Fig. 2). We could express this relation of the development of goods as,

$$\text{Value} = \frac{P}{I + O},$$

where P is the performance of the material, $I + O$ are the input and output of the material when manufactured, used, and scrapped.

In general, if the value for people is less than one, there is no merit to developing the material or goods. Development should aim to raise this value to five, ten, or even the hundreds. Attain entirely new approaches, might be necessary, disregarding any current concepts. Now, let us think specifically about materials that could be developed using the $P/(I + O)$ valuation concept.

Figure 2. A new value for the manufacturing.

SMART MATERIALS FOR THE LIVING ENVIRONMENT

Foremost among materials for maintaining a comfortable living space, while reducing the burden on the earth's environment, is the development of high heat insulation houses. Of course, this is not a consideration in hot and humid regions with monsoon climates. Primarily, there is the case of Japanese dwellings.

Japan, which is located in a monsoon zone, has a relatively distinct climate compared to other developed nations. In this unique hot and humid climate, much damage is caused by the high humidity. Although the humidity itself is lower than that of say, London, Paris, or San Francisco, Japan is at the top with regard to humidity-related damage to houses. This is due to the fact that fungi and bacilli that affect human health and cause damage to houses are able to breed rapidly under the warm and humid Japanese climate. To counter these adverse influences, elevated houses emerged in Japan as far back as the ninth century. Elevated floors allow for underfloor ventilation. The materials used for construction were paper, wood, and soil. Some 50 years ago airtight houses were introduced in Japan following examples in Europe and America. A new apartment house building trend then took root in Japan. However, it has turned out that the Western airtight dwellings were unsuited to a humid climate, and thus uncomfortable for living. The search for comfort led to the introduction of various indoor implements—electric fans, followed by coolers and air conditioners. Then the first oil

shock in 1973 forced Japanese to make significant reductions in their energy consumption, and the idea of airtight and heat-insulated housing became national policy. In the adoption of such dwelling, the technology to control indoor temperature has improved considerably, although the humidity has proved to be difficult to control. Because the rooms in Japanese houses are small, the interiors of these airtight dwellings tend to be inferior compared to houses in Europe and America (4, 5). In fact the interior environment in Japan has degenerated to a clutter of such appliances humidifiers, dehumidifiers, and air cleaners (Fig. 3). Yet, despite these measures, the sick house syndrome and allergic diseases are continuing to proliferate. Compared to 1973, when the industrial energy consumption in Japan in 1997 was 104%, today dwellings consume energy as high as 217%, and this figure has been rapidly climbing (6). The energy increases have occurred even though much progress has been made in the development of low-energy consumption type of appliances.

The technological solution to this problem would be to have a self-monitoring and self-regulating the indoor climate (humidity, in particular) by materials of the house—the floor, walls, and ceiling materials—that have high P value. At the same time, it is necessary to examine the methods of synthesizing these materials from the perspective of not using even more energy and natural resources for the synthesis—that is, to maintain a low $(I + O)$ value. If such materials could be developed, indoor climate control could be made effective even in the most airtight and heat-insulated homes. Such materials would possess high value as those to society with due consideration to humans and the earth.

CLIMATE CONTROL BY POROUS BODIES

The humidity range in which a person feels comfortable is said to be 40% to 70%. It has been reported that by maintaining humidity within this range, allergy sources such as mites, as well as the breeding of wood-eating bacteria, molds, and the like, that cause degradation of wood in wooden houses, could be restricted (7). This humidity range is also thought to be effective in curbing the spread of viruses and even the accumulation of static electricity. Chemical and physical methods of humidity regulation are available, but here, let us think about a safe method, which is humidity regulation by porous bodies.

The target material would be one that does not absorb the water vapor when the humidity is less than 40%, but if the humidity rises higher, it should work to lower the humidity by rapidly absorbing the water vapor from the atmosphere. Then, as the humidity starts to fall, the material should act to increase the humidity rapidly to the preferred 40% to 70%. In other words, the water vapor absorption isotherm of the material should be steep in the 40% to 70% humidity range (Fig. 4).

So these humidity-regulating porous materials should be capable of making the water vapor in the atmosphere to condense within the capillary pores that exist on their surface when the humidity is high. Conversely, when the humidity is low, they should function to vaporize the

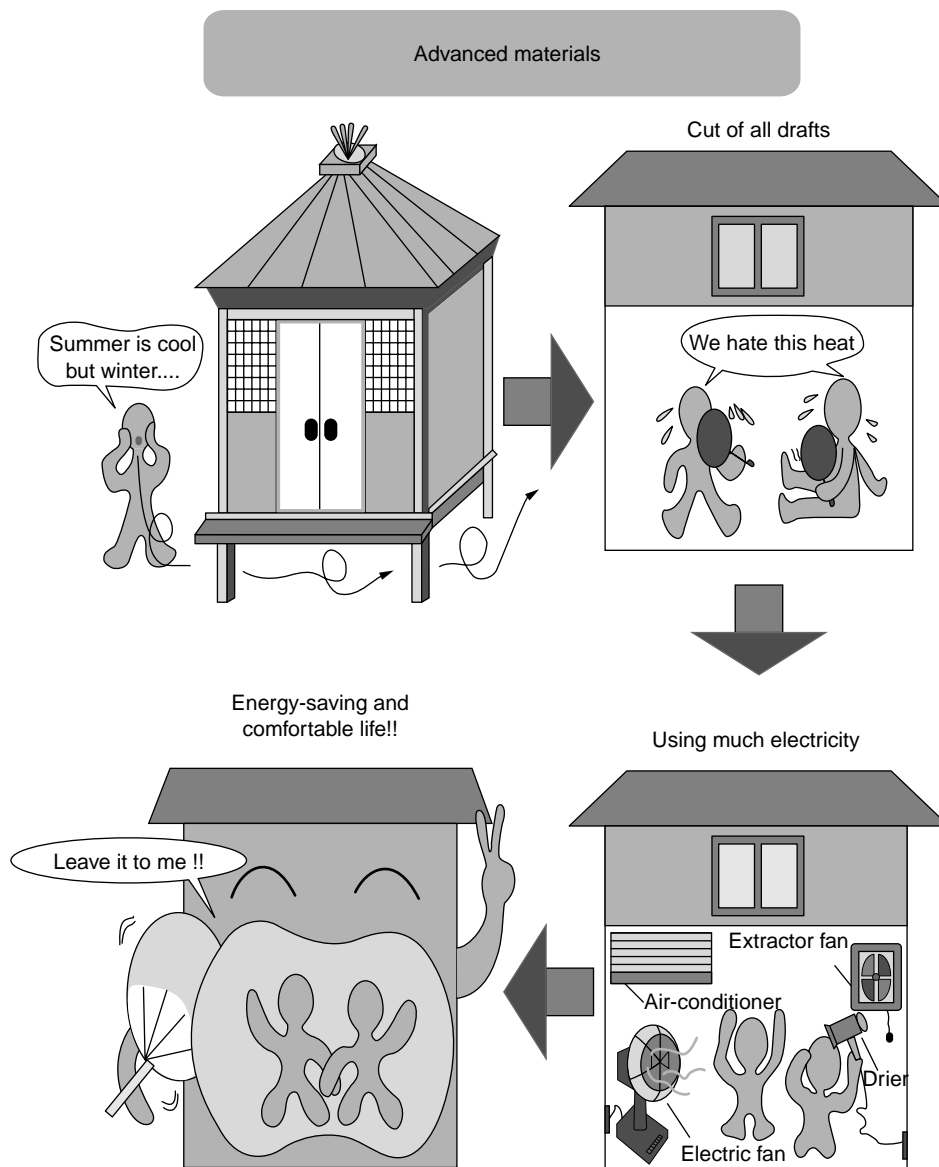

Figure 3. Earth and people conscious materials for the living environment.

condensed water. The relation between the vapor pressure, P/P_0 , required for capillary condensation and pore size, with curvature radii r_1 , r_2 , is expressed by Kelvin's equation of capillary condensation:

$$\ln\left(\frac{P}{P_0}\right) = -\left(\frac{\gamma V}{\cos\theta RT}\right)\left(\frac{1}{r_1} + \frac{1}{r_2}\right).$$

Here, r_1 and r_2 are the radii of curvature of the pores in two perpendicular directions, γ is the surface tension of the condensate, V is the molecular volume of the condensate, and θ the contact angle of the condensate within the pore.

Calculations based on this equation, corrected for the preexistence of a certain thickness of the adsorbed layer prior to capillary condensation (8), yield pore radii values of 3.2 nm for 40% relative humidity and 7.4 nm for 70% humidity. High-humidity regulating performance can be

expected from materials synthesized with their pore radii being controlled to be within this range.

USING THE GREATNESS OF NATURE WISELY

Utilizing Soil

There are many possibilities of synthesizing porous materials with humidity-regulating properties. For example, taking petroleum as the starting material, the synthesis could be done by chemical polymerization or biomimetic methods. However, the use of these methods makes it difficult to lower the input and output of the synthesized material. For this reason, we should select "soil," as the starting material. Natural soil is a material containing incipient micropores that can be effective in imparting humidity regulating performance. Even after its use in the

Figure 4. Property for the humidity-regulating porous materials.

human ecosystem is over, soil will not inflict a large burden on the natural ecosystem.

Soil appeared some 400 million years ago at a time when plenty of oxygen was supplied by the atmosphere. The composition of soil is almost the same today. The excess oxygen was decomposed in the stratosphere to form the ozone layer. The ozone layer has prevented strong ultraviolet rays from pouring onto the surface of the earth, and allowed the movement of animals and plants from the sea to land to begin. With the help of this organic matter, the land of stone and sand turned into a land of green, and soil appeared for from the weathering and decomposition of rocks (9). Were it not for soil, the perfect recirculation performance of the current natural ecosystem would not exist. So one cannot ignore the benefits obtained from soil for the existence of humankind. Humankind is, of course, indebted to soil with regard to food crops, but more so, it was through the aid of earthen dwellings that humankind was able to survive the glacial era without running out of seed.

Soil contains numerous pores, both large and small. These pores collect air, water, and many nutrients, allowing soil to carry out its functions. For example, a survey of the virgin forests of the Shiga plateau (Japan) has shown that in a 1 m by 1 m by 15 cm volume of soil, there are 360 living creatures such as centipedes and earthworms ranging about 2 cm in size, then some 2 mm in size thread earthworms, beach fleas amounting to 2.3 million in count, and finally any number of protozoan, mold, and bacteria

Figure 5. Examples for the pore size distribution of the general soil after dry-pressed under 30 MPa (solid line) and 20 MPa (broken line).

of more than 10 trillion in count (10). Figure 5 shows the pore size distribution of common earth (soil). It is clear that the 10 nm (0.01 μm) pores considered suitable for humidity regulation are incipient in the material. It is also clear that the cohesive structure in the neighborhood of 10 nm does not collapse easily even under pressure. However, even any kinds of soil if lost for some reason or the other, cannot be regenerated for an extremely long time. Furthermore, because of its complex structure, soil is a material that has not been successfully synthesized artificially up to now.

Humankind has utilized earth very cleverly as a construction material in many ways. In its natural state, it has been used for cave-type and pit-type dwellings. Soil has been processed and used to obtain various types of construction materials such as sun-dried bricks. In Japan, it was used as *Tataki*, or earthen walls. The humidity regulation and thermal insulation properties arising from the innumerable pores in soil were utilized in Japan's Edo period to build earthen storehouses that protected stock from wind, fire, and water. The technology of soil utilization was even raised to an artistic level, as can be seen from the *Nurikabe* walls of the Edo era. Once these soil materials have served their purpose in the human ecosystem, they can be returned to the natural ecosystem. Therefore, soil is an extremely rare material that can cross the system boundary zone freely. Unfortunately, the use of earth as soil, is usually not the possible in current construction practice. If, for example, soil is used in its natural state for the flooring of today's airtight and heat-insulated dwellings, the house would become dusty and the health of the inhabitants may be affected adversely. In addition, there are problems regarding strength, durability, and workability.

Figure 6. A culture of soil in human history.

Solidified ceramics such as bricks, blocks, and tiles made their appearance early in history in order to solve these problems. However, ceramics, which could be considered to have been developed in the Stone Age, are produced through high-temperature reactions. For this reason, it is difficult to say that ceramics maintain the inherent properties and performance of soil. In order to sustain the inherent properties and performance of soil (pore size distribution), the temperature of manufacture of earthen products must be lower than 500°C. In the case of earth/organic material composites, an even lower temperature is desirable.

The new technology of solidifying soil by hydrothermal treatment is a low-temperature process developed to obtain a material with properties and performance between those of soil and ceramics (6).

Hydrothermal Processing

The largest application of hydrothermal processing is in the field of building materials manufacture. It was developed in Europe and has over 100 years of history as represented by sand lime bricks (11,12). Usually, the process involves mixing quartz (SiO_2) with about 10% lime ($\text{Ca}(\text{OH})_2$) and exposing the mixture to saturated steam at about 200°C. This results in the formation of acicular calcium silicate hydrates (Fig. 7) (13). It is believed that strength development is obtained because these hydrates (tobermorite, xonotolite, etc.) are entwined with each other in the solidified bodies. From the point of view of energy consumption, this method of synthesis is an extremely high efficiency process. Numerous studies have been made regarding the reactions involved during synthesis by hydrothermal treatment and regarding the behavior of

Figure 7. Calcium silicate hydrates, the most important bonding materials in the hydrothermally solidified building material (photo: tobermorite in autoclaved sand lime brick).

calcium silicate hydrate materials, mainly in the $\text{CaO-SiO}_2\text{-H}_2\text{O}$ system (14–16). Although many of the reports deal with the purity of the starting materials, it is generally accepted that it is desirable to use SiO_2 with high purity (12). Almost no studies seem to have been made with significantly altered SiO_2 compositions. Mitsuda et al. (17,18) have studied the effects of Al_2O_3 source additions to the $\text{CaO-SiO}_2\text{-H}_2\text{O}$ system and the replacement of Si by Al in tobermorite ($\text{Ca}_5(\text{Si}_6\text{O}_{18}\text{H}_2) \cdot 4\text{H}_2\text{O}$). However, the addition of Al_2O_3 in this study was up to $\text{Al}/(\text{Al} + \text{Si}) = 0.16$, which corresponds to the solid solution limit of Al in tobermorite (19,20). An investigation by Kalousek has reported that when kaolinite is used as the Al source, hydrogarnet forms in the range $\text{Al}/(\text{Al} + \text{Si}) = 0.12 - 0.5$ (20). Generally, this hydrogarnet has a cubic structure and contains $\text{Ca}_3\text{Al}_2\text{Si}_3\text{O}_{12}\text{-Ca}_3\text{Al}_2\text{H}_{12}\text{O}_{12}$ in solid solution (21,22). In a recent study of metakaolin–quartz–lime series slurries, the effect of amount of metakaolin additions and of quartz grain size on hydrogarnet formation have been clarified (23–25). These reports indicate that with increasing $\text{Al}/(\text{Al} + \text{Si})$ ratio in the $\text{CaO-SiO}_2\text{-Al}_2\text{O}_3\text{-H}_2\text{O}$ system, hydrogarnet forms in addition to calcium silicate hydrates such as C–S–H (calcium silicate hydrate gels) and tobermorite, and that the hydrogarnet becomes the main phase for $\text{Al}/(\text{Al} + \text{Si})$ ratios higher than about 0.2. However, in the composition range over which hydrogarnet is the main phase formed, not much study seems to have been carried out on the strength development of hydrothermally synthesized bodies. Investigations about the relationship between strength development and the microstructural changes that accompany the formation of hydrogarnet cannot be found either. This is probably because of the fact that it was thought that formation of hydrogarnet causes strength deterioration in calcium silicate materials (26). Because of this belief, avoiding the formation of hydrogarnet has been an important direction of research up to now.

Figure 8. Experimental compositions (mass ratio) in the CaO–SiO₂–Al₂O₃ system. Hatched area was mainly discussed in the past.

An approach completely different from current directions of research is required here. Soil, which usually consists of minerals such as quartz, feldspar, and kaolinite (Al₂(Si₂O₅)(OH)₄), contains besides SiO₂ a considerable amount of Al₂O₃ (about 30%). For this reason, it is unsuitable as the raw material for calcium silicate hydrate formation. In order to produce solidified materials with soil as the starting material, sufficient strength development would be required in solidified bodies that contain hydrogarnet as the main phase.

Hydrothermal Solidification of Kaolinite

An example of a solidification experiment using nearly pure quartz (Indian quartz), kaolinite (Georgia kaolin—a clay mineral without micropores), and lime (CaO) is outlined here. In this experiment, the mass ratio of quartz, kaolinite, and lime were varied (Fig. 8, Table 1). So that

$$\frac{\text{kaolinite}}{\text{quartz} + \text{kaolinite}} : \frac{K}{(Q + K)} = 0, 0.1, 0.5, 0.9, 1.0,$$

and

$$\frac{\text{lime}}{\text{quartz} + \text{kaolinite}} = 0.21.$$

After weighing the materials, the lime was slaked and a further 10% of water was added and mixed to allow for easy forming. The specimens were obtained by uniaxial

Table 1. Compositions of the Experimental Mixtures

$K/(Q + K)$ (mass ratio)	Al/(Si + Al) (atomic ratio)	Ca/Al (atomic ratio)	Ca/(Si + Al) (atomic ratio)
0.0	0.00	0.23	0.23
0.1	0.05	0.24	0.23
0.5	0.24	0.31	0.24
0.9	0.45	0.45	0.24
1.0	0.50	0.50	0.25

Figure 9. Generation of the flexural strength and the phases along with the hydrothermal processing.

press forming of this mixture at 30 MPa. The press-formed specimens were cured under saturated steam pressure at 200°C for 2 to 20 hours. (The compositional range of the specimens was Ca/(Si + Al) = 0.23 to 0.25, Al/(Si + Al) = 0.0 to 0.50.

The variation in the phases formed with treatment time is shown in Fig. 9, together with the strength development characteristics. It is recognized that in all specimens, hydrothermal treatment results in increased flexural strengths. It is also clear that hydrothermal solidification is possible even in those specimens with Al/(Si + Al) = 0.24 to 0.50 where hydrogarnet is the main phase formed. In the case of specimens with Al/(Si + Al) = 0 and 0.05 that correspond to compositions investigated frequently in the past, mainly calcium silicate hydrates are formed, and the maximum flexural strength of about 30 MPa is attained in 2 hours of treatment. Longer treatment times lead to decreased strength, particularly for the specimens with Al/(Si + Al) = 0.

In kaolinite-rich specimens with Al/(Si + Al) = 0.24 – 0.50, flexural strength reaches approximately 15 to 20 MPa in 2 hours along with the formation of hydrogarnet. Longer treatment times lead to only slight strength increases. The flexural strength is maximum for specimens with Al/(Si + Al) = 0.05, and becomes lower for larger Al/(Si + Al) values. However, the rate of decrease in strength becomes small with increasing Al/(Si + Al) value. In the specimens with Al/(Si + Al) = 0.24 to 0.50, the decrease in maximum flexural strength with increase in Al content is clearly smaller than in those with Al/(Si + Al) < 0.24.

These results are extremely significant:

1. By making hydrogarnet as the main phase, sufficient strength allowing the synthesized bodies to be utilized as building materials is obtained, although the strength may be somewhat lower than those of conventional calcium silicate hydrate materials.
2. Although the strength decreases with increasing amounts of kaolinite, it is possible to limit the

Figure 10. Influence of the starting materials on the reaction rates of Ca source with processing time.

strength decrease to acceptable levels by making hydrogarnet as the main phase. As a result, in actual practice, variations in composition of natural soil will not significantly affect the final physical properties of the synthesized material. In other words, this means that the range of starting materials that can be used is wide.

Unfortunately, the mechanism of strength development by hydrogarnet formation still remains unclarified although there is a possibility that this is related to the reaction scenario of Ca as explained below. In the case of specimens with $Al/(Si + Al)$ ratios lower than 0.24, almost 100% of the calcium is consumed within the first two hours of reaction (Fig. 10). For specimens with $Al/(Si + Al) = 0.24$ to 0.50, calcium is consumed rapidly during the first two hours, but since little or no further calcium consumption occurs, after that, the reaction ratio stagnates in the range 50% to 75%. This low reaction ratio may be one of the factors influencing strength development by hydrogarnet formation.

Some interesting results are provided by microstructural evaluation (Fig. 11). For $Al/(Si + Al) = 0$ and 0.05, acicular and platelike reaction products (identified by XRD to be C-S-H, tobermorite) can be observed to fill up the interparticle spaces after two hours of treatment. In contrast, for $Al/(Si + Al) = 0.45$ and 0.50, only platelike kaolinite particles are recognizable, and hydrogarnet cannot be observed despite the fact that its existence has been confirmed by XRD. Hydrogarnet crystals in sizes ranging from a few μm to some tens of μm have been reported to have been observed in hydrothermally synthesized bodies using slag as the starting material (27) and in slurries (23–25). In the current specimens, however, such hydrogarnet crystals could not be recognized, even through TEM observation. This indicates the possibility

that the hydrogarnet formed may be existing as ultra-fine particles.

There is a clear difference in the pore size distribution between the specimens that contain mainly calcium silicate hydrate phases and those that contain hydrogarnet as the main phase formed (Fig. 12). The pore size distribution of specimens with $Al/(Si + Al) = 0$ and 0.05 shows a peak at about $1 \mu\text{m}$ in the press-formed state. This peak location shifts to smaller values and the total pore volume decreases as hydrothermal treatment progresses. This indicates that the $1 \mu\text{m}$ pores in the press-formed state are filled by the C-S-H and tobermorite formed by hydrothermal treatment, and this densification is accompanied by strength increase (28,29). When the treatment time is increased to five hours or more in $Al/(Si + Al) = 0$, the peak in the neighborhood of $0.01 \mu\text{m}$ formed by two hours of hydrothermal treatment shifts toward coarser sizes. This pore-coarsening phenomenon is due to the formation of gyrolite (28), and it appears to be connected to the observed strength reduction.

The behavior of specimens with $Al/(Si + Al) = 0.45$ and 0.50 differs greatly from that of those with $Al/(Si + Al) = 0$ and 0.05. For $Al/(Si + Al) = 0.45$ and 0.50, the pore size distribution in the press-formed state does not shift with hydrothermal treatment time, but the number of pores decrease as the treatment time increases. As a result, pores around $0.04 \mu\text{m}$ are formed. Another characteristic of these compositions is that the pore volume hardly changes during this time.

From the preceding results, it is clear that the changes in pore size distribution of specimens with $Al/(Si + Al) = 0.45$ and 0.50, where hydrogarnet is the main phase formed, are different from those with $Al/(Si + Al) = 0$ and 0.05 in which pores are filled up by the calcium silicate hydrates formed. The formation of hydrogarnet and strength development without alteration of the pore sizes existing at the time of press-forming suggests that the solidified structure may be one that corresponds to that shown in Fig. 13. It is envisaged that ultra-fine hydrogarnet particles grow densely and in situ from the surface of kaolinite particles inward (forming $0.04 \mu\text{m}$ pores). Through this solidification mechanism, bonding of the kaolinite particles occurs with almost no alteration to the pore sizes existing at the time of press forming. The reason for the amount of hydrogarnet formed reaching a near-saturation level after two hours of hydrothermal treatment may be that the reaction has become diffusion controlled because of the kaolinite particles being covered by the hydrogarnet layer.

In similar experiments using silica sand containing low-purity clay minerals as the starting material, it has been found that although the type of phases formed during hydrothermal treatment change greatly with the treatment temperature and time, the strength of the solidified material is strongly influenced not by the type but by the amount of formed phases (Fig. 14) (30). On the other hand, it has been clearly shown that the strength of bodies formed by extrusion and casting processes, which require the addition of large amounts of water (binder) to the raw material, is much lower than that of bodies formed by uniaxial pressing (dry pressing). Although the detailed mechanism of strength development by hydrothermal treatment

Figure 11. SEM photographs of the fracture surface of the specimens ($Al/(Al + Si) = 0$ (a, b), 0.05 (c, d), 0.45 (e, f), and 0.50 (g, h) cured for 2 hours (a, c, e, g) and 20 hours (b, d, f, h).

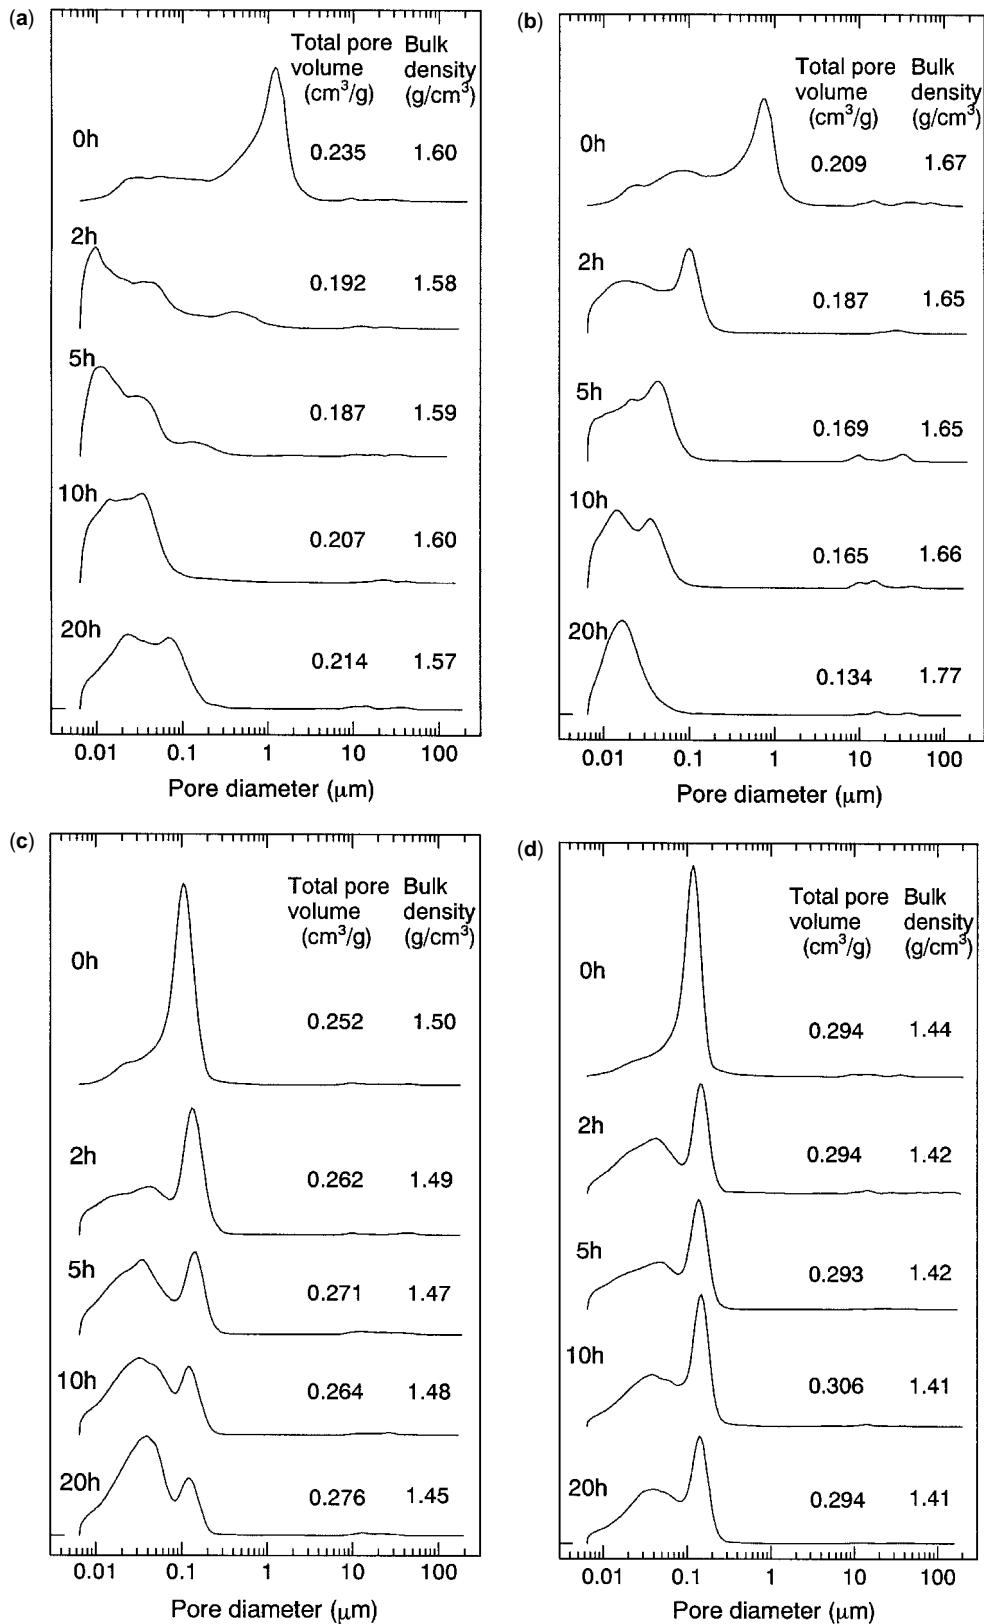

Figure 12. Pore size distributions of the specimen with processing time, a = Al/(Al + Si) of 0, b = 0.05, C = 0.45, and d = 0.50.

Figure 13. Estimated schematic figure for the formation of hydrogarnet under higher Al/(Al + Si).

of soil needs further investigations, it is believed that the strength development is attained through ultra-fine particles becoming uniformly dispersed within the densified body, that is, through a mechanism similar to the that of strength development in DSP (densified system particles—containing homogeneously arranged ultra-fine particles) (31–33).

As described previously, sufficient strength development is obtained through hydrothermal treatment of bodies that have been press-formed from a mixture of lime and the starting material, kaolinite. The strength is believed to be attained not by the filling up of the pores in the material but by the formation and dispersion of ultra-fine hydrogarnet particles within the press-formed, dense body. This solidification mechanism allows strength to be attained without destroying the agglomerated micropore structure. This is important from the point of view of the humidity regulation performance of the solidified bodies.

Figure 14. Examples for the generation of the flexural strength with amount of formed phases under the various curing time. The phases formed change with curing time and temperature. However, the strength seems to be controlled by the amount of the formed phases independently.

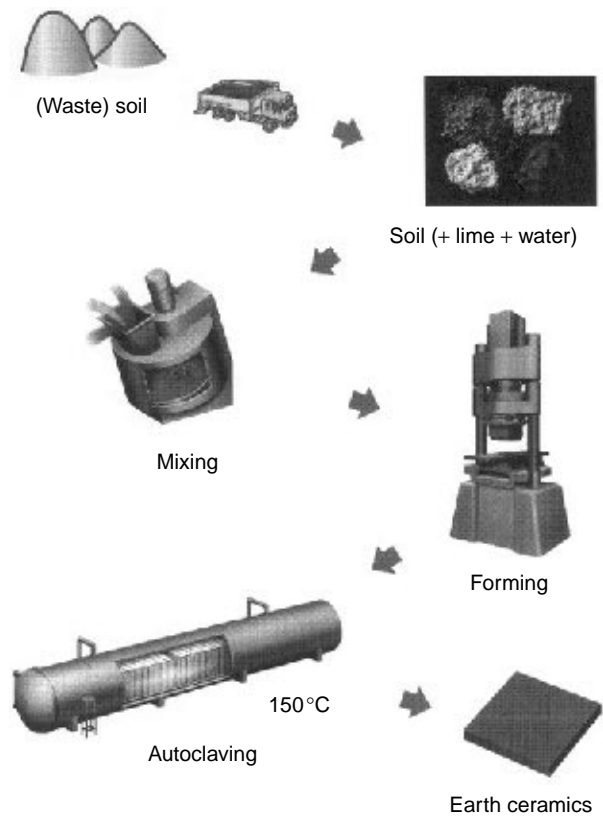

Figure 15. Actual processing of the earth ceramics manufacture

PERFORMANCE OF THE HYDROTHERMALLY SOLIDIFIED SOIL BODIES

Earth Ceramics

The industrial method of synthesizing hydrothermally solidified soil bodies is illustrated in Fig. 15. A little lime and water are added to the soil and mixed well. Since the treatment temperature is low, straw or other organic additives can be added if necessary in order to obtain higher strength or to enhance the finish. The mixture is then dry-pressed into tiles and then cured for a few hours at about 150°C in saturated steam pressure to obtain solidified bodies.

Among those industrial ceramics that utilize smaller amounts of energy (34) for their manufacture, ceramic tiles are considered to consume relatively little energy. The energy required for synthesizing earth ceramics is even lower, being about 2.7 GJ/m³ (35), which is only 1/6th that of the energy needed for ceramic tiles (Fig. 16).

Since there is little limitation with regard to the starting materials and the energy required for synthesis is small, it can be concluded from the point of view of nature's ecosystem that earth ceramics are materials with very small input and output.

Pore sizes in earth ceramics are concentrated in two regions: at around 0.05 μm corresponding to the initial pores at the time of press forming, and at around 0.01 μm (10 nm) reflecting the agglomerated structure of soil. This is about 1/10,000th of the pore diameters usually found in concrete

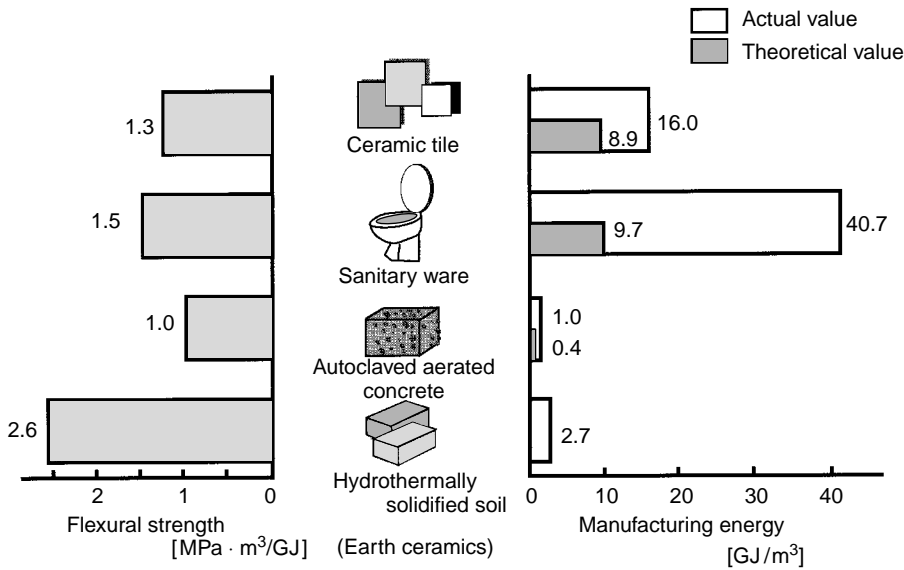

Figure 16. Energy consumption of the materials on processing.

and pottery (Fig. 17). The amount of water vapor absorbed at equilibrium when the relative humidity is varied from 40% to 80% at 25°C is shown in Fig. 18. Although the response in the case of earth ceramics is somewhat slower, it can be seen that they exhibit humidity absorbency properties as good as, or better than, that of wood because of the presence of micropores in the starting material (soil).

Living in a House of Soil

Earth ceramic tiles (size: 200 × 200 mm) were used as the flooring material for the living room of a highly airtight

Figure 17. Pore size distribution of the earth ceramics.

and heat-insulated apartment (Fig. 19), and the changes in temperature and humidity were measured. An apartment in the same apartment complex with acrylic carpet flooring was used for comparison (reference apartment), the floor plan and family makeup being the same for both apartments. The measurements during the winter of 1997 (December to June) are shown in Fig. 20. The room with earth ceramic flooring exhibits very stable temperature variation. Since there were differences in the heating systems of the two apartments, the measurements were carried out after the heaters were switched off for the night (Table 2). The high heat insulation performance of earth ceramics was confirmed by the fact that the average rate of decrease in temperature (because of the difference between indoor and outdoor temperatures) in the earth ceramic floor apartment was 1.3°C compared to 5.7°C for the reference apartment. In the former apartment the humidity was also unaffected by the outdoor atmosphere and remained

2/10	1.4	3.3
2/11	1.4	8.4
Mean	1.3°C	5.7°C

stable. In highly airtight and heat-insulated houses, the relative humidity increases as the temperature falls. The superior ability of earth ceramics for self-regulation of humidity is evident from the fact that the increase of relative humidity was 1.6%/°C in the reference apartment, but only 0.1%/°C in the earth ceramic floor apartment (Table 2). The variations of temperature and humidity measured at 6 am, 12 noon, and at 8 pm during one winter month are shown in Fig. 21. The temperature and humidity in the earth ceramic flooring were within the range 15 to 18°C and 40% to 50%, respectively. This shows that extremely stable and comfortable living environment can be obtained by the use of earth ceramics. The nighttime temperatures in the earth ceramic floor apartment were about four or five degrees lower compared to the reference apartment, but there was little recognizable difference in the effective temperature felt by the human body. This might be because the air temperatures near the ceiling, floor, and intermediate locations were about the same, the temperature difference being only about 0.5 to 1.0°C.

The measurements were continued for one year. It was found that compared to the reference apartment, the

Figure 21. Variations of temperature and relative humidity during one winter month when the earth ceramics or carpet was used on the floor.

Table 3. Examples of the Relative Humidity Variation after Turning off the Air Conditioner

	Earth Ceramics	Carpet
2/5	0.0%/°C	1.7%/°C
2/6	-0.6	1.0
2/7	-0.8	1.0
2/8	1.4	1.4
2/9	0.0	1.8
2/10	-0.8	2.4
Mean	-0.1%/°C	1.6%/°C

variations of temperature and humidity were small throughout the year in the earth ceramic flooring apartment. In particular, the humidity was within the 40% to 70% RH range, which is the normal range of comfort for humans. Therefore, the use of humidifiers or dehumidifiers was not necessary, and the period of air-conditioner operation was short, resulting in low use of fossil energy. The amount of energy utilized for living (electricity, gas, water) in the apartment before and after the earth ceramic floor was installed is shown in Fig. 22 converted into an equivalent amount of CO₂. After remodeling, the amount of electricity thought to have been used for air-conditioning dropped sharply, and the seasonal fluctuation of energy consumption was controlled. On average, there was a 17% reduction of energy consumption that year. This energy consumption refers to the entire quantity required for living in the apartment (floor area = 72 m²). The energy

consumption reduction effect with respect to the living room (floor area = 32 m²) where the earth ceramics floor was laid was considerably greater.

In addition to the above beneficial effects, earth ceramics proved to be effective in controlling a chronic allergy suffered by the occupants of the apartment. Breeding tests with ticks, which are one of source of allergy, showed that at 25°C, 90% RH, 200 ticks multiply in number to 990, 1470, and 1895 in earth ceramics, vinyl cloth, and acrylic carpet, respectively. This clearly demonstrates the advantage of earth ceramics over other materials in restricting the breeding of allergy sources. It remains unclear at present, however, whether the low breeding rate in earth ceramics is due to the good humidity regulation characteristics of the material or whether it is the result of changes in the pH of the surface by humidity absorption.

NEW FUNCTIONAL MATERIALS

It is thought that hydrothermally solidified soil materials attain strength through the ultra-fine hydrogarnet particles becoming uniformly dispersed within the densified press-formed body, similar to DSP materials. This type of material synthesis holds many possibilities as the process for producing new functional materials. Such possibilities need to be investigated through further experiments. For example, another functional material could be tried in place of the ultra-fine dispersed particles.

From the point of view of humidity regulation, the author has investigated here only the process of hydrothermal synthesis. There are many other promising possibilities of using low-energy processes for producing new materials. One is the use of natural porous materials. Sepiolite ($Mg_5Si_8O_{20}(OH)_2 \cdot 8H_2O$) contains micropores of about 1 nm and mesopores that are a few nm in size. Allophane ($1-2SiO_2 \cdot Al_2O_3 \cdot nH_2O$) is an amorphous substance aluminosilicate formed during the weathering of volcanic glass, which is the major constituent of volcanic ash. It is widely distributed in nature in the form of hollow spheres of 3–5 nm in diameter (36, 37). As shown in the water vapor absorption/desorption isotherms of Fig. 23, both sepiolite and allophane exhibit high humidity absorption/desorption ability. Even at relative humidities less than 40%, they show this high ability. This is thought to result from the disordered surface structure and micropores smaller than 1 nm formed by the adsorbates. By adding a small quantity of binder to allophane-rich soil (Kanuma-soil/Japan), dry-forming the material to shape and firing at about 900°C, it is possible to obtain a solidified material that has high humidity regulation ability (trade name: Eco-carat). The humidity absorption/desorption characteristics of Eco-carat at 40% to 80% RH is shown in Fig. 24. Although there is limitation in the choice of material, the micropore volume of Eco-carat is around three times that of earth ceramics, and it shows extremely high humidity regulation performance. However, since these micropores disappear at about 1000°C because of phase changes, it is not possible to raise the firing temperature. With this restricted firing temperature, one cannot expect sufficient strength to develop by the characteristic sintering mechanism of

Figure 22. Amount of energy utilized for living (electricity, gas and water) before (carpet) and after the use of the Earth Ceramics floor.

Figure 23. Water vapor absorption/desorption isotherms of sepiolite, allophane, and plasterboard.

ceramics. But because of the high humidity regulation performance, sufficient performance is obtained even if thin material is used. In actual practice, the material has been laid on interior walls to good effect.

CONCLUSIONS

The present age is one in which ignoring the global environment will have serious consequences for humankind. In maintaining, as far as possible, the inherent highly advanced properties and abilities of nature, it is important to develop technologies that convert, using the least amount of energy possible, these gifts of nature into forms that can be utilized in the human ecosystem. Earth ceramics can

Figure 24. Humidity absorption/desorption characteristics of Eco-carat at 40% to 80% RH.

be obtained using almost any kind of soil including waste soil, and the temperature required for their solidification is low enough to allow waste industrial heat to be utilized for the solidification process. When used in the human ecosystem, earth ceramics exhibit energy-saving characteristics such as self-detection and self-regulation of temperature and humidity. After use, they can be returned to nature without burdening the natural ecosystem.

The development of new values of life and living by changing today's synthetic materials into smarter ones that minimize the load on Mother Earth and creation of such technology and culture should be considered as our greatest responsibility toward the next generation.

ACKNOWLEDGMENT

SOUND CONTROL WITH SMART SKINS

C.R. FULLER

Virginia Polytechnic Institute
and State University
Blacksburg, VA

INTRODUCTION

In the last decade, there has been an increased interest in developing methods for the active control of sound radiation from vibrating structures (1). In one promising method, termed active structural acoustic control (ASAC), actuators are attached directly to the structure and are used to modify its structural vibration characteristics (spatial and temporal) in order to minimize the sound radiation (1). In ASAC, the actuators tend to be compact and thus cover only a very small portion of the structure; their effect is achieved because of the distributed elastic response of the structure. This technique has worked well for a number of applications, usually where the structure has a reasonable mobility and a low modal density of response. In some applications, however, the structure is quite massive or stiff (e.g., an electrical transformer casing), and it is extremely difficult to elicit the necessary control field response with practical control actuators. In this article we discuss a variant of the ASAC approach in which the control inputs come from a *smart* or *active skin* that covers all or most of the vibrating surface. A schematic of the smart skin approach is shown in Fig. 1.

The objective of the smart skin is to locally change the radiation impedance (the resistive component) of the structure in order to control the total radiated power in contrast to the conventional ASAC, which alters the dynamic response of the host structure. The sound radiation levels are directly coupled to the normal displacement w_{sk} of the smart skin. Thus modification of the transfer function between the structural displacement w_s and the smart skin displacement w_{sk} will lead to a change in sound radiation. This modification can occur via a decrease in the amplitude of w_{sk} , thus decreasing the sound levels, or via a change in the amplitude distribution of w_{sk} , causing the normal skin surface to be an inefficient sound radiation over an extended area. Since it does not drive the host structure,

Figure 1. Concept of a smart skin for sound radiation control.

an active skin is suitable for heavy or stiff structures with low mobility. The negative trade-off, however, of the active skin approach, is that since it covers the structure completely, it may require many independent sections if the structural response is complex and near or above the sound radiation critical frequency (1). For illustrative purposes, two different skins are described: one based on a composite of acoustic foam and the piezoelectric polymer PVDF and the other on ceramic piezoelectric elements arranged in a motion amplification configuration.

SMART FOAM SKIN

Acoustic foam is commonly employed as a form of passive liner or skin in order to reduce sound radiation. For example, in aircraft interiors, a layer of acoustic foam is located between the inside surface of the fuselage and the interior trim panels. Generally, the foam completely covers the fuselage surface, and its acoustic purpose is to reduce noise transmitting through the fuselage to the interior. However, it is well known that passive treatments such as foam work well at high frequencies (>1000 Hz), and their performance is poor at low frequencies. Here we describe the use of a smart foam skin, which is a hybrid of the materials of passive foam and active piezoelectric elements (2). The objective is to develop a flexible active skin that combines good high-frequency passive performance with the low-frequency performance of an active system.

The smart skin has to be of such a form that it can be extended to cover complex, distributed surfaces similar to conventional acoustic foam. A typical configuration of the smart foam is shown in diagrammatic form in Fig. 2. The smart foam can be seen to consist of conventional acoustic foam with embedded layers of the flexible polymer piezoelectric material, PVDF (1). Two aspects of the embedded PVDF are significant. First, the PVDF is curved in order to couple the predominantly in-plane piezoelectric effect

Figure 2. PVDF actuator configuration: (a) Original and (b) parallel.

Figure 3. (a) Actuator and error sensor configuration. (b) Spherical dome for power measurements.

with the required normal motion (in effect creating a motion amplifier as discussed below), and second, as shown in Fig. 2(b), alternate half-wave sections of the PVDF can be wired out of phase. This second aspect is designed to increase the radiation efficiency of the active element (and thus its control authority) by causing all the PVDF sections to move in the same direction when a voltage is applied across the PVDF electrodes.

Figure 3(a) shows a picture of a smart foam active skin covering a plate of dimensions $170 \times 50 \times 1.5$ mm(3). The smart foam skin can be seen to be comprised of six independently controllable skin cells constructed as described above. In addition, each cell has a lightweight balsa wood wall used to increase the normal displacement by constraining the foam edge. Above each smart foam cell is a microphone located close to the foam surface and used as an error sensor in a MIMO feedforward Filtered-x LMS control approach (1) (see Fig. 11 for a typical feedforward LMS arrangement). The plate and smart foam skin is located in a rigid baffle located in an anechoic chamber. Figure 3(b) shows a hemispherical array of ten microphones located over the plate and in the radiated sound field. The microphones are used to estimate the total radiated sound power from the plate-smart foam system. The disturbance to the plate was provided by a piezoelectric patch actuator (1), bonded to the back. The

Figure 4. Radiated power for a broadband 1I1O case using multiple smart foam modules operating in phase.

reference signal for the LMS control approach was taken from the internal signal generator used to drive the disturbance (termed internal reference).

Figure 4 presents the radiated power with and without control, when all the smart skin cells are wired together in phase as a single channel of control. The error signal is provided by a single microphone located close to the smart foam surface and at the plate-foam center. Also shown is the passive effect of the smart skin when it is located on the plate but not activated. It is apparent that the passive effect of the skin is good at high frequencies above 1000 Hz but is limited to resonant frequencies of the base plate below this value. Turning on the active control provides reasonable attenuation at low frequencies, though there are some frequency ranges where the control is negligible, for instance near 900 Hz. In this case the smart skin transfer function is reduced in level. We now extend the controller so that the six smart skin modules can be controlled independently with a six by six LMS control arrangement. Figure 5 presents these new results for the low frequency range. For the results of Figure 5 three different reference signals control configuration are also studied: one using

an internal reference, one using an external reference signal taken from an accelerometer located on the plate (representing a more realistic arrangement), and an external reference signal with feedback (FB) from the active component of the smart skin removed (1). It is apparent that much improved performance is achieved over the SISO case of Fig. 4, particularly for the internal reference case, due to the multicell active skin being able to match the complex radiation impedance load near 900 Hz, for example (3). In this case the smart skin transfer function is also modified in a distributed manner.

Using an external reference signal also provides reasonable attenuation; however, it is reduced from the internal case implying that the system is acausal (1). Some of the lost performance is recovered when feedback removal is employed, indicating that the smart foam vibration has some input to the plate system.

Recently the smart foam skin has been used to demonstrate control of interior noise in aircraft (4). Figure 6 shows a smart foam skin covering four panels in the crown section of the fuselage of a Cessna business jet. The application is focused toward reducing cockpit noise due

Figure 5. Attenuated SPL for broadband 6I6O case using multiple-independent smart foam modules.

Figure 6. Cessna crown panel control arrangement.

to exterior flow separation over the crown of the aircraft. Error microphones were located as shown at the ear locations of the crew and a microphone traverse was used to measure the sound pressure levels in a plane at the crew head height. The flow noise disturbance was simulated by an exterior speaker located just over the crown of the aircraft and driven by band-limited white noise. A four by four feedforward LMS control approach was implemented using a realistic reference signal taken from an interior mounted accelerometer located on the fuselage at the aircraft crown (i.e., just under the excitation location). Figure 7 presents tabular results of the attenuation achieved at the error sensors (near the crews' ears) with an excitation band of 500 to 900 Hz. The reference speaker refers to the use of a reference signal from the signal driving the disturbance. The reference accelerometer refers to the use of a fuselage-mounted accelerometer as a reference sensor and in this case attenuation of the order of 2 to 4 dB are achieved. The global attenuation measured using the microphone traverse was found to be 2.5 dB with the active skin turned on. However, the active skin also provides a passive attenuation of 4 dB when it is installed over the bare fuselage panels and not turned on. Thus the total global attenuation of the smart foam active skin is around 6.5 dB, a significant difference. It also apparent from Fig. 7 that one of the main limitations on achievable attenuation is the causality of the controller when using an accelerometer as a reference signal. When the reference signal is taken from the speaker drive signal the control path delay is less, and the performance increases markedly. The results do, however, demonstrate the potential of the smart foam skin in reducing structurally radiated sound in a realistic application.

PIEZOELECTRIC DOUBLE AMPLIFIER SMART SKIN

Piezoelectric transducers tend to be high-force, low-displacement devices (1). In contrast, active noise control applications in air require high-displacement actuators, particularly at very low frequencies. Thus much of the work in developing piezoelectric based actuators for active noise control applications has been in designing devices that amplify their displacement. This amplification

Figure 7. Averaged attenuation microphones for band-limited 500 to 900 Hz excitation.

is usually based on a geometric lever-type principle, and thus results in lower output force. More explicitly, the actuators are designed to have the correct source impedance relative to their load. In our application, the load is air with a relatively low impedance, thus the device needs to have a low source impedance for maximum power output.

Figure 8 shows a schematic diagram of a piezoelectric double amplifier actuator, which is the basis of the second active skin concept (5). The legs of the element consist of piezoelectric bimorphs or unimorphs. In this case, the piezoelectric transducers are manufactured from the ceramic material PZT (1). These devices are amplifiers in that due to their asymmetry, small in-plane motions are amplified to larger transverse tip motions at the top of the legs. The tops of the legs are connected to a triangular or curved stiff, lightweight diaphragm as shown. Thus as the legs move in, the diaphragm is squeezed upward. Since the diaphragm axis is transverse to the tip motion, very small tip motions cause very large diaphragm motions (i.e., amplify it) in a vertical direction. Thus the complete structure comprises a double amplifier actuator and gives amplification ratios of diaphragm to piezoelectric element in-plane deflection of the order of 20 : 1. The whole configuration can be built in heights typically ranging from

Figure 8. The active skin element. (domains in mm)

Figure 9. Smart skin constructed from piezoelectric double-amplifier elements.

3 to 6 cm, leading to a fairly compact device. In constructing an active skin of such devices, a number of them are positioned to completely cover the surface of a structure as shown in Fig. 9. The devices can be either located directly on the structure as shown or positioned just above it with a small air gap. In addition, the devices can be wired together as one channel of control or independently controlled, depending on the complexity of the base structural response.

Figure 10 shows an actual device designed and constructed by the Materials Research Laboratory at Pennsylvania State University. The device is 50×60 mms, 34 mms high, and was found to have a maximum cover displacement of $300 \mu\text{m}$ at 100 Hz. Figure 11 shows six of the devices arranged to completely cover the surface of a 170×150 mm aluminum plate of 1.5 mm thickness. In this test arrangement, the active skin cells are located on a perforated aluminum sheet which is located 5 mm from the surface of the radiating plate. Thus the active skin has a small air gap between its bottom surface and the radiating surface of the structure (5). Small accelerometers located on each active cell diaphragm are also apparent in Fig. 11. These accelerometers are used to provide time domain estimates of the radiated pressure in the far-field from the

Figure 10. A single active-skin cell.

Figure 11. The active-skin in a top-mounted SAS configuration.

measured surface vibration data, termed structural acoustic sensing (SAS) and described in (6). Such approaches allow integration of the sensors into the smart skin itself.

The test plate and the active cells were mounted in a rigid baffle located in the anechoic chamber at VAL. A noise disturbance to the plate was provided by a small shaker attached to the back of the plate and driven with band-limited random noise. The radiated sound from the plate-skin structure was measured using an array of 16 microphones located on a hemispherical tube structure as described above and a microphone traverse that could measure the sound directivity in the horizontal midplane of the plate. The total radiated power from the plate could be calculated from the 16 pressure levels measured by the microphone hemispherical array (5).

Figure 12 depicts a schematic of the experimental rig and the control arrangement. The control approach used was the Filtered -x LMS algorithm (1) implemented on a TMS40 DSP. The shaker was driven with band limited noise of 175 to 600 Hz. The Filtered -x algorithm was

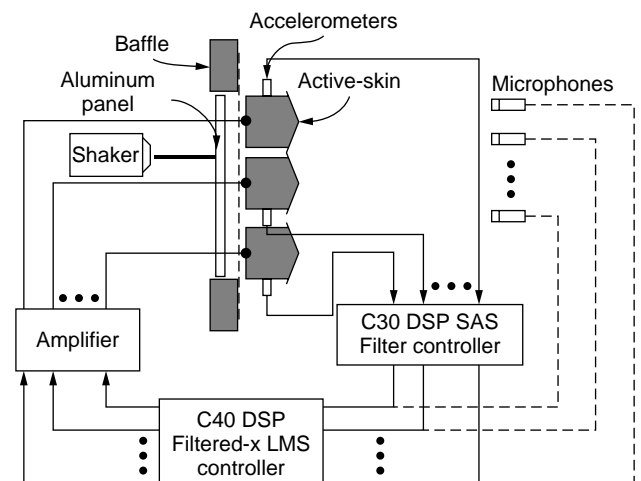

Figure 12. The active-skin experimental setup.

Figure 13. Total in-plane acoustic directivity (SPL), top-mounted accelerometer configuration with microphone error sensing.

executed with a 2000 Hz sample rate, and 175 and 96 tap FIR filters were used for the control and system identification paths, respectively. Since six independent cells were located on the structure to comprise the active skin, a six by six controller was implemented (5). Two tests were performed using different error sensors. In the first test, six microphones evenly distributed over the microphone array were used as conventional pressure error sensors located in the radiated far field. In the second test, the diaphragm accelerometer signals were used in the structural acoustic sensing approach, described in (6), to estimate the pressures at the same locations as the previous error microphones. These estimates were then used as error signals for the LMS algorithm.

Figure 13 presents experimental results of the directivity of the total radiated sound power measured using the far-field microphone traverse before and after the control using the active skin elements. It is apparent that the active skin provides global sound pressure level attenuation of the order of 10 dB, which is impressive since the excitation band encompasses multiple modes of vibration of the radiating plate (5). Figure 14 shows the corresponding radiated power versus frequency. Good control is seen over the complete bandwidth of 170 to 600 Hz except around 350 and 530 Hz, where anti-resonances occur in the plate-active skin system. The overall sound power reduction for the results of Fig. 14 is 10.9 dB. Further experiments were conducted using the accelerometers in the SAS approach, and the results are presented in Fig. 15. Good attenuation is evident across the frequency band, except near the system anti-resonance. The overall reduction is now 9.5 dB, which is still impressive. Thus the results demonstrate that it is possible to utilize an active skin that can provide significant attenuation of sound radiated from a structure vibrating in complex response shapes. The successful use of the accelerometers is significant in that it shows that an active skin with completely integrated actuators and sensors can be constructed to provide very significant broadband attenuation of sound radiated from structures under broadband excitation (5).

Figure 14. Radiated sound power spectra, top-mounted accelerometer configuration with microphone error sensing.

SMART SKINS FOR SOUND REFLECTION CONTROL

It should be noted that the above mentioned smart skin approaches could also be used to absorb sound impinging on structures by coating the structure with the smart skin. However, in this application, a modified sensing approach is needed in which the reflected or scattered wave components are independently (than the total pressure field) sensed and minimized by the controller. Fuller et al. (7) discuss such approaches using the smart foam noted above, and a combination of two microphones located near the smart foam surface are used to separate out the reflected wave information from the total pressure field (7). Figure 16 shows a schematic of the experimental testing in a plane wave acoustic standing wave tube. The noise is generated by a speaker at the right end of the tube and impinges on the smart foam. The two microphones are used to separate out the reflected and incident wave responses from the total pressure field. The reflected wave signal is used as error information to the LMS controller. The controller thus provides a control signal to the smart foam to minimize the reflected signal.

Figure 17 presents the measured intensity of the incident and reflected wave intensities versus frequency with the control off and on. With the control off, the incident and reflected intensities are almost equal at low frequencies

Figure 15. Radiated sound power spectra, top-mounted accelerometer configuration with SAS error sensing.

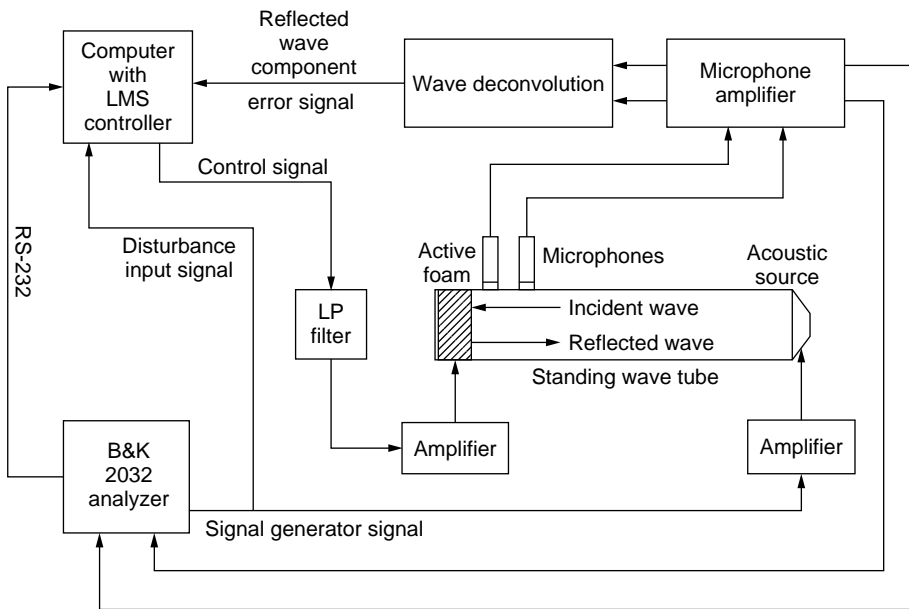

Figure 16. Smart skin reflection control experimental arrangement.

below 300 Hz, implying that the smart foam is acting like a rigid surface with very little sound absorption. Above 300 Hz, as is expected, the foam provides increasing passive sound absorption, and the reflected intensity is less than the incident. When the active control is turned on, the incident intensity remains the same, but the smart skin leads to a significant reduction in reflected sound energy below 300 Hz. This reduction in reflected sound due to the smart skin is apparent over the complete frequency range of Fig. 17. The two microphones can also be used to measure the acoustic impedance of the smart foam. When the control is turned on at low frequencies, the normal acoustic impedance of the foam falls from very large values to be almost identical to the characteristic impedance of the air. Thus the active element in conjunction with the controller

of the smart foam have modified the smart foam dynamics so that it looks like a perfectly sound absorbing surface.

ADVANCED CONTROL APPROACHES FOR SMART SKINS

The conventional control approaches used with a smart skin can be divided into two types; multi-channel feedforward, which is generally used when access to a coherent reference signal is available, and multiple input-multiple output state space feedback methods, which are often used when such a convenient reference signal is not available. These approaches are summarized in (1). As discussed above, the smart skin approach relies on covering a major part of the structure with independently controllable

Figure 17. Reflection control using a smart skin.

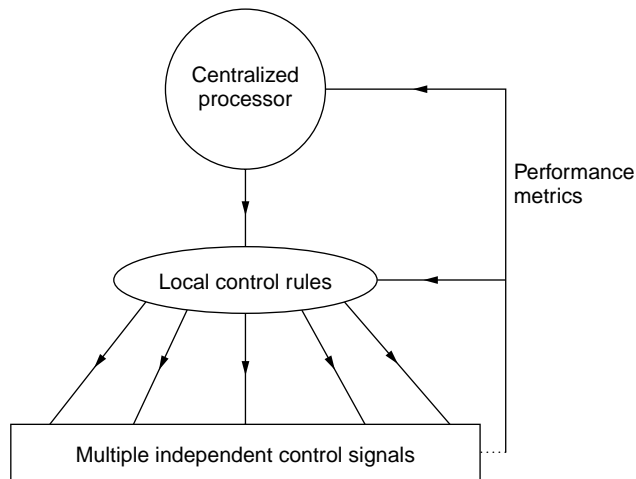

Figure 18. Biological control approach.

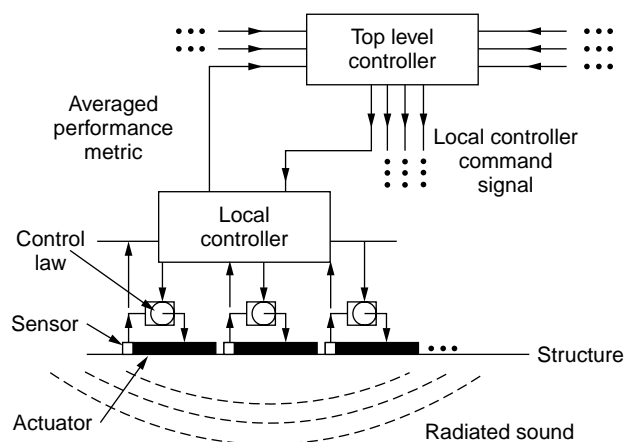

Figure 20. Schematic of a BIO controller arrangement.

elements. It can thus be seen that when the structure is large and/or the frequency of interest high (or wavelength relative to the structure short), many smart skin elements are required, implying a control approach with a very high number of control channels. In this case, the conventional approaches are likely to be unsuitable due mainly to computational limits on the control processor and stability/performance aspects. There are two different approaches suitable for high sensor/actuator count systems (8,9). Both approaches are hierarchical and are inspired by biological systems of muscle control. They are thus termed BIO controllers.

In the first approach, the smart skin elements are arranged into groups of “slave” actuators under the control of a “master” actuator. A schematic of the controller is shown in Fig. 18. A top-level centralized controller is used to send signals to the master actuators. Simple local control laws are used to modify and apply the same signal to nearby slave actuators. For example a very simple local law discussed in (8) would be take the same control signal, apply it to an in-phase, out-of-phase, or off-phase

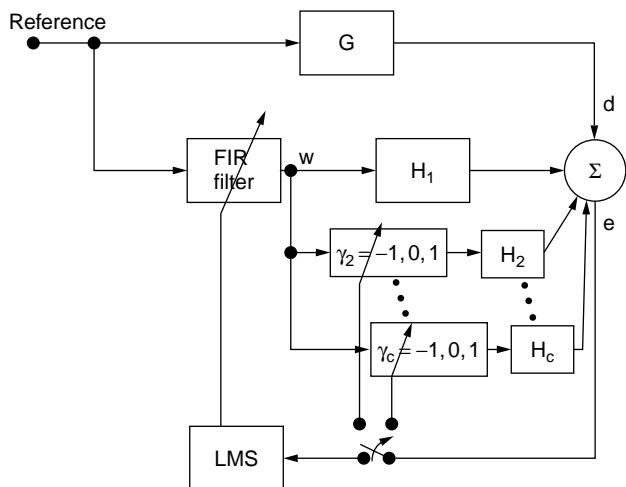

Figure 19. BIO controller with phase local control law.

slave actuator via simple analog switches and keep the setting that gives the lowest cost function value. Figure 19 shows a block diagram realization of such a control system for a feedforward approach. The process then continues to the next slave actuator, and so on, in a predetermined pattern. For the system of Fig. 19 the top-level controller could be digital, while the local control changes occur via simple analog-switching circuits. The approach in effect takes many independent actuators and connects them together via the local controller to create a suboptimal distributed actuator driven by one (or few) channel of control from the top-level centralized controller. The net result of such approaches is a large reduction in control channels to the top-level digital controller, and thus the computational overhead requirements are vastly reduced. The BIO approach in effect takes advantage of some limited knowledge of the dynamics of the distributed system to be controlled in order to reduce the extensive number crunching required in fully coupled optimal approaches.

In the second approach, local analog feedback loops are closed around individual smart skin elements and associated sensors as shown in Fig. 20. The analog local feedback loops have programmable feedback gains that are adapted by a higher-level digital controller in order to minimize a global cost function (obtained from an array of sensors) such as radiated sound power from the structure covered by the smart skin (9). Such approaches have been used to control sound radiation from very large structures. As with all feedback approaches, stability is an important issue. Thus work has also been performed to increase the stability margins via using directional feedback sensors to partially de-couple each local feedback loops. In addition, specialized distributed actuators are used that rolloff in level in the higher-frequency regions where the local open loop transfer function becomes non-minimum phase.

CONCLUSION

The results presented have demonstrated the high potential for the implementations of a smart skin approach for reducing sound radiated from vibrating structures when the radiating structure is massive, stiff (i.e., low mobility), or the source vibration pattern is complex. The smart skin

has also demonstrated the possibility of combining active and passive control approaches in order to increase the control bandwidth and the efficiency of the active portion. A configuration has been demonstrated that further shows that the error sensors can be integrated directly into the skin and still result in a far-field sound reduction.

SPIN-CROSSOVER MATERIALS

JOEL S. MILLER
University of Utah, Chemistry
Salt Lake City, UT

Smart materials respond to their environment as illustrated by photochromic eyeglasses, that darken upon exposure to ultraviolet light to attenuate additional ultraviolet light. Hence, materials that have fast reversible responses to environmental stimuli are sought as components of smart systems. Similar to photochromic materials, thermochromic materials reversibly respond to heat and exhibit substantial color changes upon small changes in temperature. Spin-crossover materials(1) are a class of thermochromic materials that possess fast, reversible color changes amenable to display and memory devices (2). These color changes can also be induced by light (photochromic) or pressure (piezochromic) as well as heat. Due to the nature of the mechanism of their thermo-, photo-, or piezochromic responses (i.e., redistribution of the electron density at a metal ion site within the molecule), they are extremely fast and reversible. As a consequence of the (1) fast color change, (2) strong contrast between colors, and (3) the intermolecular interactions within the solid, the differing colors can be maintained for a long period of time, and (4) due to the lack of moving parts (i.e., no bond breaking or forming), these materials are completely recyclable and amenable to fast, low power-consuming, high-data-density display (2,3) and storage devices and “smart” materials and systems of the future.

Figure 1. Switchover from a high-spin ($S = 2$) state to a low-spin ($S = 0$), as a Fe(II) state compound is cooled, requires ligands in the middle of the spectrochemical series. This transition can also be induced by light or pressure.

Thermochromism results from transition-metal complexes, such as Fe(II), which can be thermally stimulated to change from a colored low-spin electronic state to a frequently colorless high-spin state (1a) (Fig. 1). The high-spin ${}^5T_{2g}$ ground state for Fe(II) has a $t_{2g}-e_g$ splitting Δ , of $<11,000\text{ cm}^{-1}$, and the low-spin ${}^1A_{1g}$ excited state for Fe(II) has a Δ of $>21,000\text{ cm}^{-1}$. $\Delta \sim 16,000\text{ cm}^{-1}$ for Fe(II) surrounded with six unsaturated nitrogen-bound ligands, FeN_6 , can be induced to switch between the high-spin and low-spin states. Upon switching between the high- and low-spin states on cooling, FeN_6 has a significant decrease in Fe–N distances by $19 \pm 5\text{ pm}$, and an increase in the magnetic susceptibility χ due to a change of four in the number of unpaired electrons. From a thermodynamic perspective, the enthalpy ΔH is $10 \pm 6\text{ kJ/mol}$, and the entropy ΔS is $52 \pm 13\text{ J/K}\cdot\text{mol}$; hence, the transition is entropy-driven (1a). Additionally and importantly, the color changes from deeply colored red/purple to colorless upon switching to the high-spin state (see later). Concomitantly, the unit cell typically changes significantly.

The color change of the spin state switch is similar to that of liquid crystal displays (LCD) prevalent in digital watches; however, as a consequence of the mechanism, the thermochromic metal complexes change colors much faster without degradation upon cycling with respect to LCDs (3). Due to the change from low to high spin, this class of materials is referred to as spin-crossover materials. In addition to the technologically important color changes, spin-crossover materials also exhibit a small, but measurable change in magnetic susceptibility. This sharp transition in the change in the magnetic properties is illustrated by the temperature dependence of the magnetic susceptibility–temperature product for $\text{Fe}(\text{o-phenanthroline})_2(\text{NCS})_2$, which undergoes a first-order phase transition from a low- to a high-spin state at -97°C (4), (Fig. 2).

Materials that can be easily and reversibly stimulated to change colors for an innumerable number of cycles have been exploited for display devices. Liquid crystal displays (LCD) found in digital watches, are a common example (3). Materials that have greater switching speeds, sharper contrast, and enhanced stability enabling more duty cycles may lead to improved display and memory devices in the future. Spin-crossover materials can exhibit sharp color changes from small changes in temperature (i.e., they are dramatically thermochromic). As a consequence of the thermochromic mechanism (redistribution of the electron density within the molecule without either bond breaking

Figure 2. Temperature dependence of the magnetic susceptibility–temperature product for $\text{Fe}(\text{o-phenanthroline})_2(\text{NCS})_2$, which undergoes a first-order phase transition from a low- to a high-spin state at 176 K (-97°C) (4a).

or forming), they are extremely fast and recyclable and hence are candidates for high-data-density display and storage devices of the future.

For display/memory devices, it is necessary that the transition temperature (T) is near room temperature, $\sim 22^\circ\text{C}$. This is, however, insufficient because the ambient temperature fluctuates and hence the transition needs to be effected over a broad temperature range, $17 \pm 27^\circ\text{C}$. To achieve this, the system must exhibit history-dependent behavior (hysteresis) such that the transition temperature for color change upon increasing temperature ($T\uparrow$) exceeds the transition temperature for color change upon decreasing temperature ($T\downarrow$) ideally by at least 50°C , that is, $T\uparrow - T\downarrow > 50^\circ\text{C}$. Molecules cannot exhibit hysteretic effects, but in a solid or film, interactions between molecules can lead to hysteretic effects. Hysteresis has been reported for $\text{FeL}_2(\text{NCS})_2$ ($L = (\text{N}_2(\text{CH}_2)_2\text{N}-)_2$), where $T\uparrow = -128.7^\circ\text{C}$ and $T\downarrow = -149.5^\circ\text{C}$ (Fig. 3). (5) Thus, although the transition and $T\uparrow - T\downarrow$ temperatures are too low to be practical, the necessary phenomena have been demonstrated, and new systems that exhibit higher temperatures are needed.

Using a mixture of triazole, $\text{HN}(\text{CH}_2)_2\text{N}_2$ (trz), and aminotriazole, $\text{H}_2\text{NN}(\text{CH}_2)_2\text{N}_2$ (H_2Ntrz) ligands coordinated with Fe(II), a polymer of $[\text{Fe}(\text{trz})_{3-3x}(\text{H}_2\text{Ntrz})_{3x}]$

Figure 3. Temperature dependence of the magnetic behavior of $\text{FeL}_2(\text{NCS})_2$ showing the low-moment (purple) behavior below -149.5°C ($T\uparrow$) and high-moment (colorless) behavior above -128.7°C ($T\downarrow$) (5).

Figure 4. Temperature dependence of the magnetic behavior of $\text{Fe}(\text{trz})_{2.85}(\text{H}_2\text{Ntrz})_{0.15}](\text{ClO}_4)_2 \cdot n\text{H}_2\text{O}$ showing the low-moment (purple) (Figs. 5 and 6) behavior below 39°C ($T\uparrow$) and high-moment (colorless) behavior above 13°C ($T\downarrow$) (6).

$(\text{ClO}_4)_2 \cdot n\text{H}_2\text{O}$ composition has been isolated, which for $x = 0.05$ exhibits $T\uparrow = 39^\circ\text{C}$ and $T\downarrow = 13^\circ\text{C}$ (2,6,7) (Fig. 4). These values bracket room temperature and demonstrate the feasibility of room temperature applications. In addition to the change in magnetic behavior, the color concomitantly as with hysteresis occurs (Fig. 5), from purple to colorless at 21°C (Fig. 6). Solid solutions of triazole and aminotriazole can be blended to lead to a systematic change in the transition temperatures: $T\uparrow = 296 - 160x$ and $T\downarrow = 313 - 180x$ in units of Kelvin.

Smart materials for future applications need to respond to environmental stimuli, and spin-crossover materials (1) are a moderately large class of materials that respond to heat, light, and/or pressure. This summary focuses on the use of heat to change the electronic structure of a material, which in turn leads to substantial and reversible color, magnetic, and structural changes. Most of the materials discussed in this context are inorganic coordination complexes demonstrating that (1) reversible first-order transitions occur, (2) such materials exhibit the technologically important property of hysteresis, and (3) both the transitions and hysteresis can occur at room temperature.

Figure 5. Temperature dependence of the optical density of $\text{Fe}(\text{trz})_{2.85}(\text{H}_2\text{Ntrz})_{0.15}](\text{ClO}_4)_2 \cdot n\text{H}_2\text{O}$ at 520 nm showing hysteresis (purple) (1a).

Figure 6. Dramatic color change for the dark purple low-spin state of $[\text{Fe}(\text{trz})_{2.85}(\text{H}_2\text{Ntrz})_{0.15}](\text{ClO}_4)_2 \cdot n\text{H}_2\text{O}$ below 21°C to the colorless high-spin state at 21°C (6).

THERMORESPONSIVE INORGANIC MATERIALS

JOHN S.O. EVANS
University of Durham
Durham, UK

INTRODUCTION

The encyclopedia of Chemical Technology (1) defines a smart material as one that “responds to its environment in a timely manner” and “receives, transmits, or processes a stimulus and responds by producing a useful effect. . . .” One of the most common everyday stimuli is, of course, temperature. The effect of temperature on the vast majority of materials is well known—as materials are heated, they initially expand in volume before eventually melting, subliming, or decomposing. Thermal expansion is often viewed as a deleterious property. Engineers have to build expansion gaps into structures such as railway lines and bridges; the design of components in a car engine must be somewhat compromised so that they function both during start-up on a cold morning and when the engine is hot; historically, clock pendulums had to be carefully engineered to prevent slow running on warm days. Thermal expansion can, however, also be put to good use. It has long been known that the walls of bowed buildings can be pulled back into shape by a cooling iron bar; steel tires can be shrink-fitted onto the wheels of railway carriages. Although these examples represent a technologically useful response to the stimulus of increased (or decreased) temperature, they do not quite fall into the category of “smart.” However, the very simple concept of coupling together two materials, one that has a large and one a smaller coefficient of thermal expansion to produce a bimetallic strip can certainly be considered to create a smart composite body. Here, the strains induced by the higher expansion of one material cause the strip to bend as temperature is increased, leading to a simple temperature-sensing/responsive device.

The vast majority of materials known and used in technological applications have a positive coefficient of thermal expansion; the reasons for this behavior are discussed later. Certain materials, however, display the opposite property and contract in volume when heated. These materials thus have a negative coefficient of thermal expansion, α_l (vide infra), which has led to their somewhat confusing description as “negative thermal expansion” (NTE) materials. The properties of these materials and the origin of these effects form the main topic of this article.

Materials that have this unusual thermoresponse have a number of important technological applications. Applications related to specific materials are discussed later; more general comments are appropriate here. The first major area of application is in producing composite bodies. By mixing normal materials with a negative thermal expansion phase, one can achieve a composite that has a precisely controlled positive, negative, or even zero coefficient of

expansion. Second, certain of the materials discussed later can be chemically doped to control their expansion properties. Thus, one can envisage a single material that could be adjusted to have zero overall expansion. Such materials are of use where repeated thermal shock might lead to mechanical failure (an everyday example is oven-to-table cookware) or in optical devices such as high precision mirrors where any thermal expansion might distort optical properties. Materials that have strong intrinsic thermal contraction are most likely to be used as compensators for the positive expansion of other phases. For example, there is obvious interest in the electronics industry in producing circuit boards and heat sinks whose expansion properties match those of silicon; the dental industry would like ceramic fillings whose properties match those of teeth; the expansion properties of materials used in optical components such as refractive index gratings and optic fibers must be precisely controlled.

The observation that normal materials expand when heated can be explained at the most simple level by referring to Fig. 1 which shows a potential energy well for a typical diatomic molecule. As molecules are warmed, one excites higher and higher energy vibrational levels. Because interatomic potentials are typically asymmetrical (bonds are more extensible than compressible), this leads to an increase in bond length with temperature. A more formal explanation for the thermal expansion of solids is given by the Gruneisen relationship that relates the thermal expansion of a material [$\alpha_v = (1/v)(\partial V/\partial T)_P$ to its volume (V), specific heat at constant volume (C_V) and isothermal compressibility ($K = -(1/v)(\partial^2 V/\partial P^2)_T$]

$$\alpha_v = \frac{\gamma C_v K}{V}. \quad (1)$$

The Gruneisen parameter γ is defined by $\gamma = -d(\ln v)/d(\ln V)$, where v is a vibrational frequency and reflects the anharmonicity of a typical potential in a solid.

The frequencies of most modes in a normal crystal decrease as the volume increases, and the Gruneisen parameter of normal materials is typically positive in the range of 1 to 3 and only weakly temperature-dependent. Thus, the thermal expansion of normal materials may be expected to have a temperature dependence similar to their specific heat capacity. Therefore, one would expect thermal expansion to be zero at absolute zero, to increase rapidly as temperature is increased, and to approach a constant value at temperatures above the Debye temperature of the material. This simple behavior is at least approximated in many materials. In “negative thermal expansion” materials considered in the remainder of this article, there will always be an underlying expansive component caused by vibrational modes that tend to increase bond distances. In certain circumstances, however, these modes may be dominated by other more exotic effects. It is well known that strong chemical bonds (for example, those between highly charged elements and oxygen: Si–O, W–O, etc.) expand significantly less than weaker bonds (e.g., Na–O, K–O, etc.) (2). Thus

Figure 1. A typical interatomic potential well.

materials in which the unusual effects dominate normal expansion will often contain strongly bonded atoms.

There are two simple expressions commonly found in the literature to describe the thermal expansion of materials. The linear coefficient of thermal expansion may be defined by the differential form $\alpha_l = 1/l(dl/dT)$ or by the average coefficient of thermal expansion $\alpha_l = (l - l_0)/(l_0(T - T_0))$. Because the expansion coefficient generally changes as a function of temperature, it is important to quote the temperature range for any value of α_l . For anisotropic materials, α_l has been defined as $1/3\alpha_V$. Values of α_l for typical materials are quoted in Table 1 and are plotted in terms of % length extension for selected examples in Fig. 2.

ORIGINS OF NEGATIVE THERMAL EXPANSION

Phonons

The previous section described how thermal expansion can be related to the specific heat capacity of a material and, in turn to the population of vibrational modes. In general, this

Table 1. Thermal Expansion Coefficients of Common Materials

Material	$\alpha (\times 10^{-6}) \text{ K}^{-1}^a$	Temperature (K)	Ref.
Si	+2.45	373–223	3
Cu	+16.64	293	4

^a α Values are, in general, temperature-dependent. Values are quoted at a specific temperature or across a given temperature range.

Figure 2. Thermal expansion curves for selected materials.

leads to positive thermal expansion. However, it was first pointed out in the 1950s that certain vibrational modes can lead to the opposite effect and negative thermal expansion (14–16). The simplest example of such an effect can be readily understood by referring to Fig. 3. If one considers an metal–oxygen–metal linkage in a structure, a longitudinal vibration (e.g., along an M–O–M bond) will lead to an extension of the M–M distance. During a transverse vibration, however, if the M–O distance remains essentially unchanged, the M–M distance decreases. This can be understood with respect to the Gruneisen constant for such a mode. A simple analogy for a transverse mode in a M–O–M linkage is a guitar string. If one plucks a note (excites a transverse vibrational mode) on a guitar string, then stretches the string using the tuning forks, the note moves to a higher frequency. Therefore, the Gruneisen parameter, $\gamma = -d(\ln v)/d(\ln V)$ for such a mode is negative. The contribution to thermal expansion for such a mode will also be negative.

Equation (1) is, of course, a simplification of the properties of a real material. In a real structure, different vibrational modes have different energies and are populated at different temperatures. In reality, one must consider the actual population of modes and use the average Gruneisen parameter at a given temperature where $\gamma_{av} = \sum c_i \gamma_i / \sum c_i$, and c_i weights the contribution of a mode to the overall specific heat C_V . In general, transverse modes have lower energy than longitudinal modes and are preferentially populated at low temperature. Thus,

Figure 3. Schematic representation of the effect of different types of vibrational modes on thermal expansion. Shaded circles represent metal atoms and the open circle an oxygen atom. Longitudinal vibrations tend to expand metal–metal distances; transverse vibrations can lead to contraction.

Figure 4. Thermal expansion curves of CuFeS_2 , using data of Knight (17). The solid line represents a fit to a simple two Debye type model. At low temperatures, the population of modes that have negative Gruneisen parameters leads to negative thermal expansion. At higher temperatures, modes that have a positive Gruneisen parameter dominate.

they may dominate the overall Gruneisen parameter at low temperatures and lead to negative thermal expansion. The population of low-energy transverse modes is the origin of negative thermal expansion at very low temperatures in a number of materials. Examples of this phenomenon are shown in Figs. 4 and 5. Figure 4 shows the cell volume of CuFeS_2 derived from powder neutron diffraction data as a function of temperature (17). Here, the thermal expansion is essentially zero at low temperatures [in accordance with expectations of Eq. (1)], is negative at temperatures below 100 K, where modes that have negative Gruneisen parameters presumably dominate, & approaches a constant positive value at high temperatures. Similar phenomena occur in many materials, including compounds that have rock salt, diamond, and zinc blende structures. Barron and co-workers have provided extensive data in this field (4). Interesting correlations can be made between the magnitude of the negative thermal expansion and factors such as the openness of the lattice and the rigidity (covalency) of the chemical bonds.

In the context of phonon-induced negative thermal expansion, the properties of ice are worth mentioning. The

Figure 5. Thermal expansion of ice using data of Rottger (5).

increase in volume of water when freezing is one of the best known examples of an unusual thermoresponsive effect. Both the normal hexagonal and cubic forms of ice have a density (0.92 g/cm^3) that is significantly lower than that of water. This leads to the costly winter phenomenon of frozen pipes bursting then leaking during a thaw, and it also means that ice floats on water. For this reason, ponds and lakes always freeze from the top down, giving rise to a protective layer of ice on top of the water. This process is essential for the survival of aquatic life. This expansion of water can also be incorporated into simple, cheap devices to monitor the temperature history of frozen food and other commodities. Water can be sealed in a thin glass vial, and surrounded by paper impregnated by a water-soluble dye. When the water freezes, it expands and breaks the glass vial. Subsequent warming of the vial causes the water to melt, flow into the dye, and color the surrounding area. Thus, one can monitor whether the temperature of a commodity has ever exceeded 0°C during its storage/shipment. Less well known is the fact that ice shows negative thermal expansion in the solid state at temperatures below about 60 K. Figure 5 shows the temperature dependence of the cell volume of ice as determined by synchrotron X-ray diffraction (5). This cell volume contraction is again caused by the population of low-energy ($<50 \text{ cm}^{-1}$) transverse vibrational modes at low temperatures (5,18).

Rigid Unit Modes

The previous section described how vibrational modes may cause negative thermal expansion at low temperatures in certain materials. The population/importance of individual modes are intimately related to a material's structure. Vibrational modes can, however, give rise to NTE across far more extensive temperature regions in certain categories of materials.

Figure 6 shows the structure of quartz (7). Its thermal expansion properties are included in Fig. 2. At low

Figure 6. Structure of quartz viewed down the c axis showing corner-sharing SiO_4 tetrahedra. The ab plane of the unit cell is shown in bold lines.

temperatures, quartz has a positive coefficient of thermal expansion; at high temperatures ($>573^{\circ}\text{C}$), the thermal expansion becomes low or even negative. The ideas that led to an explanation of this phenomenon can be traced to the structural description of phase transitions in quartz given by Megaw (19). The structure of the high temperature (β) form of quartz can be described as a network of corner-sharing SiO_4 tetrahedra that form paired helical chains parallel to the crystallographic c axis (a 6_4 or 6_2 screw axis). The intertwined chains give rise to the hexagonal channels (important in the structure of β -eucryptite described later) through the structure that are visible in Fig. 6. The structure of the low temperature (α) form of quartz can be derived from that of β quartz by a coupled rotation of these tetrahedra through an angle θ about the $\langle 100 \rangle$ axes. In the more symmetrical β -quartz, θ is 0° ; in α -quartz, θ is 16.3° at room temperature (20). This coupled static rotation of essentially rigid polyhedral groups leads to a rapid reduction in volume on cooling and a large positive expansion coefficient on warming. Similar dynamic rotations of such groups at high temperature can explain the negative thermal expansion of β -quartz.

Dove and co-workers built on the concepts of rigid tetrahedral building blocks to produce models for negative thermal expansion in terms of such distortions (21). Figure 7 shows a schematic representation of a simple two-dimensional structure that can be considered a logical extension to the 1-D schematic of Fig. 3. If this figure represents a hypothetical 2-D structure containing metal atoms strongly bound to a square coordination environment of oxygen atoms, it can be readily appreciated that the structure has inherent flexibility. Certain distortions of the structure are possible in which (strong) M–O distances and (rigid) O–M–O bond angles remain unchanged. Such distortions are likely to be energetically facile and thus are good candidates as low energy vibrational modes of the material. Dove and co-workers termed such modes “rigid unit modes” (RUMs) and developed methodologies for identifying them in real 3-D structures.

Figure 7. Schematic representation of rigid unit mode vibrations in a framework oxide structure as polyhedral and atomic views. Metal atoms are shaded; oxygen atoms are open circles.

It can also be seen that this type of mode is directly analogous to the negative Gruneisen parameter transverse vibration of Fig. 3. In fact, the area of the unit cell of Fig. 7 is proportional to the tilt angle θ . The thermal average of this angle $\langle \theta \rangle_T$ increases with temperature so that the overall cell area $A(T)$ is given by

$$A(T) = A_0 \cos^2 \theta \approx (1 - \langle \theta^2 \rangle_T). \quad (2)$$

If one assumes simple harmonic motion and the principle of equipartition of energy, $A(T)$ can be related to the temperature T , the moment of inertia I of the rigid body, and the vibrational frequency ν by

$$A(T) = A_0 \left(1 - \eta_A \frac{k_B T}{I \nu^2} \right), \quad (3)$$

where k_B is the Boltzmann constant and η_A is a constant specific to the mode in question (22).

A more detailed description of the thermal expansion properties of β -quartz has recently been given in which the ideas of RUMs are developed within the standard Gruneisen theory of thermal expansion (22). This work emphasized the importance of optical modes of the type shown in Fig. 7 but also showed that acoustic modes can make an important contribution to negative thermal expansion.

Concepts of RUMs can also be used to understand displacive phase transitions of the type displayed by quartz and many other framework materials. It is interesting to note, and it is a general feature of many framework materials that display negative thermal expansion, that displacive phase transitions and NTE behaviour are intimately linked. Many framework materials possess a large positive coefficient of thermal expansion as they are warmed. This may be viewed as evidence that the rigid units are “unwinding” in the structure. Once materials reach their high symmetry (maximum volume) structures, they display negative thermal expansion.

Phase Transitions

As suggested by Fig. 1, chemical bonds usually expand as temperature increases. Consequently, the majority of materials have positive expansion coefficients. There are, however, unusual circumstances, often in the region of structural phase transitions, in which at least average bond distances can actually decrease as temperature increases. The ideas of bond valence which originate in the work of Pauling and were developed extensively by Brown and O’Keeffe (23,24) showed that the contribution of a given bond to the valence sum of any atom depends approximately exponentially on the bond length $v = \exp(r_0 - r/0.37)$, where r_0 is a constant for a given E–X combination of elements and v is the valence contribution due to bond length r . This observation can be thought of at the simplest level as short bonds being proportionately stronger than long bonds. From the form of this relationship, one can readily appreciate that if a metal coordination environment changes from being distorted to being more regular at a phase transition, the average bond length decreases.

Figure 8. Cell parameters of PbTiO_3 as it approaches its tetragonal–cubic phase transition.

For example, the bond length r in an undistorted MO_6 octahedron is always shorter than the average bond distance in a distorted octahedron that has, for example, three short and three long bonds.

One example of this effect will be discussed here. Figure 8 shows the temperature dependence of the cell parameters of PbTiO_3 as it approaches its ferroelectric-paraelectric phase transition at 490°C (25). PbTiO_3 contains highly distorted Ti octahedra at room temperature, Ti–O bond lengths are 1.766, 4×1.979 , and 2.390 Å (26). When warmed, these octahedra become less distorted, and the average Ti–O bond length decreases from 2.012 to 1.983 Å (this represents a bond length expansion coefficient of $\alpha_l = -3 \times 10^{-5} \text{K}^{-1}$). The overall coefficient of thermal expansion of PbTiO_3 from 30– 400°C is $\alpha_l = -3.3 \times 10^{-6} \text{K}^{-1}$ (27). Presumably, the contraction of the Ti–O bond lengths in this material dominates the normal expansion of other bonds.

Negative volume changes at phase transitions have also been described in materials such as $\text{Co}_2\text{P}_2\text{O}_7$. As described later, such phases have been included as fillers in glass bonding frits to help match thermal expansion coefficients of materials to be joined. Control of displacive phase transitions is also important in the thermal expansion properties of $\text{ZrV}_{2-x}\text{P}_x\text{O}_7$ and $\text{A}_2(\text{MO}_4)_3$ families and will be discussed later.

Magnetic Transitions

Magnetostrictive phenomena in the region of magnetic phase changes can also give rise to materials of low thermal expansion. The “normal” phonon-driven positive thermal expansion of materials that have a significant magnetoelastic coupling can be compensated for by a large contraction driven by changes in the magnetic structure. This is the case for alloys such as “Invar”, $\text{Fe}_{0.65}\text{Ni}_{0.35}$ (see later), and transition metals such as Cr and α -Mn. Correctly processed, Invar has been quoted as having a thermal expansion coefficient of $0.02 \times 10^{-6} \text{K}^{-1}$, though across a restricted temperature range (28,29). Materials such as $\text{Lu}_2\text{Fe}_{17}$ and Y_2Fe_{17} also exhibit negative thermal expansion below approximately 400 K (30).

Linking Themes

Perhaps the best framework in which all of these phenomena may be described is to consider the change in the internal pressure of a solid caused by heating. This internal pressure, will in turn, gives rise to a volume change. The volume coefficient of thermal expansion can be related to the isothermal compressibility K and the internal pressure by

$$\alpha_V = \frac{1}{V} \left(\frac{\partial V}{\partial T} \right)_P = K \left(\frac{\partial P}{\partial T} \right)_V = K \left(\frac{\partial S}{\partial V} \right)_T. \quad (4)$$

Thus the sign of the coefficient of thermal expansion can be related to the sign of $(\partial S/\partial V)_T$. The entropy of normal materials (or the amount of structural disorder) decreases as pressure increases and volume decreases; materials that have NTE, however, increase in disorder as volume is reduced.

A further link between many of the materials of the next section is their proximity to a structural phase transition. Many of the Invar phases described in the next section are close to a structural phase transition to a body-centered structure. Cubic zirconium tungstate discussed later is thermodynamically unstable at temperatures below 1000°C with respect to more condensed binary phases and undergoes a number of phase transitions as a function of applied pressure and temperature. These instabilities are relevant to its unusual properties. Interestingly, metallic plutonium, which has negative thermal expansion in its δ and η phases has no less than six allotropes (α , β , γ , δ , η , ϵ) at atmospheric pressure; the NTE δ phase has an atomic volume 26% larger than the α .

Thus, it is possible to identify several criteria that might be expected to give rise to unusual thermoresponsive effects in solids:

1. proximity of the material to a structural phase transition
2. proximity of the material to a magnetic or electronic transition
3. the presence of a framework structure containing strong metal anion bonds and two coordinate anions
4. the absence of interstitial cations in a framework structure
5. framework structures in which volume-reducing displacive phase transitions are frustrated

Finally, it is interesting to note that it is possible to make composites that exhibit negative thermal expansion without relying on any of these mechanisms. Sigmund and Torquato showed that it is theoretically possible to produce three-phase composites that exhibit isotropic negative thermal expansion by engineering a topologically specific combination of two materials whose thermal expansion is positive (one high, one low) and empty space (31). In theory, such composites can be designed so that when heated, the bimaterial interfaces of the composite bend into the void space and the overall composite contracts—the material literally folds in on itself.

MATERIALS THAT DISPLAY NEGATIVE THERMAL EXPANSION

Invar

Probably the first technologically exploited example of an “unusual” thermoresponsive effect occurred in 1897 when Swiss physicist Charles Edwarde Guillaume working at the International Bureau of Weights, Sevres, discovered that an Fe/Ni alloy of approximate composition $\text{Fe}_{0.65}\text{Ni}_{0.35}$ showed almost zero thermal expansion across a broad temperature range. This material was christened “Invar,” and because of its discovery, Guillaume was awarded the Nobel prize for Physics in 1920. Invar is used in manufacturing many high precision devices. Perhaps the most widespread current application of Invar is in television and computer screens where it is used as a mask to prevent the electron beam from unintentionally hitting phosphor spots of the wrong color that would lead to blurred images. The low expansion of Invar is essential in this application due to the possibility of heating by the electron beam. Historically, Invar was used in clock pendulums where its low expansion prevented losses in accuracy as temperature changes. Other areas of application include waveguide tubes, surveying tapes, molds for shaping composites in aircraft products, and thermostat controls. Invar is also used in both tankers and tubing for liquid natural gas facilities. In typical applications, Invar has an expansion less than one-tenth that of steel, yet retains strength and is typically cheaper than a material such as Ti. Guillaume is also credited with the invention of “Elinvar” which has extremely small changes in elasticity and hence, mechanical strength as a function of temperature. Thus, this material was used in producing watch springs.

It was realized very quickly that the unusual expansion properties of Invar were intimately connected to its magnetic properties. Invar itself is a disordered face-centered cubic alloy that has a magnetic phase transition at around 500 K. Invar has an extremely low coefficient of thermal expansion below this temperature and a more normal one above it.

The connection between magnetism and thermal expansion led Weiss to propose the “ 2γ state” model to explain the Invar effect (32). There are two different magnetic states in this model, separated by a low energy barrier: a ferromagnetic ground state in which magnetic spins are parallel and the volume is larger, and an antiferromagnetic (antiparallel spins) state at a slightly higher energy, but with a smaller volume. As temperature is increased, the higher energy state becomes increasingly populated, and its smaller volume compensates for the usual expansion effects caused by thermal vibrations. Very recently, van Schilfgaarde et al. described ab initio calculations of the volume (and hence temperature) dependence of the magnetic and thermodynamic properties of Invar (33). Their work describes how noncollinear spin arrangements are crucially important in the Invar system. The magnetic structure undergoes a continuous transition from a high volume ferromagnetic state to a disordered noncollinear spin arrangement at lower volumes. This noncollinearity leads to an unusual dependence of the binding energy as a

function of volume and hence, to unusual thermal expansion properties.

Many other materials (both crystalline and disordered) exhibit the Invar effect, including Fe_3Pt , Cr, $\alpha\text{-Mn}$, $\text{Lu}_2\text{Fe}_{17}$, and Y_2Fe_{17} . There is also a related phenomenon known as the anti-Invar effect in which a magnetic phase transition leads to an anomalously high thermal expansion. Such a property could be used as an activator in a micromachine.

ZrW_2O_8

The thermal expansion properties of ZrW_2O_8 are perhaps the most unusual of any crystalline material. ZrW_2O_8 can be prepared as a simple cubic phase that displays isotropic negative thermal expansion from 2 to more than 1000 K (34). The magnitude of this effect is significant; the coefficient of thermal expansion from 2 to 350 K is $-9.07 \times 10^{-6} \text{ K}^{-1}$ (10). No other material displays such large isotropic contraction across such a wide temperature range. Even though this material has been known since the late 1950s, only in the last few years have its structure and unusual properties been fully understood.

The structure of $\alpha\text{-ZrW}_2\text{O}_8$, determined by powder neutron diffraction, is shown in Figure 9. It is a cubic material (space group $P2_13$) and can be described as a network of corner-sharing ZrO_6 octahedra and WO_4 tetrahedra. Each octahedron shares all six corners with a WO_4 tetrahedron; each tetrahedron shares only three of its four corners with an octahedron leaving one oxygen strictly

Figure 9. The structure of cubic ZrW_2O_8 . (a) A polyhedral representation of corner-sharing ZrO_6 octahedra and WO_4 tetrahedra. (b) A ball-and-stick view of a section of the framework structure. Zr small dark circles, W small light circles, oxygen large grey circles. The one-coordinate oxygen is shaded a lighter gray.

Figure 10. Thermal expansion behavior of ZrW_2O_8 . The plot shows the cubic unit cell parameter of ZrW_2O_8 from 2 to 1443 K. Data are derived from powder neutron diffraction and dilatometric studies (see text for details). The dilatometric data, where the physical length of a ceramic bar is measured, have been scaled to the cell parameter derived from neutron diffraction data at 298 K. Regions of overlap have been omitted for clarity. ZrW_2O_8 is kinetically stable up to 1050 K, unstable in the dotted region of the curve, and thermodynamically stable at 1443 K.

one-coordinate. The temperature dependence of the cubic unit cell of ZrW_2O_8 is shown in Fig. 10. Data points from 2 to 520 K were determined by powder neutron diffraction, where the unit cell parameter is measured directly. Data from 520 to 960 K were determined by dilatometric measurements on a ceramic block of the material, whereas the single data point at 1443 K was determined by neutron diffraction. The only region of this graph where ZrW_2O_8 is thermodynamically stable is the single data point at 1443 K. Below approximately 1050 K, however, ZrW_2O_8 is metastable for extended periods of time. The origin of this negative thermal expansion can be directly traced to the structure of the ZrW_2O_8 framework. Dove and co-workers showed that the topology of the structure is such that ZrW_2O_8 has intrinsic flexibility and can support a large number of rigid unit modes (35). Thus, ZrW_2O_8 is a three-dimensional analog of the simple 2-D model of Fig. 7. Their calculations predict that ZrW_2O_8 will support a large number of low-energy vibrations that tend to contract the lattice.

Experimental evidence for this model has been obtained by a number of techniques. David et al. showed how information about the Gruneisen parameter weighted vibrational density of states can be extracted directly from the cell parameter information of Fig. 10 by using maximum entropy techniques (Fig. 11) (36). This work shows that the negative thermal expansion can be attributed to a family of modes whose energy ranges from 3 to 8 meV. Ernst et al. used inelastic neutron scattering to probe the phonon density of states directly (Fig. 12) (37). These measurements show that there are a significant number of low-energy phonons in ZrW_2O_8 , and again led the authors to conclude that modes in the energy range of 1.5–8.5 meV are most important for NTE. Specific heat capacity measurements by Ramirez and Kowach again highlighted the importance of low-energy vibrations in ZrW_2O_8 (38). Recent calculations

Figure 11. A maximum entropy reconstruction of the Gruneisen parameter weighted phonon density of states extracted from the cell parameter data of Fig. 10. The negative peak around 55 K (4.7 meV) corresponds to a family of low-energy modes that tend to contract the lattice; those centered at 850 K (73 meV) tend to expand the lattice.

provide further support for the importance of these vibrations (39).

It has been shown that the structure of ZrW_2O_8 gives this material a number of other highly unusual properties as a function of both applied temperature and pressure. As the material is warmed to 450 K, it undergoes a phase transition to β - ZrW_2O_8 in which the lighter shaded oxygen atoms of Fig. 9 become dynamically disordered (34,40). Oxygen migration at such low temperatures is highly unusual. Under an applied pressure of around 0.3 GPa, ZrW_2O_8 undergoes a further phase transition to γ - ZrW_2O_8 , which also involves the migration of oxygen atoms to new sites in the structure (41–43). When heated to 100°C, the γ form reverts to the low pressure α form. This series of phase transitions it has been suggested, is a potential method of energy storage. At higher pressures,

Figure 12. Generalised phonon density of states $g(\omega)$ of ZrW_2O_8 at 300 K. Data recorded by inelastic neutron scattering using time-of-flight (<40 meV) and filter-analyzer spectroscopy (>40 meV) [reproduced from article by Ernst et al., with permission(37)].

the material becomes amorphous (44). Recently Wilkinson et al. successfully prepared a new room temperature polymorph—trigonal ZrW_2O_8 . Taken together, these observations suggest that the unusual thermoresponses of ZrW_2O_8 are related to the metastability of the material, its unusual topology, and its proximity to a number of different phase transitions.

Other materials such as HfW_2O_8 and $\text{ZrW}_{2-x}\text{Mo}_x\text{O}_8$ have been prepared recently and characterized (45–48).

AM_2O_7 and Related Phases

It has been known for a number of years that members of the cubic AM_2O_7 family (e.g., ZrV_2O_7 and ZrP_2O_7) exhibit unusual thermal expansion properties. Their structure (Fig. 13) is closely related to that of ZrW_2O_8 and again contains corner-sharing ZrO_6 octahedra and AO_4 tetrahedra. In contrast to ZrW_2O_8 , however, the tetrahedra form A_2O_7 pyrophosphate/vanadate units and thus share all four of their corners; therefore, all oxygens are two-coordinate. This basic structural type is known for a range of A metals, including $A = \text{Si, Ge, Ti, Re, Mo, Nb, Sn, Zr, Mo, W, Pb, Ce, U, and Th}$, and for $M = \text{P, V}$. The structural properties of many of these materials as a function of temperature are complex. At high temperatures, they have the simple cubic structure of Fig. 13. When cooled, however, many members of this family undergo displacive phase transitions. In ZrP_2O_7 , the unit cell parameter as a function of temperature shows a single phase transition to what is apparently a $3 \times 3 \times 3$ cubic supercell at room temperature (49). ZrV_2O_7 , on the other hand, undergoes two

clear phase transitions, initially to an incommensurately modulated $\sim 3 \times 3 \times 3$ superstructure, then, finally to an ordered $3 \times 3 \times 3$ superstructure (50). Both SiP_2O_7 and TiP_2O_7 show similar behavior (51,52).

Thus, these structures show the classic behavior of framework materials, as described previously: a strong positive coefficient of thermal expansion as they approach a displacive phase transition, followed by low or negative thermal expansion thereafter. High temperature coefficients of thermal expansion are $\alpha_l = -7.1 \times 10^{-6}$ (400–500 K) and $+5.4 \times 10^{-6} \text{ K}^{-1}$ (600–700 K) for ZrV_2O_7 and ZrP_2O_7 respectively.

Interestingly, Sleight and co-workers showed how the formation of solid solutions of the type $\text{ZrV}_{2-x}\text{P}_x\text{O}_7$ can be used to suppress these phase transitions and extend the range of negative thermal expansion to include room temperature (53). Figure 14 contains dilatometric data for selected members of the family. Materials such as ZrVPO_7 have low or negative thermal expansion at room temperature and below. This represents an important way in which thermal expansion properties may be effectively controlled and material properties fine-tuned.

NZP Phases

The NZP or Nasicon family of materials is one of the most widely investigated for controllable low or negative thermal expansion properties. This family derives its name from the parent composition $\text{NaZr}_2(\text{PO}_4)_3$ and has general formula $\text{M}^1\text{M}^2\text{A}_2(\text{BO}_4)_3$, where M^1 , M^2 , A, and B can be a variety of metal cations. The name Nasicon is usually reserved for the $\text{Na}_{1+x}\text{Zr}_2(\text{SiO}_4)_x(\text{PO}_4)_{3-x}$ family that has been widely investigated as a solid-state electrolyte due to its high ionic conductivity [see, for example, Brevail et al. for a review (54)] Nasicon derives its name from Na superionic conductor.

The structure of NZP is shown in Fig. 15. It can be described as a framework of fully corner-sharing ZrO_6 octahedra and PO_4 tetrahedra. Two octahedra are linked by three PO_4 tetrahedra to form $\text{Zr}_2(\text{PO}_4)_3^-$ units. These groups align in chains that run parallel to the c axis and are cross-linked via PO_4 groups to adjacent units to form a 3-D framework. The framework created contains a number of interstitial sites where charge balancing M^1 and M^2 cations are located. Within the $\text{Zr}_2(\text{PO}_4)_3^-$ units, there is a trigonal prismatic site that is usually empty. There are approximately octahedral sites (site symmetry -3) between adjacent $\text{Zr}_2(\text{PO}_4)_3^-$ units in the same chain that are occupied by Na in the parent structure. In addition, there are three more approximately octahedral sites between the chains. This network of full and empty sites provides the low-energy migration pathways that give these phases their ionic conduction properties.¹

¹The description here is of the rhombohedral $R\bar{3}c$ form of the material. Several NZP compositions [e.g., $\text{LiZr}_2(\text{PO}_4)_3$ at room temperature and $\text{Na}_{1+x}\text{Zr}_2(\text{SiO}_4)_x(\text{PO}_4)_{3-x}$ for $1.8 < x < 2.2$] undergo a phase transition to a monoclinic structure when cooled from elevated temperatures. This phase transition is displacive and involves static rotations of the polyhedra. The essential features of the structure remain unchanged, though thermal expansion properties are influenced.

Figure 15. The structure of NZP materials. ZrO_6 octahedra share corners with PO_4 tetrahedra to form a 3-D framework. Na cations (circles) sit in interstitial sites in this framework. (a) A view down the c axis of the material. (b) A view perpendicular to the c axis emphasizing the chains of polyhedra in the structure. The “lantern” group of two octahedra and three tetrahedra linked together is also present in the structure of $Sc_2(WO_4)_3$ (Fig. 16).

The NZP family meets many of the criteria laid out previously. The structure contains a framework of corner-sharing polyhedra that have two-coordinate bridging oxygen atoms and a significant number of “vacant” interstitial sites that can accommodate vibrational modes of the polyhedra.

Interest in this family of materials was originally stimulated by a paper by Boilot et al. (55) who described dilatometric data for $Na_{1+x}Zr_2(SiO_4)_x(PO_4)_{3-x}$ materials, where x ranges from 1 to 3, and gave the prescient statement that “the compound $x = 1$ displays an important shrinkage which could allow this material to be useful when expansion is undesirable.” Stemming from this original comment, there has been a considerable body of work on these materials, most notably by Roy, Agrawal, McKinstry, and their co-workers at Pennsylvania State University.

Diffraction measurements show that the low overall thermal expansion in the simple $MZr_2(PO_4)_3$ phases ($M = Li, Na, K, Rb, Cs$) is due to significant anisotropy in the thermal expansion of the a and c axes; the c axis typically shows an expansion, and the a axis shows a contraction. Lenain et al. (56) related this fact to the observation that similar changes in cell parameters are observed as one substitutes successively larger alkali metals at the M site. An elegant model was proposed to explain this anisotropy based on geometrically coupled rotations of the polyhedral units of the structure. Expansion of the M^1 site causes coupled displacements of the framework polyhedra. The inference from this work was that increasing temperature has an effect comparable to increasing the size of the alkali metal. Sleight and Khosrovani (57) took a more quantitative approach and used a combination of the temperature dependence of $M-O$ distances from the literature and the purely geometric distance least squares (DLS) modeling technique to rationalize the properties of these phases. Variable temperature diffraction studies of $LiGe_2(PO_4)_3$ by Alami and more recently by Lightfoot and co-workers (58–61) support these models and confirm the basic ideas. The overall change in cell parameters as a function of

^aData in this table have been selected from those in an extensive review (62) and are examples where the results of both diffraction and dilatometry were presented in the same study.

temperature is caused by changes in the size and shape of the M¹ site which causes the octahedra and tetrahedra to undergo geometrically coupled rotations along with minor internal distortions (octahedra typically distort to a greater extent than tetrahedra).

One of the most technologically significant features of the NZP structure is the wide range of both iso and aliovalent cation substitutions possible at the M¹, M², A, and B sites. The M cations can be substituted by a range of species, including H⁺, Li⁺, K⁺, Rb⁺, Cs⁺, Ag⁺, NH₄⁺, Mg²⁺, Ca²⁺, Sr²⁺, and Ba²⁺; the Zr site by Na⁺, Mg²⁺, Mn²⁺, Ni²⁺, Cu²⁺, Zn²⁺, Al³⁺, Co³⁺, Fe³⁺, In³⁺, Sc³⁺, Y³⁺, Yb³⁺, Nd³⁺, Ti⁴⁺, Ge⁴⁺, Sn⁴⁺, Hf⁴⁺, Th⁴⁺, U⁴⁺, and Nb⁵⁺; and the P site can be substituted by Si⁴⁺, Ge⁴⁺, As⁵⁺, and S⁶⁺. This combination of doping possibilities leads to an essentially infinite family of materials whose low thermal expansion properties are controllable (see Table 2). In terms of cation substitution, NZP is one of the most flexible inorganic materials known. Another potential use of these materials is in nuclear waste storage. Roy et al. showed that NZP will accommodate all of the ions in a normal nuclear fuel reprocessing scheme to form a single-phase ceramic; this has clear environmental implications.

The vast majority of NZP phases actually expand at the unit cell level, even though they show strong bulk contraction (as measured, for example, by dilatometry). NaTi₂(PO₄)₃, for example, has a bulk expansion reportedly as low as $-4.55 \times 10^{-6} \text{ K}^{-1}$ (62), yet the intrinsic cell volume change from the same study is $+3.2 \times 10^{-6} \text{ K}^{-1}$ (22–1000°C). This discrepancy between intrinsic and extrinsic behavior can again be related to the marked anisotropy of expansion of these phases; the overall properties of a ceramic body depend strongly on intergrain interactions. The anisotropy can lead to microcracking in bulk specimens due to stresses induced by different expansions of neighbouring grains in the ceramic body and can frequently lead to hysteresis in the thermal expansion of composites. The healing of microcracks gives an additional component to the contraction on warming; their formation on cooling an expansion. Breval et al. (63) showed that introducing Si in NZP phases can lead to the formation of glassy grain boundaries that soften at relatively low temperature and lead to further discrepancy between extrinsic and intrinsic properties.

An important consequence of the possibility of aliovalent doping in NZP is the ability to prepare materials where the M¹ site is either fully occupied [e.g., NaZr₂(PO₄)₃],

50% occupied [e.g., Ca_{0.5}Zr₂(PO₄)₃], 33% occupied [e.g., La_{0.33}Zr₂(PO₄)₃], or fully vacant [e.g., NbTi(PO₄)₃]. Because the behavior of the M¹ site influences polyhedral tilts in these materials to such an extent, one has a relatively straightforward method of controlling thermal expansion properties. For example, though phases such as NaZr₂(PO₄)₃ show a positive expansivity of the c and negative expansivity of the a axes, this situation is reversed in certain materials such as Ca_{0.5}Zr₂(PO₄)₃, with the c axis contracts, and a expands. The presence of a partially vacant and therefore compressible M¹ site provides a flexible buffer to accommodate expansion of the full sites.

Ca_{0.5-x}Sr_xZr₂(PO₄)₃ is one system that has been investigated in some detail. This interest was again prompted by the observation that in Ca_{0.5}Zr₂(PO₄)₃, the a axis contracts and c expands whereas in Sr_{0.5}Zr₂(PO₄)₃ a expands and c contracts.² Workers at Penn State were successful in synthesizing Ca_{0.25}Sr_{0.25}Zr₂(PO₄)₃ in which α_a and α_c remained nearly constant when heated to 500°C. Acoustic emission studies showed that microcracking in such a material when cooled can be greatly reduced (64). The overall coefficient of thermal expansion of such a composite was reported to be $-0.1 \times 10^{-6} \text{ K}^{-1}$ between 298 and 873 K.

Another interesting phase is NbTi(PO₄)₃ which has fully vacant M sites. It is unusual among the NZP family because it shows intrinsic negative thermal expansion; the a-axis contraction dominates the c-axis expansion. Woodcock et al. (65) provided detailed thermal expansion data for this compound and found that α_l (defined as $1/3 \alpha_V$) ranges from -3 at room temperature to around $+0.5 \times 10^{-6} \text{ K}^{-1}$ at 1000°C. The larger alkali metal (K and Rb) systems have also been reported to show intrinsic contraction. LiZr₂(PO₄)₃ exhibits sharp contraction [$\alpha_l = -10.1$ to $-22.2 \times 10^{-6} \text{ K}^{-1}$] between 20 and 155°C (66).

Agrawal and Roy also demonstrated that low expansion composite bodies can be made between NZP members and other ceramics such as MgO, ZnO, Nb₂O₅, ZrSiO₄. Another interesting application of NZP phases in producing smart high-tech materials was described by Agrawal and co-workers (67). Carbon-carbon composites have a number of properties that make them ideal for certain

²The observation that Ca_{0.5}Zr₂(PO₄)₃ shows the behavior typical of an ordered R3c structure rather than the behavior of a disordered R3 structure has been rationalized in terms of the vacancy site in Ca_{0.5}Zr₂(PO₄)₃ which is smaller and thus less compressible than in the Sr compound.

applications in space vehicles. These include a high strength to weight ratio, good strength retention at high temperature, and good resistance to thermal shock. They do, however, have one major drawback—they are readily oxidized at high temperatures. A number of materials have thus been tested as potential protective coatings. Most, however, suffer from poor thermal mismatch to C–C composites, which leads to their ultimate failure. Agrawal et al. showed that members of the NZP family whose coefficients of thermal expansion match those of the composites can be successfully used as coatings. $\text{Ba}_{0.875}\text{Zr}_2(\text{SiO}_4)_{0.175}(\text{PO}_4)_{2.825}$, for example, can be successfully hot pressed around composite bars, and the resultant body can be heated to 1200°C without any significant oxidation of carbon.

The $\text{Sc}_2(\text{WO}_4)_3$ Family

Negative thermal expansion has also been reported in the $\text{A}_2(\text{MO}_4)_3$ family of materials with $\text{Sc}_2(\text{WO}_4)_3$ related structures. These materials can be described as containing AO_6 octahedra that share all six of their corners with MO_4 tetrahedra (Fig. 16). These materials crystallize in the orthorhombic space group $Pnca$ at high temperatures, as originally described by Abrahams and Bernstein, though several members of the family undergo a volume-reducing displacive phase transition to a monoclinic structure when cooling (68,69). These materials meet many of the criteria laid out previously (strong metal-to-oxygen bonds, rigid polyhedra, no interstitial cations), and it is not surprising that they show low or negative expansion coefficients. It is also relevant to emphasize their structural similarities to several of the other materials described before. Corner-sharing octahedra and tetrahedra are common to the ZrW_2O_8 , ZrV_2O_7 , and NZP families of materials. In particular, the $\text{A}_2(\text{MO}_4)_3$ family is closely related to the interstitial cation-free members of the NZP family such as $\text{NbTi}(\text{PO}_4)_3$; the basic building blocks of the two structures are identical, but their 3-D connectivity differs.

Figure 16. The structure of $\text{Sc}_2(\text{WO}_4)_3$. ScO_6 octahedra (white) share corners with WO_4 tetrahedra (shaded).

Figure 17. Thermal expansion properties of selected members of the $\text{In}_{2-x}\text{Al}_x(\text{WO}_4)_3$ family of materials.

This family of materials also has a high degree of chemical flexibility. The A^{3+} site can be doped by using a variety of elements ranging in size from Al^{3+} ($r = 0.535 \text{ \AA}$) to Gd^{3+} ($r = 0.938 \text{ \AA}$). Additionally, aliovalent doping using, for example, Zr^{4+} on the A site and P^{5+} on the M site to produce phases such as $\text{Zr}_2(\text{PO}_4)_2(\text{WO}_4)$ is possible. These substitutions again lead to controllable thermal expansion properties (70–73). $\text{Y}_2(\text{WO}_4)_3$, which contains the largest A^{3+} cation studied crystallographically, has the most negative coefficient of thermal expansion (72). The monoclinic to orthorhombic phase transition can also be influenced by the A-site electronegativity. $\text{In}_2(\text{WO}_4)_3$ undergoes a monoclinic to orthorhombic transition at around 600 K (Fig. 17); $\text{Al}_2(\text{WO}_4)_3$ is orthorhombic at all temperatures above 300 K. By preparing solid solutions such as $\text{AlIn}(\text{WO}_4)_3$ it is possible to produce ceramic bodies displaying near zero net expansion (Fig. 17). Expansion coefficients for selected materials are included in Table 3.

It is worth noting that, like the NZP materials, most members of the $\text{Sc}_2(\text{WO}_4)_3$ family display anisotropic expansion. Intrinsic expansion (measured by diffraction methods) can be very different in bulk properties. $\text{Sc}_2(\text{WO}_4)_3$, for example, has a cell volume expansion coefficient $\alpha_V = -6.5 \times 10^{-6} \text{ K}^{-1}$ corresponding to $\alpha_l = -2.2 \times 10^{-6} \text{ K}^{-1}$ but can show linear expansion coefficients as low as $-11 \times 10^{-6} \text{ K}^{-1}$ as a bulk ceramic body.

Zeolites

Zeolites are another group of materials that meets many of the criteria laid out previously for unusual expansivity. Zeolites can be described as frameworks built up from corner-sharing SiO_4 and AlO_4 tetrahedra and have charge-balancing species (atomic or molecular) located in voids of the frameworks. Thus, their general formula can be expressed as $\text{M}_{x/n}[(\text{AlO}_2)_x(\text{SiO}_2)_{2-x}]_y\text{H}_2\text{O}$, where M^{n+} cations occupy cavity sites in the framework. There are around 200 aluminosilicate frameworks known of which around 40 are natural minerals. In addition to the zeolites, there are a significant number of materials, often called zeotypes, that contain elements such as P, Be, Ga, and Zn at the tetrahedral sites. Of particular interest in the

$\text{Zr}(\text{PO}_4)_2(\text{WO}_4)$	-3.0 (100–400)	-5.5 (303–873)	70

^aValues are derived from dilatometric data on bulk samples and diffraction data. Linear coefficients of thermal expansion from diffraction measurements are defined as $1/3\alpha_V$. Temperature range in K is given in parentheses.

search for negative thermal expansions are the pure silica frameworks [i.e., $x = 0$ in the preceding general formula] in which there are no interstitial cations. Therefore, they can be described as (metastable) polymorphs of silica. Cation-free frameworks are also found in the Al/P framework materials such as AlPO_4 . The thermal expansion properties of the zeolites provide an interesting example in which computer modeling predicted an unusual property before it was experimentally measured. In 1993, Parker and co-workers used atomistic simulations to predict that certain zeolites should contract as temperature increases (74). These properties were confirmed by subsequent diffraction experiments. In 1995, they modeled 18 different zeolite structures and predicted that all but two ought to contract as temperature increases. This behavior was subsequently confirmed by diffraction measurements. Negative thermal expansion has since been found in a number of zeolites, including pure SiO_2 polymorphs of faujasite and chabazite ITQ-1, ITQ-3, ITQ-9, SSZ-23, ZSM-S, AlPO_4 -5, and ALPO -17 (75–80). Park et al. (79) emphasized the difference in thermal expansion properties of synthesized and calcined zeolites. Typical coefficients of thermal expansion are included in Table 4.

β -Eucryptite/Spodumene

β -Eucryptite, LiAlSiO_4 , can be described as a “stuffed-quartz” structure (20). Half of the Si atoms of quartz are replaced by Al atoms, and charge-balancing Li^+ cations

reside in the sixfold channels visible in Fig. 6 (at the cell origin). Al/Si atoms are ordered parallel to the c axis leading to a doubling of the unit cell c axis, and Li ordering in the various tetrahedral sites of the channels leads to doubling of the a and b axes. β -Eucryptite has been well studied due to its low or negative thermal expansion; α_V is $-6 \times 10^{-6} \text{ K}^{-1}$ from 20 to 523 K and $+0.29 \times 10^{-6} \text{ K}^{-1}$ from 523 to 873 K (82). This low expansion is achieved via significant anisotropy; the c axis contracts, and the a axis remains approximately constant ($<298 \text{ K}$) or expands. As a result, β -eucryptite and other structurally similar compounds in the $\text{Li}_2\text{O}-\text{Al}_2\text{O}_3-\text{SiO}_2$ (LAS) system are used extensively in low-expansion glass ceramics. Products based on these systems include oven-to-table cookware and high precision engineering components.

Various workers have proposed mechanisms to explain the low expansion of β -eucryptite. Recently Xu et al. compared the expansion properties of ordered and disordered Al/Si samples (82). They concluded that a variety of mechanisms determine the overall expansion properties, including tilting of the Si/Al tetrahedra, tetrahedral distortion, and disordering of the Li atoms. This Li ion disordering also gives rise to significant ionic conductivity parallel to the c axis of the material. Several authors have discussed how the population of different Li sites at different temperatures may influence thermal expansion properties. At low temperatures, however, the principal mechanisms underlying anisotropic expansion are tetrahedral tilting and the expansion of an unusually short O–O bond which arises

Table 4. Expansion Coefficients of Zeolites^a

Zeolite	α (diffraction) $\times 10^{-6} \text{ K}^{-1}$	Temperature Range	Ref.
Chabazite	-16	293–873	81
ITQ-4	-4.3	95–510	81
Si-faujasite	-4.2	25–573	77
ALPO -17	-17	18–300	76
ITQ-1	-12.1	323–773	75
ITQ-3	-11.4	323–823	75
SSZ-23	-10.3	323–773	75
MFI	-15.1	393–975	79

DOH	-3.1	573–996	79
MTN	-5.0	463–1002	79
DDR	-8.7	492–1185	79

^aAll values are defined as $1/3\alpha_V$ derived from cell parameter data in the literature.

from edge sharing of LiO_4 and SiO_4 tetrahedra; tetrahedra are described as lengthening parallel to c and shortening perpendicular to this axis.

A second important member of the LAS family is β -spodumene ($\text{LiAlSi}_2\text{O}_6$). Whereas β -eucryptite can be described as a stuffed quartz structure, β -spodumene can be described as derived from keatite, a high pressure form of SiO_2 that has not been found in nature. Keatite is a tetragonal material built from corner-sharing SiO_4 tetrahedra and contains five-, seven-, and eight membered rings. β -Spodumene is derived from this structure and contains Al/Si disordered across two tetrahedral sites and Li disordered across four sets of split tetrahedral sites. β -Spodumene again shows highly anisotropic behavior; the c -axis expands and the a and b axes contract as temperature increases. This effect has again been explained by coupled rotations of tetrahedral groups.

One interesting application which has been demonstrated for β -eucryptite, and for which materials such as ZrW_2O_8 are also being investigated, is for athermalizing fiber Bragg gratings (FBGs). FBGs are created in optical fibers by introducing a periodic modulation into the refractive index of a material and can be manufactured so that they have precisely controlled optical transmission and reflection properties. As such they can be used to control the wavelength of light, combine lights of different wavelengths, and split certain wavelengths from a fiber. These are important properties needed, for example, in wavelength-division multiplexing (WDM) for optical communication networks.

One problem of FBGs is the thermal variation of the Bragg wavelength λ_B , which is influenced by both the temperature dependence of the refractive index (frequently the dominant term) and the thermal expansion of the materials used. A typical temperature dependence in GeO_2 -doped SiO_2 at 1550 nm is 0.012 nm K^{-1} . This temperature dependence can be eliminated by actively controlling the temperature of the unit, though this is an expensive and complex option. Passive control can be achieved by mounting the grating on a negative expansion support. Early designs relied on using two materials that have different (positive) expansion to achieve this effect. By using an NTE mount, both the reliability and ease of manufacture may be improved. Corning, for example, reported a system based on a β -eucryptite glass ceramic substrate in which the temperature dependence of λ_B is reduced from 0.012 to 0.001 nmK^{-1} . In this application, the microstructure (determined by processing conditions) of the NTE support is extremely important. By correct processing, it is possible to reduce the expansion coefficient of β -eucryptite ceramics from their crystallographic value of $\sim -0.4 \times 10^{-6} \text{ K}^{-1}$ to as low as $-7 \times 10^{-6} \text{ K}^{-1}$ (293–393 K). Achieving this high a negative coefficient is important because the temperature dependence of λ_B can be approximated by

$$\frac{d\lambda_B}{dT} = 2\Lambda \left[\frac{dn}{dT} + n\alpha \right], \quad (5)$$

where Λ is the grating spacing. For an average refractive index of $n = 1.461$ and a value of $dn/dT = 11 \times 10^{-6} \text{ K}^{-1}$, a thermal expansion coefficient around $-7.5 \times$

10^{-6} K^{-1} is required to compensate for refractive index changes (83).

A second interesting technical challenge in the development of such devices is the production of frits for bonding fibers to low or negative thermal expansion substrates. For the device described before, Corning used $\text{SnO-ZnO-P}_2\text{O}_5$ inorganic frits containing $\text{Co/Mg}_2\text{P}_2\text{O}_7$ fillers (84). These fillers themselves undergo a martensitic transition that is accompanied by a significant decrease in volume. This volume change can be used to adjust the expansion properties of the frit to match the components it must bond.

Cordierite

Cordierite ($\text{Mg}_2\text{Al}_4\text{Si}_5\text{O}_{18}$) has been widely investigated for its low thermal expansion properties (85). The structure can again be described in terms of a framework of corner-sharing Al/SiO₄ tetrahedra that form four- and six-membered rings. There is an additional octahedral site that is occupied by Mg. The Al and Si atoms in cordierite are ordered in six-membered tetrahedral rings that have an overall orthorhombic symmetry. In many synthetic samples, however, there is no such order, and the symmetry is hexagonal; such materials have been called indialites. The structure of cordierite is closely related to the mineral beryl ($\text{Al}_2\text{Be}_3\text{Si}_6\text{O}_{18}$) in which the tetrahedral sites are occupied by a mixture of Be and Si. Like many silicates, a variety of cations can be doped into this structural type. Synthetic solid solutions have been investigated using elements such as Ga, Ge, and Mn; cation substitution again leads to controllable changes in thermal expansion properties. Cation substitutions in the beryl framework are also evidenced in commercially important phases such as emerald (Cr/Fe substitution) and related minerals such as aquamarine (blue green), morganite (pink), and heliodor (yellow).

These materials (similarly to β -eucryptite and β -spodumene) achieve a low overall volume expansion (typically $< 2 \times 10^{-6} \text{ K}^{-1}$ between 298 and 873 K) via significant structural anisotropy. Most substituted cordierites expand in the a - b plane and contract along the c axis. The magnitude of c -axis contraction typically decreases as T increases. In cordierite itself, c reaches a minimum value around 500°C. This behavior can again be ascribed to coupled rotations of the constituent polyhedra. Cordierite materials are used extensively as low-expansion catalyst supports, especially in automotive catalytic converters.

Selected Commercially Available Materials

Zerodur is a glass ceramic material developed by Schott Glass for various applications where controlled low thermal expansion is required (86). An initial glassy material is produced that contains predominantly $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{P}_2\text{O}_5/\text{Li}_2\text{O}$, though it also has smaller amounts of cations such as Zn, Mg, Ti, Zr, Na, and As. This glass is then subjected to careful heat treatment to produce a composite glass-ceramic containing approximately 70–78% crystalline material. The crystalline component has the β -quartz structure and displays a negative coefficient of thermal expansion which compensates for the positive expansion of the glassy component. Correctly processed, Zerodur can have a coefficient of thermal expansion as low

as $0 \pm 0.02 \times 10^{-6} \text{ K}^{-1}$. Zerodur is routinely fabricated in blocks weighing several tons, and still larger blocks can be manufactured for special applications. Circular mirror blanks for high powered telescopes up to 8.6 m in diameter that weigh 45 tonnes have been manufactured. Zerodur also has extremely low permeability to He which has led to its use as building frames for laser gyroscopes which are used for angle measurements in aircraft, helicopters, and in spacecraft such as the Ariane rocket. Other areas of application include temperature stable distance spacers in lasers, supports in microlithography, and in the imaging optics for microchip manufacture.

In the 1960s Corning developed "ULE", an ultra low expansion titanium silicate glass. The average coefficient of thermal expansion between 5 and 35°C is certified as $0 \pm 0.03 \times 10^{-6} \text{ K}^{-1}$. The thermal expansion properties of ULE are unchanged by thermal cycling, regardless of the heating rates employed. ULE lightweight mirror blanks can also be produced that are reduced in weight up to 95% by using a frit bonding process to produce a "honeycomb" structure whose cell walls are as thin as 1.3 mm. A fusion-based process leading to an 80% weight reduction in which small pieces of ULE are welded together was used to manufacture the 2.4-m mirror blank for the Hubble Space Telescope.

INTRODUCTION

Triboluminescence is the emission of photons caused by applying mechanical energy to a solid. The word Triboluminescence, coined by Wiedemann (1) in 1895, has its root in the Greek “tribein” to rub. The word has broad general usage and covers a variety of mechanical methods of excitation, spectroscopic origins of luminescence, and mechanisms of excitation.

Triboluminescence (TL) has very long history. To the best of our knowledge, TL was first reported by Francis Bacon in the early seventeenth century and is mentioned in *The Advancement of Learning* (2,3). He observed that lumps of sugar emit light when they are scraped. At present, it is known that nearly one-half of all inorganic compounds and between one-quarter to one-third of all organic compounds exhibit TL. Spectroscopic examination and characterization of the emitted light are useful for determining the excited-state origins of TL. The best general spectroscopic characteristics that can be expected from a crystal is that the TL is similar to photoluminescence (PL) at the same temperature. TL and PL spectra are expected to be identical if the sole effect of a fracture is a population of excited electronic states. The importance of perturbations to the crystal and/or the emitting centers caused by fracture is evidenced by the differences between PL and TL spectra. For instance, some crystals show TL at room temperature but do not exhibit PL at that temperature. More commonly, a triboluminescent crystal exhibits PL, but the TL spectrum contains features that are absent from the PL spectrum. These features may be emission bands that do not occur in the PL spectrum or changes in the relative intensities of bands in the TL spectrum compared to those in the PL spectrum.

A number of different mechanisms are required to account for the phenomenon of TL, although its details are still poorly understood. In this review, the mechanisms of different types of TL along with their spectroscopic experimental examples are given first. Then, our experimental results on TL in inorganic crystals that contain rare-earth ions are presented. Finally, the potential applications of TL are briefly described.

CLASSIFICATION OF TL

The mechanisms by which TL is excited have not yet been well clarified. Thus, in addition to elucidating excited-state origins and spectral features that are possible due to advances in TL spectroscopy, classification of the mechanisms of TL is required to understand the phenomenon. The four mechanisms of triboexcitation that are currently under active consideration can be broadly categorized as electrically induced, thermally induced, chemically induced and mechanically induced. Each consists of a broad range of physical processes. As will be seen, the problem is not an absence of mechanisms that can explain the excitation, but rather is too many variable possibilities. The purpose of this section to present briefly the mechanisms currently under consideration.

Electrically Induced TL

The electrical mechanisms that have been proposed all require that mechanical energy generates free electrons, which leads to the emission of photons by electron collision with molecules, recombination luminescence of cations and anions, or electroluminescence (EL).

Piezoelectricity in a crystal from pressure requires that the crystal be noncentrosymmetric (4). When a piezoelectric crystal is cleaved or fractured, one of its newly created surfaces becomes positively charged and the other surface of the crack is negatively charged (Fig. 1). Generally, all

piezoelectric crystals exhibit the phenomenon of TL, and the crystals that do not show TL are nonpiezoelectric (5). Furthermore, several polymorphic crystals that belong to the piezoelectric point group exhibit TL, whereas crystals that do not belong to the piezoelectric point group do not show TL (5). Walton et al. (6) calculated the voltage generated by the fracture of a piezoelectric crystal under the assumption that the crystal is subjected to a tensile stress directed along a polar axis of the crystal and estimated whether or not the voltage is sufficient to initiate gas discharge. The piezoelectric constant in this direction is generally of the order of 10^{-12} C/N, and the stress near the tip of a crack is of the order of 10^8 N/m². Thus, if it is assumed that the relaxation time of the stress is less than the time it takes for the fracture to spread across the crystal, the charge density of the newly created surfaces is of the order of 10^{-4} C/m². The electric field between the oppositely charged density of newly created surfaces is ρ/ϵ_0 , that is, nearly 10^7 V/m, where ρ is the charge density and ϵ_0 is the permittivity constant. Such a field has sufficient magnitude to cause dielectric breakdown of the ambient gas. Several examples of materials where triboluminescence is, induced by piezoelectricity during fracture are tabulated in Table-1 (5–18). The TL of the first two materials is so intense that it can be seen in daylight.

The TL spectrum of sucrose provided clear evidence of emission from nitrogen gas molecules. The nitrogen emission observed corresponds to ${}^3\Pi_u \rightarrow {}^3\Pi_g$ fluorescence (19). A well-defined vibronic band structure is observed, as shown in Fig. 2 (11). A minimum energy of 8.9×10^4 cm⁻¹ is needed to excite nitrogen to its ${}^3\Pi_u$ excited state. The ultraviolet part of the nitrogen gas discharge can excite the PL of surrounding materials; the TL of uranyl nitrate hexahydrate, for instance, has such an origin (5,12). On the other hand, it was found that the TL spectrum of Cu, Ag or Mn-doped ZnS that is piezoelectric corresponds to the PL spectrum that has a small shift in the energy of the peak maxima (18). All of these shifts in TL spectra were in the same direction as those observed upon applying hydrostatic pressure. The spectrum of Cu-doped ZnS exhibits two bands and matches the EL spectrum more closely than the PL spectrum.

Figure 2. Triboluminescent spectrum of sucrose, corresponding to emission from a nitrogen molecule [from (11)].

In several cases, the crystals and glasses whose structures possess a center of symmetry and are nonpiezoelectric exhibit TL. This means that processes other than piezoelectricity are also responsible for charging newly created surfaces. In alkali halides such as LiF and NaCl without piezoelectricity, direct evidence of positive and negative surface charges on fresh fracture surfaces was provided by Wollbrandt et al. (20) using an electrostatic probe that had a 100- μm spatial resolution. Such electrical activity was so strongly supported by the observation that electromagnetic radiation in the radio range was detected coincident with the fracture of LiF, NaCl, and MgO (21,22). One possible source for creation of charged surfaces is the motion of charged dislocations intersected by the fracture surface (23,24). Another source is internal electrification at cleavage or shear planes in the crystal (23,24). If the charge density is sufficiently high, microdischarge takes place in the vicinity of the crack tip, where catastrophic ionization results in dielectric breakdown of the ambient atmosphere. The electrical discharge yields emission of photons, electron, and other particles that accompanies the fracture of solids, including metals, semiconductors, and insulators (25–27). The emission of photons, electrons, and other particles can also excite other luminescent centers, such as impurity ions or defect centers. Even in the absence of microdischarging, local concentrations of surface charge accelerate previously emitted electrons toward the surface. Because the energy of emitted electrons is in the keV range (28), electron bombardment can be sufficiently energetic to cause further emission of photons, electrons, and other particles.

In the 1965 Matsushiro earthquake swarm, where many cracks and fissure zones were formed at the surface (29), luminescence, as well as an anomalous change in the earth's potential, was observed (30). Such surface cracking causes emission of charged particles such as the exoelectron, which is responsible for exciting luminescence, as suggested by Brady and Rowell (31). They recorded the emission spectra of photons induced by the fracture of rocks

such as granite and basalt in argon, helium, air, water, and vacuum and found that the emission consists of line spectra corresponding to the excitation of the ambient atmosphere. Although many rock materials contain minerals, known as piezoelectrics, the basalt was free from any strong piezoelectric minerals. In addition, the spectrum of basalt in argon was identical to that produced by granite in argon. Deformation of piezoelectric minerals does occur during fracture of rocks, but these facts imply that the piezoelectric mechanism is not associated with TL in these minerals. It was proposed that an exoelectron bombardment mechanism is responsible for exciting the ambient atmosphere.

Moreover, photons, electrons, and other particles are emitted by the fracture of silica glass (32–34). Silica glass has excellent optical properties that can be used for practical applications. One of the superior properties of silica glass as an optical material is high transparency, which makes it possible to use silica glass as windows, lenses, prisms, waveguides, and fibers for optical telecommunications. Kawaguchi (34) investigated the time-resolved TL of silica glass in vacuum and nitrogen atmosphere. Two emission bands at 1.9 and 2.7 eV were observed in the spectra. The 1.9-eV band peaks around $5\mu\text{s}$ and decays around $100\mu\text{s}$ after the instant of fracture. The 2.7-eV band rises in about $50\mu\text{s}$, peaks around $500\mu\text{s}$, and decays in several tens of milliseconds after fracture. The energy position and the time response of the two bands were similar to those in PL. The 2.7-eV band was ascribed to the luminescence of oxygen vacancies on the fracture surface of the silica glass, and the 1.9-eV band was related to relaxation of nonbridging oxygen hole centers. A plausible mechanism by which TL can be excited is that the defect centers created at fracture are excited by collisions of emitted electrons and ions. Another mechanism is that the defect centers are excited directly during defect formation by mechanical energy supplied.

Chemically Induced TL

Chemical reaction takes place between atoms and ions liberated during the fracture of crystals, and subsequently, the release of energy gives rise to luminescence. Moreover, molecules of the surrounding gases are absorbed or adsorbed on newly created surfaces when the solid is fractured, and the release of energy in this process causes luminescence. Kasemo and Walden (35) reported spontaneous emission of photons and electrons during chemisorption of chlorine on sodium. Kasemo (36) also observed luminescence during chemisorption of oxygen on aluminum and magnesium surfaces.

Thermally Induced TL

When fracture occurs, plastic work is transformed into heat. The heat produced near the crack tips either stimulates the defect centers and causes luminescent excitation or leads to blackbody radiation or incandescent emission if it is very high. Although incandescent emission does not involve luminescence, it is included here to account for different processes of light emission during deformation or fracture.

Wick (37) pointed out that the TL of X- or γ -ray irradiated synthetic fluorites (CaF_2) that contain different rare-earth ions occurs by deformation-induced thermoluminescence. The TL spectra were composed of emission bands characteristic of trivalent rare-earth ions such as Dy and Tb. Deformation-induced thermoluminescence was also observed for X- or γ -ray irradiated alkali halides (6). On the other hand, by solving the thermal conduction equation, it was shown that temperatures of the order of 10^4 K can be sustained within the plastically strained regions in the vicinity of crack tips (6). Fracture of alkali halide crystals such as LiF, NaF, and NaCl in vacuum was accompanied by flashes of high temperature luminosity, that is, incandescent TL (6). The blackbody curves were fitted to the spectra by assuming a temperature of 10^4 K for LiF and NaF and of 6×10^3 K for NaCl. Because these temperatures are higher than the melting points of the samples, it was postulated that the time taken by the crack to grow by a length equal to the diameter of the local hot spot is less than the time for the heat to be conducted away through the body of the crystal.

Chapman and Walton (38) measured TL spectra of a variety of glasses and of crystalline quartz cut slowly by a rotating diamond-impregnated saw blade and found that the TL spectra resemble the emission of a blackbody radiator at a temperature that corresponds to that of the heated material. Emission temperatures were estimated at around 1850 K for armor plate glass, 2100 K for Pyrex glass, 2400 K for soda lime glass, 2300 K for high-density lead glass, and 2800 K for cut quartz. Because the TL spectra of quartz and glasses did not contain incandescent emission during fracture, it seems that the blackbody emission produced during cutting of these materials by an diamond-impregnated saw blade is attributable to the heat produced by the friction between the blades and the samples.

Mechanically Induced TL

There is a possibility that thermally activated electronic transitions occur in large strain or high stress regions. This effect is the inverse of thermal radiationless quenching of excited states. When displacements along the configuration coordinate fluctuate greatly, the potential curves of the ground and excited states cross each other (Fig. 3), and the subsequent transition of excited electrons to the ground state gives rise to luminescence. The mechanism of radiationless transitions that lead to a population of excited electronic states in large strain or high stress regions near a crack tip was theoretically advanced by Lin et al. (39). Recently, Li and his co-workers (40,41) investigated TL during cleavage of semiconductors, and found that when the number of atomic bonds that are broken on an average cleaved pair of surfaces is about 10^{15} , the number of emitted photons is nearly 10^8 – 10^9 . The observation that the number of emitted photons is much less than the number of broken bonds reveals that the cleavage process is mainly nonradiative. It appears that the TL of Si, Ge, InP, and other semiconductors is caused by radiationless transitions via thermal excitation, where the interatomic distance among some of the atoms of broken bonds is very

Figure 3. Schematic illustration of TL originating from an excited electronic state via radiationless transition. The $|g\rangle$ and $|e\rangle$ represent the potential energy curves of ground and excited states, respectively.

large and therefore, the thermal movement of electrons from the ground state to the excited state is possible.

On the other hand, Chapman and Walton (42) observed TL for single crystals of fluorite (CaF_2) doped with Tb^{3+} , Dy^{3+} , Sm^{3+} , or Eu^{3+} . The crystals were chosen because the possibility of piezoelectrically induced TL can be ruled out. When the crystals were cut by a diamond-impregnated circular saw, the TL spectra show significantly more structure than the room-temperature PL spectra. Although the excited-state origins of TL are rare-earth ions, it is likely that emitting rare-earth ions are located in the vicinity of the tip of a growing crack and/or on the faces of the virgin crack, where the applied stress is concentrated in a severely distorted crystal lattice. Hence, the rare-earth ions are subjected to a significantly distorted environment for time of the order of an atomic vibrational period. This, in turn, leads to changes in the Frank–Condon factors and thus to enhanced vibrational spectral components. The perturbing effect of high stress or large strain on electronic structures unambiguously appears in TL spectra. However, questions remain as to whether or not the TL of fluorites doped with rare-earth ions originates from the population of excited electronic states by radiationless transitions because the microdischarge of gas molecules takes place in nonpiezoelectric crystals, as mentioned before. Photons that originate from the microdischarge may excite the rare-earth ions, and subsequently yield TL. Measurements of TL in fluorites without rare earths are needed to reveal the detailed mechanisms of TL.

TL OF OXIDE CRYSTALS DOPED WITH RARE EARTHS

Rare-earth-doped inorganic crystals and glasses have optical properties that are interesting and important from

fundamental and practical viewpoints. The optical properties of rare-earth-doped inorganic materials are applicable to the development of optoelectronics devices such as lasers, optical amplifiers, optical memories, and optical modulators. As mentioned in the previous section, some inorganic crystals doped with rare-earth ions exhibit TL. For instance, TL was observed in single crystalline fluorite (CaF_2) doped with trivalent rare-earth ions, and it was shown that the rare-earth ions are responsible for TL (42). As for oxide materials, our research group found that polycrystalline hexacelsians ($\text{BaAl}_2\text{Si}_2\text{O}_8$ and $\text{SrAl}_2\text{Si}_2\text{O}_8$) doped with rare-earth ions exhibit TL caused by the $4f-4f$ and/or $4f-5d$ electronic transitions of rare-earth ions (43–45). Intense TL was also observed in polycrystalline $\text{Sr}_3\text{Al}_2\text{O}_6:\text{Eu,Dy}$ and $\text{SrAl}_2\text{O}_4:\text{Eu}^{2+}$, as revealed by Akiyama et al. (46) and Xu et al. (47,48), respectively. In addition, Sage et al. (49) demonstrated TL in a rare-earth complex and urged its application to sensing of structural damage and fracture.

In the next section, we describe our recent experimental results for TL in polycrystalline oxides doped with rare-earth ions.

TL of Hexacelsians Doped with Rare Earths

The fact that polycrystalline barium hexacelsians ($\text{BaAl}_2\text{Si}_2\text{O}_8$) doped with rare-earth ions exhibit TL was accidentally discovered by Ishihara et al. (43). The polycrystalline samples were prepared from reagent-grade BaCO_3 , Al_2O_3 , SiO_2 , and rare-earth oxides. After the raw materials were mixed thoroughly, the mixture was heated above the melting point of $\text{BaAl}_2\text{Si}_2\text{O}_8$. A densified body of polycrystalline $\text{BaAl}_2\text{Si}_2\text{O}_8$ doped with rare-earth ions was obtained by cooling from its liquid state. The crystal structure of $\text{BaAl}_2\text{Si}_2\text{O}_8$ is schematically illustrated in Fig. 4. The structure consists of layers of silicate and aluminate structural units between which Ba^{2+} layers are inserted.

TL was measured at room temperature while pressing the polycrystalline samples with a pressure device. TL spectra were obtained by using a CCD detector equipped with a multichannel analyzer. Photoluminescence (PL) spectra were measured using a fluorescence spectrophotometer for comparison. As an example, TL (solid circles) and PL (solid line) spectra of $\text{BaAl}_2\text{Si}_2\text{O}_8:\text{Dy}^{3+}$ are shown in Fig. 5. The emission lines at 483, 576, and 662 nm in both TL and PL spectra are ascribable to the ${}^4\text{F}_{9/2}-{}^6\text{H}_{15/2}$, ${}^4\text{F}_{9/2}-{}^6\text{H}_{13/2}$, and ${}^4\text{F}_{9/2}-{}^6\text{H}_{11/2}$ transitions of Dy^{3+} , respectively. The peak positions and the relative intensities of the emission lines in the TL spectrum are almost identical to those in the PL spectrum. It is unambiguous that the TL is caused by the electronic transitions of the doped Dy^{3+} ions. Figure 6 shows TL (solid circles) and PL (solid line) spectra of $\text{BaAl}_2\text{Si}_2\text{O}_8:\text{Tb}^{3+}$. The excitation wavelength for PL is 350 nm. All of the emission lines observed in the TL spectrum are assigned to the ${}^5\text{D}_4-{}^7\text{F}_J$ and ${}^5\text{D}_3-{}^7\text{F}_J$ transitions of Tb^{3+} , as indicated in the figure. The emission lines due to the ${}^5\text{D}_3-{}^7\text{F}_4$ and ${}^5\text{D}_3-{}^7\text{F}_5$ transitions in the TL spectrum do not appear in the PL spectrum, presumably because the excitation wavelength (350 nm) is not suitable for emission from the ${}^5\text{D}_3$ state. In fact, these emission lines become

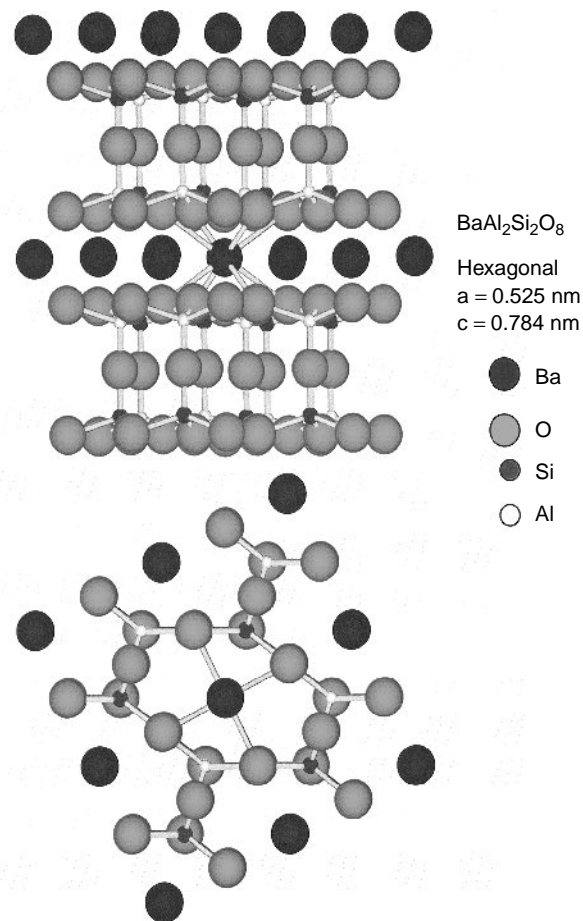

Figure 4. Schematic illustration of crystal structure of $\text{BaAl}_2\text{Si}_2\text{O}_8$.

Figure 5. TL (closed circles) and PL (solid line) spectra of a $\text{BaAl}_2\text{Si}_2\text{O}_8:\text{Dy}^{3+}$ polycrystal.

Figure 6. TL (closed circles) and PL (solid line) spectra of a $\text{BaAl}_2\text{Si}_2\text{O}_8:\text{Tb}^{3+}$ polycrystal.

visible in the PL spectrum when the excitation wavelength is changed to 250 nm. Similar TL and PL spectra were obtained for polycrystalline $\text{SrAl}_2\text{Si}_2\text{O}_8:\text{Tb}^{3+}$. Thus far, TL characterized by the electronic transitions of doped rare-earth ions was observed in $\text{BaAl}_2\text{Si}_2\text{O}_8$ doped with Eu^{2+} , Sm^{2+} , Sm^{3+} , Yb^{2+} , or Ce^{3+} and $\text{SrAl}_2\text{Si}_2\text{O}_8$ doped with Eu^{2+} or Dy^{3+} , in addition to the examples previously mentioned. In our early work on the TL of hexacelsians, we argued that the emission peak of TL is shifted to a longer wavelength compared with PL for 4f–5d transitions (44). However, the difference in the peak position between TL and PL spectra is explained mainly in terms of the incomplete sensitivity correction of the detector used for measuring TL, in addition to the fact that the S/N ratio in the TL spectra is very low.

It is also known that TL is observed in $\text{BaAl}_2\text{Si}_2\text{O}_8$ without intentional dopants. The TL spectrum of $\text{BaAl}_2\text{Si}_2\text{O}_8$ without intentional dopants manifests intense emission lines at around 315, 335, 355, and 380 nm, as shown in Fig. 7. Whether or not a crystal exhibits TL depends on its crystal structure. Table 2 shows the relationship among crystal structure, piezoelectricity, and the presence of TL, as summarized by Chandra (5). The hexacelsian has a space group of symmetry D_{6h} ($P6/mmm$) which precludes piezoelectricity according to this table. Nonetheless, TL is observed for a hexacelsian without intentional dopants, as shown in Fig. 7. Brady and Rowell (31) proposed that the light emission observed in earthquakes is caused by exo-electron excitation of the ambient atmosphere. Nakayama (50) found that many charged particles are emitted from

Figure 7. TL spectrum of a $\text{BaAl}_2\text{Si}_2\text{O}_8$ polycrystal without any intentional dopants.

mica when it is scratched and argued that triboemission originates from a discharge from ambient atmosphere in the vicinity of the frictional surface. A comparison between Figs. 2 and 7 reveals that the TL spectrum observed for $\text{BaAl}_2\text{Si}_2\text{O}_8$ without intentional dopants is ascribable to

Figure 8. X-ray diffraction pattern of a $\text{SrAl}_2\text{O}_4:\text{Eu}^{2+}, \text{Dy}^{3+}$ polycrystalline sample prepared by the conventional solid-state reaction. All of the diffraction lines but those indicated by closed and open circles, which are ascribable to $\text{R}_3\text{Al}_5\text{O}_{12}$ and RAlO_3 (R corresponds to Eu^{3+} and/or Dy^{3+}), are assigned to SrAl_2O_4 .

the light emission brought about by the discharge from nitrogen molecules. The discharge presumably results from cleavage at the Ba^{2+} layer of the $BaAl_2Si_2O_8$. Doped rare-earth ions are excited by photons caused by the discharge from nitrogen molecules because a TL was measured in air. The excited rare-earth ions lead to luminescence due to $4f-5d$ and/or $4f-4f$ transitions.

TL of Alkaline-Earth Aluminates Doped with Rare Earths

As described before, intense TL was observed from polycrystalline $Sr_3Al_2O_6:Eu,Dy$ and $SrAl_2O_4:Eu^{2+}$ (46–48). Rare-earth-doped strontium aluminate crystals are very interesting because some of them exhibit long lasting phosphorescence (51). In particular, $SrAl_2O_4$ doped with Eu^{2+} and Dy^{3+} shows intense phosphorescence that lasts a very long time. The long lasting phosphorescence is a phenomenon where a solid irradiated by UV or white light beforehand continues to emit light even after the excitation ceases. In this section, we mention our experimental results for TL of polycrystalline $SrAl_2O_4:Eu^{2+},Dy^{3+}$, Dy^{3+} -doped $(Sr,Ba)Al_2O_4$, and $(Sr,Ca)Al_2O_4$ polycrystals.

An interesting application of the TL of $SrAl_2O_4:Eu^{2+}$ for sensing stress was demonstrated by Xu et al. (47,48) and is cited in the following section.

Figure 8 shows the X-ray diffraction pattern of polycrystalline $SrAl_2O_4:Eu^{2+},Dy^{3+}$ prepared by the conventional solid-state reaction. Although very weak diffraction lines ascribed to $R_3Al_5O_{12}$ and AlO_3 (R corresponds to Eu^{3+} and/or Dy^{3+}) are observed, as indicated by solid and open circles in the figure, almost all of the diffraction lines are attributable to $SrAl_2O_4$. In addition, although Dy^{3+} and Eu^{3+} form the crystalline phases previously mentioned, some of the Dy^{3+} and Eu^{2+} ions are incorporated into the $SrAl_2O_4$ phase and replace the Sr^{2+} ions because the sample exhibits long lasting phosphorescence.

Figure 9 shows photographs of TL taken at various periods using a video camera after uniaxial compressive stress was applied to the $SrAl_2O_4:Eu^{2+},Dy^{3+}$ polycrystal. In the figure, the periods calculated from the shutter velocity of the video camera are represented below each photograph as times of 0s to 11/30s, respectively. No luminescence was found before the fracture of the sample (at 0s). A green emission is clearly observed in the photographs after the

Figure 9. Photographs of the TL of a $\text{SrAl}_2\text{O}_4:\text{Eu}^{2+}, \text{Dy}^{3+}$ polycrystal. The photographs were taken at various periods after a uniaxial compressive stress was applied to the sample. In (48), a real-time image of stress-induced luminescence was also demonstrated for $\text{SrAl}_2\text{O}_4:\text{Eu}^{2+}$. Here, it should be stressed that our TL data are based on the fracture of solids, whereas nondestructive deformation of the crystal gives rise to TL in (48).

Figure 10. TL (closed circles) and PL (solid line) spectra of a $\text{SrAl}_2\text{O}_4:\text{Eu}^{2+},\text{Dy}^{3+}$ polycrystal.

fracture of the sample, although the stress required for the fracture could not be estimated by using our equipment. Because the TL was measured after the long lasting phosphorescence ceased, the luminescence in Fig. 9 is undoubtedly caused by fracture of the sample. In Fig. 9, it is observed that the part that exhibits green emission within the sample varies from place to place with time. This time dependence results from the possibility that the stress is not applied uniformly to the polycrystalline sample.

TL (solid circles) and PL (solid line) spectra of $\text{SrAl}_2\text{O}_4:\text{Eu}^{2+},\text{Dy}^{3+}$ are shown in Fig. 10. The excitation wavelength for PL is 330 nm. A broad band is observed at around 500–520 nm in both spectra. The wavelength region of this broad band coincides with the green emission. A comparison of the broad band between TL and PL spectra reveals that the peak position and the profile are similar to, indicating that the origin of the luminescence is the same as that of TL. This broad band is ascribable to the $4f^{65d}-4f^7$ transition of the doped Eu^{2+} ion. Emission due to the $4f-4f$ transitions of Dy^{3+} is not observed in the TL nor the PL spectrum.

In PL, light at a wavelength of 330 nm excites Eu^{2+} ions, and radiative decay in Eu^{2+} is observed. It is thought that Dy^{3+} plays the role of acceptor for an electron or a positive hole in long lasting phosphorescence (51,52). As for TL, emission of electrons, ions, and photons takes place when triboluminescent solids are fractured. Hence, the following model is proposed for the mechanism of TL in a $\text{SrAl}_2\text{O}_4:\text{Eu}^{2+},\text{Dy}^{3+}$ polycrystal. Initially, photons emitted by the fracture of SrAl_2O_4 excite Eu^{2+} ions. Some excited electrons relax to the ground state of Eu^{2+} and radiate. Other electrons and positive holes also formed by the excitation are trapped at defect sites relevant to Dy^{3+} , and luminescence due to recombination of the hole and electron at the Eu^{2+} site takes place via long lasting phosphorescence. We speculate that the former process is dominant because the emission does not last for a long period,

as indicated in Fig. 9. The intensity of green emission decays rapidly (within one second or so), as found in the photographs in Fig. 9. Another possible cause of TL is fracture- and/or deformation-induced thermoluminescence (53). The frictional heat generated by the fracture and/or deformation of a crystal stimulates an electron and trapped at a defect site in advance, and the recombination of the released electron and a hole trapped beforehand at the Eu^{2+} site (i.e., Eu^{3+}) yields the emission due to Eu^{2+} . It is commonly known that the europium ion can be in its trivalent state (Eu^{3+}) in many solids.

Note that another mechanism was proposed by Xu et al. (47) for TL based on the nondestructive deformation of $\text{SrAl}_2\text{O}_4:\text{Eu}^{2+}$. They argued that a positive hole trapped at a certain localized level in the energy gap is released by the movement of a dislocation which is caused by the deformation of the crystal, and that the recombination of the hole with an electron trapped at the Eu^{2+} site (i.e., Eu^+) gives rise to the emission of photons as TL. Nonetheless, the monovalent state of europium ion (Eu^+) is unusual from the chemical viewpoint, and the existence of Eu^+ is unclear, to date. Thus, the mechanism of TL in this material is controversial.

To clarify the influence of crystal fracture on the local structure and on the luminescent properties of doped rare-earth ions in alkaline earth aluminates, we have measured TL in Dy^{3+} -doped $(\text{Sr},\text{Ba})\text{Al}_2\text{O}_4$ and $(\text{Sr},\text{Ca})\text{Al}_2\text{O}_4$ polycrystals. Dy^{3+} was selected because the coordination state relevant to Dy^{3+} , including the coordination symmetry around Dy^{3+} and the electronic state of the chemical bond between Dy^{3+} and a ligand, can be readily deduced from the relative intensity of the emission lines assigned to the $4f-4f$ transitions of Dy^{3+} . Besides, one can alter the ligand field around Dy^{3+} systematically by using a solid solution such as $(\text{Sr},\text{Ba})\text{Al}_2\text{O}_4$ and $(\text{Sr},\text{Ca})\text{Al}_2\text{O}_4$ as the host material. It is known that broad composition ranges of solid solution are present and the compositional dependence of the lattice parameter manifests a monotonic variation in the $\text{SrAl}_2\text{O}_4-\text{BaAl}_2\text{O}_4$ and $\text{SrAl}_2\text{O}_4-\text{CaAl}_2\text{O}_4$ systems (54). According to X-ray diffraction analysis, the substitution of Sr by Ba in the $(\text{Sr},\text{Ba})\text{Al}_2\text{O}_4$ system does not lead to any change in the crystal structure when the amount of Ba that replaces Sr is less than 40 mol%. The structure of $\text{Sr}_{1-x}\text{Ba}_x\text{Al}_2\text{O}_4$ polycrystals prepared by the conventional solid-state reaction is mainly monoclinic ($\alpha\text{-SrAl}_2\text{O}_4$ structure) at least for $x < 0.4$, although the hexagonal phase (BaAl_2O_4 structure) exists mainly when the concentration of Ba^{2+} is larger than 40 mol%. On the other hand, for the $\text{SrAl}_2\text{O}_4-\text{CaAl}_2\text{O}_4$ system, a drastic change in the X-ray diffraction pattern, that is, crystal structure, is observed when the composition changes from $\text{Sr}_{0.9}\text{Ca}_{0.1}\text{Al}_2\text{O}_4$ to $\text{Sr}_{0.8}\text{Ca}_{0.2}\text{Al}_2\text{O}_4$, whereas the crystal structure of SrAl_2O_4 is very similar to that of $\text{Sr}_{0.9}\text{Ca}_{0.1}\text{Al}_2\text{O}_4$. The $\text{Sr}_{1-x}\text{Ca}_x\text{Al}_2\text{O}_4$ polycrystals take pseudohexagonal and monoclinic structures for $x > 0.2$ and $x < 0.2$, respectively.

TL spectra of $(\text{Sr},\text{Ba})\text{Al}_2\text{O}_4$ and $\text{Sr}_{0.9}\text{Ca}_{0.1}\text{Al}_2\text{O}_4$ doped with Dy^{3+} are shown in Fig. 11. Three emission lines are observed in all of the spectra. These lines are assigned to the $4f-4f$ transitions of Dy^{3+} ; the emission lines at around 480, 575, and 660 nm are attributable to the ${}^4\text{F}_{9/2}-{}^6\text{H}_{15/2}$, ${}^4\text{F}_{9/2}-{}^6\text{H}_{13/2}$, and ${}^4\text{F}_{9/2}-{}^6\text{H}_{11/2}$ transitions of Dy^{3+} ,

Figure 11. TL spectra of Dy³⁺-doped (a) Sr_{0.6}Ba_{0.4}Al₂O₄, (b) Sr_{0.8}Ba_{0.2}Al₂O₄, (c) Sr_{0.9}Ba_{0.1}Al₂O₄, (d) SrAl₂O₄, and (e) Sr_{0.9}Ca_{0.1}Al₂O₄. The assignment of emission lines is indicated in the figure.

respectively, as indicated in the figure. These samples exhibit PL as shown in Fig. 12. These spectra were obtained under excitation at 350 nm. All of the emission lines in the figure are attributed to the 4f–4f transitions of Dy³⁺, as indicated in the figure. Noted that TL was barely observed in Sr_{0.8}Ca_{0.2}Al₂O₄:Dy³⁺ and Sr_{0.6}Ca_{0.4}Al₂O₄:Dy³⁺, although these compounds exhibit PL under excitation at 350 nm. Presumably, this occurs because the crystal structure of Sr_{0.8}Ca_{0.2}Al₂O₄ and Sr_{0.6}Ca_{0.4}Al₂O₄, a pseudohexagonal structure, is different from those of the other compounds; the other crystalline phases take a monoclinic structure, as mentioned before.

Comparison of Figs. 11 and 12 suggests that the intensity ratio of the 480-nm emission (⁴F_{9/2}–⁶H_{15/2} transition) to the 575-nm emission (⁴F_{9/2}–⁶H_{13/2} transition) is almost independent of the composition for the TL spectra, whereas the relative intensity of the 480-nm emission to the 575-nm emission varies with composition for the PL spectra. Besides, the intensity ratio of 480-nm emission to 575-nm emission is smaller in the TL than in the PL spectra.

Figure 12. PL spectra obtained under excitation at 350 nm for Dy³⁺-doped (a) Sr_{0.6}Ba_{0.4}Al₂O₄, (b) Sr_{0.8}Ba_{0.2}Al₂O₄, (c) Sr_{0.9}Ba_{0.1}Al₂O₄, (d) SrAl₂O₄, and (e) Sr_{0.9}Ca_{0.1}Al₂O₄. The assignment of emission lines is indicated in the figure.

To visualize this relationship, the integrated intensity was evaluated for the 480-nm and 575-nm emissions, and the intensity ratio was plotted against the mean ionic radius of the alkaline earth in the crystal in Fig. 13. The open and closed circles correspond to TL and PL, respectively. The ratio $I_{(480\text{nm})}/I_{(575\text{nm})}$ increases as the mean ionic radius increases for PL, whereas the ratio is almost independent of the mean ionic radius for TL. The intensity ratio is also smaller for TL than for PL. Two possibilities are suggested to explain this phenomenon. One is the effect of self-absorption (55); the photons emitted from an optically active center such as rare-earth ions are reabsorbed by the other active center in TL. Because TL usually occurs within the bulk, photons are reabsorbed until they come out of the bulk. A comparison among TL, PL, and excitation spectra for the transition that corresponds to 480 nm is shown for SrAl₂O₄:Dy³⁺ in Fig. 14. The TL, PL, and excitation spectra are represented by closed circles, solid line, and open circles, respectively. An overlap of the PL and the excitation spectra is observed at around 475 nm. Although it is

Figure 13. Variation of integrated emission intensity ratio, $I_{(480 \text{ nm})}/I_{(575 \text{ nm})}$ vs. the mean ionic radius of the alkaline earth in the crystals. Open and closed circles denote the TL and PL, respectively.

difficult to compare the integrated intensity of these emission and absorption lines quantitatively, the possibility of self-absorption cannot be ruled out.

Another possibility for the difference in relative emission intensity between TL and PL spectra involves the characteristics of the ligand field around Dy^{3+} . It is well known that the emission intensity for each electronic transition of a rare-earth ion can be approximately connected to ligand fields via the Judd–Ofelt theory (56,57). According to this theory, the radiative transition probability for

Figure 14. TL (closed circles), PL (solid line), and excitation (open circles) spectra at around 480 nm for $\text{SrAl}_2\text{O}_4:\text{Dy}^{3+}$.

the electric dipole transition A is expressed as

$$A = \left(\frac{64\pi^2 e^2}{3h(2J+1)} \right) \left(\frac{1}{\lambda^3} \right) \left(\frac{n(n^2+2)^2}{9} \right) S(aJ:bJ'), \quad (1)$$

where h is Planck's constant, J is the total angular momentum, n is the refractive index, e is the elementary electric charge, λ is the peak wavelength of the emission line, and $S(aJ:bJ')$ is the line strength for the transition between the $|a\rangle$ and $|b\rangle$ states. The line strength $S(aJ:bJ')$ is expressed by

$$S(aJ:bJ') = \sum_{t=2,4,6} \Omega_t |\langle aJ \| U^{(t)} \| bJ' \rangle|^2, \quad (2)$$

where $\langle aJ \| U^{(t)} \| bJ' \rangle$ is the reduced matrix element that can be calculated for each electronic transition of rare-earth ions. The reduced matrix element is independent of the difference in the environment in which the rare-earth ion is located. On the other hand, because the parameter Ω_t includes the distance between the rare-earth ion and the ligand, the charge of the ligands, and so forth, Ω_t varies depending on the kinds of ligand fields and the rare-earth ions. The line strength in Eq. (2) is proportional to the integrated intensity of the lines in the optical absorption and emission spectra, so that the Ω parameter which represents the characteristics of ligand fields is reflected by the integrated intensity of absorption and emission lines. It is thought that Ω_2 is relevant to the coordination symmetry of ligands and Ω_6 is an indicator of the covalency of the chemical bond between a rare-earth ion and a ligand (58,59). As for the Dy^{3+} , the integrated intensity ratio of 480-nm to 575-nm emissions correlates with Ω_6/Ω_2 . This suggests that the integrated intensity ratio becomes small when the coordination symmetry for Dy^{3+} is low (60). Hence, the variation of the relative integrated intensity for PL shown in Fig. 13 indicates that the ligand field for Dy^{3+} changes as the size of alkaline earth ion changes, as expected. Presumably, this variation is based on the average coordination structure around Dy^{3+} because Dy^{3+} ions can occupy at least two different positions at Sr^{2+} sites in the SrAl_2O_4 crystal (61). On the other hand, the fact that the relative integrated emission intensity is almost independent of the mean ionic radius of the alkaline earth in TL suggests that the average coordination symmetry for Dy^{3+} which gives rise to the TL does not change even though the kind of alkali-earth ion is varied. Furthermore, the smaller value of $I_{(480 \text{ nm})}/I_{(575 \text{ nm})}$ in TL spectra compared with PL spectra indicates that the average coordination symmetry for Dy^{3+} , which brings about the TL, is low. Consequently, it is suggested that the TL observed is the emission of photons from Dy^{3+} placed in a distorted site such as a fractured surface and/or the vicinity of a crack tip.

APPLICATIONS OF TL

Recent findings for rare-earth-doped materials that show intense TL have attracted attention because of their potential application for sensing structural damage, fracture, and deformation. We describe one example of sensing deformation demonstrated by Xu et al. (47,48) using the $\text{SrAl}_2\text{O}_4:\text{Eu}^{2+}$ polycrystal. They mixed the $\text{SrAl}_2\text{O}_4:\text{Eu}^{2+}$

powder with an optical epoxy resin to make a composite disk 25 mm in diameter and 15 mm thick. A compressive stress was applied in the direction of the diameter. As a result, an intense green emission was observed. Besides, the emission intensity was distributed within the disk, and the distribution of emission intensity fairly coincides with the distribution of deformation calculated by using a theory of elastics. Similarly, Xu et al. (62) showed that an artificial skin that consists of piezoluminescent film (ZnS) could act as a self-diagnosing material to detect mechanical stress remotely by visible light emission. Sage et al. (49) also proved the effectiveness of TL for sensing structural damage. They prepared composite materials doped with Eu, Tb, and Mn complexes that exhibit intense TL. They successfully showed that these materials are useful for real-time monitoring of the magnitude and the location of structural damage. These experiments demonstrate that the distribution of stress and damage within a solid can be visualized by using TL materials.

INTRODUCTION

Structural systems that have a built-in capability to sense external stimulus and respond to it depending on a predetermined criteria are commonly referred to as smart structures. An example of a smart structure is a flexible satellite antenna that can sense its own vibration and apply corrective action to dampen it out. A smart structure consists of four major components: the structure itself, sensors, actuators, and the control system. Smart structures can achieve performance objective that cannot be achieved by a traditional passive structure. Through the use of an active control system, a lightweight structural member can replicate the vibration suppression characteristics of a heavy structural member. To be effective, the design of the structure and the achievable control performance must be considered in an integrated manner. This approach enables the trade-offs among structural weight, geometry, and control performance to be optimized to achieve a specified operational characteristic.

Large flexible space structures (LFSS) have lightly damped vibrational modes that range from very low to high frequencies. The degradation to mission performance caused by structural flexibility must be eliminated. Conflicting requirements of structural stiffness and lightweight must be balanced by the structural engineer.

There are two possible ways of dealing with flexibility in a structure: use stiffer structural members, which increase weight, or augment the inherent damping in the structure. Due to weight restrictions, only the second approach is feasible. Viscoelastic materials can be used to passively augment the damping of the high-frequency modes. Unfortunately, these materials do not provide significant damping for low-frequency modes. As it is the low-frequency modes that most severely impact structural performance, active damping is required.

Active damping techniques make use of sensors and actuators to measure structural deflection and perform corrective action. This minimizes the maximum deflection amplitude and the settling time of the undesired oscillations. These techniques require a knowledge of the dynamic behavior of a structure. Complex structures are modeled mathematically using analytical techniques based on finite element analysis, or experimental model identification based on modal testing. In our research, we use analytical techniques to develop a dynamic model. The model is then validated by empirical modal tests.

One issue that arises, when modeling a dynamic system for control purposes, is the accuracy of the model behavior, compared to that of the actual structure. The dynamics of a LFSS are theoretically characterized by infinite-order eigenfunction expansions. In practice, some form of model reduction is used to develop a finite-order state-space model. The state space model is used for both controller design and simulation. The modeling error of dynamics takes two forms: neglected high-order modes and inaccurately modeled low-order modes. The errors associated with the low-order modes are due to uncertainty in the knowledge of mechanical parameters, and simplifications taken during the modeling process. The analytical modeling approaches assume an a priori damping factor of zero. Empirical tests must be used to determine the correct damping factors. Empirical testing of the LFSS in a terrestrial laboratory is problematic, due to the effects of gravity and the atmosphere, as the structures are intended for use in the zero gravity and vacuum of space. Accordingly, the controller design methodology must be able to cope with the inherent uncertainty in the model of the structural dynamics.

Active Vibration Control of Flexible Structures

The linear–quadratic–Gaussian control method, or LQG control, was developed in the 1960s and is capable of obtaining controllers for multiple input–multiple output systems such as the ones in consideration in this article. LQG controllers give good response when model dynamics are known exactly. However, LQG controllers do not necessarily cope well with model uncertainty (1). Furthermore, the infinite bandwidth of LQG controllers can excite unmodeled higher-order dynamics. This effect is termed the “spillover problem” (2). Allen et al. (3) applied the LQG method directly to the problem of vibration suppression in a truss structure. They employed a frequency-weighted LQG method in which the system dynamics are augmented with bandpass filters for the input and output signals. This compensated for the traditional deficiencies of LQG controllers: the bandpass filters restricted the control bandwidth to frequencies over which the structural

dynamics were well modeled. They demonstrated the limited bandwidth and robustness characteristics of their controller design on an experimental truss structure.

The H_∞ control design method (4–6) has recently been applied to the problem of control of large flexible space structures. This method enables the design of a controller that robustly stabilizes a system in the presence of bounded structured and unstructured uncertainties. Furthermore, the control design can also incorporate performance requirements that must be met in the presence of uncertainties. Current research is focused on the manner in which uncertainties and performance can be specified to obtain a useful controller design.

Buddie et al. (7) used a “weighted gap optimization” approach for the synthesis of the H_∞ controller, employing input and output weighting functions to “shape” the open loop response of the system. Experiments performed on both a flower-shaped structure and a truss structure successfully achieved an increased damping for particular modes while maintaining a specified level of robustness. Their experiments made use of momentum exchange actuators that were operated by linear dc motors. The accelerometer sensors were collocated at the actuator locations, and their signals are integrated to provide velocity.

A good survey on the subject of vibration problems associated with flexible spacecraft is provided by van Woerkom (8). In particular, he discusses the OGO series of satellites and the Hubble space telescope. He gives an overview of the various control techniques that were applied to stabilize these satellites.

Piezoelectric Materials in Smart Structures

The use of piezoelectric materials as sensors and actuators in flexible systems has been a topic of research since the mid-1980s. Hubbard and his collaborators (9,10) proposed the application of piezoelectric polymer (PVDF) as actuator for the active damping of beams with different boundary conditions. The sensors employed were tip-mounted linear and angular accelerometers for the case of cantilever beams and a base-mounted angular accelerometer for the case of the simply supported beam. They used several linear and nonlinear velocity–feedback control techniques to artificially increase the modal damping ratios of the flexible beams. These control laws were applied to rectangular and spatially varying distributed PVDF films, with voltage levels of up to ± 250 V. A significant level of damping increase was attained, particularly when using nonlinear on–off velocity–feedback control.

Crawley and de Luis (11) developed a quasi-static analysis procedure for modeling the interaction between rectangular piezoelectric materials and the structure to which they are attached. They considered the cases of

surface-bonded and embedded actuators, in bending and extension. Their predictions were compared to experiments performed on cantilevered beams of various materials and actuator placement. Lee and Moon (12) analyzed the effect of etching and splicing to shape the electrode of a piezoelectric film. Lee and Moon constructed a modal sensor that was able to observe a single mode of a flexible plate. Miller and his co-workers (13,14) showed that spatial filters could also be realized in terms of etched piezoelectric films. A state feedback control law can be implemented by etching piezoelectric films; this has the potential of simplifying the hardware required for control. Vaz (15–18) used the quasi-static analysis procedure of Crawley and de Luis to develop interaction equations for modeling the behavior of shaped piezoelectric sensors and actuators. The interaction equations were validated through experimental testing; (19–21). The interaction equations were generalized into a finite element framework in (7,22,23).

TRUSS STRUCTURE CONFIGURATION

A truss structure was designed to be a testbed for evaluating potential control techniques for LFSS using piezoelectric actuators and sensors. The design criteria for the selection of the final configuration were the following:

1. Have similarity to structures used in flexible structure literature.
2. Include at least 10 modes under 100 Hz.
3. Not include local bending of truss members in first 5 modes of vibration.
4. Meet cost, weight, and actuation power requirements.

The structure was constructed from polycarbonate tubing with 12.7 mm outer diameter, connected at the nodes by joining blocks. The polycarbonate material was selected because of its advantages over metals such as aluminum and steel in this application. The main selection criteria were cost, machinability, weight, strength, electrical properties, ease of assembly, and bonding of piezoelectric materials to the structure. Table 1 shows the mechanical properties and the dimensions of the polycarbonate tubes used in the structure, including the parameters needed for the finite element simulation. The configuration of the structure is shown in Fig. 1. The truss members represented by the dark lines undergo the most strain during vibration of the truss structure. These truss members are ideally suited to sensor and actuator placement.

The truss structure was vertically cantilevered at the bottom, and it was composed of six vertical bays, each a 300-mm cube. The thick lines represent the active truss

Table 1. Dimensions and Mechanical Properties of Polycarbonate Tubing

Material	Outside Diameter (mm)	Thickness (mm)	Young's Modulus (N/m ²)	Density (kg/m ³)

members, which are fitted with sensors and actuators. Not all the active truss members are to be used in the control design simultaneously. The design was iterated until the desired design criteria were met. The structure was approximately 1800 mm high. Figure 2 gives a detailed view of two bays of the structure, showing more clearly the topology of the truss. At each junction there is a joining block, also made of polycarbonate material.

Figure 2. Detail of two bays.

Figure 3. Experimental truss structure.

The experimental truss structure is shown in Fig. 3. The truss members are bonded to the junction blocks using a liquid plastic solvent containing methylene chloride. The associated electronics are shown in the background. The five gray boxes contain the custom designed high-voltage amplifiers. The amplifiers are powered by an HP 6521A dc power supply. Accelerometers are placed at the top of the structure. The lower portion of the truss structure is shown in closeup in Fig. 4. The active truss members are the lower truss members that have bonded piezoelectric films.

The active truss members are fitted with two identical polyvinylidene fluoride (PVDF) rectangular piezoelectric sensors. One sensor measures the open circuit voltage, which is proportional to the strain. The second measures the short circuit current, which is proportional to the strain rate. In the midspan of the active truss member, there is a piezoceramic actuator, which receives the control signal and transforms it into actuation forces.

FINITE ELEMENT AND MODAL ANALYSIS OF THE TRUSS STRUCTURE

In the finite element method, a continuous structure is discretized into a finite number of elements (24). This converts the dynamics of the continuous structure, with infinite number of degrees of freedom, to a finite-dimensional representation. The discretized structure has dynamics that are characterized by a system of ordinary differential

Figure 4. Active truss members.

equations, whereas the continuous structure dynamics are characterized by a system of partial differential equations.

Assembly of Finite Element Model

The truss members are modeled by an interconnected set of rod elements. A rod element has two nodes with one degree of freedom per node that corresponds to the displacement in the axial direction. Figure 5 shows a diagram of the rod element. The displacement varies linearly along the rod element. The nodes are labeled with a local numbering scheme $\mathcal{L}_{\text{NODE}} = \{1, 2\}$. The axial displacement of at local node i is denoted by ξ_i for $i = 1, 2$.

The mesh used for the finite element model with rod elements is shown in Fig. 6. The nodes are placed at the junctions, and are indicated by star symbols. The cross section of the rod elements is indicated by the ovals at midspan. Using rod elements is equivalent to assuming that the structure is pin-jointed, and thus the strain profile along each element is constant. For this reason, increasing mesh density, by partitioning the truss members with additional rod elements, would not alter the strain profile. Concentrated mass elements are added at each junction to simulate the effect of the extra weight of the junction blocks, and are denoted in by small squares coincident with the nodes. The finite element model has 83 rod elements and 28 nodes. Each node has 3 degrees of freedom; hence the structure has a total of 84 degrees of freedom. The structure is fixed at the base; this restricts 3 degrees of freedom at each of the four base nodes, for a total of 12 constrained degrees of freedom.

Figure 5. Rod element k .

Figure 6. Finite element mesh for the rod element model.

The nodes are labeled with a global numbering scheme $\mathcal{G}_{\text{NODE}} = \{1, 2, \dots, n\}$, where $n = 28$. Each truss member is associated with a unique rod element. The rod elements are labeled with a global numbering scheme $\mathcal{G}_{\text{ELEM}} = \{1, 2, \dots, m\}$, where $m = 83$. The function G_{NODE} maps a global element number and a local node number to global node number; that is, $G_{\text{NODE}}: \mathcal{G}_{\text{ELEM}} \times \mathcal{L}_{\text{NODE}} \rightarrow \mathcal{G}_{\text{NODE}}$.

Each node has three coordinates that define its *undeformed* position with respect to a global coordinate frame. We let p_1^α , p_2^α , and p_3^α respectively denote the x , y , and z position coordinates of node α , $\alpha \in \mathcal{G}_{\text{NODE}}$. The 123 coordinate frame is an alternate representation of the x - y - z coordinate frame: 1 corresponds to x , 2 to y , and 3 to z . We consider a rod element k with nodes α and β , where $k \in \mathcal{G}_{\text{ELEM}}$, and $\alpha, \beta \in \mathcal{G}_{\text{NODE}}$. The projection of the length of rod element k on axis i of the global the coordinate coordinate frame is given by

$$\Delta p_i^k = |p_i^\alpha - p_i^\beta|, \quad i = 1, 2, 3. \quad (1)$$

The length of rod element k , denoted by L^k , is given by

$$L^k = \sqrt{(\Delta p_1^k)^2 + (\Delta p_2^k)^2 + (\Delta p_3^k)^2}. \quad (2)$$

The direction cosines for rod element k are computed as

$$\cos \theta_i^k = \frac{\Delta p_i^k}{L^k}, \quad i = 1, 2, 3. \quad (3)$$

When the truss structure is subjected to forces, the rod elements deform and the nodes move from their rest position. To illustrate this, we let q_1^α , q_2^α , and q_3^α , respectively, denote the x , y , and z coordinates of the displacement of the *deformed* position of node α , $\alpha \in \mathcal{G}_{\text{NODE}}$, from its *undeformed* position. We consider a rod element k with nodes α and β , where $k \in \mathcal{G}_{\text{ELEM}}$, and $\alpha, \beta \in \mathcal{G}_{\text{NODE}}$. The components of the deformation of rod element k , in the global coordinate frame, can be found by subtracting the node displacements as follows:

$$\Delta q_i^k = (q_i^\beta - q_i^\alpha) \operatorname{sgn} (p_i^\beta - p_i^\alpha), \quad i = 1, 2, 3. \quad (4)$$

The component of deformation Δq_i^k corresponds to an elongation if $\Delta q_i^k > 0$, and a compression if $\Delta q_i^k < 0$. The total

deformation $\Delta q_{\text{TOTAL}}^k$ of the rod element k is given by

$$\Delta q_{\text{TOTAL}}^k = \Delta q_1^k \cos \theta_1^k + \Delta q_2^k \cos \theta_2^k + \Delta q_3^k \cos \theta_3^k, \quad (5)$$

where $\cos \theta_i^k$ is the direction cosine of element k and axis i . The strain of element k , denoted by ε^k , is given by

$$\varepsilon^k = \frac{\Delta q_{\text{TOTAL}}^k}{L^k}. \quad (6)$$

Now, let q^α denote the displacement vector at node α , $\alpha \in \mathcal{G}_{\text{NODE}}$. The composite displacement vector q comprises the displacement vectors at each node of the structure. These vectors are defined as

$$q = \begin{bmatrix} q^1 \\ \vdots \\ q^n \end{bmatrix}, \quad q^\alpha = \begin{bmatrix} q_1^\alpha \\ q_2^\alpha \\ q_3^\alpha \end{bmatrix}. \quad (7)$$

Let Δq^k denote the deformation vector of element k , $k \in \mathcal{G}_{\text{ELEM}}$. The composite deformation vector Δq comprises the deformation vectors at each element of the structure. These vectors are defined as

$$\Delta q = \begin{bmatrix} \Delta q^1 \\ \vdots \\ \Delta q^m \end{bmatrix}, \quad \Delta q^k = \begin{bmatrix} \Delta q_1^k \\ \Delta q_2^k \\ \Delta q_3^k \end{bmatrix}. \quad (8)$$

The composite total deformation vector Δq_{TOTAL} comprises the total deformations of each element of the structure. In particular, Δq_{TOTAL} is defined as

$$\Delta q_{\text{TOTAL}} = \begin{bmatrix} \Delta q_{\text{TOTAL}}^1 \\ \vdots \\ \Delta q_{\text{TOTAL}}^m \end{bmatrix}. \quad (9)$$

The composite strain vector ε comprises the strains of each element of the structure. In particular, ε is defined as

$$\varepsilon = \begin{bmatrix} \varepsilon^1 \\ \vdots \\ \varepsilon^m \end{bmatrix}. \quad (10)$$

The $3m \times 3n$ matrix S is constructed so that

$$\Delta q = S q. \quad (11)$$

In particular, the ab element of S , denoted by $(S)_{ab}$, is given by

$$(S)_{ab} = \begin{cases} \text{sgn}(p_i^{\text{GNODE}(k,1)} - p_i^{\text{GNODE}(k,2)}) & \text{if some } i \in \{1, 2, 3\} \text{ and } k \in \mathcal{G}_{\text{ELEM}} \text{ satisfies} \\ & a = 3(k-1) + i \text{ and } b = 3[\text{GNODE}(k,1) - 1] + i, \\ \text{sgn}(p_i^{\text{GNODE}(k,2)} - p_i^{\text{GNODE}(k,1)}) & \text{if some } i \in \{1, 2, 3\} \text{ and } k \in \mathcal{G}_{\text{ELEM}} \text{ satisfies} \\ & a = 3(k-1) + i \text{ and } b = 3[\text{GNODE}(k,2) - 1] + i, \\ 0 & \text{otherwise,} \end{cases}$$

where $1 \leq a \leq 3m$ and $1 \leq b \leq 3n$.

The $m \times 3m$ block diagonal matrix R is constructed so that

$$\Delta q_{\text{TOTAL}} = R \Delta q. \quad (12)$$

In particular, R is given by

$$R = \text{diag} \left[(\cos \theta_1^1, \cos \theta_2^1, \cos \theta_3^1), \dots, (\cos \theta_1^m, \cos \theta_2^m, \cos \theta_3^m) \right]. \quad (13)$$

The $m \times m$ matrix N is constructed so that

$$\varepsilon = N \Delta q_{\text{TOTAL}}. \quad (14)$$

In particular, matrix N is given by

$$N = \text{diag} \left[\frac{1}{L^1}, \frac{1}{L^2}, \dots, \frac{1}{L^m} \right]. \quad (15)$$

Consider further an element k with local displacements ξ_1^k and ξ_2^k as shown on Fig. 5. The local displacements can be determined from the displacement vector q . In particular,

$$\xi_1^k = \cos \theta_1^k q_1^{\text{GNODE}(k,1)} + \cos \theta_2^k q_2^{\text{GNODE}(k,1)} + \cos \theta_3^k q_3^{\text{GNODE}(k,1)}, \quad (16)$$

$$\xi_2^k = \cos \theta_1^k q_1^{\text{GNODE}(k,2)} + \cos \theta_2^k q_2^{\text{GNODE}(k,2)} + \cos \theta_3^k q_3^{\text{GNODE}(k,2)}.$$

In accordance with the above expressions, a $2 \times 3n$ matrix G_e^k is constructed so the following relationship holds.

$$\begin{bmatrix} \xi_1^k \\ \xi_2^k \end{bmatrix} = G_e^k q. \quad (17)$$

In particular, the ab element of G_e^k , denoted by $(G_e^k)_{ab}$, is given by

$$(G_e^k)_{ab} = \begin{cases} \cos \theta_i^k & \text{if some } i \in \{1, 2, 3\} \text{ and } k \in \mathcal{G}_{\text{ELEM}} \text{ satisfies} \\ & a = 1 \text{ and } b = 3[\text{GNODE}(k,1) - 1] + i, \\ & \text{or} \\ & a = 2 \text{ and } b = 3[\text{GNODE}(k,2) - 1] + i, \\ 0 & \text{otherwise,} \end{cases}$$

The following mass and stiffness matrices are obtained from finite element modeling (24): the rod element k has a consistent mass matrix M_e^k , and a consistent stiffness

matrix K_e^k given by

$$M_e^k = \frac{\rho^k A_{CS}^k L^k}{6} \begin{bmatrix} 2 & 1 \\ 1 & 2 \end{bmatrix} \quad \text{and} \quad K_e^k = \frac{E^k A_{CS}^k}{L^k} \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix}. \quad (18)$$

Element k has the parameters density ρ^k , cross-sectional area A_{CS}^k , Young's modulus of elasticity E^k , and length L^k . The mass matrix of the complete structure, M , is given by

$$M = \sum_{k=1}^m (G_e^k)^T M_e^k G_e^k. \quad (19)$$

The matrix M is positive definite. To incorporate the effect of the junction block masses, concentrated mass elements are added at the nodes. The stiffness matrix of the complete structure, K , is given by

$$K = \sum_{k=1}^m (G_e^k)^T K_e^k G_e^k. \quad (20)$$

The matrix K is positive semidefinite.

The result of a finite element discretization of a structure is a system of ordinary differential equations, which are called the *free system model*:

$$M\ddot{q} + Kq = f, \quad (21)$$

where q is the displacement vector and f is a vector of actuation forces applied to the structure. The vector f is defined in a later section where the operation of piezoelectric film actuators is explained. Equation (21) does not incorporate the boundary conditions associated with the structure. Accordingly, Eq. (21) has $n = 84$ degrees of freedom.

In the structure shown in Fig. 1, the bottom four nodes are clamped to the support base. Hence the displacements at nodes 1, 2, 3, and 4 are zero; that is, $q_i^\alpha = 0$ for $i = 1, 2, 3$ and $\alpha = 1, 2, 3, 4$. Hence there are 12 restricted degrees of freedom. There are $\bar{n} = 72$ constrained degrees of freedom. The constrained displacement vector \bar{q} only includes the components q_i^α , $i = 1, 2, 3$, and $\alpha \in \mathcal{G}_{\text{NODE}}$, that are not forced to be zero. The $\bar{n} \times n$ matrix P maps q to \bar{q} by $\bar{q} = Pq$. For our truss structure, the corresponding P matrix is given by

$$P = [0_{\bar{n} \times 12}, I_{\bar{n} \times \bar{n}}]. \quad (22)$$

Note that the following relationship also holds: $q = P^T \bar{q}$. The constrained mass matrix \bar{M} and the constrained stiffness matrix \bar{K} are given by

$$\bar{M} = PMP^T \quad \text{and} \quad \bar{K} = PKP^T. \quad (23)$$

The matrices \bar{M} and \bar{K} can be from obtained from M and K , respectively, by deleting the rows and columns associated with the clamped nodes. The *constrained system model* is

$$\bar{M}\ddot{\bar{q}} + \bar{K}\bar{q} = \bar{f}, \quad (24)$$

where $\bar{f} = Pf$.

Modal Analysis

The constrained system model, Eq. (24), is used to model the dynamics of the structure. The vibrational mode shapes and their frequencies are obtained from an eigenvalue analysis of Eq. (24). Since \bar{M} is positive definite, the following eigenvalue problem has \bar{n} solutions:

$$\omega_j^2 \bar{M} \hat{v}_j + \bar{K} \hat{v}_j = 0 \quad \text{for } j = \{1, 2, \dots, \bar{n}\}. \quad (25)$$

Order the eigenvalues ω_j^2 and eigenvectors \hat{v}_j so that $\omega_j^2 \leq \omega_{j+1}^2$. Construct the modal matrix Φ so that $\Phi = [\hat{v}_1, \dots, \hat{v}_{\bar{n}}]$. Construct the modal frequency matrix Ω so that $\Omega = \text{diag}[\omega_1^2, \dots, \omega_{\bar{n}}^2]$. The vectors v_j , $j = \{1, 2, \dots, \bar{n}\}$, are normalized according to the following relationships:

$$\begin{aligned} \Phi^T \bar{M} \Phi &= I, \\ \Phi^T \bar{K} \Phi &= \Omega. \end{aligned} \quad (26)$$

The modal matrix Φ defines a coordinate transformation from the modal coordinate vector η to the physical coordinate vector \bar{q} , that is,

$$\bar{q} = \Phi \eta. \quad (27)$$

Substituting this in the system model and premultiplying by Φ^{-1} , the system model yields the *modal model* of the system:

$$\Phi^T \bar{M} \Phi \ddot{\eta} + \Phi^T \bar{K} \Phi \eta = \Phi^T \bar{f},$$

which is equivalent to

$$\ddot{\eta} + \Omega \eta = \Phi^T \bar{f}. \quad (28)$$

To account for structural damping, a diagonal modal damping matrix H can be added.

$$\ddot{\eta} + H\dot{\eta} + \Omega \eta = \Phi^T \bar{f}. \quad (29)$$

The matrix H has the following form

$$H = \text{diag}[2\zeta_1\omega_1, 2\zeta_2\omega_2, \dots, 2\zeta_{\bar{n}}\omega_{\bar{n}}], \quad (30)$$

where ζ_j is the damping factor for mode j , $0 \leq \zeta_j \leq 1$, $j = \{1, 2, \dots, \bar{n}\}$. The form of the model in equation (30) has the advantage that it is uncoupled, since the matrices Ω and H are both diagonal. The damping factors ζ_j , $j = \{1, 2, \dots, \bar{n}\}$, can be determined from either material properties or experimentation.

The finite element modeling program I-DEAS (25) is used to analyze the truss structure. The program allows a structure to be defined in a graphical manner. The program constructs a representation of Eq. (24) once the material properties and boundary conditions are defined. The modes of the structure are obtained by solving Eq. (25) to obtain the mode shapes \hat{v}_j and frequencies ω_j for $j = \{1, 2, \dots, \bar{n}\}$. The graphical representations of the first four mode shapes are given in Fig. 7.

Figure 7. Mode shapes and frequencies of the structure.

ACTUATOR AND SENSOR CONSTRUCTION

Table 2 shows some of the relevant mechanical and piezoelectric properties of the piezoelectric materials used in this research. For sensor construction, polyvinylidene fluoride (PVDF) piezoelectric film was selected. This material was chosen because it produces relatively large voltages for a given strain (high g_{31} coefficient). For actuator construction, the piezoceramic material lead zirconate titanate (PZT) was selected. Piezoceramics produce a relatively high strain for a given electric field (high d_{31} coefficient).

The sensors and actuators piezoelectric films are attached to the tubular truss member as illustrated on Fig. 8. The actuators are cylindrical shells of ceramic PZT material, split longitudinally to facilitate the installation in the active truss members. The sensors are rectangular pieces of PVDF. The sensors are installed in pairs: one PVDF film measures strain, whereas the other measure strain rate. The dimensions of the sensors and actuators are given in Table 3. The length is measured along the axis of the truss member; the width refers to the dimension along the

circumference of the member, and the thickness is measured across the radius, as shown on Fig. 8. A sensor film has length L_s^k , width W_s^k , and thickness t_s^k , whereas an actuator has length L_a^k , width W_a^k , and thickness t_a^k .

For later convenience, we introduce the following notation: Let $S_{\text{SEN}} = \{1, 2, \dots, r\}$ be the index set for the piezoelectric film sensor pairs on a truss member. The function SEN maps a sensor number to a global element number; that is, SEN: $S_{\text{SEN}} \rightarrow \mathcal{G}_{\text{ELEM}}$. Let $S_{\text{ACT}} = \{1, 2, \dots, \bar{r}\}$ be the index set for the piezoelectric film actuators on a truss member. The function ACT maps an actuator number to a global element number; that is, ACT: $S_{\text{ACT}} \rightarrow \mathcal{G}_{\text{ELEM}}$.

FORMULATION OF THE STATE SPACE DYNAMIC MODEL

In this section the dynamic interaction equations for the piezoelectric sensors and actuators with the finite element model are derived. The interaction equations are used to formulate the state space model of the dynamic equations. The state space model is the canonical form for designing control systems and simulation.

Table 2. Properties of Piezoelectric Materials

Material	Application	d_{31} (C/N)	g_{31} (V m/N)	Young's Modulus E (N/m ²)	Permittivity ϵ (F/m)
PVDF	Sensor	23×10^{-12}	216×10^{-3}	2×10^9	106×10^{-12}
BM527 (PZT)	Actuator	215×10^{-12}	7×10^{-3}	6.9×10^{10}	3.54×10^{-8}

Observation Matrix for the Piezoelectric Sensor

The open circuit voltage $v_{oc}(t)$ of a piezoelectric film sensor is proportional to the strain of the film. The short circuit current $i_{sc}(t)$ of a piezoelectric film sensor is proportional to the strain rate of the film. Let $v_{oc}^k(t)$ and $i_{sc}^k(t)$ denote the open circuit voltage and short circuit current associated with the piezoelectric film attached to the truss member k , $k \in \mathcal{G}_{ELEM}$. Lee and Moon (12) developed equations relating the deformation of a piezoelectric film and the resulting open circuit voltages and short circuit currents. Adapting these equations yields the following equations for the open circuit voltage $v_{oc}^k(t)$ and short circuit current $i_{sc}^k(t)$:

$$v_{oc}^k(t) = -\frac{d_{31s}^k E_s^k W_s^k}{C_s^k} \int_0^{L_s^k} \epsilon_s^k(x, t) dx, \quad (31)$$

$$i_{sc}^k(t) = -d_{31s}^k E_s^k W_s^k \int_0^{L_s^k} \frac{\partial \epsilon_s^k(x, t)}{\partial t} dx, \quad (32)$$

where d_{31s}^k is the transverse piezoelectric charge to stress ratio, E_s^k is the Young's modulus of the film, W_s^k is the width of the piezoelectric film, C_s^k is the capacitance of the film, and $\epsilon_s^k(x, t)$ is the strain profile of the piezoelectric film. Note that the subscript s denotes parameters of the sensor film, while superscript k denotes the rod element associated with the truss member to which the sensor is attached.

Modeling the truss member with rod elements yields a strain profile that is constant along the tubular truss member. Hence the strain for element k can be represented as $\epsilon^k(t)$, and determined from Eq. (6). Due to the negligible thickness of the PVDF sensor films, and the hardness of

Figure 8. Piezoelectric film attached to tubular truss member.

the epoxy, we assume $\epsilon_s^k(x, t) = \epsilon^k(t)$. Accordingly, the expressions for the open circuit voltage and closed circuit current simplify as

$$v_{oc}^k(t) = \gamma_{V_{oc}}^k \epsilon_s^k(t), \quad \gamma_{V_{oc}}^k = -\frac{d_{31s}^k E_s^k W_s^k L_s^k}{C_s^k}, \quad (33)$$

$$i_{sc}^k(t) = \gamma_{I_{sc}}^k \dot{\epsilon}_s^k(t), \quad \gamma_{I_{sc}}^k = -d_{31s}^k E_s^k W_s^k L_s^k. \quad (34)$$

>From the preceding equations, it is easy to see that measurements of open circuit voltage and short circuit current can be employed to obtain the strain and strain rate in a truss member. By using Eqs. (6), (10), and (11), the above-mentioned voltage and currents can be related to the displacement of vector q in Eq. (7).

Let the composite vector of open circuit voltages $V_{oc}(t)$, and the composite vector of short circuit currents $I_{sc}(t)$ be given by

$$V_{oc}(t) = \begin{bmatrix} v_{oc}^{SEN(1)} \\ \vdots \\ v_{oc}^{SEN(r)} \end{bmatrix} \quad \text{and} \quad I_{sc}(t) = \begin{bmatrix} i_{sc}^{SEN(1)} \\ \vdots \\ i_{sc}^{SEN(r)} \end{bmatrix}. \quad (35)$$

Matrices $M_{V_{oc}}$ and $M_{I_{sc}}$ of size $r \times m$ can be constructed so that

$$V_{oc} = M_{V_{oc}} \epsilon \quad \text{and} \quad I_{sc} = M_{I_{sc}} \dot{\epsilon}. \quad (36)$$

In particular, the ab elements of matrices $M_{V_{oc}}$ and $M_{I_{sc}}$ are given by

$$(M_{V_{oc}})_{ab} = \begin{cases} \gamma_{V_{oc}}^{SEN(a)} & \text{if } b = SEN(a), \\ 0 & \text{otherwise,} \end{cases} \quad (37)$$

$$(M_{I_{sc}})_{ab} = \begin{cases} \gamma_{I_{sc}}^{SEN(a)} & \text{if } b = SEN(a), \\ 0 & \text{otherwise,} \end{cases} \quad (38)$$

where $1 \leq a \leq r$ and $1 \leq b \leq m$.

Control Matrix for the Piezoelectric Actuator

In the following derivation, perfect bonding between a piezoelectric film and the truss member is assumed. This is a valid assumption due to the hardness of the epoxy used to bond the piezoelectric films. The manner in which the

Table 3. Dimensions of Sensors and Actuators

Application	Material	Length (mm)	Width (mm)	Thickness (mm)
Sensor	PVDF	42	17.0	28×10^{-3}
Actuator	BM527 (PZT)	25.4	39.9	1.0

strain in a substructure varies when it is bonded to a piezoelectric film is given by a coupled set of partial differential equations analyzed in (11,16). For the case of perfect bonding, with a substructure undergoing axial deformation, the following simplification is possible. The piezoelectric strain $\varepsilon_a(\bar{\xi})$ at the *normalized coordinate* $\bar{\xi}$, where $\bar{\xi} = -1$ denotes one end of the piezoelectric film, and $\bar{\xi} = +1$ denotes the other end, is given by the formula

$$\varepsilon_a(\bar{\xi}) = \frac{\Psi}{\Psi + 2} \left[\frac{\varepsilon_{\text{SUB}}^+ + \varepsilon_{\text{SUB}}^-}{2} - \left(\frac{\varepsilon_{\text{SUB}}^+ - \varepsilon_{\text{SUB}}^-}{2} \right) \bar{\xi} + \frac{2}{\Psi} \Lambda \right] \quad (39)$$

The strain of the substructure at $\bar{\xi} = -1$ and $\bar{\xi} = +1$ are denoted by $\varepsilon_{\text{SUB}}^-$ and $\varepsilon_{\text{SUB}}^+$, respectively. The stiffness ratio between the piezoelectric film and the substructure is denoted by Ψ . The effective strain of due to the piezoelectric effect is denoted by Λ . Although the strain of the piezoelectric film is the same as the strain of the substructure underneath the film, the strain of the substructure is different in locations not covered by the film.

We will now adapt Eq. (39) to the case where the substructure is a truss member modeled by a rod element. In such a case, the substructure strains at either end of the piezoelectric film are identical; this corresponds to $\varepsilon_{\text{SUB}}^- = \varepsilon_{\text{SUB}}^+$. Hence the strain over the piezoelectric film is uniform. The strain of a piezoelectric film bonded to the truss member associated with rod element k is denoted by ε_a^k , and given by

$$\varepsilon_a^k = \left(\frac{\Psi^k}{\Psi^k + 2} \right) \varepsilon^k + \left(\frac{2}{\Psi^k + 2} \right) \Lambda_a^k, \quad (40)$$

where ε^k is the strain of the truss member k on the portion *not* underneath the piezoelectric film, and Λ_a^k is the effective strain due to the piezoelectric effect. The effective strain Λ_a^k is given by

$$\Lambda_a^k = \left(\frac{d_{31a}^k}{t_a^k} \right) v_a^k, \quad (41)$$

where v_a^k is the voltage applied to the piezoelectric film associated with element k . The stiffness ratio for element k is given by

$$\Psi^k = \frac{E^k t^k}{E_a^k t_a^k}, \quad (42)$$

where E^k and E_a^k are, respectively, Young's modulus of elasticity for the truss member k and the piezoelectric film actuator attached to it; t^k and t_a^k are, respectively, the thickness of truss member k and the piezoelectric film actuator attached to it.

When there is perfect bonding between a piezoelectric film and its substructure, the force exerted by the piezoelectric on the structure is concentrated at the ends of the piezoelectric film (11,16). Let g_e^k denote the force exerted by the ends of piezoelectric film on the truss member associated with element k . Summing the stress at the end of

the piezoelectric yields

$$g_e^k = E_a^k A_{aCS}^k (\varepsilon_a^k - \Lambda_a^k), \quad (43)$$

where A_{aCS}^k is the cross-sectional area of the piezoelectric actuator film bonded to truss member k . The transmitted forced can be rearranged as

$$g_e^k = g_{e\text{STIFF}}^k + g_{e\text{ACTIVE}}^k, \quad (44)$$

where

$$g_{e\text{STIFF}}^k = \mu_{\text{STIFF}}^k \varepsilon^k, \quad (45)$$

$$g_{e\text{ACTIVE}}^k = \mu_{\text{ACTIVE}}^k v_a^k, \quad (46)$$

and

$$\mu_{\text{STIFF}}^k = E_a^k A_{aCS}^k \left(\frac{\Psi^k}{\Psi^k + 2} \right), \quad (47)$$

$$\mu_{\text{ACTIVE}}^k = -E_a^k A_{aCS}^k \left(\frac{\Psi^k}{\Psi^k + 2} \right) \left(\frac{d_{31a}^k}{t_a^k} \right). \quad (48)$$

The force g_e^k has two components. The component $g_{e\text{STIFF}}^k$ is the passive force due to the intrinsic elasticity of the piezoelectric film, which augments the stiffness of the truss member. The component $g_{e\text{ACTIVE}}^k$ is the active force contributed by the piezoelectric effect that varies with the applied voltage v_a^k .

Equations (45) and (46) only define the forces $g_{e\text{STIFF}}^k$ and $g_{e\text{ACTIVE}}^k$ for truss members k that have a piezoelectric film actuator; that is, $k = \text{ACT}(j)$ for some $j \in \mathcal{S}_{\text{ACT}}$. We extend the definition to all truss members in the following manner. For all $k \in \mathcal{G}_{\text{ELEM}}$,

$$g_{e\text{STIFF}}^k = \begin{cases} \mu_{\text{STIFF}}^k \varepsilon^k, & \text{if } k = \text{ACT}(j) \text{ for some } j \in \mathcal{S}_{\text{ACT}}, \\ 0 & \text{otherwise;} \end{cases}$$

and

$$g_{e\text{ACTIVE}}^k = \begin{cases} \mu_{\text{ACTIVE}}^k v_a^k, & \text{if } k = \text{ACT}(j) \text{ for some } j \in \mathcal{S}_{\text{ACT}}, \\ 0 & \text{otherwise.} \end{cases}$$

Let the composite vector of passive element forces $g_{e\text{STIFF}}^k$, and the active element forces $g_{e\text{ACTIVE}}^k$ be given by

$$g_{e\text{STIFF}} = \begin{bmatrix} g_{e\text{STIFF}}^1 \\ \vdots \\ g_{e\text{STIFF}}^m \end{bmatrix} \quad \text{and} \quad g_{e\text{ACTIVE}} = \begin{bmatrix} g_{e\text{ACTIVE}}^1 \\ \vdots \\ g_{e\text{ACTIVE}}^m \end{bmatrix}. \quad (49)$$

Let the composite vector of applied voltages V_a be given by

$$V_a = \begin{bmatrix} v_a^{\text{ACT}(1)} \\ \vdots \\ v_a^{\text{ACT}(\bar{r})} \end{bmatrix}. \quad (50)$$

The $m \times m$ matrix Y_{STIFF} is constructed so that

$$g_{e\text{STIFF}} = Y_{\text{STIFF}} \varepsilon, \quad (51)$$

where strain vector ε is given by Eq. (10). In particular, the ab element of matrix Y_{STIFF} is given by

$$(Y_{\text{STIFF}})_{ab} = \begin{cases} \mu_{\text{STIFF}}^{\text{ACT}(a)} & \text{if } a = b \text{ and } a = \text{ACT}(j) \text{ for some} \\ & j \in \mathcal{S}_{\text{ACT}}, \\ 0 & \text{otherwise,} \end{cases}$$

for $1 \leq a \leq m$ and $1 \leq b \leq m$.

The $m \times \bar{r}$ matrix Y_{ACTIVE} is constructed so that

$$g_{e\text{ACTIVE}} = Y_{\text{ACTIVE}} V_a. \quad (52)$$

In particular, the ab element of matrix Y_{ACTIVE} is given by

$$(Y_{\text{ACTIVE}})_{ab} = \begin{cases} \mu_{\text{ACTIVE}}^{\text{ACT}(b)} & \text{if } a = \text{ACT}(b) \text{ and } b \in \mathcal{S}_{\text{ACT}}, \\ 0 & \text{otherwise,} \end{cases}$$

for $1 \leq a \leq m$ and $1 \leq b \leq \bar{r}$.

In the context of finite element model, Eq. (21), the applied force f has two components:

$$f = f_{\text{STIFF}} + f_{\text{ACTIVE}}, \quad (53)$$

where

$$f_{\text{STIFF}} = S^T R^T Y_{\text{STIFF}} N R S q \quad (54)$$

and

$$f_{\text{ACTIVE}} = S^T R^T Y_{\text{ACTIVE}} V_a. \quad (55)$$

Matrices S , R , and N are defined in Eqs. (11), (13), and (15), respectively.

State Space Model Construction

In this section, we construct a state space model for the modal model of Eq. (29). The canonical form of a state space is shown below.

$$\begin{aligned} \dot{x} &= Ax + Bu, \\ y &= Cx + Du. \end{aligned} \quad (56)$$

The state x of the modal model is the composite vector of mode amplitudes η and mode amplitude rates $\dot{\eta}$. The input vector u is the vector of voltages applied to piezoelectric actuators V_a . The output vector y is the composite vector of open circuit voltages and short circuit currents for the piezoelectric film sensors. In particular, x , u , and y are given by

$$x = \begin{bmatrix} \eta \\ \dot{\eta} \end{bmatrix}, \quad u = V_a, \quad \text{and} \quad y = \begin{bmatrix} V_{oc} \\ I_{sc} \end{bmatrix}.$$

The dimension of the modal amplitude vector η is the number of modes in the model. Although the constrained system model in Eq. (29) has $\bar{n}=72$ modes, we can construct a model with a reduced set of modes. This is typically done to simplify the computational complexity of control design. For a \bar{n} mode model, $1 \leq \bar{n} \leq \bar{n}$, state space matrices are A , B , C , and D are given by

$$A = \begin{bmatrix} 0 & I_{\bar{n} \times \bar{n}} \\ -\Omega_{\bar{n}} & -H_{\bar{n}} \end{bmatrix} + \Phi_{\bar{n}}^T S^T R^T Y_{\text{STIFF}} N R S P^T \Phi_{\bar{n}}, \quad (57)$$

$$B = \Phi_{\bar{n}}^T S^T R^T Y_{\text{ACTIVE}}, \quad (58)$$

$$C = \begin{bmatrix} M_{voc} N R S P^T \Phi_{\bar{n}} & 0 \\ 0 & M_{isc} N R S P^T \Phi_{\bar{n}} \end{bmatrix}, \quad (59)$$

$$D = 0_{2r \times \bar{r}}, \quad (60)$$

where

$$\Phi_{\bar{n}} = [\hat{v}_1, \hat{v}_2, \dots, \hat{v}_{\bar{n}}], \quad (61)$$

$$\Omega_{\bar{n}} = \text{diag} [\omega_1^2, \omega_2^2, \dots, \omega_{\bar{n}}^2], \quad (62)$$

$$H_{\bar{n}} = \text{diag} [2\zeta_1 \omega_1, 2\zeta_2 \omega_2, \dots, 2\zeta_{\bar{n}} \omega_{\bar{n}}]. \quad (63)$$

The modal matrix $\Phi_{\bar{n}}$ contains the first \bar{n} eigenvectors of Eq. (25).

Two state space models are used for modeling the dynamics of the truss structure. A low-order *design model* is used for controller design, and a high-order *evaluation model* is used to simulate the controller performance. The design model retains the first five modes ($\bar{n} = 5$) and assumes no damping ($\zeta_j = 0, j = 1, 2, \dots, 5$). This is consistent with the fact that the true damping of structure is not known until it is tested. The evaluation model retains the first 30 modes ($\bar{n} = 30$) and uses the estimated modal damping factors ($\zeta_j = 0.004, j = 1, 2, \dots, 30$) obtained from empirical tests on the structure.

CONTROL DESIGN AND SIMULATIONS

LFT Framework for H_∞ Feedback Control Design

A robust H_∞ feedback controller has been designed for the truss structure. To obtain the controller using this technique, the dynamic model of the system has to be written in lower linear fractional transformation (LFT) form. This formulation framework is convenient because it allows for the inclusion of the effects of the sensor and control disturbances, as well as loop-shaping weights on the inputs and outputs. Figure 9 shows the block representation of the lower LFT form of the control problem. The signal z is the *exogenous output*, y is the *controlled output*, w is the *exogenous input*, and u is the *control input*. The relationship

Figure 9. Lower LFT representation of control problem.

between these signals can be represented in the following manner:

$$\begin{aligned} \dot{x} &= Ax + B_1 w + B_2 u, \\ z &= C_1 x + D_{11} w + D_{12} u, \\ y &= C_2 x + D_{21} w + D_{22} u. \end{aligned} \quad (64)$$

In the *LFT* framework, it is desired to minimize the H_∞ norm from w to z . The nature of these signals and their relationship to controller design is explained later.

Consider the state space model of the truss dynamics in Eq. (56). The model has the matrix transfer function $\hat{P}(s)$ that is given by

$$\hat{P}(s) = C(sI - A)^{-1}B + D \quad (65)$$

Figure 10 shows the conventional block diagram of the closed loop control system, including the sensor noise n and disturbances d to the control. In order to put the problem in the *LFT* framework, we aggregate the unwanted inputs n and d into an exogenous input signal w . We also aggregate the signals that we wish to penalize, the state x and the control input u , into an exogenous output signal z . The resulting exogenous input and output vectors are

$$w = \begin{bmatrix} d \\ n \end{bmatrix}, \quad z = \begin{bmatrix} x \\ u \end{bmatrix}. \quad (66)$$

Different frequency ranges in the input signals and outputs can be penalized through the use of loop-shaping filters. This is illustrated in Fig. 11 for a system in lower *LFT* form with an input filter \hat{W}_1 and an output filter \hat{W}_2 .

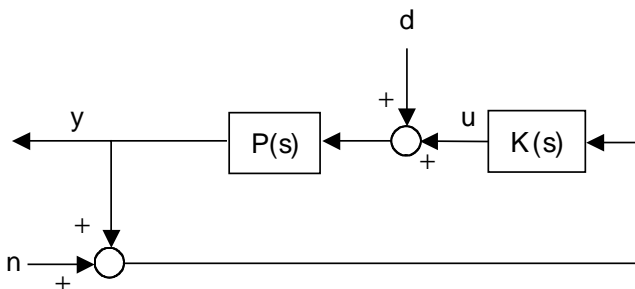

Figure 10. Block diagram of the closed loop system.

Figure 11. Shaping of the open loop.

The system model can be uncertain over different frequency ranges. For example, uncertainty in the high-frequency region can result from modal truncation. Uncertainty in the low frequency can result from low-frequency disturbances being applied to the system due to ground movements. The uncertainty can be handled by specifying appropriate filters in \hat{W}_1 , such as a bandpass filter, to introduce robustness to the perturbations in the model dynamics. The output filter \hat{W}_2 can be used to introduce performance requirements by placing weights on different elements of the control signal and state space. These specification techniques are explained by Zhou et al. (6)

The dynamic controller that minimizes the H_∞ norm of the closed loop is given by (26)

$$\hat{K} = C_k(sI - A_k)^{-1}B_k + D_k \quad (67)$$

The state space matrices that form the controller are found from the solution of the following matrix inequality

$$H_{X_L} + Q^* J^* P_{X_L} + P_{X_L} J Q < 0, \quad (68)$$

where the unknowns are X_L and J . The matrices in equation (65) are defined as follows.

$$J = \begin{bmatrix} A_k & B_k \\ C_k & D_k \end{bmatrix}, \quad H_{X_L} = \begin{bmatrix} \bar{A}^* X_L + X_L \bar{A} & X_L \bar{B} & \bar{C}^* \\ \bar{B}^* X_L & -I & D_{11}^* \\ \bar{C} & D_{11} & -I \end{bmatrix},$$

$$\bar{A} = \begin{bmatrix} A & 0 \\ 0 & 0_{n_k \times n_k} \end{bmatrix}, \quad \bar{B} = \begin{bmatrix} B_1 \\ 0 \end{bmatrix}, \quad \underline{B} = \begin{bmatrix} 0 & B_2 \\ I & 0 \end{bmatrix},$$

$$\underline{C} = \begin{bmatrix} 0 & I \\ C_2 & 0 \end{bmatrix}, \quad \bar{C} = [C_1 \quad 0],$$

$$\underline{D}_{21} = \begin{bmatrix} 0 \\ D_{21} \end{bmatrix}, \quad \underline{D}_{12} = [0 \quad D_{12}],$$

$$P_{X_L} = \begin{bmatrix} \bar{B}^* X_L & 0 \\ \underline{D}_{12}^* \end{bmatrix}, \quad Q = \begin{bmatrix} \underline{C} & \underline{D}_{21} & 0 \end{bmatrix}.$$

Gahinet (26) shows that if a controller with the structure in Eq. (67) exists, then X_L is given by

$$X_L = \begin{bmatrix} X & X_2 \\ X_2^* & I \end{bmatrix}, \quad X - Y^{-1} = X_2 X_2^*, \quad (69)$$

where X and Y are the solutions to the following linear matrix inequalities.

$$\begin{bmatrix} N_y & 0 \\ 0 & I \end{bmatrix}^* \begin{bmatrix} A^*X + XA & XB_1 & C_1 \\ B_1^*X & -I & D_{11}^* \\ C_1 & D_{11} & -I \end{bmatrix} \begin{bmatrix} N_y & 0 \\ 0 & I \end{bmatrix} < 0, \quad (70)$$

$$\begin{bmatrix} N_x & 0 \\ 0 & I \end{bmatrix}^* \begin{bmatrix} AY + YA^* & B_1 & YC_1^* \\ B_1^* & -I & D_{11}^* \\ C_1Y & D_{11} & -I \end{bmatrix} \begin{bmatrix} N_x & 0 \\ 0 & I \end{bmatrix} < 0, \quad (71)$$

The matrices N_x and N_y are full rank and satisfy the following.

$$\text{Im}(N_y) = \text{Ker}[B_2^* \quad D_{12}^*],$$

$$\text{Im}(N_x) = \text{Ker}[C_2 \quad D_{21}].$$

Once X_L has been found, the matrix inequality given in Eq. (68) becomes linear. Accordingly, Eq. (65) can be solved using LMI solution techniques to obtain the matrix J . The controller matrices (A_k, B_k, C_k, D_k) are obtained as partitions of J . The numerical solutions to the above LMI problems can be obtained using the LMI Lab toolbox (27) in MATLAB (28).

Controller Design for Vibration Suppression of Truss

In the simulations, an impact test was performed. Figure 12 shows the location of the impact. Sensor-actuator pairs were placed on the four truss members indicated by thick lines. This selection is made due to the high axial strains that these truss members undergo compared to other members in the first five vibrational modes. All the considered modes are controllable and observable with this sensor and actuator configuration.

The controller for the truss is designed using a five mode reduced order model of the dynamics. The truss members with both sensors and actuators are shown in Fig. 12. The state space matrices $A, B, C,$ and D are, respectively, given by Eqs. (57) to (60) with $\tilde{n} = 5$. The corresponding LFT representation is obtained as follows:

$$\begin{aligned} B_1 &= [0.1B \quad 0_{10 \times 4}], \quad B_2 = B, \\ C_1 &= \begin{bmatrix} Q \\ 0_{4 \times 10} \end{bmatrix}, \quad C_2 = C, \\ D_{11} &= 0_{14 \times 8}, \quad D_{12} = \begin{bmatrix} 0_{10 \times 4} \\ R \end{bmatrix}, \\ D_{21} &= 0.01 \times [0_{4 \times 4} \quad I_{4 \times 4}], \quad D_{22} = D. \end{aligned}$$

The Q and R are weights on the state and control are given by

$$Q = \text{diag}[20 \quad 20 \quad 30 \quad 40 \quad 50 \quad 0 \quad 0 \quad 0 \quad 0 \quad 0] \quad \text{and} \\ R = 1 \times 10^4 I_{4 \times 4}.$$

This choice corresponds to a 10% actuation disturbance and 1% sensor noise. The control input is heavily weighted to avoid saturation of the control input. The modal amplitudes are penalized, whereas modal amplitude rates are

Figure 12. Impact test: Location of disturbance and active truss members.

not. This LFT formulation provides reasonable trade-off between performance and robustness to sensor noise and amplifier nonlinearities. Figure 13 shows a maximum singular value plot. The decreased peaks of the closed loop indicate the increased damping of the first five modes of the closed loop system relative to the open loop system. It also shows that outside this range, the frequency response

Figure 13. Maximum singular value plot for H_∞ control.

Figure 14. Displacement of node 24 during H_∞ control (simulation).

of the system is almost unchanged. This shows that the controller does not destabilize high frequency unmodeled modes.

The high-order evaluation model is used for the dynamics of the truss structure. The model includes the first 30 modes of vibration. The simulated actuation voltage was limited to a range of ± 265 volts to match the voltage swing available from the high voltage amplifiers. Simulink (29) was used to simulate the closed loop response of the truss with a dynamic controller. The displacement and control signal response are shown on Figs. 14 and 15.

EXPERIMENTAL RESULTS

The architecture of the truss structure testbed is shown on Fig. 16. The feedback controller is performed by a high-performance DSP card in a Pentium-based computer. The control logic is specified using the Simulink (29) graphical interface, which runs in the Matlab (28) environment. The control logic is compiled into a real-time executable by and Wincom (30) software, which also runs in the Matlab environment. The executable code is downloaded by the computer to a Quanser MultiQ-3 I/O card. The MultiQ card has a DSP and supports 8 input ADC and 8 output DAC channels with a 12 bit resolution at a sampling frequency of 15 kHz. Piezoelectric film actuators and sensors are bonded to the truss structure as shown in Fig. 4. Each piezoceramic actuator is driven by a custom-designed high-voltage amplifier, with a maximum voltage output of 560 V. A HP 6521A dc high-voltage power supply is used

to power the high-voltage amplifiers. For calibration purposes, strain gauges are fitted to some of the truss members. Two accelerometers are installed at the top corner of the structure to measure accelerations in the X and Y directions as shown in Fig. 12. The accelerations are integrated to obtain displacement measurements.

Two types of experiments are performed: impact tests and shaker tests. The impact test uses an impact hammer to strike the truss structure, and thereby impart an initial deflection. The shaker test uses one of the active truss member actuators as a disturbance source. A disturbance signal is applied to the piezoelectric actuator to cause resonant vibrations in the truss structure. The open loop and closed loop responses of the structure are compared for both tests.

Impact Test

The impact test is performed by using an impact hammer to strike the location shown on Fig. 12. The impact hammer is equipped with an internal accelerometer. By integrating the accelerometer signal, the initial deflection resulting from the impact can be determined. Since the dominant time constant of the truss dynamics is much lower than the impact duration, the impact behaves like it imparts an initial deflection to the truss structure. The open loop and closed loop responses of the structure can then be compared.

The open loop tests are carried out to have a reference against which to compare the performance of the closed loop controlled system. The results were also used to calibrate the modal damping ratios in the test model used

Figure 15. Control signals during H_∞ control (simulation).

in the simulations. Figure 17 shows the displacement response of the system to the impact, obtained from double integration of the accelerometer signals. The small inherent structural damping of the system is visible. The structure oscillates without control for 8 seconds. Figure 18 shows the frequency response of the open loop system. The dominant resonant peak corresponds to the second mode of vibration, at 13.3 Hz.

The H_∞ controller design explained earlier was implemented on the testbed. The displacement and control signal are shown in Figs. 19 and 20, respectively. The settling time of the vibrations is dramatically shorter for the closed loop case. The oscillations damp out in less than 2.5 seconds. The improvement in performance is easier to notice

in the frequency response plot, shown in Fig. 21. The maximum resonant peak, at 13.3 Hz, is reduced by 25 dB when compared to the open loop case.

Shaker Test

In the shaker experiment, a continuous sinusoidal disturbance signal is applied to a piezoceramic actuator on the structure. The active truss member, whose actuator is used as a disturbance source, is shown on Fig. 22. The sinusoidal disturbance signal is adjusted to the dominant resonant frequency of 13.3 Hz with the maximum amplitude of 560 V. The acceleration measurements were taken at node 24 in both the X and Y directions. Double integration

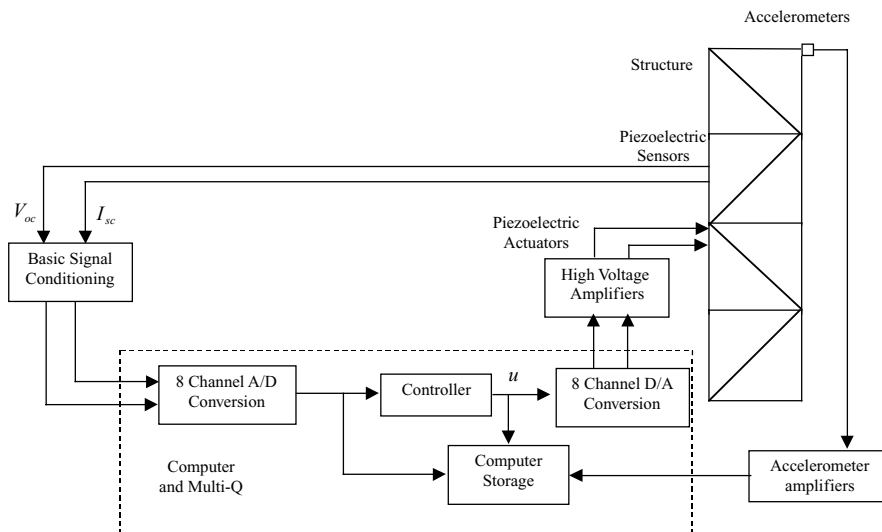

Figure 16. Schematic of testbed system architecture.

Figure 17. Displacement of node 24 of open loop (experimental).

of the acceleration signals yields displacement measurements at node 24. The resonant vibrations are allowed to build up to a steady state before the H_∞ controller is applied.

The displacement at node 24 in the X and Y directions is shown in Fig. 23. The control signals applied to actuators 1 to 4 are shown in Fig. 24. The first 4.6 seconds of both responses shows the open loop resonant behavior of the structure when no control is applied. At 4.6 seconds, the H_∞ controller is applied. The oscillation amplitude is decreased to its steady state value about 1.4 seconds later. The steady state oscillation amplitude is about a factor 10 smaller than the open loop amplitude.

Figure 18. Frequency response of open loop (experimental).

The experiments match well with the numerical simulation, confirming the findings obtained earlier the optimal H_∞ controller is effective in providing a considerable increase in the amount of vibration suppression, due to its ability to target the control energy on a few specific modes of vibrations, as stipulated by the designer. The attenuation provided by the control law for the first five modes of the nominal structure, compared to the open loop case is shown in Table 4.

CONCLUSION

The use of piezoelectric film actuators and sensors for active vibration suppression in truss structures has been investigated. Techniques for modeling truss dynamics and the design robust controllers for suppressing vibrations have been developed. The techniques have been successfully used on an experimental truss structure. The truss structure was designed to be representative of the complex dynamics of the large flexible space structures under consideration by the Canadian Space Agency.

The dynamics of truss structures with piezoelectric actuators and sensors are modeled using a two-step procedure. First, a finite element model of the truss dynamics, without piezoelectric actuators and sensors, is developed. Second, the interaction equations for modeling the coupling dynamics of piezoelectric film actuators and sensors to the finite element model of a truss are developed. This two-step analysis procedure allows the sensor and actuator placement to be optimized for a given finite element model. The dynamic modeling methodology has been validated by tests on an experimental truss structure.

Figure 19. Displacement of node 24 during H_∞ control (experimental).

Figure 20. Control signals during H_∞ control (experimental).

Figure 21. Frequency response during H_∞ control (experimental).

Flexible structures are difficult to control because their dynamics are characterized by a large number of vibrational modes. To reduce computational complexity, controller design is typically performed using a reduced order model. The H_∞ controller design procedure yields a controller that concentrates the control energy on the modes included in the design model. The design procedure accounts for sensor noise and disturbances resulting from nonlinearities in the amplifier and piezoelectric actuators. Control input saturation can be avoided by using a high penalty on the control energy during the controller design. The H_∞ controller performance is analyzed using a high-order evaluation model. The simulations showed that the H_∞ controller provides significant increase in damping to the modes included in the design model, but does not affect the higher-order excluded modes. This behavior is ideal, as it ensures that the structure will not become unstable through the excitation of higher-order modes.

Figure 22. Application point for the continuous disturbance.

Figure 23. Displacement of node 24 during continuous disturbance test with H_∞ control (experimental).

Experimental results with the truss structure have confirmed the validity of the simulations. Two tests have been performed, an impact test and shaker test. Comparisons between the open loop and the closed loop responses show that the H_∞ controller significantly decreases the vibrational mode amplitudes. The controller targets its efforts on the modes retained in the design model.

Piezoelectric materials are ideally suited for constructing actuators and sensors for vibration suppression in flexible structures. Polyvinylidene fluoride (PVDF) is ideally suited for sensor construction. It is lightweight, flexible, and provides a high voltage for a given strain. Piezoceramic materials are suited to actuator construction. Piezoceramics are stiff, rugged, and provide relatively

Table 4. Mode Attenuation

Mode	Attenuation (dB)

large strains when subjected to an electric field. The predominately linear behavior of the piezoelectric materials, and the simple manner in which they can be integrated into a structure, make them a good choice for actuators and sensors in a vibration suppression control system.

VIBRATION CONTROL

SEUNG-BOK CHOI
Inha University
Inchon, Korea

INTRODUCTION

The insatiable demand for high performance on various dynamic systems quantified by high-speed operation, high control accuracy, and lower energy consumption has triggered vigorous research on vibrational control of distributed flexible structures and discrete systems. Numerous control strategies for conventional electromagnetic actuators have been proposed and implemented to suppress unwanted vibration. However, the successful empirical realization of electromagnetic actuators may be sometimes very difficult under certain conditions due to hardware limitations such as saturation and response speed. This difficulty can be resolved by employing smart material actuators in vibrational control. As is well-known, smart material technology features actuating capability, control capability, and computational capability (1). Therefore, these inherent capabilities of smart materials can execute specific functions autonomously in response to changing environmental stimuli. Among many smart material candidates, electrorheological(ER) fluids, piezoelectric materials, and shape-memory alloys (SMA) are effectively exploited for vibrational control in various engineering applications. A viable vibrational control algorithm can be optimally synthesized by integrating control strategies, and actuating technology, and sensing technology, as shown in Fig. 1. The design philosophy presented in Fig. 1 contains a very large number of decisions and design parameters for the characteristics of controllers, actuators, and sensors. Furthermore, the designer seeking a global optimal solution for the synthesis of a closed-loop smart structure system must also address other crucial decisions concerning the time delay of a high-voltage/current amplifier, the speed of the signal converter, and the microchip hardware of the control software. In this article, two different flexible smart structures fabricated from ER fluids and piezoelectric materials are introduced, and vibrational control techniques for each smart structure are presented. In addition, vibrational control methodology for a passenger vehicle under various road conditions is given by adopting an ER damper, followed by vibrational control of a flexible robotic manipulator that features piezoceramic actuators.

VIBRATIONAL CONTROL OF SMART STRUCTURES

ER Fluid-Based Smart Structures

Significant progress has been made in developing smart structures that incorporate electrorheological(ER) fluids. Typically, this class of smart structures features an autonomous actuating capability that makes them ideal

for vibrational control applications in variable service conditions and in unstructured environments. This may be accomplished by controlling the stiffness and energy dissipation characteristics of the structures. This, of course, is possible due to the tunability of rheological properties of ER fluids by the intensity of the electric field. The development of ER fluid-based smart structures was initiated by Choi et al. (2). They completed an experimental study of a variety of shear configurations based on sandwich beam structures. Gandhi et al. (3) suggested using an ER fluid as an actuator to suppress deflections of the flexible robotic arm structures by avoiding resonance. In this work, a phenomenological governing equation was derived by assuming that the structures are viscoelastic materials. A passive control scheme for obtaining a desired transient response was developed on the basis of experimentally obtained phenomenological governing equation, in which field-dependent modal properties were used as pseudocontrol forces (4). Vibrational control logic to minimize the tip deflections of an ER fluid-based cantilever beam structures was illustrated by field-dependent responses in the frequency domain (5). Coulter and Duclos (6) suggested a methodology for replacing a conventional viscoelastic material by an ER fluid. Following the formulation of an analytical model for ER fluid-embedded structures via the conventional sandwich beam theory, they presented a feasibility that the controllability of the complex shear modulus of an ER fluid itself can be used to obtain the desired responses of the structures. Rahn and Joshi (7) developed dynamics for an ER fluid-based on the complex shear modulus of the ER fluid and also theoretically suggested a feedback controller for transient vibration control. Oyadiji (8) developed a theoretical equation to predict the field-dependent frequency response by treating the ER fluid layer as a constrained damping layer and verified its validity by experiment. Choi et al. (9) presented a dynamic model for an ER fluid-based smart beam, in which the complex shear modulus of the ER fluid itself, measured by a rotary oscillation test, was taken into consideration. To validate the methodology, the predicted elastodynamic properties, such as damped natural frequencies and loss factors, were compared with those measured. Gong and Lim (10) experimentally investigated the vibrational properties of sandwich beam structures in which an ER fluid layer was partially or fully filled as a constraint damping layer. Yalcintas and Coulter (11) proposed a vibrational model based on thin-plate theory, and the transverse vibration response of a nonhomogeneous ER smart beam was investigated. In addition, the vibrational control capacity of an ER beam was illustrated by emphasizing mode shape control associated with an on and off state of the electric field. On the other hand, Choi and Park (12) controlled vibration of ER smart beam structures by using a closed-loop control. The vibrational control technique was empirically realized by activating a field-dependent fuzzy controller.

In this article, the field-dependent fuzzy control scheme is introduced after briefly explaining the typical block

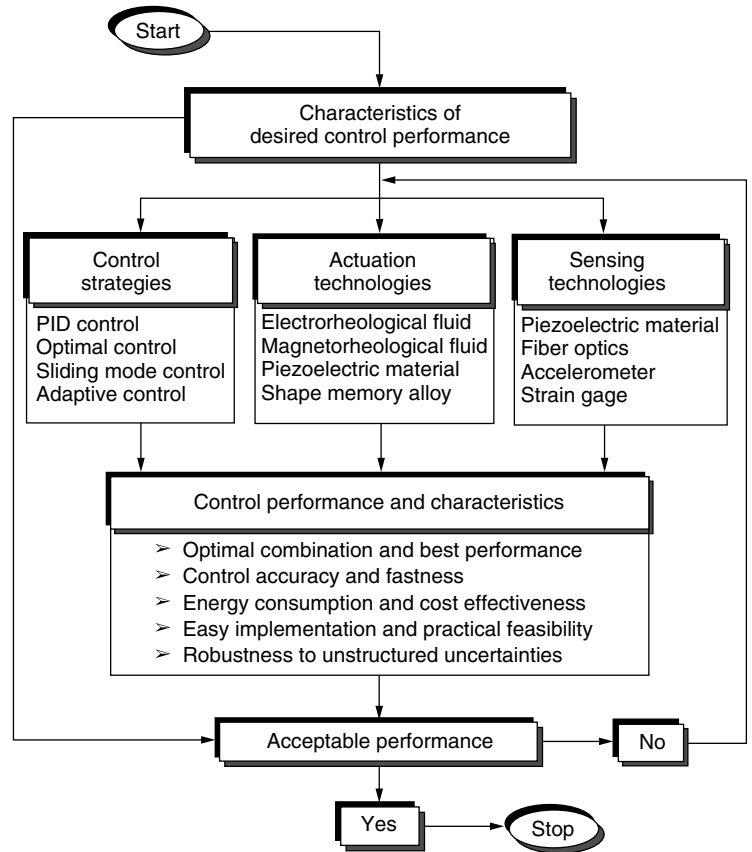

Figure 1. An algorithm for synthesizing a closed-loop smart structure system.

diagram for vibrational control of ER fluid-based smart structures, shown in Fig. 2. The control system consists of a set of sensors, signal converters, microprocessor, high-voltage amplifier, and control algorithm. Most of the sensors currently available such as accelerometers can be adapted to measure the dynamic response of ERfluid-based smart structures. The microprocessor which includes A/D (analog–digital) and D/A(digital–analog) signal converters plays a very important role in closed-loop control time. The

microprocessor should have at least 12 bits to realize control software and also should take into account a high sampling frequency up to 10 kHz. The high-voltage amplifier should have enough power to generate the required ER effect in smart structures. Furthermore, the response time of the high-voltage amplifier to the source input control voltage should be fast enough not to delay the control action of the feedback control system. Typically, a smart structure consists of two host(face) structures, insulators, and an ER

Figure 2. Schematic diagram for controlling the vibration of an ER fluid-based smart structure.

Figure 3. Field-dependent frequency responses of an ER beam structure.

fluid layer, as shown in Fig. 2. For the composite laminate, the lay-up angle of the laminates can be selected as a design parameter to investigate the effect of the ER fluid for different stiffnesses. The insulator is a seal to maintain the integrity of the structure and is also used to adjust the volume fraction of the ER fluid relative to the total volume of the structure. For certain elastodynamic purposes, a smart structure can be constructed that consists of multilayers of ER fluids whose rheological properties are different.

The elastodynamic properties of an ER fluid-based smart structure vary with the level of the electric field, as shown in Fig. 3. This implies that the natural frequency of each vibrational mode can be adjusted by tailoring the electric field and that, consequently, vibration in real time can be effectively suppressed in the presence of resonant disturbances (excitations). In other words, the desired response for minimizing the vibrational magnitude can be obtained by selecting the lowest envelope in the frequency range considered. The desired electric field corresponding to the desired response can be expressed as a fuzzy control algorithm (12): if $\omega_i \leq \omega < \omega_{i+1}$, then $E_d = E_j$. The variable ω denotes the disturbance frequency, and E_d is the desired electric field. Note that the variation potential of elastodynamic properties with respect to the applied field may be different upon operating conditions such as the magnitude of excitation when are altered. Therefore, the frequency bandwidth and the corresponding desired field for the control algorithm should be modified. From fuzzy logic, the control field for the case shown in Fig. 3 is determined as follows: if $0 \leq \omega < \omega_1$, then $E_d = E_2$; if $\omega_1 \leq \omega < \omega_2$, then $E_d = 0$; if $\omega_2 \leq \omega < \omega_3$, then $E_d = E_1$; if $\omega_3 \leq \omega < \omega_4$, then $E_d = E_2$; if $\omega_4 \leq \omega < \omega_5$, then $E_d = 0$; and if $\omega_5 \leq \omega < \omega_6$, then $E_d = E_1$. Figure 4 presents the tip deflection of a cantilevered ER beam in the frequency domain, which has been experimentally obtained by implementing the fuzzy control logic (12). It is evident from this figure that there are effective vibrational suppressions in the neighborhood of the resonant frequencies. However, a small nonzero vibrational magnitude exists across a broad frequency range. This indicates that ER fluids do not provide an actuating force but change the stiffness and the damping properties to avoid resonance. To improve vibrational control performance of the fuzzy control logic,

Figure 4. Forced vibrational responses of a cantilevered ER beam.

appropriate membership functions for the excitatory magnitudes and frequencies can be used to determine the electric fields desired.

On the other hand, it is known that an ER fluid contained in a distributed parameter structural system under continuous and periodic small deformations remains in the preyield state, which shows viscoelastic properties represented by a complex shear modulus (7,9). The complex shear modulus G_r^* of an ER fluid is expressed by $G_r^* = G_r^s + iG_r^l$, where $i = \sqrt{-1}$. Here, G_r^s is defined as the storage shear modulus (in-phase), a measure of the energy stored, relating to the stiffness of the structure that contains the ER fluid. G_r^l is the loss shear modulus (out-of-phase), a measure of the energy dissipated. The shear loss factor is the ratio of the energy lost to the energy stored in a cycle of deformation and denotes the damping characteristic of the ER fluid-embedded smart structure. The complex shear modulus of the ER fluid is normally measured by employing the oscillation mode of an electrorheometer (9). The measured complex shear modulus is integrated with a sixth-order partial differential equation, which is obtained by adopting conventional sandwich beam theory (13). Then, the field-dependent elastodynamic properties of the structure such as the natural frequency are determined through a finite-element model which is governed by $[M]\{\ddot{u}(t)\} + [C(E)]\{\dot{u}(t)\} + [K(E)]\{u(t)\} = \{f(t)\}$. The global mass, damping, and stiffness matrices are denoted by $[M]$, $[C(E)]$, and $[K(E)]$, respectively. Clearly, both the stiffness matrix $[K(E)]$ and damping matrix $[C(E)]$ are functions of the electric field (E) applied to the ER fluid domain. Thus, these matrices can be tuned as functions of the electric field. The variable $\{u(t)\}$ is a displacement vector, (\cdot) is the time derivative, and $\{f(t)\}$ represents the external (or disturbance) force vector. By introducing modal coordinates and also adopting mode shape characteristics of the smart structure, the finite-element model can be rewritten in a typical form of state space representation as follows (4): $\dot{x}(t) = Ax(t) + A(E)x(t) + Bf(t)$. The state vector $x(t)$ represents modal coordinates and the matrix B indicates the influence matrix of the disturbance. A represents the system matrix in the absence of an electric field, and $A(E)$ denotes the additional system matrix due to the electric field. This implies that the desired response of the

Figure 5. Transient vibrational responses of a cantilevered ER beam.

structure can be achieved by tuning the field-dependent $A(E)$. In transient vibrational control without an external disturbance, the desired eigenvalues of the system, which directly indicate the desired natural frequencies and damping ratios of the system, can be obtained by adjusting the intensity of the electric field in the matrix $A(E)$. One of the effective control algorithms for achieving this goal is a so-called pseudostate feedback controller proposed by Choi et al. (4). In this method, the state equation is modified to fit a PD (proportional-derivative) controller in which the proportional gain is related to the field-dependent natural frequency, and the derivative gain is related to the field-dependent damping ratio. In addition, we can easily shift the desired eigenvalues of the system to avoid resonant phenomena by employing this control algorithm. Figure 5 presents the transient vibrational control response of a cantilevered ER beam (4). The first mode eigenvalues of the structure are calculated from $-1.7313 \pm i91.167$ in the absence of an electric field. However, the desired eigenvalues of $-11.44 \pm i122.114$ are achieved by employing appropriate control parameter, which indicate the intensity of the electric field.

An ER beam structure for vibrational control can easily be extended to an ER plate structure. In the vibrational control of flexible plate structures, the significance of mode shape control is no less important than vibrational magnitude control. When we consider large flexible structures such as aircraft wings and helicopter blades, the mode shape is directly related to lift distribution and stability due to internal and external disturbances and other aeroelastic problems in a stringent environment. Therefore, much research on the mode shape control of plate structures have been undertaken by using smart material actuators (14). Choi et al. (15) proposed an ER plate and investigated its field-dependent mode shapes. Figure 6 presents the measured mode shape of an ER plate which has clamped-clamped boundary conditions (15). It is clearly observed that the magnitude of each mode shape is efficiently suppressed by applying a control electric field. Note that we can also control the mode shape in part of the plate structure (15) by partitioning the ER plate and applying an electric field to the specific portion. By doing this, we may alter the twist/camber of an airfoil in the aircraft wing, which in turn controls the lift distribution, to produce desirable performance by real-time control.

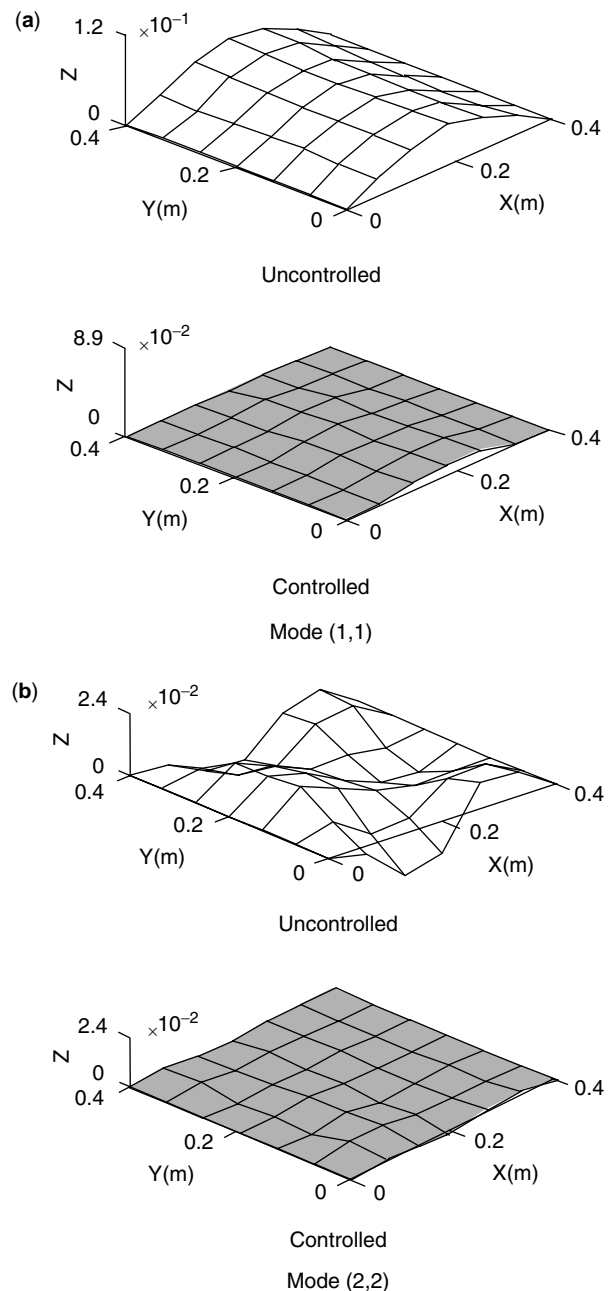

Figure 6. Measured mode shapes of an ER plate.

Smart Structures That Feature Piezoelectric Actuators and Sensors

So far, many natural and synthetic materials that exhibit piezoelectric properties have been proposed and developed. Natural materials include quartz, ammonium phosphate, paraffin, and bone; synthetic materials include lead zirconate titanate (PZT), barium titanate, lead niobate, lithium sulfate, and polyvinylidene fluoride (PVDF). Among these materials, PZT and PVDF are the most popular and commercially available. Both classes of materials are available in a broad range of properties suited to vibrational control applications as actuators or sensors. One of the salient properties of a piezoelectric material is that it responds very fast to voltage, and hence has a wide control

bandwidth. In addition, we can fabricate simple, compact, low-power devices that feature a set of piezoelectric actuators or/and sensors. Applications that use piezoelectric materials include vibrational control of flexible structures such as beams, plates, and shells; noise control of cabins; positional control of structural systems such as flexible manipulators; vibrational control of discrete systems such as engine mounts; ultrasonic motors; and various type of sensors, including accelerometers, strain gauges, and sound pressure gauges. The successful development of a technology that incorporates piezoelectric materials involves several issues. When we fabricate smart structures that use piezoelectric actuators and sensors, we must consider, the fabrication method (surface bonding or embedding), the curing temperature when embedding, insulation between piezoelectric layers, and the harness of electric wires. The important issues to considered in modeling piezoelectric-based smart structures include structural dynamics, actuator dynamics, sensor dynamics, the bonding effect, the hysteresis phenomenon, the optimal location of actuators and sensors, and the number of actuators and sensors.

The control technique for vibrational control of piezoelectric-based smart structures is very similar to that of a conventional vibrational control system, except that it uses a voltage amplifier, as shown in Fig. 7. The response time of the voltage amplifier, which normally has an amplification factor of 200, should be fast enough so that it does not deteriorate the dynamic bandwidth of the piezoactuators. The microprocessor that has A/D(analog to digital) and D/A(digital to analog) signal converters needs to have at least a 12-bit memory, and also needs to account for high sampling frequency up to 10 kHz. Most of the currently available control algorithms for piezoactuators are realized in an active manner. Therefore, a wide range of control techniques has been proposed for using piezoelectric material to control the vibration of flexible structures actively. Bailey and Hubbard (16) applied a piezofilm as an active vibrational damper for distributed

structural systems. Simulations and experimental investigations of transient vibrational control of a cantilever beam were conducted. They derived two types of controllers based on Lyapunov stability: a constant-amplitude controller (CAC) and a constant-gain controller (CGC). Favorable vibrational suppression was achieved by implementing these two controllers. It has been also shown that the CAC is more effective than the CGC for the same maximum voltage. However, when the CAC is employed, undesirable residual vibration is generated in the settled phase due to the excessive supply of control voltages from the inevitable time delay of the hardware system. Baz and Poh (17) proposed a modified independent modal space control method to suppress actively the unwanted vibration of a flexible beam structure that features piezoelectric actuators. The effects of the bonding layer material and the actuator location on the vibrational control performance were evaluated by numerical simulation. Tzou and Gadre (18) derived a physical model for vibrational control, in which a piezofilm slab was sandwiched between two other plates. The effectiveness of active vibrational control has been demonstrated by implementing CGC. Tzou (19) also applied a piezofilm for vibrational control of arbitrarily shaped shells. Control performance of the distributed systems was successfully evaluated through computer simulations by using the CAC and the CGC. Baz et al. (20) integrated the independent modal space control method and the positive position feedback method. Vibrational control performance was enhanced by argumenting the so-called time sharing strategy, and its effectiveness was validated by showing multimode controllability by a single piezoelectric actuator. On the other hand, Choi et al. (21) proposed a multistep constant-amplitude controller (MCAC) to reduce undesirable chattering in the settled phase. They experimentally demonstrated the effectiveness of the MCAC by comparing the vibrational control response of the CAC. Choi and Kim (22) also proposed a new type of discrete-time, fuzzy, sliding mode controller to reduce unwanted

Figure 7. Schematic diagram for vibrational control of a smart structure that features a piezoactuator and a sensor.

vibrational magnitude favorably in the settled phase. Yang and Lee (23) developed three neural networks for smart structures that feature a PZT actuator and sensor, one for system identification, the second for on-line state estimation, and the third for vibrational suppression. The effectiveness of the proposed neural networks was demonstrated by experimentally undertaking transient vibrational control of a cantilevered beam structure. Meyer et al. (24) proposed two control methodologies for vibrational control of large flexible structures: positive position feedback (PPF) and linear quadratic Gaussian (LQG). It has been shown that PPF is effective in providing high damping for a particular mode, and LQG is very effective in meeting specific requirements such as minimization of tip motion. On the other hand, it is generally known that flexible structures are easily subjected to parameter variations in practice. Therefore, a robust vibrational control technique that can guarantee favorable structural performance under system uncertainties needs to be developed. Tang et al. (25) proposed an active-passive hybrid piezoelectric method that used a sliding mode controller to suppress unwanted vibration of flexible structures. A robust sliding mode controller that compensates for parameter variations such as material frequency and the hysteretic nonlinearity of the piezoactuator was designed and successfully implemented; it substantially reduced the vibrational magnitude. Choi et al. (26) formulated a robust quantitative feedback theory (QFT) controller to suppress the vibration of a flexible structure subjected to parameter variations and hysteretic nonlinearity. It has been demonstrated through experiment that the QFT controller is very effective for robust vibrational control of piezoelectric-based smart structures.

In this article, the CAC, CGC, and MCAC schemes, which are relatively easy to implement and very effective for vibrational control of piezoelectric-based smart structures, are introduced by considering the simple cantilevered beam structure shown in Fig. 7. From the figure, it is seen that the control objective is to reduce the vibration in the y direction by activating the piezoactuator. To stabilize the structural system, a positive-definite Lyapunov function F , which is basically a measure of the energy (potential and kinetic) in the system, is adopted as follows: $2F = \int_0^L [(\partial^2 y(x, t)/\partial x^2)^2 + (\partial y(x, t)/\partial t)^2] dx$. Here, L is the length of the beam, and $y(x, t)$ is the deflection of the beam. Minimizing the time derivative of the function, vibrational control is achieved by bringing the system to equilibrium. Taking the time derivative of the function and substituting the governing equation of the beam yields the following (21): $\partial F/\partial t = \int_0^L \{ (1 - EI/\rho A)[\partial^3 y(x, t)/\partial t \partial x^2][\partial^2 y(x, t)/\partial x^2] dx + [cV(t)/\rho A][\partial^2 y(x, t)/\partial t \partial x] \}_{x=L}$. The variables E , I , ρ , and A represent the elastic modulus, inertia, density, and cross-sectional area of the beam, respectively. $V(t)$ is the control voltage, and c is a constant that implies the bending moment per volt. This constant is normally determined by the geometric and material properties of the structure. It is clear that the control voltage $V(t)$ should be chosen so that the second term of the time derivative equation is always as negative as possible. Therefore, two types of control laws are easily synthesized: (1) CAC: $V(t) = -K_1 \cdot \text{sign}(\dot{V}_f)$, and

(2) CGC: $V(t) = -K_2(\dot{V}_f)$. Here K_1 and K_2 are feedback gains. The variable $V_f(t)$ represents the output voltage produced from the piezoelectric sensor. The sensor voltage $V_f(t)$ is proportional to the sign of the angular displacement at the tip of the beam (16). It has been experimentally verified that the CAC is more effective than the CGC at the same maximum voltage (16). This is due to the fact that a square wave has more area than a sine wave of equal magnitude. However, from the practical point of view, the CAC causes undesirable residual oscillations in the settled phase that are attributed to the excessive control voltage from the time delay of the hardware system. This problem becomes more serious when small vibrational levels are considered at relatively high control voltages. On the other hand, the CGC also has some shortcomings under forced vibrational control. Due to insufficient control forces, the suppression efficiency is degraded. This problem becomes more serious when large vibrational levels are considered at relatively low control voltages. The multistep constant-amplitude controller (MCAC) has been also proposed to circumvent the drawbacks of the conventional CAC and CGC (21). The MCAC is given as follows: MCAC: $V(t) = -K_1 \cdot \text{sign}(\dot{V}_f)$, for $(V_f)_m > [(V_f)_{\max}/a_1]$; $V(t) = -K_2 \cdot \text{sign}(\dot{V}_f)$, for $[(V_f)_{\max}/a_2] < (V_f)_m \leq [(V_f)_{\max}/a_1]$; $V(t) = -K_3 \cdot \text{sign}(\dot{V}_f)[(V_f)_m/(V_f)_{\max}]$, for $(V_f)_m \leq [(V_f)_{\max}/a_2]$. The variable K_i is feedback gain, a_i is a switching constant to determine an appropriate voltage magnitude, $(V_f)_{\max}$ is the initial angular displacement in the absence of the control voltage, and $(V_f)_m$ is the controlled angular deflection at a certain time. The feedback gain K_i is chosen so that the maximum voltage amplitude does not exceed the voltage limit V_{\max} . This limit depends upon the breakdown voltage of the piezoactuator. The determination of the switching constant a_i is the key issue that makes the MCAC algorithm effective. The chattering magnitudes in the settled phase are normally experimentally evaluated with respect to imposed initial vibrational magnitudes and also to applied magnitudes of the control voltage in the CAC. And then, from this information, the switching constants are appropriately chosen so that undesirable chattering can be minimized for a certain initial magnitude and corresponding control voltage. The MCAC may be able to self-tune the voltage magnitude via the ratio $(V_f)_m/(V_f)_{\max}$. Implementing this type of controller provides a relatively large control force to suppress large oscillations at the beginning of the control action and subsequently a small control force to remove undesirable chattering in the settled phase. Figure 8 schematically presents the types of control input voltage for the CAC, the CGC and the MCAC, respectively.

Figure 9 presents the measured, transient vibrational control responses of a cantilevered beam that features a piezofilm actuator and sensor (21). The transient vibrational response characteristics were obtained by exciting the beam using the first-mode natural frequency and subsequently removing this excitation and feedback voltage applied. It is clearly observed that the CAC is more effective than the CGC but shows unwanted residual vibration (chattering) in the settled phase. The chattering phenomenon arises from the combined effect of the excessive supply of control voltage on the relatively small

Figure 8. Vibrational control algorithms for a smart structure that features a piezoactuator and sensor.

oscillation and inevitable time delay of the hardware system. However, chattering was fairly well eliminated by employing the MCAC algorithm. This implies that the MCAC produces a relatively small adverse control force for the time delay in the settled phase. Note that the feedback signal from the piezofilm sensor represents the angular

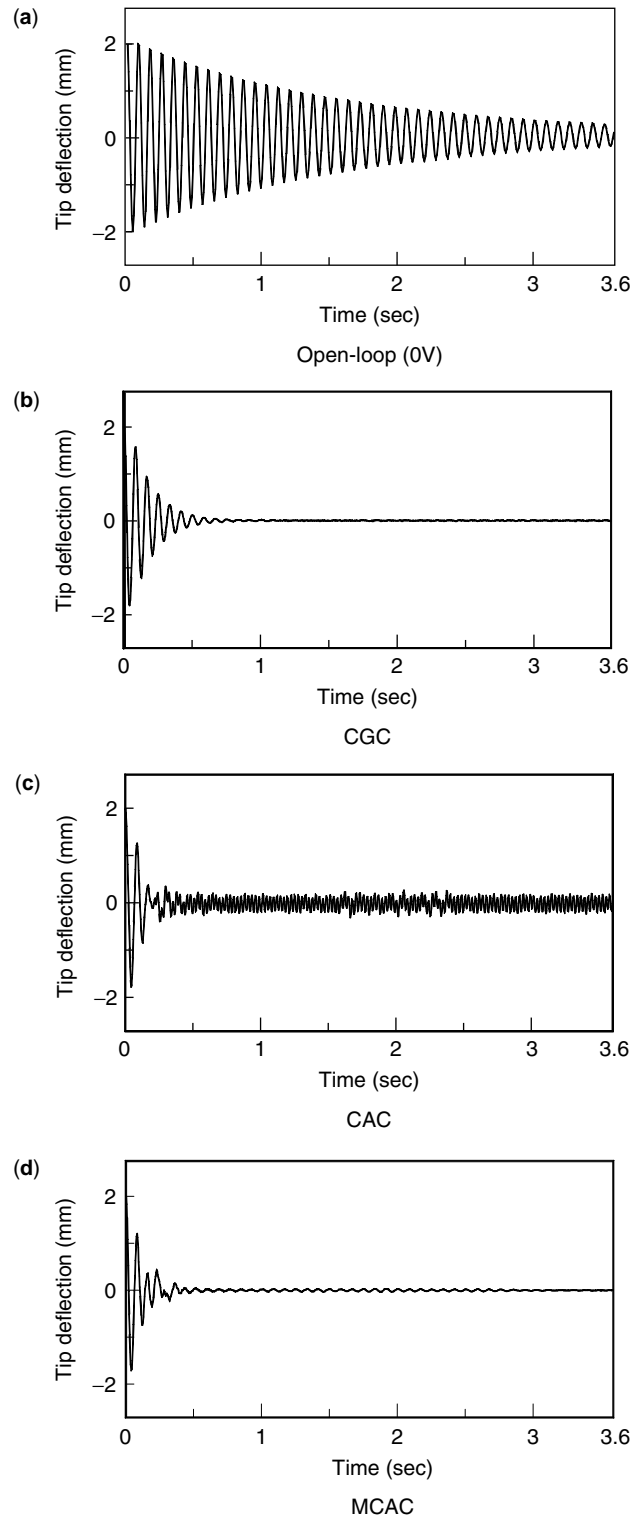

Figure 9. Transient vibrational responses of a cantilevered beam that features a piezoactuator and sensor.

displacement at the tip of the cantilevered beam. Thus, the distributed-parameter sensor catches the corresponding response caused by all of the vibrational modes. Furthermore, the CGC, the CAG, and the MCAC are derived without modal truncation of the plant model. These inherent

Figure 10. Simultaneous controllability of various vibrational modes in a piezofilm-based smart beam.

characteristics of the distributed sensor and control laws allow one the possibility of controlling all transverse vibrational modes at once, hence avoiding problems of spillover of uncontrolled vibrational modes (16). Figure 10 presents the measured transfer function, which is obtained from the ratio of the excitatory input force measured by the accelerometer to the tip deflection measured by the piezofilm sensor (21). It is clearly observed that both the first and second modes are effectively controlled by applying the MCAC algorithm without causing spillover problems.

The vibrational control of the piezoelectric-based smart beam structures can be extended without difficulties to vibrational control of the plate or shell structures. In the vibrational control of large structures, determining the optimal location for piezoactuators or/and sensors is very important to suppress effectively unwanted vibration caused by random disturbances which lead to exciting several mode shapes simultaneously. Furthermore, in practice, large flexible structures can easily be subjected to parameter variations such as natural frequency. Therefore, a robust control algorithm should be formulated for the piezoactuators to protect the robust vibrational control performance from these system uncertainties.

VIBRATIONAL CONTROL OF SMART SYSTEMS

Vehicle Suspension Using ER Damper

Recently, a great deal of attention was focussed on a damper design that significantly suppressed the vibration of a vehicle system (27). The vehicle vibration was to be attenuated for various road conditions. This is normally accomplished by employing a suspension system. So far, three types of suspensions were proposed and successfully implemented: passive, active, and semiactive. The passive suspension system that features an oil damper (or shock absorber) is simple to design and cost-effective. However, performance limitations are inevitable. On the other hand, the active suspension provides high control performance across a wide frequency range. However, the active suspension requires large power, sources, many sensors, servovalves, and sophisticated control logic. One way to resolve these requirements of the active suspension system

is to use a semiactive suspension system. The semiactive suspension system offers desirable performance that is generally enhanced in the active mode without large power sources and expensive hardware. Recently, a very attractive and effective semiactive suspension system featuring ER fluids was proposed by many investigators (28–34).

One of the salient properties of an ER fluid is its responds fast to an electric field, and hence it has a wide control bandwidth. This inherent feature has triggered tremendous research activities in the development of various engineering applications including dampers for controlling the vibration of vehicles. Sturk et al. (27) proposed a high-voltage supply unit that has an ER shock absorber and proved its effectiveness via a quarter-car suspension system. Nakano (28) constructed a quarter-car suspension model using an ER damper and proposed a proportional control algorithm to isolate vibration. Petek et al. (29) constructed a semiactive full suspension system that uses four ER dampers and evaluated the suspension performance by implementing a skyhook control algorithm that considers the heave, pitch, and roll motions of the car body. Gordaninejad et al. (30) proposed a cylindrical ER damper that has multielectrodes and proved its favorable capability for vibration control by implementing a bang-bang and a linear proportional controller. Sims et al. (31) proposed an ER valve-controlled vibrational damper, and obtained the linear behavior of the damping force with respect to the velocity by using a proportional feedback control gain. Peel et al. (32) proposed a long-stroke ER damper for effective vibrational control. Choi et al. (33) proposed a cylindrical ER damper for a passenger car, and proved its controllability of damping force by implementing a skyhook controller. Recently, Choi et al. (34) developed a sliding mode controller for a full car suspension in using four ER dampers. They constructed a full-car model, and evaluated its vibrational control performance via the hardware-in-the-loop simulation. The field test for the ER suspension system has also been undertaken (35).

In this article, a cylindrical ER damper shown in Fig. 11 is introduced to evaluate the vibrational control

Figure 11. Schematic configuration of an ER damper.

Figure 12. Field-dependent damping force of an ER damper.

performance in a passenger vehicle. The ER damper is divided into upper and lower chambers by a piston, that is filled with ER fluid. The ER fluid flows by the piston's motion through the duct between the inner and outer cylinders from one chamber to the other. A positive voltage is produced by a high-voltage supply unit connected to the inner cylinder, and the negative voltage is connected to the outer cylinder. The gas chamber located outside the lower chamber acts as an accumulator of the ER fluid induced by the piston's motion. If no electric field is applied, the ER damper produces a damping force caused only by fluid resistance. However, if a certain level of the electric field is supplied to the ER damper, the ER damper produces an additional damping force owing to the yield stress of the ER fluid. This damping force of the ER damper can be continuously tuned by controlling the intensity of the electric field. The damping force F of the ER damper shown in Fig. 11 can be obtained as follows (34): $F = k_e X_P + c_e \dot{X}_P + F_{ER}$. The variable k_e is the effective stiffness due to gas pressure, c_e is the effective damping due to the fluid viscosity, X_P is the excitation displacement, and F_{ER} is the field-dependent

damping force which is tunable as a function of applied electric field E . By adopting the Bingham model for the ER fluid, the controllable damping force F_{ER} can be expressed as $F_{ER} = (2L/h)(A_P - A_r)\alpha E^\beta \text{sign}(\dot{X}_P)$. A_P and A_r represent piston and piston rod area, respectively, L is the electrode length, h is the electrode gap, and α and β are intrinsic values of the ER fluid to be experimentally evaluated.

Figure 12 presents the measured damping force of a cylindrical ER damper for a passenger vehicle (35). As seen in the figure, the damping force increases as the electric field increases. For instance, the damping force is increased up to 1000 N at a piston velocity of 0.25 m/s by applying an electric field of 3 kV/mm. Note that the level of the damping force of a conventional passive oil damper is almost the same as this one at 0 kV/mm. Thus, we can expect improved suspension performance of the vehicle system by controlling the damping force. To evaluate the vibrational control performance of the vehicle system using the ER damper, we can construct a closed-loop control vehicle system, as shown in Fig. 13. A portable computer (microprocessor) equipped with a DSP (digital signal processor) board is normally positioned beside the driver's seat. Four pairs (one for the car body and the others for the wheels) of accelerometers are installed on four independent suspensions to measure the vertical motions of the vehicle. The signals from the accelerometers, gyroscope, and LDT (linear differential transformer) are fed back to the microprocessor, and depending upon the control algorithm employed, the required control input voltages are determined and applied to the four ER dampers through four high-voltage amplifiers positioned at four corners in the trunk. Among many controllers are candidates for the vehicle suspension, the skyhook control algorithm, which can be easily implemented, is frequently adopted and given as follows: $u_i = C_i |\dot{z}_{si}|$, for $\dot{z}_{si}(\dot{z}_{si} - \dot{z}_{usi}) > 0$; $u_i = 0$, for $\dot{z}_{si}(\dot{z}_{si} - \dot{z}_{usi}) < 0$. The variable u_i is the control damping force F_{ER} , \dot{z}_{si} denotes the vertical velocity of the car body, and \dot{z}_{usi} represents the

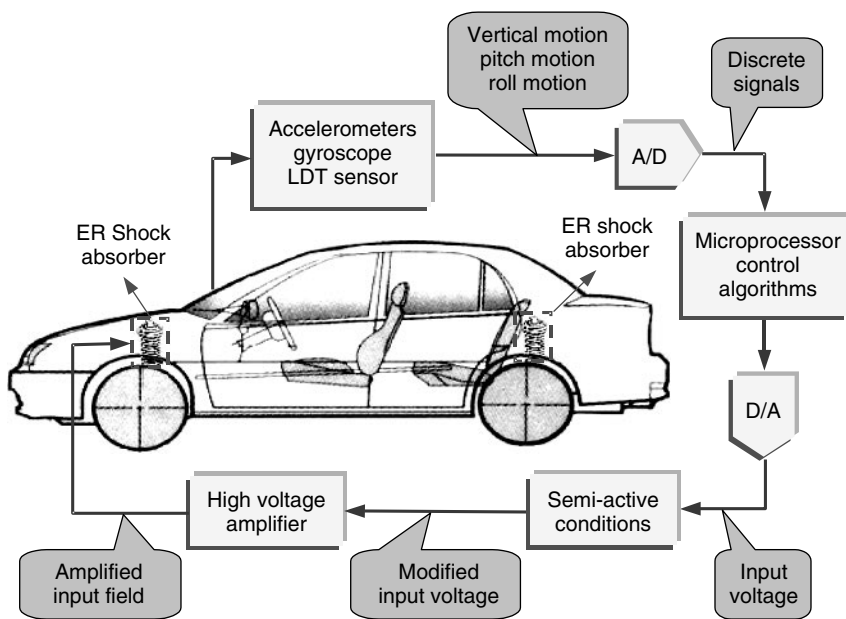

Figure 13. Vehicle configuration for an ER suspension test.

vertical velocity of the wheel. The control gain C_i needs to be determined depending upon the road excitation. In the final stage for practical use, the high-voltage amplifier should have short response time and should be integrated with an electronic control unit (ECU). Note that once the control input u_i is determined, the control electric field to be applied to the ER damper is obtained from the relationship between the electric field and the damping force.

The control characteristics for suppressing the vibration of the full-car suspension system are evaluated under two types of road excitation. The first excitation normally used to reveal the transient response characteristic is a bump. In bump excitation, the vehicle travels over the bump at a constant velocity of 3.08 km/h ($= 0.856$ m/s). The second type of road excitation normally used to evaluate the frequency response is a stationary random process. In random excitation, the values of road irregularity are chosen assuming that the vehicle travels on a paved road at a constant velocity of 72 km/h ($= 20$ m/s). Figure 14a presents the temporal responses of the ER suspension system to the bump excitation (34). It is generally known that vertical acceleration of the sprung mass and tire deflection are used to evaluate the ride comfort and the road holding of the vehicle, respectively. It is seen that both vertical acceleration of the sprung mass and tire deflection are substantially reduced by employing the control electric field. This implies that the ER suspension system can simultaneously provide both good ride comfort and driving safety to a driver by applying a control electric field to the ER dampers. Figure 14b presents frequency responses to random excitation (34). The frequency responses are obtained from the power spectral density (PSD) for the suspension travel and tire deflection. As expected, the power spectral densities for the suspension travel and tire deflection are substantially reduced in the neighborhood of body resonance (1–12 Hz). It is also observed that tire deflection is substantially reduced at wheel resonance (10–15 Hz). This indicates significant enhancement of the steering stability of the vehicle.

Note that most currently employed control algorithms for vibrational attenuation that use an ER fluid-based actuator are dubbed semiactive. The semiactive control system offers desirable performance generally enhanced in the active mode without requiring large power sources. One of the most popular control logics for the semiactive control system is the skyhook control algorithm because it is easy to formulate and implement in practice. Possible candidates for active controllers for the semiactive control system are the sliding mode control, neural network control, Lyapunov-based state feedback control, and optimal control. However, because the semiactive actuator cannot increase the mechanical energy of the control system, special attention (semiactive conditions in Fig. 13) should be given when these active control strategies are adopted. On the other hand, we can construct an active control system using an ER fluid by employing a hydraulic, closed-loop, ER valve–cylinder system. In this case, control logics adapted to conventional hydraulic servomechanism can be applied without any modification. The only difference is replacing the electromagnetic servovalve by the ER valve.

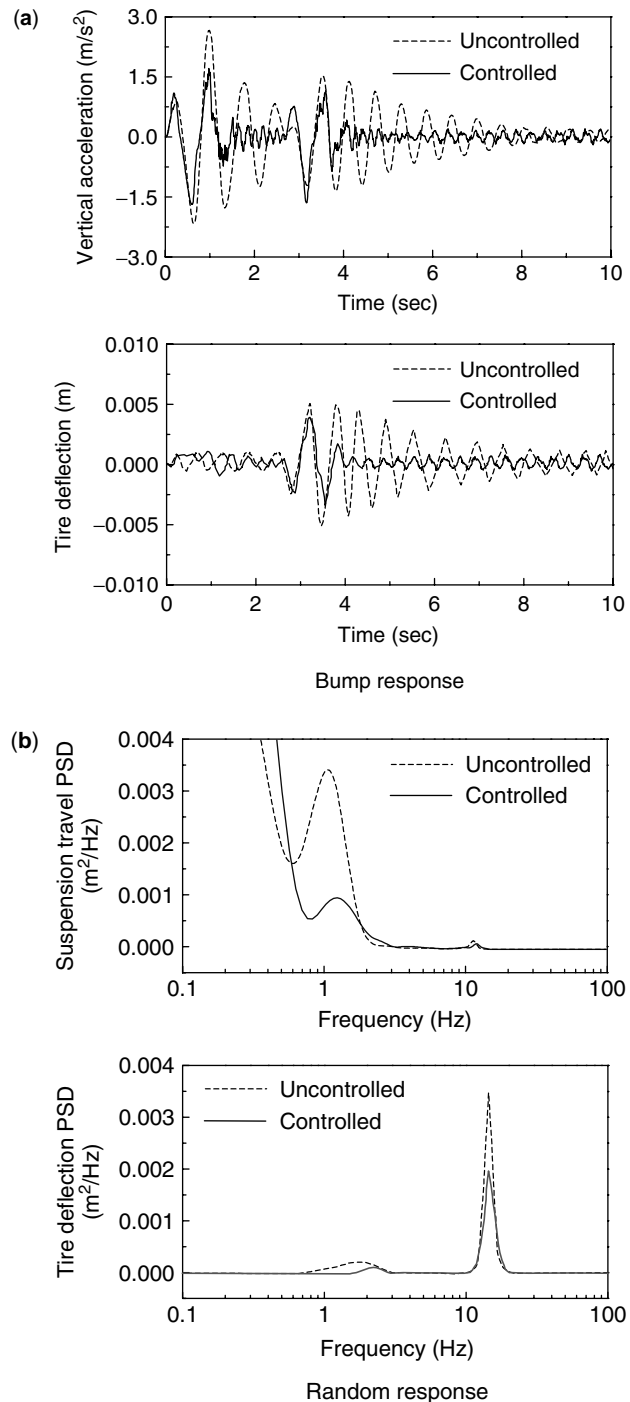

Figure 14. (a) Bump and (b) random responses of a passenger vehicle using ER dampers.

Flexible Manipulator That Features Piezoactuators

Though flexible robotic manipulators have some inherent advantages over conventional rigid robots, they have posed more stringent requirements on the control system design, such as accurate end-point sensing and fast suppression of transient vibration during rapid arm movements. Furthermore, model parameter variations such as natural frequencies and damping ratios may easily arise in practice due to a wide spectrum of various conditions in the design

and manufacturing process, dynamic modeling, and operating conditions. Numerous control strategies for flexible manipulators have been proposed in an attempt to find a successful and practical feedback control. Many of the previously proposed control strategies are based on optimal control theory (36,37). A few investigators strove to achieve effective control logics that accounted for the sensitivity of the control to parameter variations and extraneous disturbances. A robust control that guarantees stable system performance for all possible variations of the parameters was designed by employing the properties of the uniformly and ultimate uniformly boundedness of solving the system state equation (38). There were also several studies on sliding mode controllers (39,40) and an H_∞ controller (41) for the feedback control of flexible manipulators subjected to system uncertainties. The input torque of the motor in most of these control techniques for flexible manipulators is determined by simultaneously considering both the rigid body mode and finite elastic modes. The successful experimental realization of this type of torque may be very difficult under certain conditions due to hardware limitations such as saturation of the motor, computer speed, and signal noises from the motor and sensors. Furthermore, so-called spillover problems will occur because only some finite elastic modes are considered for controlling a distributed parameter system of infinite order. Other problems that plague existing conventional control methods include accurate estimation or measurement of state variables and the complexity of the control algorithm which makes on-line implementation infeasible.

Recently, a hybrid actuator control scheme that consists of two types of actuators, motors mounted at the hubs and piezoactuators bonded to the surface of the flexible links, has been proposed to resolve some of the existing problems and hence, to achieve accurate end-point position by suppressing unwanted vibration (42–44). In this article, this control technique is introduced by considering the elastodynamic flexural response in the horizontal plane (no gravity effect) of a two-link flexible manipulator that features surface-bonded piezoceramics (PZT) and piezofilms, as shown in Fig. 15. Piezoceramics on the right faces play the role of actuators, and piezofilms have the role of distributed sensors to measure elastic deflections caused by vibrational modes. The arm consists of two links connected by a revolute joint. Two links are normally modeled as a

Figure 15. A two-link flexible manipulator that features piezoelectric actuators and sensors.

continuous and uniform beam. It is also generally assumed that the beams are flexible only in the direction transverse to their length in the plane of motion, so that there is no out-of-plane deflection or axial elongation of the links as the arms move. The first flexible link is clamped on the hub of the shoulder motor, and the second flexible link is clamped on the hub of the elbow motor at one end and has a concentrated tip mass at the other end. The motor torque that produces a desired angular position is obtained by employing the sliding mode controller on the rigid-link dynamics that have the same mass as that of the flexible link. Then, the torque is applied to the flexible manipulator to activate the commanded motion. However, during this control action, undesirable oscillations $w_i(x, t)$ occur due to the applied torques based on rigid-link dynamics. Subsequently, these vibrations are to be suppressed by applying the feedback voltage to the piezoceramic actuators. As a result, the desired tip motion is achieved favorably. Figure 16 presents a control block diagram that features hybrid actuators, motors and piezoceramics. In the figure, T_{fi} is the feed-forward term that compensates for the torque disturbance $[d_i(t)]$. The control torque T_i is determined so that the actual angular motion $\theta_i(t)$ tracks the desired motion $\theta_{id}(t)$ well. Because the design procedure for the sliding mode controller for the control torque T_i is the same as

Figure 16. Control block diagram for a two-link flexible manipulator that features piezoactuators.

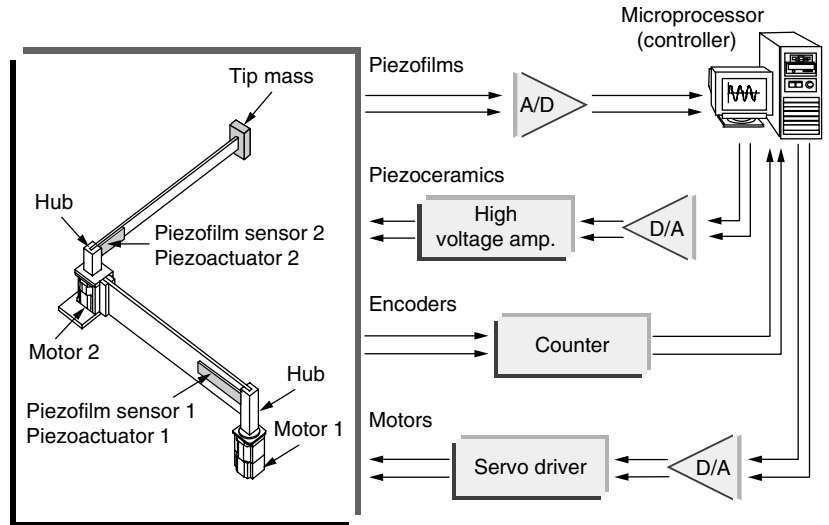

Figure 17. Schematic diagram of the experimental apparatus for end-point control.

that for the rigid-link robot, we can explain only the formulation of the controller for the piezoactuator. As mentioned earlier, one of the potential controller candidates for achieving favorable vibrational control of piezoelectric-based flexible structures is a constant-amplitude controller as follows: $V_i(t) = -K_i \cdot \text{sign}[V_{\dot{f}_i}(t)]$, $i = 1, 2$. Here, K_i is a feedback gain, and $V_{\dot{f}_i}(t)$ is the time derivative of the output signal voltage $V_{f_i}(t)$ from the piezofilm sensor bonded to the other surface of the flexible link. The output voltage produced by the piezofilm sensor is obtained by integrating the electric charge developed at a point on the piezofilm along the entire length of the film surface. The feedback gain K_i of the controller for the piezoactuator is chosen by considering the material property of the piezoceramic actuator as well as the geometry of the flexible link. Furthermore, the feedback gain should be determined so that the flexible manipulator system is stable. To investigate the stability of the system, we normally adopt a positive definite Lyapunov function that is basically a measure of the potential and kinetic energy of the system. The function is given as follows (43): $2F = \dot{\mathbf{z}}^T \mathbf{M} \dot{\mathbf{z}} + \mathbf{z}^T \mathbf{K} \mathbf{z}$. Here, \mathbf{M} is the system mass matrix, \mathbf{K} is the system stiffness matrix associated with the link elasticity, and \mathbf{z} is the generalized coordinate vector that consists of the angular displacement θ_i and the elastic deflection $w_i(x, t)$. We can guarantee the stability of a flexible manipulator system by choosing a proper feedback gain K_i that makes the time derivative of the Lyapunov function negative-definite. However, the stability of a flexible manipulator system can be violated by fast motions or by the acceleration phase of the hubs which in turn result in large oscillations of the flexible links. It is known that when the hub motions are in the deceleration phase, the stability of the system is satisfied by employing any positive feedback gain K_i . On the other hand, if the hub motions completely stop, the flexible links can be treated just as cantilever beams. Thus, in this case, Lyapunov stability is also satisfied by employing any positive feedback gain K_i . The proper determination of K_i normally depends on the magnitudes of the elastic vibration and angular velocity.

Noted that the controller for the piezoactuator is formulated on the basis of the distributed parameter model without truncating the vibrational mode. This allows one

the possibility of simultaneously controlling all of the vibrational modes. Therefore, the control spillover problem, which may occur in the truncated model from uncontrolled vibrational modes, can be avoided. We also note that the discontinuous property may cause undesirable chattering associated with time delay and hardware limitations in the actual implementation of constant-amplitude controllers. To remove the chattering effectively, we may use a so-called multistep amplitude controller that proportionally tunes the magnitude of the control voltage according to the output signal (21). In practice, we can measure the angular displacements by built-in optical encoders in the motors and the elastic deflections by the distributed piezofilm sensors. Therefore, we see that no state estimator, which may be inevitably necessary in most of the conventional control methods, is needed for implementing the hybrid actuator control scheme.

Figure 17 presents a typical experimental apparatus for implementing the hybrid actuator control scheme. The displacements of the motors are obtained from the optical encoders and sent to the microprocessor through the encoder board. The vibrational signals of the flexible links are measured by the piezofilm sensors and fed back to the microprocessor through the low-pass analog filter and A/D converter. Input torques determined from the sliding mode controller are applied to the motor through a D/A converter and a servodriver, and the input voltages determined from the constant-amplitude controller are supplied to the piezoceramic actuator through the D/A converter and high-voltage amplifier. Figure 18 presents the elastic deflections of the two-link flexible manipulator during the regulating control action (43). It is clear that the unwanted deflections are significantly reduced by applying feedback voltages to the piezoceramic actuators. This result directly indicates that the undesirable tip deflection of each flexible link can be effectively suppressed by employing the hybrid actuator control strategy that features servomotors and piezoactuators. Note that the deflection of each link could be reduced more by increasing the feedback gain K_i of the constant-amplitude controller. However, in this case, the breakdown voltage of the piezoactuator should be considered.

INTRODUCTION

The dominant sources of noise radiation in water are from ship engines and machinery—the propeller cavitation noise, the noise radiation from propeller blades, and the hydrodynamic pressure fluctuations induced by turbulent water flow along the ship's hull. At speeds below propeller cavitation inception, a ship's acoustic signature is generally dominated by structurally transmitted noise from onboard machinery. Reduction or control of ship noise

has traditionally been implemented by passive means, such as by the use of vibration isolation mounts, flexible pipe-work, and interior acoustic absorbing materials. However, these passive noise control techniques are effective mostly for attenuating high-frequency noise; they are generally ineffective for controlling low-frequency noise. There are, on the other hand, active noise control methods that have been proven to be effective in controlling low-frequency and tonal noise. These active control methods could be used instead of, or in combination with, passive techniques, for controlling or reducing ship noise.

Active noise control (ANC) involves the reduction or elimination of noise by modification of the dynamic properties of a system or by noise cancellation through linear superposition of a secondary noise field of equal but opposite strength. An active noise control system will typically consist of all or some of the following ingredients: sensors, actuators, and controllers.

FUNDAMENTAL CONCEPTS OF SHIP NOISE CONTROL

Noise Sources and Transmission Paths in Ship Structures

There are many sources of noise within a ship's structure. Among these are the propulsion systems, exhaust stacks, and various onboard equipment. The principal noise source is the engine system. A typical ship engine along with its mounting system is schematically depicted in Fig. 1. The figure shows the various vibroacoustic paths through which the engine vibration is transmitted to the ship structure and eventually radiated into the surrounding mediums. The various vibroacoustic paths transmit noise in different ways. For example:

- The noise from the exhaust stack and the fuel intake and the cooling systems can be viewed as duct and piping noise. In this mechanism the pressure wave in the duct is excited and transmitted as noise.
- The mounting systems, consisting of the engine cradle, isolation mount, raft, and foundation, are mechanical connections between the ship hull and the machine. Vibration is transmitted from the engine motion to the ship hull through these connections. The induced hull vibration is transmitted to the surrounding medium and is radiated as acoustic noise. This noise transmission mechanism is referred to as structural acoustic radiation.
- The engine vibration leads to airborne radiation within the enclosure, which may induce an acoustic load on the ship hull. This resulting excitation is radiated to the surrounding medium as acoustic noise.

The objective of ship noise control is the minimization of the acoustic radiation from the ducting and piping systems and from the ship's hull, and appendages to the surrounding water.

Passive and Active Ship Noise Control

In general, then, passive and active control methods are two distinct methods that can be used to reduce acoustic

Figure 1. Typical marine diesel engine mounted on a ship hull. AA: acoustic to acoustic coupling, SS: structural to structural coupling, AS: acoustic to structural coupling, SA: structural to acoustic coupling. The relative importance of energy coupling for radiation into seawater is illustrated by a number (1) for more important and (2) for less important.

noise and radiation. Passive noise control essentially reduces unwanted noise by utilizing the absorption property of materials. In this approach, sound absorbent materials are mounted on or around the primary source of noise or along the acoustic paths between the source and the receivers of noise. At low frequencies, however, passive control techniques are not effective because the long acoustic wavelength of the noise requires large volumes of the passive absorbers (1)

Active noise control involves the injection of secondary sound by actuators, which by linear superposition is additive, to the primary sound field. It operates on the principle of superposing waveforms, by generating a canceling waveform whose amplitude and envelope match those of the unwanted noise, but whose phase is shifted by 180° (2). The main features of an active control system are illustrated in Fig. 2. The basic components are the physical system (this encompasses the plant, the sensors and the actuators) and the electronic control system (3). The main features are:

1. The primary source of noise/disturbance and the system to be controlled. This is usually referred to as the plant.
2. The input and error sensors. The input sensors are the electroacoustic (microphones) or electromechanical (accelerometers, tachometers) devices that measure the disturbance from the primary source and communicate it to the controller. They are often referred to as reference sensors. The error

sensor monitors the performance of the active controller.

3. The actuators. These are the electroacoustic or electromechanical devices that generate the secondary noise or anti-noise in order to reduce or cancel the primary noise. In some cases, the actuators modify the dynamic properties of the system in order to reduce their noise radiation efficiencies. Examples of actuators include speakers, piezoelectric material, and vibration shakers. The actuators, plant, and the sensors are collectively referred to as the physical system.
4. The active controller. This is the signal processor (usually a digital electronic system) that gives command to the actuators. The controller bases its output on sensor signals (primary noise sensor/error sensor) and usually on some knowledge of how the plant responds to the actuator.

The performance of an active controller depends on the physical arrangements of the control sources (actuators) and the sensors, causality, controllability, observability, and the stability of the control system. Active noise control methodologies (ANC) can be classified into two main categories, namely feedforward control (FFC) and feedback control (FBC). A summary of the description of the two methodologies is given by (4). The controllers that have been used in active noise control methodologies (FFC and FBC) have evolved over the years from analog to digital designs.

Figure 2. Main features of an active noise control system.

SENSORS AND ACTUATORS FOR ACTIVE NOISE AND VIBRATION CONTROL (ANVC)

Piezoelectric Materials

Piezoelectric materials are the oldest and most reliable materials used in high-speed sensor and actuator technologies. Piezoelectricity was discovered by the Curie brothers in 1880. When a piezoelectric material is subjected to a mechanical stimulus, an electrical charge or voltage is induced in the material. This is called the “direct piezoelectric effect,” which enables the material to be used as a sensor. On the other hand, when the piezoelectric material is subjected to an electrical charge or voltage, a mechanical force or strain is induced in the material. This is called the “converse piezoelectric effect,” which enables the material to be used as an actuator. The induced strain is directly proportional to the applied electric field and the linear piezoelectric constitutive equations are given by

$$T = cS - eE, \quad (1a)$$

$$D = e^T S + \varepsilon E, \quad (1b)$$

where T , E , S , and D are the vectors of stress, electric field, strain, and electric displacement (charge per unit area), c , e , and ε are the matrices of the elastic stiffness coefficients, piezoelectric stress constants, and dielectric coefficients, respectively. Equations (1a) and (1b) describe the direct and converse effects, respectively. Piezoelectric materials are also called soft ceramics because they are characterized by high dissipation factors (dielectric losses). As a result, they have high hysteresis in the displacement versus voltage curves (5).

The three most important piezoelectric materials are lithium niobate (LiNbO_3), polyvinylidene fluoride (PVDF or PVF2), and lead zirconate titanate (PZT) (6). LiNbO_3 is a crystal with a high electromechanical coupling and very low acoustical attenuation. Piezoelectricity is obtained from a strip of PVDF by stretching it under a high voltage. PVDF, originally discovered in 1969, is known for its flexibility, lightweight, durability, and relatively low acoustic impedance. PZT is by far the most commonly used piezoelectric material. This is a ferroelectric ceramic material with direct and converse piezoelectric properties. A wide variety of PZT formulations have been developed, with PZT-5 being one of the most widely used formulations for actuator applications (7–10). PZT can be used as sensors or actuators. For actuators, the device usually consists of a stack of many layers of the PZT, alternatively connected to the positive and negative terminals of a high voltage source (7).

The mechanical, dielectric and electromechanical coupling properties of some piezoelectric materials are shown in Table 1. Many studies, both theoretical and experimental, have been focused on the application of piezoelectric materials for vibration control of flexible structures (6,11–14). Of direct relevance to the noise control problem that is of interest in this study is the work by Sumali and Cudeny (15) who developed an actuator from a stack of layers of piezoelectric material in an actively controlled engine mount that was designed to reduce structural

vibrations. Most of the theoretical and experimental studies on the use of piezoelectric materials for active noise control have been directed at aircraft cabin noise control. For instance, Grewal et al. (16) have investigated the use of piezoceramic elements to reduce cabin noise in the Havillan Dash-8 series 100/200 aircraft. Their study shows that by judicious actuator and sensor design considerations systems using bonded piezoelectric actuators and vibration sensors alone are capable of simultaneously providing significant noise reduction as well as vibration suppression. Other studies include the works of Sutliff et al (17) on active noise control of low-speed fan rotor-stator modes; and Simonich (5) on the application of rainbow piezoceramic actuators (18) for active noise control of gas turbine engines.

Electrostrictive Materials

Electrostrictive materials are similar to piezoelectric materials. When a mechanical force or strain is applied to the material, an electric charge or voltage is induced; conversely, when an electric field is applied across an electrostrictive material, a mechanical strain is induced. Hence, electrostrictive material can also be used as sensors or actuators. However, there are several differences between electrostrictive and piezoelectric materials. In electrostrictive materials, the induced mechanical strain is proportional to the square of the electric field, whereas it is proportional to the electric field in piezoelectric materials. Thus electrostrictive materials always produce positive displacements regardless of the polarity. As a result, they are always in compression when doing work and avoid typical weakness of ceramics in tension (19). Electrostrictive materials exhibit microsecond recovery time upon withdrawal of the electric field, compared to milliseconds for piezoelectric materials. Electrostrictive materials have lower dissipation factors (and low displacements and hysteresis) compared to piezoelectric materials, and are regarded as hard ceramics (5). The most commonly used electrostrictive material is lead magnesium niobate (PMN) ceramic material.

Magnetostrictive Materials

Magnetostrictive materials are those materials that undergo an induced mechanical strain when subjected to a magnetic field. On the other hand, when a mechanical stress (or strain) is applied to the material, it undergoes domain changes that yield a magnetic field. These materials can thus be used as sensors and actuators due to the direct and converse effects. The most common magnetostrictive material is TERFENOL (consisting of TERbium, FE (iron) and dysprosium, which was developed by NOL, the Naval Ordnance Laboratory). The most commonly used formulation is TERFENOL-D. Magnetostrictive materials can exhibit strains of up to 0.2% at reasonably low magnetic field strength (20).

A detailed description of a magnetostrictive actuator is presented by Giugliuto et al. (7), who show the construction of a terfenol actuator. The actuator consists of a TERFENOL-D rod inside an electric coil that is enclosed

Table 1. Advantages and Disadvantages of Various Sensor and Actuator Technologies

Type of Sensor or Actuator	Advantages	Disadvantages
<p><i>Piezoelectric materials</i></p> <p>Examples: Lead zirconate Titanate (PZT) Polyvinylidene Fluoride(PVDF)</p>	<ul style="list-style-type: none"> • Used as sensors and actuators • Very large frequency range • Quick response time • Very high resolution and dynamic range • Possibility of integration in the structure for thin PZT actuators and PVDF sensors • Possibility of shaping PVDF sensors (spatial filtering) 	<ul style="list-style-type: none"> • Relatively low strain and low displacement capability (typically, less than 0.1% strain, and 1–100 microns displacement for stack actuators) • Actuators require relatively costly voltage amplifiers • Low recoverable strain (0.1%) • Piezoelectric ceramics are brittle • Cannot measure direct current • Susceptible to high hysteresis and creep when strained in direction of poling (e.g., stack actuators)
<p><i>Electrostrictive materials</i></p> <p>Example: Lead-magnesium niobate (PMN)</p>	<ul style="list-style-type: none"> • Used as sensor and actuators • Lower hysteresis and creep compared to piezoelectric • Potentially larger recoverable strain than piezoelectric 	<ul style="list-style-type: none"> • More sensitive to temperature variations than piezoelectrics
<p><i>Magnetostrictive materials</i></p> <p>Example: Terfenol-D</p>	<ul style="list-style-type: none"> • Higher force and strain capability than piezoceramics (typically, 1000 microstrain deformation) • Suited for high-precision applications • Suited for compressive load carrying components • Very durable 	<ul style="list-style-type: none"> • Low recoverable strain (0.15%) • Only for compression components • Nonlinear behavior
<p><i>Shape-memory alloys (SMA)</i></p> <p>Example: NITINOL</p>	<ul style="list-style-type: none"> • Large recoverable strain (8%) used largely for actuation due to large force generation • Low voltage requirements 	<ul style="list-style-type: none"> • Suited for low-frequency (0–10 Hz) and low-precision application • Slow response time • Complex constitutive behavior with large hysteresis
<p><i>Optical fibers</i></p> <p>Examples: Bragg grating, Fabry-Perot</p>	<ul style="list-style-type: none"> • Suited for remote sensing of structures • Corrosion resistant • Immune to electric interference • Small, light, and compatible with advanced composite 	<ul style="list-style-type: none"> • Used for sensing alone • Behavior is complicated by thermal strains
<p><i>Electrorheological fluids (ER)</i></p> <p>Example: Alumino-silicate in paraffin oil</p>	<ul style="list-style-type: none"> • Simple and quiet devices • Suitable for vibration control • Offers significant capability and flexibility for altering structural response • Low density 	<ul style="list-style-type: none"> • Low-frequency applications • Nonlinear behavior • Cannot tolerate impurities • Fluid and solid phases tend to separate • Not suitable for low temperature applications • High-voltage requirements (2–10 kV) • Higher η_p/τ_y^2 ratio than MR*
<p><i>Magnetorheological fluids (MR)</i></p>	<ul style="list-style-type: none"> • Simple and quiet devices • Quick response time • Suitable for vibration control • Offers significant capability and flexibility for altering structural response • Low voltage requirements • Behavior not affected by impurities • Suitable for wide range of temperatures • Lower η_p/τ_y^2 ratio than ER* 	<ul style="list-style-type: none"> • Nonlinear behavior • Higher density than ER

in an annular armature. When the coil is activated, the TERFENOL rod expands and produces a displacement. The TERFENOL-D bar, coil, and armature are assembled between two steel washers and put inside a protective wrapping to form the basic magnetoactive induced strain actuator unit (7). The main advantage of terfenol is its high-force capability at relatively low cost (21). It also has the advantage of small size and light weight, which makes it suitable for situations where no reactive mass is required such as in stiffened structures of aircraft and submarine hulls. The disadvantages of TERFENOL include its brittleness and low tensile strength (100 MPa) compared to compressive strength (780 MPa). Its low displacement capability is also a major disadvantage especially in the low-frequency range (less than 100 Hz). In addition, it also exhibits large hysteresis resulting in a highly nonlinear behavior that is difficult to model in practical applications (20,21). Tani et al. (20) have reviewed of studies on modeling the nonlinear behavior of TERFENOL-D as well as its application in smart structures. Ackermann et al. (22) developed a transduction model for magnetostrictive actuators through an impedance analysis of the electro-magneto-mechanical coupling of the actuator device. This model provided a tool for in-depth investigation of the frequency-dependent behavior of the magnetostrictive actuator, such as energy conversion, output stroke, and force. The feasibility of using embedded magnetostrictive mini actuators (MMA) for vibration suppression has been investigated by (20).

Shape-Memory Alloys (SMAs)

Shape-memory alloys (SMAs) are materials that undergo shape changes due to phase transformations associated with the application of a thermal field. When a SMA material is plastically deformed in its martensitic (low-temperature) condition, and the stress is removed, it regains (memory) its original shape by phase transformation to its austenite (high-temperature) condition, when heated. SMAs are considered as functional materials because of their ability to sense temperature and stress loading to produce large recovery deformations with force generation. TiNi (nitinol), which is an alloy comprising approximately 50% nickel and 50% titanium, is the most commonly used SMA material. Other SMA material including FeMnSi, CuZnAl, and CuAlNi alloys have also been investigated (20,23).

Typically, plastic strains of 6% to 8% can be completely recovered by heating nitinol beyond its transition temperature (of 45–55°C). According to Liang and Rogers (24) restraining the material from regaining its memory shape can yield stresses of up to 500 MPa for 8% plastic strain and a temperature of 180°C. By transformation from the martensite to austenite phase, the elastic modulus of nitinol increases threefold from 25 to 75 GPa, and its yield stress increases eightfold from 80 to 600 MPa (25).

SMAs can be used for sensing or actuation, although they are largely used for actuation due to their large force generation capabilities. They have very low voltage

requirements for operation and are very suited for low-frequency applications. However, their use is limited by their slow response time, which makes them suitable for low-precision applications only. Also, they exhibit complex constitutive behavior with large hystereses, which makes it difficult to understand their behavior in active structural systems. To provide a better understanding of the behavior of SMAs, several researchers have focused on the development of constitutive models for SMAs. Some of the most prominent and commonly used ones are those by Tanaka (26), Liang and Rogers (24), and Boyd and Lagoudas (27). These models are derived from phenomenological considerations of the thermomechanical behavior of the SMAs. Because of the numerous advantages they offer, several investigations on the application of SMAs have been carried out within the present decade. Reviews of these applications, focusing on fabrication of SMA hybrid composites, analytical and computational modeling, active shape control, and vibration control, are presented in (20,23).

Optical Fibers

For many applications, ideal sensors would have such attributes as low weight, small size, low power, environmental ruggedness, immunity to electromagnetic interference, good performance specifications, and low cost. The emergence of fiber-optic technology, which was largely driven by the telecommunication industry in the 1970s and 1980s, in combination with low-cost optoelectronic components, has enabled fiber-optic sensor technology to realize its potential for many applications (28–30). A wide variety of fiber-optic sensors are now being developed to measure strain, temperature, electric/magnetic fields, pressure, and other measurable quantities. Many physical principles are involved in these measurements, ranging from the Pockel, Kerr, and Raman effects to the photoelastic effect (31). These sensors use intensity, phase, frequency, or polarization modulation (32). In addition, multiplexing is largely used for many-sensor systems. Fiber-optic sensors can also be divided in discrete sensors and distributed sensors to perform spatial integration or differentiation (33). Three types of fiber-optic strain sensors are reviewed in the following: extrinsic interferometric sensors, Bragg gratings, and sensors based on the photoelastic effect.

The most widely used phase modulating fiber-optic sensors are the *extrinsic interferometric sensors*. Two fibers and directional couplers are generally used for these sensors. One of the fibers acts as a reference arm, not affected by the strain, while the other fiber acts as the sensing arm measuring the strain field. By combining the signals from both arms, an interference pattern is obtained from the optical path length difference. This interference pattern is used to evaluate the strain affecting the sensing arm (e.g., by fringe counting). These sensors have a high sensitivity and can simultaneously measure strain and temperature. One interferometer now being used in industrial applications is the Fabry-Perot interferometer, where a sensing cavity is used to measure the strain (34). This sensor uses a white-light source and a single multiple mode

Figure 3. Fabry-Perot sensors used for ice impact monitoring and encapsulated version.

fiber, and provides absolute measurements. This extrinsic interferometer sensor is shown in Fig. 3.

Bragg grating reflectors can be written on an optical fiber using a holographic system or a phase mask to generate a periodic intensity profile (35). These sensors can be used as point or quasi-distributed sensors. The reflected signal from these sensors consist of frequency components directly related to the number of lines per millimeter of each grating reflector and, thus, to the strain experienced by the sensor. Fiber-optic sensors based on Bragg gratings are used to measure strain and temperature, either simultaneously or individually (36). The Bragg gratings are traditionally interrogated using a tunable Fabry-Perot or a Mach-Zender interferometer. Recently, long-period gratings have been used to interrogate Bragg sensing gratings (37). Bragg gratings have been used to measure vibrations either directly or through the development of novel accelerometers. A typical fiber Bragg grating (FBG) system is illustrated in Fig. 4.

The principle of operation of the sensors based on the *photoelastic effect* is a phase variation of the light passing through a material (fiber) that is undergoing a strain variation. This phase variation can be produced by two effects on the fiber: (1) the variation of the length produced by the strain; (2) the photo-elastic effect and the modal dispersion caused by the variation of the diameter of the fiber. These sensors are classified in modal interferometric sensors and polarimetric sensors. As it integrates the strain effect over its length, the modal interferometric sensor can act as a spatial filter if the propagation constant is given a spatial weighting (38).

Figure 4. Bragg grating on an optical fiber.

Electrorheological Fluids (ER)

Electrorheological fluids (ER) are a class of controllable fluids that respond to an applied electric field with a dramatic change in rheological behavior. The essential characteristic of ER fluids is their ability to reversibly change from free-flowing linear viscous liquids to semisolids having controllable yield strength in milliseconds when exposed to an electric field (23). The ER fluids provide very simple, quiet and rapid response interfaces between electronic controls and mechanical systems. They are very suitable for vibration control because of the ease with which their damping and stiffness properties can be varied with the application of an electric field.

ER materials consist of a base fluid (usually a low viscosity liquid) mixed with nonconductive particles, typically in the range of 1 to 10 μm diameter. These particles become polarized on the application of an electric field, leading to solidification of the material mixture. Typical yield stresses in shear for ER materials are about 5 to 10 kPa. The most common type of ER material is the class of dielectric oils doped with semiconductor particle suspensions, such as aluminosilicate in paraffin oil. The material exhibits nonlinear behavior, which is still not completely understood by the research community. This lack of understanding has hindered efforts in developing optimal applications of ER materials. However, electrorheological fluids may be suitable for many devices, such as shock absorbers and engine mounts (23,25).

Magnetorheological Fluids (MR)

Magnetorheological fluids (MR) are similar to ER materials in that they are also controllable fluids. These materials respond to an applied magnetic field with a change in the rheological behavior. MR fluids, which are less known than ER materials, are typically noncolloidal suspensions of micron-sized paramagnetic particles. The key differences between MR and ER fluids are highlighted in Table 1. In general, MR fluids have maximum yield stresses that are 20 to 50 times higher than those of ER fluids, and they may be operated directly from low-voltage power supplies compared to ER fluids which require high-voltage (2–5 kV) power supplies. Furthermore, MR fluids are less sensitive to contaminants and temperature variations than are ER fluids. MR fluids also have lower ratios of η_p/τ_y^2 than ER materials, where η_p is the plastic viscosity and τ_y the maximum yield stress. This ratio is an important parameter in the design of controllable fluid device design, in which minimization of the ratio is always a desired objective. These factors make MR fluids the controllable choice for recent practical applications. Several MR fluid devices developed by Lord Corporation in North Carolina under the Rheo-etic trade name (23).

Microphones

Microphones are usually the preferred acoustic sensors in active noise control applications. Relatively inexpensive microphones (electret or piezoelectric microphones) can be used in most active noise control systems because the frequency response flatness of the microphones is not critical

Figure 5. Sound pressure and particle velocity sensing.

in digital active control systems, as it is compensated in the identification of the control path. The most common types of microphones are omni-directional, directional, and probe microphones.

Whenever turbulent flow is present in the acoustic medium (e.g., a turbulent flow in a duct conveying a gas or a fluid), turbulent random pressure fluctuations are generated in the flow, adding to the disturbance pressure field. The most common way of reducing the influence of turbulent noise is to use a probe tube microphone consisting of a long, narrow tube with a standard microphone mounted at the end. The walls of the tube are porous or contain holes or an axial slit. The probe tube microphone must be oriented with the microphone facing the flow. Probe tube microphones are convenient as reference sensors in active control systems in ducts because they act as both directional sensors and turbulence filtering sensors. Details on the principle of operation can be found in (39). Low-cost microphone probes for hot corrosive industrial environments are also available from Soft dB Inc. Figure 5 shows a microphone adapted for such environments.

Displacement and Velocity Transducers

Although their dynamic range is usually much less than that for accelerometers, displacement and velocity transducers are often more practical for very low frequencies (0–10 Hz) where vibration amplitudes can be of the order of a millimeter or more for heavy structures whose corresponding accelerations are small. Also, in low-frequency active control systems, displacement or velocity rather than acceleration can be the preferred quantities to minimize. The displacement and velocity transducers are described below.

Proximity probes are the most common type of displacement transducers. There are two main types of proximity probes, the capacitance probe and the Eddy current probe. Proximity probes allow noncontact measurement of vibration displacements. They are well suited to vibration displacement measurements on rotating structures. The dynamic range of proximity probe is very small—typically 100 : 1 for low-frequency applications (<200 Hz). The resolution varies from 0.02 to 0.4 mm.

The *linear variable differential transformer (LVDT)* is a displacement transducer that consists of a single primary and two secondary coils wound around a cylindrical bobbin.

A movable nickel iron core is positioned inside the windings, and it is the movement of this core that is measured. The dynamic range of an LVDT is typically 100 : 1, with a resolution ranging from 0.01 to 1 mm. The frequency range is typically dc to 100 Hz. The total length of the sensor varies from 30 to 50 mm for short stroke transducers to about 300 mm for long stroke transducers.

The *linear variable inductance transformer* (LVIT) is a displacement transducer based on the measurement of inductance changes in a cylindrical coil. The coil is excited at about 100 kHz, and the inductance change is caused by the introduction of a highly conductive, nonferrous coaxial rod sliding along the coil axis. It is the movement of this coaxial rod that is measured. This type of transducer is particularly suited for measuring relative displacements in suspension systems. Transducer sizes vary from diameters of a few millimeters to tens of millimeters.

Often used among the velocity transducers is the *non-contacting magnetic type* consisting of a cylindrical permanent magnet on which is wound with an insulated coil. A voltage is produced by the varying reluctance between the transducer and the vibrating surface. This type of transducer is generally unsuitable for absolute measurements, but it is very useful for relative velocity measurement such as needed for active suspension systems. The frequency range of operation is 10 Hz to 1 kHz; the low-resonance frequency of the transducer makes it relatively heavy. Velocity transducers cover a dynamic range between 1 and 100 mms^{-1} . Low-impedance, inexpensive voltage amplifiers are suitable.

Accelerometers

Accelerometers are the most employed technology for vibration measurements. They provide a direct measurement of the acceleration, usually in the transverse direction of a vibrating object. The acceleration is a quantity well correlated to the sound field radiated by the vibrating object. Therefore, accelerometers can be a convenient alternative to microphones as error sensors for active structural acoustic control. Accelerometers usually have a much larger dynamic range than displacement or velocity sensors. A potential drawback of accelerometers, in low-frequency active noise control systems, is their low sensitivity at low frequency (typically 0–10 Hz).

Small accelerometers can measure higher frequencies, and they are less likely to affect the dynamics of the structure by mass loading it. However, small accelerometers have a lower sensitivity than bigger ones. Accelerometers range in weight from miniature 0.65 g for high-level vibration amplitudes up to 18 kHz on lightweight structures, to 500 g for low-level vibration amplitudes on heavy structures up to 1 kHz. Because of the three-dimensional sensitivity of piezoelectric crystals, piezoelectric accelerometers are sensitive to vibrations at right angle to their main axis. The transverse sensitivity should be less than 5% of the axial sensitivity. There are two main types of accelerometers: piezoelectric and piezoresistive.

A *piezoelectric accelerometer* consists of a small seismic mass attached to a piezoelectric crystal. When the accelerometer is attached to a vibrating body, the inertia force

due to the acceleration of the mass produces a mechanical stress in the piezoelectric crystal that is converted into an electric charge on the electrodes of the crystal. Provided that the piezoelectric crystal works in its linear regime, the electric charge is proportional to the acceleration of the seismic mass. The mass may be mounted to produce either compressive or tensile stress, or alternatively, shear stress in the crystal. A piezoelectric accelerometer should be used below the resonance of the seismic mass–piezoelectric crystal system. Since piezoelectric accelerometers essentially behave as electric charge generators, they must generally be used with high-impedance charge amplifiers. The cost of such amplifiers can represent a significant amount of the total cost of an active control system when a large number of accelerometers are used.

Piezoresistive accelerometers rely on the measurement of resistance change in a piezoresistive element usually mounted on a small beam and subjected to stress. Piezoresistive accelerometers are less sensitive than piezoelectric. They require a stable, external dc power supply to excite the piezoresistive elements. However, piezoresistive accelerometers have a better sensitivity at low frequency, and they require less expensive, low-impedance voltage amplifiers. The piezoresistive element is sometimes replaced by a piezoelectric polymer film (PVDF), and the electric charge across the electrodes of the PVDF is collected as the sensor output. Such a PVDF accelerometer has a sensitivity and frequency response similar to the piezoresistive accelerometer, and it is less expensive than the piezoelectric accelerometer.

Loudspeakers

The electrodynamic loudspeaker is the most commonly employed actuator technology for active noise control applications. When selecting a loudspeaker for an active noise control system, the important parameter is the cone volume velocity required to cancel the primary sound field (21).

For small systems, (small-duct, low-noise, domestic ventilation system), active acoustic noise control can be achieved with small commercial medium-quality speakers (radio-type speaker). However, for bigger systems, precautions have to be taken.

Electrodynamic loudspeakers exhibit a nonlinear behavior when they are driven close to maximum power or maximum membrane deflection. It can significantly degrade the performance of active control systems based on linear filtering techniques. It is thus important that loudspeakers should be driven at a fraction of the maximum power or maximum deflection specifications, especially in situations where single-frequency or harmonic noise has to be attenuated. For random noise, the peak cone velocity requirements for active control are likely to be four or five times the estimated rms velocity requirements (39).

In active control of single-frequency noise, it is desirable to design the loudspeaker so that its mechanical resonance lies close to the frequency of interest. This resonance frequency can be adjusted to suit a particular application either by adding mass to the cone (to reduce the frequency) or by adding a backing enclosure to the speaker (to increase the frequency).

Figure 6. Protective system for loudspeaker membrane.

Operation in industrial environments requires considerable precautions. In high-humidity, high-temperature and corrosive environments, the loudspeaker cone must be protected with a heat shield. Soft dB used a Teflon membrane and a perforated metal sheet to protect the membrane of the speaker from corrosive gas (see Fig. 6).

Electromagnetic Actuators

For vibration control purposes, electromagnetic actuators can be classified into electrodynamic shakers and electrical motors. The latter can be used for low-frequency vibration control. Electrodynamic shakers are generally defined as devices having a central inertial core (usually a permanent magnet) surrounded by a winding. This type of inertial actuator applies a point force to a structure by reacting against the inertial mass. As in a loudspeaker, a time-varying voltage is applied to the coil in order to move the inertial mass and to force the movement of the structure onto which the shaker is attached.

Other inertial type actuators are available which use, for example, the piezoelectric effect, instead of a coil, to move the inertial mass. Proof-mass actuators (also called inertial actuators) are very similar in their operation to electrodynamic shakers. They usually consist of a mass that is moved by an alternating electromagnetic field. These devices can generate relatively large forces and displacements and can be good alternatives to costly electrodynamic shakers. The devices can excite very stiff structures such as electrical power transformers. Another advantage of proof-mass actuators is that their resonant frequency can be easily tuned for optimal efficiency at a given frequency.

Electrical Motors

The advent of new control strategies and digital controllers has revolutionized the way electrical motors can be used and now allows for the use of motor technologies that were previously difficult to implement in practical applications. Simple motor drives were traditionally designed with relatively inexpensive analog components that suffer from susceptibility to temperature variations and component aging. New digital control strategies now allow for the use of electrical motors in active vibration control applications. These efficient controls make it possible to reduce torque ripples and harmonics and to improve dynamic behavior in all speed ranges. The motor design is optimized due to lower vibrations and lower power losses such as harmonic losses in the rotor. Smooth waveforms allow an optimization of power elements and input filters. Overall, these improvements result in a reduction of system cost and better reliability.

Electrical motors can be divided into motors with a permanent magnet rotor (ac and dc motors) and motors with a coiled rotor. Figure 7 illustrates a detailed classification of the electrical motors. With the advent of new controllers, the tendency is to classify electrical motors under ac or dc according to the control strategy.

Due to its high reliability and high efficiency in a reduced volume, the *brushless motor* is actually the most

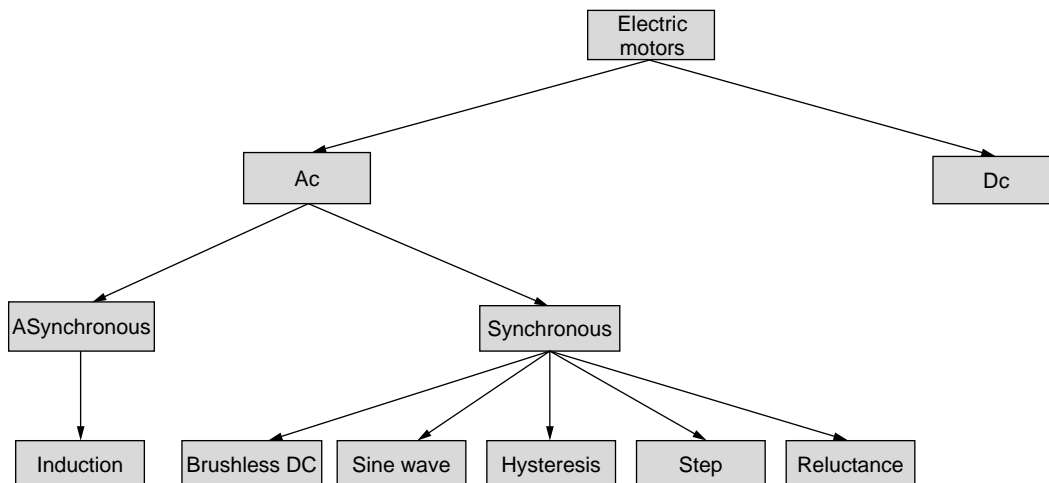

Figure 7. Classification of electric motors (42).

interesting motor for application to active vibration control (40). Although the brushless characteristic can be applied to several kinds of motors, the brushless dc motor is conventionally defined as a permanent magnet synchronous motor with a trapezoidal back EMF waveform shape, while the brushless ac motor is conventionally defined as a permanent magnet synchronous motor with a sinusoidal back EMF waveform shape. New brushless and coreless motors are now available which are very linear over a wide speed range (41). The brushless motor control consists of generating variable currents in the motor phases. The regulation of the current to a fixed 60° reference can be realized in two modes: *pulse width modulation* (PWM) or *hysteresis* mode. Shaft position sensors (incremental, Hall effect, resolvers) and current sensors are used for the control. Linear permanent magnet motors are also available that, in addition to the linear action, allow better magnetic dissipation in the core as it is distributed in space.

If volume is not a major concern, a second type of motor to be used in active vibration control is the *induction or ac motor* (41). As for the brushless motor, the performance of an ac motor is strongly dependent on its control. DSP controllers enable enhanced real time algorithms. There are several ways to control an induction motor in torque, speed, or position; they can be categorized in two groups: the *scalar* and the *vector control*. Scalar control means that variables are controlled only in magnitude, and the feedback and command signals are proportional to dc quantities. The vector control is referring to both the magnitude and phase of these variables. Pulse width modulation techniques are also used for the control of induction motors, and indirect current measurement (using a shunt or Hall effect sensor) is used as a feedback information for the controller.

The third electrical motor used for active vibration control is the *switched reluctance motor* (40). This motor is widely used mainly because of its simple mechanical construction and associated low cost and secondarily because of its efficiency, its torque/speed characteristic and its very low requirement for maintenance. This type of motor, however, requires a more complicated control strategy. The switched reluctance motor is a motor with salient poles on both the stator and the rotor. Only the stator carries windings. One stator phase consists of two series-connected windings on diametrically opposite poles. Torque is produced by the tendency of its movable part to move to a position where the inductance of the excited winding is maximized. There are two ways to control the switched reluctance motor in torque, speed and position. Torque can be controlled by the *current control method* or the *torque control method*. The pulse width modulation (PWM) strategy is used in both current and torque control approaches to drive each phase of the switched reluctance motor according to the controller signal.

Hydraulic and Pneumatic Actuators

Hydraulic and pneumatic actuators are good candidate technologies when low frequency, large force, and displacements are required. Hydraulic actuators consist of a hydraulic cylinder in which a piston is moved by the action of a high-pressure fluid. The main advantage of hydraulic

actuators is their large force and large displacement capability for a relatively small size. The disadvantages include the need for a hydraulic power supply (which can require space and generate noise), the high cost of servo-valves, the nonlinear relation between the servo-valve input voltage and the output force or displacement produced by the actuator, and the limited bandwidth of the actuator (0–150 Hz). Hydraulic actuators have been used in the design of active dynamic absorbers for ship structures (42,43).

The principle of operation of pneumatic actuators is very similar to hydraulic actuators, except that the hydraulic fluid is replaced by compressed air. Due to the higher compressibility of air, the bandwidth of pneumatic actuators is reduced (typically 0–10 Hz), which restricts the application to nonacoustic problems. Pneumatic actuators may be an attractive option when an existing air supply is already available

APPLICATIONS OF NOISE CONTROL IN SHIP STRUCTURES

A typical marine diesel engine mounted on a ship hull is schematically depicted in Fig. 1. The figure shows the various vibroacoustic paths through which the engine vibration is transmitted to the ship structure, and eventually radiated into seawater. In the figure the coupling between structural and acoustic energy is classified using the following symbols: AA: acoustic to acoustic coupling, SS: structural to structural coupling, AS: acoustic to structural coupling, SA: structural to acoustic coupling. The relative importance of energy coupling for radiation into seawater is illustrated by a number. As shown, there are five possible energy transmission paths, including (1) the mounting system, consisting of the engine cradle, isolation mounts, raft, and foundation; (2) the exhaust stack; (3) the fuel intake and cooling system; (4) the drive shaft; and (5) the airborne radiation of the engine. In this study, these five paths are grouped into four categories, corresponding to generic active control problems:

- Path 1: Active vibration isolation (mounting system).
- Path 2: Active control of noise in ducts and pipes (exhaust stack; fuel intake and cooling system).
- Path 3: Active control of vibration propagation in beam-type structures (drive shaft).
- Path 4: Active control of enclosed sound fields (airborne radiation of the engine).

Path 1: Active Vibration Isolation

Active vibration isolation involves the use of an active system to reduce the transmission of vibration from one body or structure to another (e.g., transmission of periodic vibration from a ship's engine to the ship's hull). Such an active isolation system will be used in practice to complement passive, elastomeric isolation mounts between the engine and supporting structure. An active isolation system is usually much more complex and expensive than its passive counterpart, but has the advantage of offering better low-frequency isolation performances, and can

be designed for a better static stability of the supported equipment.

The first class of system involves the control of system damping, and is often referred as a *semiactive* isolation system, Fig. 8(a). The damping modification is usually achieved by a hydraulic damper with varying orifice sizes. This system is often used for active suspensions in cars. Such a system involves control time constants significantly longer than the disturbance time constants, with the advantage of a simpler and less expensive implementation. However, low-frequency performance is much less than for fully active systems described in the following.

A second class of system involves an *active control actuator in parallel* with a passive system, with the actuator

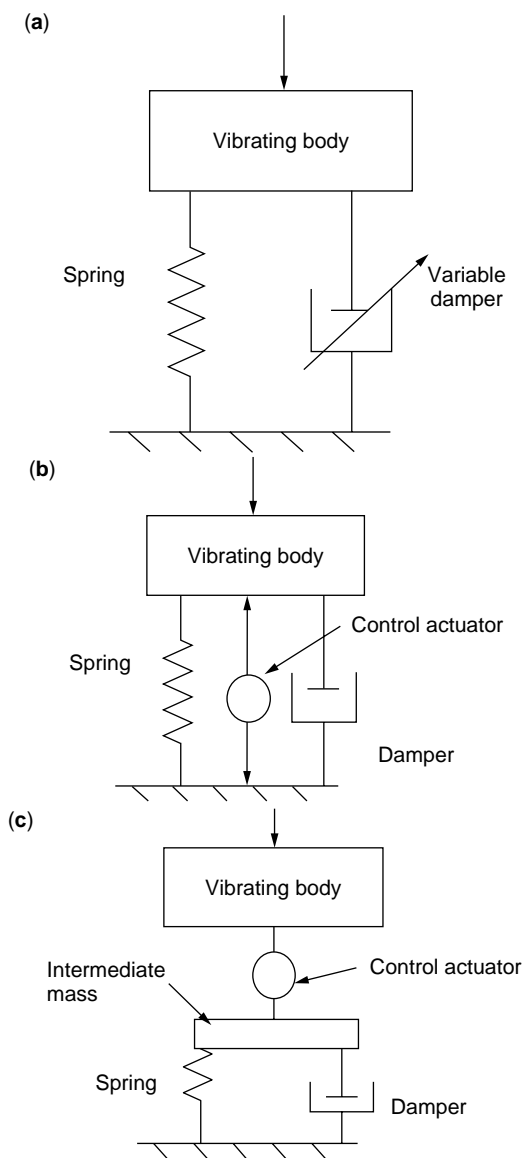

Figure 8. Active vibration isolation systems: (a) semiactive system with variable damper; (b) active system with control force applied to both vibrating body and base structure; (c) active system with control force in series with passive mount.

exerting a force on either the base structure or the rigid mass, Fig. 8(b). In this parallel configuration, the actuator is not required to withstand the weight of the machine; as compared to the configuration of Fig. 8(c), the required control force is smaller above the natural frequency of the system (44). The main disadvantage of this configuration is that at higher frequency (outside the frequency range where the actuator is effective), the actuator itself can become a transmission path. At low frequency, the large displacement/large force requirements for heavy structures preclude the use of piezoelectric, magnetostrictive actuators. Instead, hydraulic, pneumatic, or electromagnetic actuators (with their associated weight, space, and possibly fluid supplies problems) must be used. As far as practical application of active control is concerned, the use of an actuator in parallel with a passive isolation stage could have distinct advantages. In a given application, if an actuator can be found that provides a control force of the order of the primary force exciting the machine, then it may be possible to use of much higher mounted natural frequency associated with the passive isolation stage than would be otherwise possible. This in turn has advantages for the stability of the mounted machine.

A third configuration with the active system in series with the passive mount is shown on Fig. 8(c). Such a system has several advantages over the parallel configuration. The active system is now isolated from the dynamics of the receiving structure, which simplifies the control in the case of a flexible base structure, and the use of an intermediate mass creates a two-stage isolation system that offers better isolation performance in higher frequency.

Path 2: Active Control of Noise in Ducts and Pipes

The reduction of duct noise is the first-known application of active noise control. Active control systems for duct noise are now a mature technology, with several commercial systems available for ventilation systems, chimney stacks, or exhausts. All existing commercial systems are based on feedforward adaptive control systems. In the case of ducts containing air or a gas, loudspeakers are generally used as control sources, and microphones as error sensors.

Two important classes of systems must be distinguished, depending on the frequency and the cross-sectional dimension of the duct:

1. Systems for which only plane wave propagation exists in the duct. Such systems will necessitate a single-channel control system (one control source and one error sensor).
2. Systems for which higher-order acoustic modes propagate in the duct. Such systems will require a multi-channel control system.

The occurrence of higher-order modes in a duct depends on the value of the cut-on frequency. For a rectangular duct, the cut-on frequency is given by $f_c = c_0/2d$, where d is the largest cross-sectional dimension and c_0 is the speed of sound in free space. For a circular duct, $f_c = 0.586 c_0/d$, where d is the duct diameter. Higher-order modes will propagate at frequencies larger than f_c .

For active noise control (ANC) in the large duct, multichannel acoustical ANC systems are necessary, and M error sensors have to be used to control M modes for high-order propagation cases. The error sensors should not be located at the nodal lines (observability condition) (45). For a rectangular duct, the location of the error sensors is relatively simple because the nodal lines are fixed along the duct axis. However, in circular ducts, the location of the nodal lines changes along the duct axis, since the modes usually spin as a function of the frequency, temperature, and speed (46,47). Those variations of the nodal lines may explain why ANC of high-order modes in circular or irregular ducts appears to be difficult (48). Instead of using the modal approach (i.e., the shape of the modes to be controlled) to determine the error sensors location, an alternative strategy has recently been proposed by A. L'Espérance (49)—the error sensor plane concept. This concept calls for a quiet cross section to be created in the duct so that, based on the Huygen's principle, the noise from the primary source cannot propagate over this cross section. A multichannel ANC in a circular duct accords with this strategy (50).

The principles of active control of noise propagating in liquid-filled ducts are much the same as in air ducts (51). The higher speeds of sound in liquids means that plane wave propagation occurs in a larger frequency range than in air ducts. However, considerable care must be exercised to the possible transmission of energy via the flexible duct walls in this case, as a result of the strong coupling between the duct walls and the interior fluid.

Path 3: Active Control of Vibration Propagation in Beam-Type Structures

The active control of vibration in one-dimensional systems such as beams, rods, struts, and shafts can be approached from two different perspectives, depending on the description of the structural response. The response can be described in terms of vibration modes or in terms of waves propagating in the structure. The modal perspective is more appropriate to finite, or short, beams and to *global* reduction of the vibration. The description of the response in terms of structural waves is more appropriate to infinite, or long, beams and to reducing energy flow from one part of the beam to another (control of vibration transmission). The wave description is then more appropriate to the case of the transmission of vibration from a ship's engine via the drive shaft, since in this case the source of vibration is known and the objective is to block the vibration transmission along the shaft. The active control of vibration in beams is widely covered in the literature (21,44). The following presentation is mostly limited to feedforward control systems, since it is assumed that for the problem of vibration transmission along a marine drive shaft, an advanced signal correlated to the disturbance, or a measurement of the incoming disturbance, wave is possible.

Simultaneous Control of All Wave Types (Flexural, Longitudinal, Torsional). In a general adaptive feedforward controller used for the active control of multiple wave types

in a beam, sensor arrays (e.g., accelerometer arrays) are used to measure the different types of waves propagating upstream (detection array) or downstream (error array) of the control actuators, and an array of actuators is used to inject and control the various wave types in the beam (44).

Wave analyzers are necessary to extract the independent wave types (assumed uncoupled) from the sensor arrays, and wave synthesizers are necessary to generate the appropriate commands to the individual actuators. This approach has the advantage that independent control filters can be used to control the flexural, longitudinal, and torsional waves. However, it necessitates excellent phase matching of the sensors and a detailed knowledge of the structure in which the waves propagate. An experimental laboratory implementation of this approach has been conducted by (52), on a thin beam, for the control of two flexural wave components and one longitudinal wave using PZT actuators. Another, easier option avoids implementing wave analyzers and synthesizers by simply minimizing the sum of squared output of the error sensors to control the different wave types. This approach, however, requires a fully coupled multichannel control system. This approach has been tested for the control of two flexural waves and one longitudinal wave in a strut using three magnetostrictive actuators (53,54).

Control of Flexural Waves. The dispersive nature of flexural waves implies that a control force applied transversely to the beam generates propagative waves as well as evanescent waves localized close to the point of application of the force. If one transverse control force is applied at some location on the beam, it generates downstream and upstream propagating waves plus downstream and upstream evanescent waves. This actuator can minimize the total, transmitted downstream wave, but it generates a reflected wave toward the source and two evanescent components that may be undesirable. A total of four actuators will be necessary to control downstream and upstream, propagating, and evanescent components. Therefore, the control of flexural waves in beams will in general require *actuator arrays* (55). Combinations of *force* and *moment* actuators can also be used in the actuator array. The simplest feedforward control system uses only one control force and one error accelerometer, together with one reference accelerometer to measure the incoming wave. This system has been studied theoretically (56), and tested experimentally (57).

Physical limits of this system have been identified. The first limit is associated with the detection of the control actuator evanescent wave by the error sensor that puts a limit on the actuator-error sensor separation: in practice, the sensor should be at least 0.7λ from the control actuator (λ being the flexural wavelength). The second limit is related to the delay between detection and actuation that should be sufficient to allow the active control system to react at the control actuator location before the primary wave has propagated from the detection sensor to the control actuator. This puts a limit on the reference sensor-actuator separation, which depends on the characteristics of the control system.

Similarly to control actuator arrays, error sensor arrays need to be implemented for the control of flexural waves

Figure 9. Typical experimental setup for the control of active structural intensity.

to distinguish between the various propagating waves and evanescent waves at the error sensor locations. This is particularly needed if the error sensors must be located at a short distance from the control actuators. In this case, an array of four accelerometers can discriminate between the two propagating waves and the two evanescent waves at the location of the error sensor array, and extract the components that need to be reduced (e.g., the downstream propagating wave).

Other sensing strategies have also been suggested, such as measuring and minimizing the structural intensity due to flexural waves (58,59). Structural intensity can be measured in practice using an array of four or more closely spaced accelerometers, as presented in Fig. 9.

Practical Implementations. There are a limited number of practical implementations of these principles to large, machinery structures. Semiactive or active devices have been used to attenuate the transmission of *longitudinal* vibration on a large tie-rod structure (60). The tie-rod is similar to that found in marine machinery to maintain the alignment of a machinery raft. A tunable pneumatic vibration absorber was used as the semiactive device, and an electrodynamic shaker or a magnetostrictive actuator was used as the active device. A load cell was used as the error sensor, such that the force applied by the tie-rod to a receiving bulkhead was minimized.

The suppression of vibration that is generated on rotating machinery with an overhung rotor has been presented (61). In this case, the vibration of the rotor-shaft system is controlled by active bearings. The active bearings consist of a bearing housing supported elastically by rubber springs and controlled actively by electromagnetic actuators. These actuators are controlled by displacement sensors at the pedestal and/or the roller and can apply an electromagnetic force that suppresses any vibration of the roller. The active vibration control (AVC) of rotating machinery utilizing piezoelectric actuators was also investigated (62). The AVC is shown to significantly suppress vibration through two critical speeds of the shaft line.

Path 4: Active Control of Enclosed Sound Fields

There exists a vast body of literature on the subject of active control of enclosed sound fields. Only the previous work relevant to the problem of canceling the sound field radiated

by a ship engine in its enclosed space will be reviewed here. More comprehensive presentations of the generic problem can be found in (3,21). Active control of enclosed sound fields has found applications essentially for automobile interior noise (63,64) and for aircraft interior noise (65–67), leading in some cases to commercial products.

There are two main categories of active control systems related to enclosed sound field minimization:

- Active control of sound transmission through elastic structures into an enclosure.
- Active control of sound field into rigid enclosures.

Only the second category will be reviewed here. The active control of sound transmission has been investigated using essentially modal approaches (68,69). The same type of analytical approach based on modes of the acoustic enclosure can be used to investigate the active control of sound field into rigid enclosures. It should be mentioned, however, that finite element approaches have also been used to study the active control of sound field into enclosures of complex geometries (70,71). Additionally, the objective of the *active* control in an enclosure can be to minimize the sound field *globally*, or *locally*. Only the approaches directed toward global attenuation of the sound field are reviewed here. In this respect, some important physical aspects of this problem are discussed in the following. These physical aspects depend primarily on the modal density of the enclosure.

Enclosures with a Low Modal Density. For enclosures with a low modal density (i.e., a small enclosure, or at low frequency), the active control will usually consist of placing a series of control loudspeakers in the enclosure; the loudspeakers are driven to minimize the sound pressure measured by discrete error microphones. In the case of an enclosed acoustic space, the performance metrics for the control should be the acoustic potential energy integrated over the volume of the enclosure,

$$E_p = \frac{1}{4\rho_0 c_0^2} \int_V |p(\mathbf{r})|^2 dv,$$

where $p(\mathbf{r})$ is the local sound pressure, ρ_0 is the density of the acoustic medium, and c_0 is the speed of sound. The active control scheme should aim at reducing the acoustic potential energy as much as possible.

It has been shown that active control of sound fields in lightly damped enclosures is most effective at the resonance of the acoustic modes (72). In these instances, the problem is essentially the control of a single mode. Significant attenuation of the acoustic potential energy is obtained using a single control source and a single error microphone (provided that neither the control source nor the error microphone is located on a nodal surface of the acoustic mode). For a multiple-mode (off-resonance) response of the cavity, the number of control sources and error microphones should be increased. However, the potential for attenuation is never as large as at a resonance frequency.

The number and placement of control sources and error sensors are critical for multiple-mode control. The corresponding optimization problem is nonlinear and usually involves many local minima. Optimization processes, such as multiple regression (21) or genetic algorithms (73), are used. As a general rule is that the number and locations of the control sources should be such that the secondary sound field matches as closely as possible the primary sound field in the enclosure.

Enclosures with a High Modal Density. As the frequency increases or the enclosure becomes larger, global attenuation of the sound field becomes more difficult to achieve using an active control system. To quantify these limitations, there are some approximate formulas, which are summarized here. These formulas are approximate, but they give useful expected performance of an active control system in a high modal density enclosure.

First, assuming a single primary point source and a single secondary point source in the enclosure, it is possible to derive the ratio of the minimized potential energy (after control) to the original potential energy (before control), (74):

$$\frac{E_{p,\min}}{E_{p,0}} = 1 - \left[1 + \frac{\pi}{2} M(\omega) \right]^{-2},$$

where $M(\omega)$ is the modal overlap of the cavity, which quantifies the likely number of resonance frequencies of other modes lying within the 3 dB bandwidth of a given modal resonance. For a rigid rectangular enclosure and for oblique acoustic modes, namely three-dimensional modes, such as the (1,1,1) mode,

$$M(\omega) = \frac{\zeta \omega^3 V}{\pi c_0^3},$$

where ζ is the damping ratio in the enclosure (assumed identical for all acoustic modes), ω is the angular frequency of the sound field, and V is volume of the enclosure.

If the modal density is low (at low frequency),

$$\frac{E_{p,\min}}{E_{p,0}} \approx \pi M(\omega),$$

which means that the achievable attenuation is dictated by the modal overlap (and hence the modal density and damping of the enclosure).

If the modal density is large (at high frequency),

$$\frac{E_{p,\min}}{E_{p,0}} \approx 1,$$

which means that no attenuation can be obtained after control. Another expression can be derived from the asymptotic expression of modal overlap in high frequency (75),

$$\frac{E_{p,\min}}{E_{p,0}} = 1 - \sin^2 kd,$$

where k is the acoustic wave number and d is the separation between the primary and control sources. Thus, as the control source becomes remote from the primary source, such that $kd \geq \pi$, any global attenuation of the sound field becomes impossible. This provides an explicit analytical demonstration that the global control of enclosed sound fields of high modal density is only possible with closely spaced compact noise sources. In other words, assuming an extended primary source such as a ship engine, the only viable solution in this case is to distribute control loudspeakers around the engine and in the close vicinity of it (within a fraction of the acoustic wavelength).

Advanced Sensing Strategies. Recently, alternatives to sensing and minimizing squared sound pressure have been suggested in active control of enclosed spaces. Sensing strategies based on total acoustic energy density minimization instead of sound pressure minimization have been suggested (76,77). The advantage of sensing the total energy density is that the control is less sensitive to the sensor locations, and in general, a superior attenuation is obtained. The energy density can be measured using combinations of microphones (2 to 6); in this case, finite differences between individual microphones are applied to obtain approximate measurements of the pressure gradient in several directions. Precise measurements of the pressure gradient requires an excellent phase matching of the individual microphones, which can result in more expensive microphones. Associated adaptation algorithms for the minimization of energy-based quantities have been derived (78).

RECOMMENDATIONS ON SENSORS AND ACTUATORS FOR ANVC OF MARINE STRUCTURES

Steps in Design of Active Control Systems in Marine Structures

The choice of the sensors and actuators in an active control system will depend on factors such as the frequency of the disturbance, operating environment, cost, expected performance, and magnitude of the vibratory or acoustic disturbance to be controlled along the various vibroacoustic paths. Figure 10 suggests a systematic approach that proceeds through the various steps of the active control system design. As a general recommendation, the first (and perhaps most important) phase of the design of every active control system is to acquire a thorough understanding of the vibroacoustic behavior of the system on which active control is to be applied. This involves carefully identifying and ranking the various paths along which vibroacoustic energy flows. This may imply addressing questions such as the transmission of moments or in-plane forces through the engine mounting, or the relative contribution of fluid-borne and structure-borne energy along pipes. This early phase is crucial in determining the active control strategy to be implemented. A number of experimental techniques and numerical simulation tools can be used to estimate the relative contribution of the various paths at a given receiving point (e.g., in water). Based on some contractors' previous experiences, a major transmission path appears to be the engine-mounting system.

Figure 10. Suggested design steps of an active control system.

The second phase will determine the *type, number, and locations of the control actuators*. When global control is desirable (e.g., when attenuation of the sound field is desired at all positions in water), these parameters are determined by the requirement that the sound field generated by the control actuators should spatially match the primary sound field. The type of control actuators to be used will be based primarily on the frequency of the disturbance and the magnitude of the disturbance at the actuator location (for simplicity, the control actuators need to generate a secondary field with a magnitude equal to the disturbance at the actuator location). Once the type, number, and locations of the control actuators are known, extensive transfer function measurements need to be taken between individual actuators and field points (vibratory or acoustic), with the primary source turned off. Since this may involve a considerable experimental task, numerical simulations can be of a great help here.

The third phase will address the error sensors. Again, if global control is desirable, the *type, number, and locations of the error sensors* are dictated by the requirement that if the control actuators are driven to minimize the signal at the error sensors, then the resulting sound field is globally reduced. The measured transfer functions between individual actuators at field points and the magnitude of the primary disturbance at these field points are used, in conjunction with classical exact quadratic optimization

techniques, to calculate the optimal control variables (i.e., the required inputs of the control actuators) that minimize the error signals for a given error sensor arrangement. The final phase will be to test the active control with a real controller.

Recommended Sensor and Actuator Technologies for Various Ship Noise Paths

Path 1: Active Vibration Isolation. In selecting sensors and actuators for active vibration isolation of engine noise, due consideration has to be given to the size and weight of the structure (engine) being isolated. Since the engine is a heavy structure weighing over 6000 kg, it is necessary that the actuators are capable of delivering very high control forces. In addition, the nature of the noise through this path is nonacoustic, and hence nonacoustic sensors and actuators have to be used. Based on these considerations, the recommended sensors and actuators are (1) accelerometers and force transducers for sensing and (2) hydraulic and electrodynamic actuators for actuation. The recommendations are summarized in Table 3. For increased efficiency, the control systems must be designed to provide control forces in translational and rotational directions, since engine vibrations could take place in all directions. Furthermore, the active control systems should be used in conjunction with passive control systems, to reduce cost as well to provide fail-safe designs.

Path 2: Active Control of Noise in Ducts and Pipes. The feedforward algorithm has been recommended for the control of noise associated with a marine diesel engine where a reference signal is accessible (4). For ducts, generally associated with large cross-sectional dimensions, higher-order modes are more likely to exist, requiring a large number of sensors and actuators with an appropriate positioning strategy. For pipes, generally associated with small cross-sectional dimensions, it is expected that only plane wave propagation will exist, thereby limiting the number of elements needed to one sensor and one actuator. The following sensing configurations are possible: microphones, piezoelectric sensors, or accelerometers. For actuation, loudspeakers and inertial actuators are recommended.

Path 3: Active Control of Vibration Propagation in Beam-Type Structures. Feedforward control was recommended for the vibration control of a propeller shaft (4). The configuration of sensors and actuators to be used will depend on the excitation source and on the modal behavior of the shaft. For modal control, the sensors and actuators can be located either on the shaft itself or connected to it by a stationary mechanical link, such as by a bearing mounted on the shaft. Potential mounted actuators include curved piezoelectric actuators (PZT) and magnetostrictive actuators. For wave transmission control, sensors and actuators arrays are required to measure the downstream propagating and evanescent waves and to inject the control waves in the structure.

Mounted sensors to be used include piezoelectric (PVDF) sensors to measure the strain and accelerometers,

if the rotation speed permits, for acceleration measurement. The mounted actuators include piezoelectric (PZT) actuators to induce strain in the structure. For robustness, it is recommended that the actuators be combined with passive control elements such as a viscoelastic layer bonded to the shaft.

Path 4: Active Control of Radiated Sound Fields. There are two types of radiated noise to be controlled for ship structures. These are the airborne engine noise into an enclosure, and the noise radiated by the noise into the sea. As stated in (4) both cases require the use of global control techniques that involve multiple input and multiple

output transducers. Control of radiated noise can be achieved either by active noise cancellation (ANC) or by active structural acoustic control (ASAC) techniques. For active cancellation, the following sensors and actuators are recommended: (1) combination microphones and accelerators as sensors and (2) loudspeakers as actuators. For active structural acoustic control the following sensors and actuators are recommended: (1) piezoelectric sensors (shaped or not) and accelerometers as sensors, and (2) piezoelectric and magnetostrictive materials as actuators.

SUMMARY AND CONCLUSIONS

Among the wide range of sensor and actuator materials that could be used for active noise and vibration control in ship structures are piezoelectric and electrostrictive materials magnetostrictive materials, shape-memory alloys, optical fibers, electrorheological and magnetoheological fluids, microphones, loudspeakers, electrodynamic actuators, and hydraulic and pneumatic actuators. In making the selection, due consideration must be given to factors such as cost, frequency of the disturbance, operating (marine) environment, experience in other applications, ease of implementation, and the expected performance. In general, the following recommendations are made:

1. Nonacoustic sensors and actuators (e.g., accelerometers, force transducers, hydraulic actuators, piezoelectric materials, and electrodynamic actuators) are best for nonacoustic paths, namely for the engine-mounting system, the drive shafts, and mechanical couplings.
2. Acoustic sensors and actuators (e.g., microphones and loudspeakers) are best for acoustic paths, namely for the exhaust stacks and piping systems, and the air-borne noise.

It was also recommended that the active control strategies be combined with passive treatments whenever possible, to increase the robustness of the control system and to provide a fail-safe design.

VIBRATIONAL ANALYSIS

DAVE S. STEINBERG
Westlake Village, CA

INTRODUCTION

Vibration is present almost everywhere we travel in modern society. Vibrationally induced failures are very common in products such as television sets and computers that are shipped by trains and trucks. Vibrational failure in a television set may be just an inconvenience. However, vibrational failure in a large passenger airplane can lead to many deaths. Methods of vibrational analysis are available that are accurate and can reveal weak structural areas. Steps can then be taken either to repair or replace critical items. Vibrational analysis is a combination of science and art. The science uses sophisticated computers extensively to solve large complex problems. This method requires extensive training and often takes a long time to reach a satisfactory solution. The art uses approximations, short cuts, and test data to reduce the time needed to reach a

satisfactory solution. The approximations and short cuts can sharply reduce the time required for a solution, but it also reduces the accuracy of the analysis. Vibrational analysis can be used to make some materials work smarter by making small changes in their physical properties. These changes can often increase the fatigue life of critical structural members without a significant increase in the size, weight, cost, or impact on production and delivery schedules.

VIBRATIONAL REPRESENTATION

In a broad sense, vibration means an oscillating motion, where something moves back and forth. If the motion repeats itself, it is called periodic. If continuous motion never repeats itself, it is called random motion. Simple harmonic motion is the simplest form of periodic motion, and it is typically represented by a sine wave, as shown in Fig. 1. The reciprocal of the period is known as the frequency, and it is measured in cycles per second, or hertz (Hz). The maximum displacement is called the amplitude of the vibration.

DEGREES OF FREEDOM

A coordinate system is usually used to locate the positions of various elements in a system. When only one element is involved, it is restricted to moving along only one axis, and only one dimension is required to locate the position of the element at any instant, then it is called a single-degree-of-freedom system. The same is true for a torsional system. When one element is restricted to rotating about one axis so that only one dimension is required to locate the position of the element at any instant, it is a single-degree-of-freedom system. Two degrees of freedom requires two coordinates to locate the positions of the elements, and so on.

A single rigid body is usually considered to have six degrees of freedom, translation along each of the three orthogonal x , y , and z axes and rotation about each of the same three axes. Real structures are usually considered to have an infinite number of degrees of freedom.

VIBRATIONS OF SIMPLE STRUCTURES

The natural frequency (often called the resonant frequency) of a simple single-degree-of-freedom system can

Figure 1. Simple harmonic motion: a sine wave.

Figure 2. Single-degree-of-freedom spring-mass system.

often be obtained from the strain energy and the kinetic energy of the system. Consider the single spring and mass system shown in Fig. 2. When there is no damping in the system, then no energy is lost, and the strain energy must be equal to the kinetic energy. This results in the natural frequency equation (1),

$$f_n = \frac{1}{2\pi} \sqrt{\frac{g}{Y_{st}}} \quad (\text{Hz}), \quad (1)$$

where

$g = 9.80 \text{ m/s}^2$ (386 in/s^2), the acceleration of gravity and Y_{st} in meters (inch) is the static displacement.

Sample Problem: Natural Frequency of a Simple Structure

When the static displacement of a structure $Y_{st} = 1.27 \times 10^{-5} \text{ m}$ (0.00050 in), its natural frequency is 140 Hz.

The natural frequency is important because it is often considered the heart of a vibrating system. It influences the number of fatigue cycles and the displacement, which affect the fatigue life of a system. It also influences the damping, which affects the dynamic acceleration Q level, and the stress level, which also affects the fatigue life.

NATURAL FREQUENCIES OF UNIFORM BEAM STRUCTURES

Natural frequencies of uniform beam structures can be determined by equating the strain energy to the kinetic energy without damping. This method of analysis leads to simple solutions and very little error because beam types of structures normally have very little damping. The resulting equations for natural frequency apply to uniform beams that are forced to bend only in the vertical axis without bending in the horizontal axis and without torsion or twisting. The beam equation is (1)

$$f_n = \frac{a}{2\pi} \sqrt{\frac{EIg}{WL^3}} \quad (\text{Hz}), \quad (2)$$

where

- $a = 3.52$ for a cantilevered beam,
- $a = \pi^2 = 9.87$ for a beam that is supported (hinged) at each end,
- $a = 22.4$ for a beam that is clamped (fixed) at both ends,
- E in newtons (N) m^2 (lb/s in^2) is the modulus of elasticity for beam material,
- I in m^4 (in^4) is the area moment of inertia for a beam cross section,
- $g = 9.80 \text{ m/s}^2$ (386 in/s^2), the acceleration of gravity,
- W in Ns (N) (lb) is the total weight of the beam, and
- L in m (in.) is the length of the beam between supports.

Figure 3. Uniform beam simply supported at each end.

Sample Problem: Natural Frequency of a Simply Supported Uniform Beam

For example, consider the simply supported (hinged) aluminum beam shown in Fig. 3, where $E = 6.894 \times 10^{10} \text{ N/m}^2$ ($10 \times 10^6 \text{ lb/in}^2$), $L = 0.254 \text{ m}$ (10.0 in), $I = 6.937 \times 10^{-8} \text{ m}^4$ (0.1667 in^4), and $W = 8.896 \text{ N}$ (2.0 lb). The resulting natural frequency is 890 Hz.

NATURAL FREQUENCIES OF UNIFORM PLATES AND CIRCUIT BOARDS

The natural frequencies of different types of flat, uniform plates that have different types of supports can often be obtained by using trigonometric or polynomial series (1). Again, when damping is ignored, the strain energy can be equated to the kinetic energy of the bending plate to obtain the natural frequency. A printed circuit board (PCB) that supports and electrically interconnects various electronic components can be analyzed as a flat rectangular plate, often simply supported (hinged) on all four sides, that has a uniformly distributed load across its surface. The natural frequency for this type of installation is (2).

$$f_n = \frac{\pi}{2} \left(\frac{D}{\rho}\right)^{1/2} \left(\frac{m^2}{a^2} + \frac{n^2}{b^2}\right) (\text{Hz}), \quad (3)$$

where

- E in newtons/ m^2 (lbs/in^2) is the modulus of elasticity for plate material,
- h in m (in) is the plate thickness,
- μ is Poisson's ratio, dimensionless,
- $D = \frac{Eh^3}{12(1-\mu^2)}$ N m (lb in), the plate bending stiffness factor, (4)
- $\rho = \frac{W}{gab}$ Ns^2/m^3 ($\text{lb s}^2/\text{in}^3$), the mass per unit area, (5)
- $g = 9.80 \text{ m/s}^2$ (386 in/s^2), the acceleration of gravity,
- W in newtons (lb), is the total weight of the PCB,
- a in m (in) is the length of the plate,
- b in m (in) is the width of the plate, and
- m and n are integers: first harmonic $m = 1, n = 1$;
- second harmonic $m = 2, n = 1$;
- third harmonic $m = 1, n = 2$; fourth harmonic $m = 2, n = 2$.

Figure 4. Uniform flat plate simply supported on four sides.

Sample Problem: Natural Frequency of a Rectangular PCB (see Fig. 4).

Consider a flat rectangular epoxy fiberglass PCB, supported (hinged) on four sides, where $E = 1.379 \times 10^{10}$ N/s m^2 , (2.0×10^6 lb/in 2), $h = 0.00157$ m (0.062 in), $\mu = 0.12$ dimensionless, $D = 4.53$ N (40.1 lb in), $W = 4.448$ N (1.0 lb), $a = 0.203$ m (8.0 in), $b = 0.178$ m (7.0 in), $\rho = 12.56$ Ns $^2/m^3$ (0.463×10^{-4} lb s $^2/in^3$). The resulting natural frequency for the first harmonic ($m = 1, n = 1$) is 52.6 Hz.

METHODS OF VIBRATIONAL ANALYSIS

Hand calculations are still being used extensively for simple sinusoidal and random vibrational analyses in small companies due to the high costs of the computers, the specialized computer software, and the skilled personnel to operate the computers. Many reference books are available that show how to perform simplified vibrational analyses on different types of simple structures. However, when large complex structures are involved, hand calculations are not adequate to ensure reasonable accuracy. Small companies often subcontract the work to outside consulting organizations that specialize in these areas. Sometimes it can be cheaper, faster, and more accurate to build a model of the structure, so it can be examined in a vibrational test laboratory.

Most large companies rely extensively on various types of computers and specially formulated finite element modeling (FEM) software programs for vibrational analyses. Their computers are usually networked together, so each has access to the wide variety of software analytical programs available on the network. The new desktop personal computers (PC) are very popular for vibrational analyses using FEM. They are more powerful and faster than the large main frame computers of a few years ago.

PROBLEMS OF VIBRATIONAL ANALYSIS

Almost all computers and computer software FEM programs for vibrational analysis agree within about 2% when

they are used to determine eigenvalues (resonant frequencies) and eigenvectors (mode shapes) for many types of complex structures. However, sample problems solved by using different FEM software programs have shown significant variations in their stress values. The stress values from four different FEM programs had a total variation of about 60%. This was 30% above the average stress value of the four programs and 30% below the average value for similar models of the same structure, subjected to the same type of vibrational excitation. Different computer FEM programs typically use different algorithms to define the building blocks for their various beam, plate, and brick elements. These algorithmic variations probably cause the variations in the stress values. Because the fatigue life of a structure is closely related to its stress value, significant variations in the calculated stress levels can result in dramatic changes in the calculated fatigue life of a structure. For example, the results of this investigation showed that the fatigue life at the critical point in the structure can be expected to vary across a wide range because of the variations in the calculated stress values. The fatigue life in the lead wires of PCB electronic component parts can be as much as five times greater than the average calculated fatigue life, or it can be as little as one-fifth of the average calculated fatigue life. [See Ref. 5, Chap. 12, Figs. 12.1–12.19 for more detailed information on finite element modeling.]

The results shown before may vary substantially. Only four different FEM software programs were involved in this investigation. At least several dozen new software programs are available now. When the different modeling techniques of different computer analysts are considered, these factors are expected to have a significant impact on the computer calculated stress values and the resulting calculated fatigue life.

PROBLEMS OF MATERIAL PROPERTIES

Material properties are often difficult to evaluate for vibrational environments. The life of any structure excited by vibration depends on the fatigue properties of the most critical materials used in fabricating and assembling the structure. When structural elements are forced to bend and twist back and forth, perhaps millions of times in severe vibrational environments, three very important factors have to be defined:

1. the very basic fatigue properties of the materials used in the structure
2. The manufacturing tolerances that will affect the physical dimensions of the parts
3. stress concentrations due to holes, notches, small radii, and rapid sectional changes.

First, consider the basic fatigue properties of the materials in the structure. Test data have shown that there are significant variations in the fatigue life of virtually identical parts that are machined to very close tolerances from the same forging, as shown in Fig. 5. These test data are plotted on log–log curves of stress (S) against the number of cycles (N) to failure. Only one average straight-line

Figure 5. S - N fatigue curve showing large variations in the life test data.

usually represents the fatigue life properties of a material (1,3-5). When all of the failure test data points for all of the test samples are plotted, a wide variation in the fatigue life is revealed. Because these are log-log plots, the spread in the possible variation in fatigue life of virtually identical parts can be very great, sometimes reaching values of 10 to 1. Engineers involved in vibrational and fatigue life analysis do not like to reveal this type of data to upper management personnel. Personal experience with nontechnical upper management people is that they often expect mechanical designers and analysts to predict the fatigue life of their structures to within plus and minus 20%. This is an almost impossible task, when all of the possible variations are considered.

To compensate for these large variations in fatigue life of virtually identical structural elements, safety factors (sometimes called factors of ignorance) must be used when these structures are being designed and analyzed. Building models for vibrational life testing in a laboratory can be a great help in estimating the fatigue life of a structure. However, if no tests are run or if the number of samples tested is low, there is always the danger of erratic bursts of high failure rates in the production units because of the large scatter associated with fatigue.

Next, consider the effects of manufacturing tolerances on the physical dimensions of the structural elements in an assembly. Mass-produced products always show some variations in the physical dimensions of what appear to be identical parts. Even die cast parts that are made from the same mold have slightly different physical dimensions. Some manufactured devices, like the automatic transmission in an automobile, can have many precision gears, ground to very close tolerances. Holding very tight manufacturing tolerances can be very expensive. Therefore, looser tolerances are used in production parts that do not require tight tolerances for precision assembly work because they this reduce costs. When manufactured parts that have loose tolerances are exposed to severe vibration, the failure rates often go up and down erratically. Changes in the physical dimensions of load-carrying structural members can alter the load path through the structure, which can change the dynamic loads and stresses in it. It is too expensive to keep

track of manufactured parts that have extremes in their dimensional tolerances. These parts can be anywhere in large production programs. This means that failures which are difficult to predict and to control, may occur randomly in harsh environments.

To reduce costs, for example, the electronics industry tends to use very loose tolerances in the dimensions that control the external physical sizes of the length, width, and thickness of their printed circuit boards (PCBs) and electronic component parts. These large variations in tolerance of these parts further increase the difficulty in trying to predict the fatigue life accurately of electronic assemblies that are exposed to different vibrational environments.

RELATION OF DISPLACEMENT TO ACCELERATION AND FREQUENCY

Vibrational displacements are often very small, so they are difficult to observe during vibrational tests. Because these displacements are small, it does not mean that the resulting stresses are also small. Vibrational environments usually impose alternating displacements and alternating stresses on various structural load-carrying elements within a system. If the vibrating system experiences many thousands of stress reversals, fatigue failures can occur in critical structural members, even at relatively low displacements and stress levels. This is the nature of fatigue failures that occur at relatively low stress levels near small holes, small notches, and sharp bends. These geometric shapes are known as stress concentration factors, which can increase peak stress levels in these areas by a factor of 3 or 4 or more (4).

When vibrational tests are run in a laboratory, the normal procedure is to use small accelerometers to monitor the resulting acceleration values in different parts of the structure. When an electrodynamic shaker is used to generate a sinusoidal wave for the vibrational test, the electronic control system will show the frequency of the imposed wave in cycles per second, or hertz (Hz). With this type of setup, the test engineer will know the acceleration level and the frequency at any instant. This information is often incomplete without the resulting displacement at any instant. The resulting displacement at any instant can be obtained by considering a rotating vector that generates a sinusoidal wave based on the full relationship (1),

$$Y = Y_0 \sin \Omega t, \quad (6)$$

where

Y is the displacement at any time,

Y_0 is the maximum single amplitude displacement from zero to peak, and

$\Omega = 2\pi(f)$ rad/s, the frequency.

The acceleration a can be obtained from the second derivative of the displacement with respect to time from the preceding equation. The maximum acceleration occurs when the sine function is one. It is convenient to represent

the acceleration in terms of gravity units G :

$$G = \frac{a}{g} \quad (\text{gravity units, dimensionless}), \quad (7)$$

where

a in m/s^2 (in/s^2) is the acceleration level and
 $g = 9.80 \text{ m/s}^2$ (386 in/s^2), the acceleration of gravity.

The final results show the displacement Y_0 in terms of the frequency f in Hz and the number of dimensionless gravity units G :

$$Y_0 = \frac{AG}{f^2} \quad (\text{single amplitude displacement}), \quad (8)$$

where

$A = 0.248$ for meters displacement (9.8 for inch displacement)

G is the acceleration, in gravity units, dimensionless (same in English units), and

f is the frequency in cycles/s (Hz) (same in English units).

Sample Problem: Finding the Displacement from the Frequency and the G Level

For example, when the acceleration G level is 3.0 dimensionless gravity units and the frequency is 120 Hz, the single amplitude displacement is 0.0000517 m (0.00204 in).

This equation is probably the most important relationship in the entire field of dynamics. It shows that when any two of the parameters of Y_0 , G or f , are known, then the third parameter is automatically known. This equation can be used for sine vibration, random vibration, shock, and acoustics (1).

EFFECTS OF VIBRATION ON STRUCTURES

Vibrational environments can dramatically magnify the dynamic forces and stresses in different types of structures, when the structural natural frequencies are excited. Forces and stresses can be magnified and amplified by factors of 10, 30, and even 100 in many different types of structures for different types of vibrational excitation. The magnitude of the magnification, called the transmissibility Q , often depends on the amount of damping in the vibrating system. Figure 6 shows damping for a single-degree-of-freedom system. There are very few single-degree-of-freedom systems in the real world. For example, consider a two-degree-of-freedom system for an electronic assembly where the chassis is mass 1. The plug-in PCBs are attached to the chassis so they are mass 2. The response of mass 1 will be the input to mass 2. Testing experience, including different damping methods, has shown that the transmissibility Q of PCBs as mass 2 will depend far more on the dynamic coupling phase relation and frequency ratio between mass 1 and mass 2 than the damping in either mass 1 or mass 2 because the transmissibility Q 's between masses 1 and 2 do not add, they multiply.

Figure 6. Effects of damping on the transmissibility Q plots.

The Q of a system is defined as the ratio of the output (or response of the system) divided by the input. The output and the input are usually defined in terms of the displacements, or the acceleration values. If the damping in a simple system is zero, the vibration theory states that the value of the transmissibility Q will be infinite. If the transmissibility Q is infinite, the resulting dynamic forces and stresses will also be infinite. However, because all real systems have some damping, Q can never be infinite. However, in lightly damped systems, Q can be very high. A high Q will result in high forces, displacements, and stresses, which can sharply reduce the fatigue life of the structure.

ESTIMATING THE TRANSMISSIBILITY Q IN DIFFERENT STRUCTURES

The transmissibility Q is strongly influenced by the damping in a vibrating structure. One form of damping is the conversion of kinetic energy into heat. This can be shown by rapidly bending a metal paper clip back and forth about 20 times through a large angle. Immediately place your finger on the paper clip in the bending area. This area will be quite warm. It may even be hot. The strain energy of bending has been converted into heat energy, which cannot be converted back into strain energy. It is lost energy. When heat energy is lost, it means there is also a loss of kinetic energy. Therefore, when damping is increased in a vibrating system, there is less energy available to convert into kinetic energy. Less kinetic energy means that there is less energy available to excite the structure at its natural frequency, so that the transmissibility Q is decreased. Conversely, when there is a decrease in the damping, this makes more kinetic energy available to excite the structure, so the transmissibility Q is increased.

In general, simple systems that have only a few structural elements have less damping than more complex systems that have many structural elements, when both systems are subjected to the same vibrational environment. Bolted joints usually have a lot of friction and damping at the bolted interfaces in vibrational environments, so structures that have many bolted joints usually have high damping. Therefore, a simple beam type of structure usually has less damping than a more complex plate type structure. Then, a beam structure should have a higher transmissibility Q than a plate structure in the same vibrational environment. The same thinking can be applied to a more complex box type of structure that has removable bolted covers to provide access to internal subassemblies. The box type of structure should have more damping than the plate structure for similar vibrational exposure because the box structure is much more complex than a plate structure. This means that the box structure should have a lower transmissibility Q than the plate structure for similar vibrational exposure. Extensive vibrational test data shows that this is the natural trend for damping in different types of structures.

Higher dynamic forces in a structure typically result in higher dynamic stresses and higher dynamic displacements. This results in higher damping, which reduces the dynamic transmissibility Q for that system. Therefore, higher acceleration G levels can be expected to result in lower transmissibility Q values.

Higher natural frequencies result in lower dynamic displacements, when the acceleration G level is held constant, as shown in Eq. (8). Lower displacements mean lower stresses. Lower stresses reduce damping. Lower damping increases the transmissibility Q value. Therefore, higher frequencies, at the same G level, increase the value of Q .

Vibrational test data from different types of structures can be used to estimate the transmissibility Q values expected for different types of common systems at the start of a preliminary vibrational analysis. The three most common types of structures in the order of their complexity are beams, plates, and enclosed boxes that have bolted covers. The approximate transmissibility Q for these three types of structures is

$$Q = J \left[\frac{f_n}{(G_{\text{in}})^{0.6}} \right]^{0.76}, \quad (9)$$

where

$J = 1.0$ for a beam type of structure (cantilever or restrained at each end),

$J = 0.50$ for a plate type of structure (supported around the perimeter),

$J = 0.25$ for a box type of structure,

f_n in Hz is the natural frequency of the structure, and G_{in} is the input acceleration G level in dimensionless gravity units.

Sample Problem: Finding the Approximate Q for Beams and Plates

For example, consider a beam structure whose natural frequency is 300 Hz and input acceleration level is 0.25 G in a sine vibrational test. The expected transmissibility Q is about 144. Now increase the input acceleration level to 5.0 G . The expected transmissibility Q will now drop to about 37. Next, consider the plate structure for the same conditions. For a 0.25 G input, the Q is about 72. For a 5.0 G input, the Q is about 18.3. Now take the square root of the 300-Hz resonant frequency for the plate structure, which is 17.3. This shows that a good approximation for the plate Q (frequently used for PCBs) is the square root of the natural frequency, when the input level is about 5 G (1,2);

$$\text{Good PCB approximation of } Q = \sqrt{f_n}. \quad (9a)$$

This demonstration should be taken as a warning. Performing vibrational tests at very low input acceleration G levels will result in very high transmissibility Q values. Very low input G levels are often used to prevent damage to prototype PCBs. These types of tests are not valid for evaluating PCBs that must operate at much higher G levels. Vibrational tests should be run on prototypes using the correct input G levels to verify the correct dynamic characteristics of the test specimen and future production models.

METHODS FOR EVALUATING VIBRATIONAL FAILURES

Vibration can cause failures in many different types of structures ranging from earthquakes and airplanes to electric knives and washing machines. Vibrational failures are often experienced during vibrational tests to evaluate the reliability of a product. Sinusoidal vibration is very useful in tests to diagnose the cause of specific structural vibrational failures, to determine the transmissibility Q of a structure, and to find the fatigue life of different types of structures. A very effective device that is often used in sinusoidal vibrational tests is the strobe light. This often allows the observer to see just how structures bend and twist during resonance. This information can be critical in determining why and where a structure will fail. Steps can then be taken to modify the structure to prevent future failures.

Finite element modeling (FEM) programs are available for use with new high speed small PCs that can generate models of very complex structural systems. When the computer models are generated by skilled engineers, the dynamic results from the model are often very similar to the actual vibrational test results. The problems most often encountered in these areas are the types of models that are generated by individuals who are familiar with FEM but do not have any real testing experience. The resulting structural models may look good, but their vibrational response will often have gross errors due to improper boundary conditions and to improper damping values. These parameters can be obtained only from extensive vibrational testing experience (1).

Vibrational failures are often difficult to trace. Sometimes the failures result from poor design, poor maintenance, or poor manufacturing processes. Very often the failures are a combination of all three. These failures are usually difficult to trace because it is often very difficult to get the information necessary to implement any corrective action.

DETERMINING DYNAMIC FORCES AND STRESSES IN STRUCTURES DUE TO SINE VIBRATION

Dynamic forces in a structure can be obtained from Newton's equation where force F is equal to mass m times acceleration a . When weight W is used with the acceleration of gravity g , and structural accelerations are in terms of dimensionless gravity units G , the following relationships are convenient:

$$F = ma, \quad (10)$$

where

$$m = \frac{W}{g}$$

and

$$G = \frac{a}{g}.$$

Substitute in this equation to obtain the dynamic force F (1).

Then,

$$F = WG. \quad (11)$$

When the dynamic transmissibility Q is included in this equation and the input acceleration level is shown in dimensionless gravity units G_{in} , then the maximum output (or response F_{out}) dynamic force due to sine vibration is obtained:

$$F_{out} = WG_{in}Q. \quad (12)$$

Sample Problem: Finding the Natural Frequency, Transmissibility Q , Dynamic Force, Displacement, and Stress in a Beam Excited by Sine Vibration

Consider the simply supported (hinged) weightless aluminum beam, shown in Fig. 7, that has a modulus of elasticity E of 7.238×10^{10} Nm² (10.5×10^6 lb/in²), a concentrated load W of 8.896 N (2.0 lb) acting at the center of the beam, a length L of 0.203 m (8.0 in), a cross-sectional width of 0.0305 m (1.2 in), a thickness of 0.0127 m (0.50 in), and an area moment of inertia of 5.206×10^{-9} m⁴ (0.0125 in⁴). Find the natural frequency, the transmissibility Q , the maximum expected dynamic force, the dynamic displacement, and the maximum expected bending stress in the beam due to a 5- G sine vibrational input.

Figure 7. Simply supported beam that has a concentrated load at its center.

Beam Natural Frequency. The beam natural frequency can be obtained from the static displacement Y_{st} of a beam that has a concentrated load, using standard beam equations from a handbook (1):

$$Y_{st} = \frac{WL^3}{48EI} \quad (13)$$

Substituting the physical properties for the beam in the preceding equation results in a static displacement of 4.114×10^{-6} m (1.62×10^{-4} in). Substituting these numbers in Eq. (1) where the acceleration of gravity is 9.80 m/s² (386 in/s²), results in a natural frequency of 246 Hz.

Beam Transmissibility Q . The transmissibility Q for the beam in a 5- G input sine vibrational environment can be obtained from Eq. (9), where $J = 1.0$ and the natural frequency is 246 Hz. This results in a Q value of about 31.5.

Dynamic Output Force on Beam. The dynamic force acting on a beam can be obtained from Eq. (12); the given concentrated load is W , the sine input level is 5 G , and the transmissibility Q is 31.5. This results in an output force of 1401 N (315 lb).

Single Amplitude Dynamic Displacement of Beam. The single amplitude dynamic displacement at the center of the beam can be obtained by using Eq. (8) and adding the transmissibility Q for sine vibrational, as shown in Eq. (14). See Eq. (8) for values of A .

$$Y_0 = \frac{AG_{in}Q}{f_n^2} \quad (14)$$

For a 5- G sine input, a transmissibility Q of 31.5 and a natural frequency of 246 Hz, the single amplitude displacement is expected to be about 0.000645 m (0.0254 in).

Maximum Dynamic Bending Stress in Beam for Sine Vibration. Equation (15) gives the dynamic bending stress S_b . Stress occurs at the center of the beam, as shown in Fig. 8. A dimensionless geometric stress concentration factor (k) should be included when machined parts will be exposed to tens of thousands of stress reversals in vibrational environments. These types of fabricated parts usually have small defects in the form of cuts, scrapes, and scratches, which are known as stress risers or stress concentrations. These defects increase the magnitude of the local stresses which reduces the fatigue life of the structure. The stress concentration must be used *only once*. It can be used directly as shown in Eq. (15), or it can be used

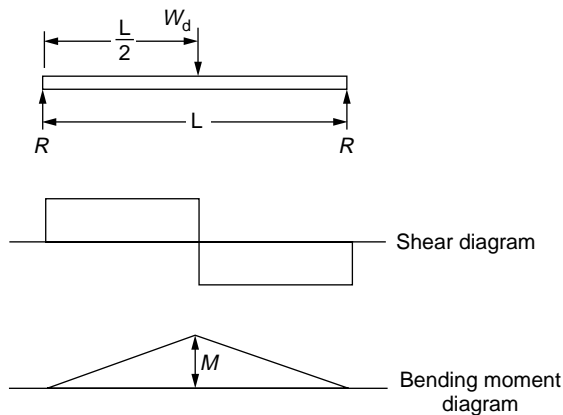

Figure 8. Shear and bending moment diagram for a beam that has a concentrated load.

to modify the slope of the fatigue curve shown in Eqs. (18) and (19), but not in both places.

$$S_b = \frac{kMc}{I}. \quad (15)$$

A stress concentration factor of about 2 is a good place to start preliminary stress investigations. The dynamic bending moment M can be obtained from the geometry of the beam, using the reaction force R , as follows:

$$M = \frac{RL}{2} \quad (16)$$

Because of symmetry, the reaction R will be half of the dynamic load or 700.5 N (157.5 lb). Using a length L of 0.203 m (8.0 in) results in a bending moment of 71.1 N m (630 lb in). The c distance is half the beam thickness, or 0.00635 m (0.25 in). Using the value of $5.20 \times 10^{-9} \text{ m}^4$ (0.0125 in⁴) for the moment of inertia from Eq. (13) and substituting it in Eq. (15) results in a dynamic bending stress of $1.737 \times 10^8 \text{ N/m}^2$ (25,200 lb/in²).

DETERMINING THE FATIGUE LIFE IN A SINE VIBRATIONAL ENVIRONMENT

Accurate fatigue properties of materials that have varying stress concentrations are very difficult to obtain. Figure 5 shows there is a great deal of scatter in typical fatigue data. The normal method for calculating the approximate fatigue life from a known stress value is to use the S - N (stress versus number of cycles to failure) curve for the particular material involved in the investigation. If the fatigue properties of the materials are unknown, then the fatigue life cannot be calculated. Tests should be run on prototypes or on structural members to establish their fatigue properties. If the fatigue properties of the materials are not known, then there is a very great risk of many fatigue failures in production units that will be exposed to vibrational environments.

When the fatigue properties of the materials are known, these properties are often plotted using a sloped line on a log-log curve. The typical fatigue curve for the aluminum

Figure 9. S - N fatigue curve for a smooth specimen of 6061 T6 aluminum.

alloy 6061 T6 shown in Fig. 9 will be used in the sample problem following.

Sample Problem: Finding the Fatigue Life of a Beam Excited by Sine Vibration

The approximate fatigue life of the beam in the previous sample problem can be obtained from Fig. 9 along with the calculated bending stress value of $1.737 \times 10^8 \text{ N/m}^2$ (25,200 lb/in²), as obtained from Eq. (15). The following fatigue damage equations can be used in several different ways to obtain the fatigue life of the structure; t is time and Z is displacement:

$$N_1 S_1^b = N_2 S_2^b,$$

or

$$t_1 G_1^b = t_2 G_2^b,$$

or

$$Z_1 G_1^b = Z_2 G_2^b. \quad (17)$$

The slope b of the fatigue line can be obtained by modifying Eq. (17) and using the Fig. 9 reference break points in the following equation:

$$\frac{N_1}{N_2} = \left(\frac{S_2}{S_1} \right)^b. \quad (18)$$

Let N_1 be 5×10^8 , N_2 be 10^3 , S_2 be $3.102 \times 10^8 \text{ N/m}^2$ (45,000 lb/in²), and S_1 be $1.034 \times 10^8 \text{ N/m}^2$ (15,000 lb/in²). Substitute in the preceding equation for the slope:

$$\frac{5 \times 10^8}{10^3} = \left(\frac{3.102 \times 10^8}{1.034 \times 10^8} \right)^b,$$

or

$$5 \times 10^5 = 3^b,$$

or

$$\log 5 \times 10^5 = b \log 3,$$

$$b = \frac{5.699}{0.477} = 11.95 \text{ (slope of fatigue line)}. \quad (19)$$

The b exponent was obtained *without* any stress concentration or safety factor in the material stress. A stress

concentration or safety factor should always be used in vibration. Sometimes, it is more convenient to use a stress concentration (typically 2) directly in the stress value, as in Eq. (15). Sometimes it is more convenient to use the stress concentration in the S - N fatigue curve. Either method can be used, as long as the safety factor is not *used twice*. If a safety factor of 2 is used in the S - N fatigue curve, the value of the b exponent is typically 6.4 for nonferrous alloys and 8.3 for ferrous alloys.

The approximate fatigue life of the vibrating beam can be obtained from the bending stress level $1.737 \times 10^8 \text{ N/m}^2$ (25,200 lb/in²) which was obtained from Eq. (15). Use reference points N_1 at 5×10^8 cycles and S_1 at $1.034 \times 10^8 \text{ N/m}^2$ (15,000 lb/in²) at the right break point in Fig. 9. This results in the number of cycles to failure:

$$N_2 = N_1 \left(\frac{S_1}{S_2} \right)^b = (5 \times 10^8) \left(\frac{1.034 \times 10^8}{1.737 \times 10^8} \right)^{11.95} \quad (20)$$

$$= 1.015 \times 10^6 \text{ cycles to failure}$$

The fatigue life expected at a natural frequency of 246 Hz for a sine resonant dwell condition can be obtained as

$$\text{Life} = \frac{1.015 \times 10^6 \text{ cycles}}{\frac{246 \text{ cycles}}{\text{s}} \times \frac{3600 \text{ s}}{\text{h}}} = 1.146 \text{ h to failure} \quad (21)$$

EFFECTS OF HIGH VIBRATIONAL ACCELERATION LEVELS

High vibrational acceleration levels can result in many different types of failures in different types of systems. High vibrational acceleration levels can be generated by earthquakes, explosions, aircraft buffeting, gunfire, unbalanced rotating devices, rough roads, and rough tracks, to name a few. Vibrational isolators are often used in the foundations of large buildings to protect them from earthquakes. Vibrational isolators are often used on military naval ships and submarines to protect sensitive equipment such as electronics from explosions. When vibrational isolation systems cannot be used, then brute force methods must be used to reinforce structural elements to keep them from failing. The method of reinforcing often results in very large, heavy, and expensive products.

High vibrational acceleration levels can be caused by high input acceleration levels, by severe coupling between adjacent structural elements, and by very low damping in the structure. High vibrational acceleration levels are often caused by careless structural designs, where the natural frequencies of closely linked structural members are very close together. When this happens, the transmissibilities of the adjacent structural elements *multiply*, they do not add. This can cause very rapid failure in almost any structure.

High accelerations in electronic systems can result in large PCB deflections, which can cause impacting between PCBs, high stresses, and rapid failures in the electrical lead wires and solder joints of the components mounted on the PCBs, when the PCBs are forced to bend back and forth thousands of times. High PCB displacements can break pins on electrical connectors and cause electrical short

circuits and cracked components. High acceleration levels can cause relays to chatter, crystal oscillators to malfunction, potentiometers slugs to slip, electrical failures, and cracked castings. Cables and harnesses can whip around causing wires and connections to fail.

MAKING STRUCTURAL ELEMENTS WORK SMARTER IN VIBRATION

One of the biggest problems in structures exposed to vibration is severe coupling between adjacent structural members. PCBs mounted within a chassis or an enclosure are a good example. When the enclosure has an input vibrational acceleration level of 10 G s and a Q of 10 and the PCBs have a Q of 10 and a natural frequency close to the enclosure, the PCBs experience acceleration levels of $10 \times 10 \times 10$ or 1000 G s. Acceleration levels this high cause electronic failures in just a few seconds.

Using the Octave Rule to Improve Vibrational Fatigue Life

One way that structures can be made to work smarter is to design them to follow the octave rule. Octave means to double. When adjacent structural members have natural frequencies that are separated by an octave, or by a factor of 2 to 1, they cannot experience severe coupling.

It does not matter if the natural frequency of each PCB is two (or more) times greater than the natural frequency of the outer housing or if the natural frequency of the outer housing is two (or more) times greater than the natural frequency of each PCB. As long as the natural frequencies of these adjacent structural members are separated by a ratio of 2 (or more), there will be a large reduction in the coupling between them, *as long as the weight of the PCB is very small compared to the weight of the housing*. If high shock levels are also expected, then it is best to use the *reverse octave rule*. The *reverse octave rule* applies when the natural frequency of the outer housing is two (or more) times greater than the natural frequency of any PCB (1).

The *reverse octave rule* works only in dynamic systems where the weight of each PCB is much smaller than the weight of the outer housing (or enclosure). Much smaller means by a factor of 10 or more. In other words, the weight of the enclosure must be more than ten times greater than the weight of any one PCB in that enclosure. If this ratio is not followed, severe dynamic coupling can occur and cause problems.

There are never any problems using the *forward octave rule*, where the natural frequency of each PCB is two or more times greater than the natural frequency of the outer enclosure. This works well no matter what the weight ratio is between the PCB and the enclosure. Each PCB can weigh four times more than the enclosure, or the enclosure can weigh four times more than any PCB. Using the *forward octave rule*, there is never a severe coupling problem. When the weight of any one PCBs is less than about one-tenth the weight of the chassis enclosure, the *reverse octave rule* works a little better in high shock environments.

The octave rule can be very effective in reducing vibrational and shock dynamic coupling acceleration levels

in plug-in types of PCBs installed in a chassis enclosure. When properly used, the octave rule is almost always more effective than damping in reducing the acceleration G levels transferred from the chassis to the internal PCBs. The dynamic acceleration G response of the chassis, which is usually the first degree of freedom, will be the dynamic input to the PCBs, which is usually the second degree of freedom. Transmissibility Q values that are transferred from the chassis to the PCBs do not add, they multiply.

Vibrational test data and computer-generated dynamic analyses have shown that the octave rule can reduce the acceleration G levels transferred from the chassis to PCBs by as much as 75%. When the natural frequencies of the chassis and the internal PCBs are close together, a good constrained layer damping system will reduce the acceleration G levels transferred to the PCBs by only about 15 to 20%. (See (1), Figs. 7.2–7.5 and Fig. 7.8.)

When a constrained layer damping system is added to a plug-in type PCB, some electronic components have to be removed to make room for the damper. When a stiffening rib must be added to a plug-in type of PCB to increase its natural frequency so that it follows the octave rule, some electronic components may have to be removed to make room for the stiffening rib. A stiffening rib will take up much less room on a PCB than a good constrained layer damper. Test data and past experience in damping and stiffening for PCBs to increase their vibrational reliability and fatigue life has shown that increasing the PCB natural frequency has almost always been the better choice.

Equation (14) shows that dynamic displacements are inversely related to the square of the natural frequency. This is a general relationship that applies to almost every type of structure exposed to dynamic vibration, shock, and acoustic environments. Consider the case where the input acceleration G level is held constant and the transmissibility Q value is approximated by Eq. (9a) as $\sqrt{f_n}$. When the PCB natural frequency is doubled, the resulting dynamic displacement of the PCB will be reduced:

$$Z = \frac{(f_n)^{\frac{1}{2}}}{(f_n)^2} = \frac{1}{(f_n)^{\frac{3}{2}}} = \frac{1}{(2)^{1.5}} = \frac{1}{2.83} \text{ (displacement ratio)} \quad (21a)$$

The fatigue life of the structure will increase because the displacement is reduced, which reduces the stress in the same proportion for a linear system. The fatigue life is strongly related to the b fatigue exponent slope of the $S-N$ fatigue curve shown in Fig. 5 and in Eq. (17).

For a smooth polished structure that has no stress concentrations where $k = 1$, Eq. (19) shows that the exponent b for materials used in electronic assemblies has a value of about 11.95. However, real structures almost always have some type of stress riser or stress concentration. A typical stress concentration value k for electronic structures is about 2. This results in a value for the b fatigue exponent slope of about 6.4. This means that the vibrational fatigue lives of typical electric components, their electrical lead wires, solder joints, fasteners, electrical connectors, and circuit traces on plug-in type of PCBs are increased when the natural frequency is doubled. However, doubling the PCB natural frequency uses up the fatigue life twice

as fast. This must be considered when the fatigue life improvement is evaluated;

$$\text{Fatigue life improvement} = \frac{(2.83)^{6.4}}{2} = 389 \text{ times} \quad (21b)$$

Various damping techniques have been applied very successfully in reducing the displacement amplitudes and stresses in tall buildings and long suspension bridges subjected to earthquakes and high winds. Damping is also used extensively to reduce noise levels in air ducts, automobile panels, washing machines, fan-cooled electronic systems, and aircraft jet engines. Damping, however, has not been used extensively to increase the dynamic fatigue life of plug-in types of PCBs because of cooling problems, repair costs, and changes in material damping properties at high temperatures.

A large midwest electronics company won a large contract to supply an electronic system that was required to operate in a severe vibrational environment. A decision was made to use viscoelastic damping materials for plug-in PCBs to reduce the vibrational acceleration G levels acting on the PCBs. Each plug-in PCB module consisted of two circuit boards bonded together, back to back, using the viscoelastic damping material. Vibrational tests were run on prototypes to verify the reliability and fatigue life of the proposed design. The tests were very successful, so the company went into full production using the viscoelastic damped plug-in PCB modules. One of the production electronic assemblies was selected for the vibrational qualification test required by the contract. The qualification test required the electronic system to be operating so that any electrical failures could be observed immediately. The vibrational qualification test was a disaster. Electronic component parts were breaking loose and flying off the PCBs. The engineers were stunned. The vibrational tests on the prototype viscoelastic damped PCBs were very successful. What happened? The engineers went back to their prototype test modules and repeated their previous vibrational tests. Their tests were successful once again. One of the engineers noted that the vibrational tests on their prototypes were run at room temperature. They decided to repeat the vibrational tests on their prototype models at an elevated temperature that simulated the temperatures experienced by the electrically operating production assembly. The elevated temperature vibrational tests on the prototype models were a disaster. Electronic components were breaking loose and flying off the PCBs. The elevated temperatures had sharply reduced the damping properties of their viscoelastic material, so that their design failed. The company was still under contract to deliver production electronic systems that could pass the vibrational requirements while they were operating electrically. The company had to redesign the electronic system and rerun prototypes at elevated temperatures to prove the new design integrity. They had to scrap the old production systems, retool for the new systems, and go into production to fulfill their contract requirements without change in the contract price. The company lost a substantial amount of money on that contract, and several engineers had to look for new jobs.

The octave rule can increase the vibrational fatigue life of a system and reduce the size, weight, and cost of the equipment at the same time. Once this rule is followed, it becomes possible to make PCB materials work smarter. This can be accomplished by understanding the relationships between the dynamic forces, displacements, stresses, and fatigue life of the materials used in fabricating and assembling electronic systems. A great deal of information related to eigenvalues (natural frequencies) and eigenvectors (mode shapes) can be obtained by using one of the many finite element analysis (FEA) programs available. Accurate dynamic stress levels in various structural members and approximate fatigue life in different environments are much more difficult to obtain from any FEA program. This cannot be done by analysis alone. An extensive amount of vibrational test data is required, where several similar electronic assemblies are vibrated until they fail. The failed parts are then examined closely to evaluate the physics of the failures. The test data are then combined with the FEA dynamic analysis and fatigue theory. This method of evaluation can result in equations that show what *minimum* natural frequency a rectangular plug-in PCB should have to achieve a fatigue life of about 10 million stress cycles in a sinusoidal vibrational environment. The physical properties of the circuit board materials, electronic component materials, solder joint materials, and the effects of surface-mounted and through-hole assembly practices must be understood to make these materials work smarter.

Finding the Maximum Allowable PCB Dynamic Displacement for Sine Vibration

Test data for sine vibrational environments are used to establish *maximum* allowable dynamic displacements Z_{\max} for PCBs to achieve a 10-million cycle life. This is based on the size of the PCB, the types and sizes of the electronic components, and the location of these components on the PCB. The following equation includes an added safety factor of 1.3 to ensure the effective fatigue life of each PCB further (1).

$$Z_{\max} = \frac{UB}{Chr\sqrt{L}} \text{ maximum allowable displacement, m (in)} \quad (22)$$

where

$$U = 8.90 \times 10^{-7} \text{ metric } (2.20 \times 10^{-4} \text{ English})$$

B in m (in), the length of the PCB parallel to the length of a component

h in m (in), thickness of the PCB

L in m (in), the length of an electronic component

C is a component type constant, metric and English

1.0 for a standard dual inline package (DIP)

1.26 for a DIP using side brazed lead wires

1.26 for a pin grid array (PGA) or hybrid that has two parallel rows of wires extending from the bottom surface of the component

1.0 for a PGA that has wires around the perimeter extending from the bottom surface of the component

2.25 for a leadless ceramic chip carrier (LCCC)

1.0 for a leadless chip carrier that has J leads or gull wing leads

0.75 for axial leaded devices such as resistors and capacitors

1.75 for ball grid array (BGA) components

r is a relative positional factor for components mounted on a rectangular PCB supported around its perimeter, metric and English

1.0 when the component is mounted at the center of the PCB at $x = a/2$ and $y = b/2$

0.707 when the component is mounted off the center of the PCB at $x = a/2$ and $y = b/4$

0.50 when the component is mounted at the one-quarter mounting points off the center of the PCB at $x = a/4$ and $y = b/4$

Extensive vibrational test data on different types of PCBs have shown that the electronic component lead wires fail far more often than their related solder joints in through-hole mounted devices. Surface-mounted components experience a small increase in the solder joint failures, but again, the greatest number of failures occur in the lead wires (1,2).

Combining Eq. (22) with Eqs. (8) and (9a) results in the following equation for the *minimum* desired natural frequency f_d that a PCB must have to provide a fatigue life of about 10 million stress cycles for the most critical components and their lead wires in a sine vibrational environment (1):

$$f_d = \left[\frac{AG_{\text{in}}Chr\sqrt{L}}{UB} \right]^{\frac{2}{3}} \text{ (minimum desired PCB natural frequency)} \quad (23)$$

where

$$A = 0.248 \text{ metric } (9.80 \text{ English})$$

$$U = 8.90 \times 10^{-7} \text{ metric } (2.20 \times 10^{-4} \text{ English})$$

G_{in} = peak input acceleration, dimensionless gravity units, metric and English

Sample Problem—Determining the Minimum Desired PCB Natural Frequency

When the octave rule is followed, it is possible to design PCBs without considering the vibrational response of the outer enclosure that supports the PCBs because there is a large reduction in the dynamic coupling between these two structures.

Find the minimum desired PCB natural frequency and the approximate fatigue life for a 0.00157 m (0.062 in) thick PCB that has a hybrid 0.0508 m (2.0 inch) long made of two parallel rows of pins extending from the bottom surface ($C = 1.26$). The hybrid is mounted at the center of a 0.152 m (6.0 in) \times 0.203 m (8.0 in) rectangular plug-in PCB, parallel to the 0.203 m (8.0 in) edge. The PCB must operate in a 5.0- G peak sine vibrational environment. Substituting in the preceding equation for metric or English units results in a minimum desired natural frequency of 210 Hz.

The approximate fatigue life for a resonant dwell condition can be obtained from the expected 10 million cycle

fatigue life for sine vibration, as follows:

$$\text{Life} = \frac{10 \times 10^6 \text{ cycles}}{\frac{210 \text{ cycles}}{\text{s}} \times \frac{3600 \text{ s}}{\text{h}}} = 13.23 \text{ h to failure} \quad (24)$$

Using Snubbers to Decrease Dynamic Displacements and Stresses (6)

High vibrational and shock accelerations can produce high dynamic displacements in structural members, which can cause very rapid failures. These high displacements can often be reduced by using snubbers. Snubbers are small devices that can be added to adjacent structural elements to make them act smarter by limiting their dynamic displacements. When these snubbers are properly placed, they leave only small clearances between the adjacent snubbing members, so that the snubbers strike each other. The striking action between the snubbers reduces the dynamic displacements, forces, and stresses in these structures and results in increased fatigue life. [See (1), Figs. 7.6 and 7.7.] Snubbers can be made from different grades and shapes of rubber, nylon, aluminum, or epoxy fiberglass. Rubber snubbers work well on PCBs that have low natural frequencies below about 50 Hz. When the PCB natural frequency is above about 100 Hz, the resulting dynamic displacements are so small that soft rubber does not work well. A harder material, similar to epoxy fiberglass, works much better. Good results have been obtained using 0.0063-m (0.25-in) diameter epoxy fiberglass snubbers epoxy bonded directly to the surface of the PCB near the center. Snubbers work well even if they cannot be mounted at the center of each PCB. For a new design, it is usually possible to leave a small amount of room at the center of each PCB for mounting snubbers. For existing PCBs, there may not be any room near the center, so the snubbers may have to be bonded to almost any convenient space between the components. The snubbers should not be directly bonded to the electronic components themselves. The snubbers should not be allowed to impact any components or any protruding lead wires or solder joints on adjacent PCBs because impact during vibration may cause failures in these areas (6).

Increasing PCB Stiffness to Decrease Dynamic Displacements

PCBs are often considered the heart of an electronic system because they hold most of the important electronic components that control the system. Large dynamic displacements on PCBs must be avoided in vibrational environments because they can result in high stresses and rapid fatigue failures. PCBs can be made to act smarter by increasing their natural frequency. This rapidly reduces the dynamic displacements and stresses and substantially increases the fatigue life. For new PCB designs, it is often very easy simply to increase the basic thickness of the circuit board. A 10% increase in the basic circuit board thickness can increase the PCBs natural frequency by 15%, which can increase the fatigue life of the components by a factor of about 6.

When the basic circuit board thickness cannot be increased, the PCBs natural frequency for a new design can often be increased to make the PCB act smarter by adding more copper planes to the multilayer board assembly. Many circuit boards already have at least two full one-ounce copper planes, 0.0000356 m (0.00140 in) thick for ground and for voltage. The natural frequency can be increased by simply doubling the thickness of the copper and adding another two copper planes (which can be called heat sinks), totaling four copper planes. The high copper modulus of elasticity can increase the natural frequency of the PCB by about 12%, which can increase the component fatigue life four times.

Stiffening ribs are often added to new designs of PCBs to increase the stiffness and the natural frequency (1). Stiffening ribs can significantly increase the natural frequency, but ribs take up room on the PCB, so that fewer components can be mounted on it. The probability of adding effective stiffening ribs to existing PCBs is very low. When improved vibrational or shock performance is required on existing hardware, a better choice is using snubbers.

Adding Doublers to Increase Local Stiffness in Critical PCB Areas

When existing PCBs experience component vibrational fatigue failures, it is often possible to make these PCBs act smarter by increasing the stiffness of the PCB in local areas of the critical components. This can often be done by simply bonding shims (sometimes called doublers) to the critical areas on the PCB. The shims should be fabricated from the same material as the circuit board. Strips about half the thickness of the board should be bonded to both sides of the PCB, where possible, under the component on the top side of the PCB and on the back side of the PCB just under the component. Metal shims are sometimes used instead of plastic shims. Metals have a higher modulus of elasticity than plastics, so they should work better than plastics. The problem is that metal shims often do not work as well as plastic shims. Metals are usually very smooth and hard. Epoxy type adhesives do not adhere well to hard smooth surfaces, so metal shims often fall off. Think of a mountain climber. It is very difficult, almost impossible, to climb a steep mountain without punching holes in the mountain-side to get a better grip. If there is no grip, the climber will slip and fall. The same holds for metal shims. If there is no grip, they will slip. A large shim may require at least eight small, well separated holes to be punched (or drilled) through the shims to allow the adhesive to flow through the holes and form adhesive rivets. Tests have shown that these plastic rivets will hold metal shims very securely to PCBs in severe vibrational, shock, and thermal cycling environments.

Making Component Lead Wires Work Smarter by Changing Their Form

Stiff component electrical lead wires have been known to cause lead wire and solder joint failures in vibrational, shock, and thermal cycling environments (2). It is often

Figure 10. Electrical lead wire camel hump and wire loop strain relief.

possible to increase the fatigue life of lead wires and solder joints by *reducing* the stiffness of the lead wires. This is the theory behind this observation.

The spring rate K of a linear elastic system is defined as the force P divided by the displacement Y . Then, the force in the system is the product of the spring rate and the displacement:

$$P = KY. \quad (25)$$

When a system has a fixed (or constant) displacement Y , this equation shows that the best way to reduce the force P is to reduce the spring rate K . A constant displacement system occurs in vibration for an existing piece of hardware, when the natural frequency is known and the acceleration G level is known. Equation (8) shows that the displacement is fixed (or constant) when the natural frequency and the acceleration G level are defined.

Most lead wire and solder joint failures in vibration can be related to the bending action of the PCB, when its natural frequency is excited. The bending action of the PCB forces the component lead wires to bend as well. The spring rate of a wire in bending can be obtained by treating the wire as a beam, as shown in Eq. (13). Again defining the spring rate as the load divided by the displacement and ignoring the parameters that define the beam end restraints, the spring rate of the bending wire is:

$$K = \frac{EI}{L^3}. \quad (26)$$

An examination of this equation shows that the easiest parameter to change is the length L of the wire. Because this is a cubic function, a small change in the length of the wire produces a large reduction in the spring rate of the wire. It is often very easy to increase the length of the wire by looping it, adding camel humps in it, or simply by adding a small kink in the wire, as shown in Fig. 10. Another popular method for reducing the spring rate of the wire is to coin the wire. In this process, the wire is squeezed from a round cross section to a flat cross section. This reduces the area moment of inertia I which reduces the spring rate but not the area.

HOW STRUCTURES RESPOND TO RANDOM VIBRATION

Random vibration contains many different frequencies simultaneously across a broad frequency range. This means that all of the natural frequencies in a structure that are within the bandwidth of the random vibration will be

Figure 11. Typical power spectral density curves for random vibration.

excited at the same time. This contrasts with sine vibration, where only one natural frequency is excited at any given time during a sine sweep across a broad frequency bandwidth. This means that failures can occur in random vibration that cannot be duplicated in sine vibration (1).

Random vibrational profiles are plotted on log-log curves where power spectral density (psd) in terms of G^2/Hz is plotted on the y axis and frequency in Hz is plotted on the x axis, as shown in Fig. 11. The square root of the area under the curve represents the root-mean-square (rms) of the acceleration level G_{rms} . (1):

$$\sqrt{\text{Area}} = \sqrt{\frac{G^2}{\text{Hz}} \times \text{Hz}} = G_{\text{rms}} \quad (27)$$

Probability distribution functions have to be used to solve random vibrational problems because many different frequencies are present at any instant. The Gaussian distribution is used by many engineers involved with electronic equipment. This function represents the probability of the value of *instantaneous* accelerations at any time. The Rayleigh distribution, which is the probability of the distributions of *peak* accelerations, is also used. The argument here is that *peak* forces and stresses cause failures. A combination of these two functions, which is known as the three-band technique (1), is a Gaussian skewed toward a Rayleigh. This method is convenient for obtaining quick and relatively accurate solutions to random vibrational problems without using a computer. In the three-band technique, the rms represents the one-sigma (1σ) acceleration G level. The two-sigma (2σ) acceleration G levels are two times greater than the rms G level. The three-sigma (3σ) acceleration G levels, which are the maximum levels expected for the Gaussian distribution, are three times greater than the rms G level. The percentage of time that these levels occur in the three-band technique are as follows:

$$\begin{aligned} 1\sigma \text{ values occur } 68.3\% \text{ of the time;} \\ 2\sigma \text{ values occur } 27.1\% \text{ of the time;} \text{ and} \\ 3\sigma \text{ values occur } 4.33\% \text{ of the time.} \end{aligned} \quad (28)$$

Response of PCBs in Random Vibrational Environments

PCBs operating in random vibrational environments can be evaluated accurately as single-degree-of-freedom systems (1). The G_{rms} response for the PCB can then be obtained from the input psd value in G^2/Hz , the natural

Table 1. Fatigue Cycle Ratio n/N

Environment	Sine Vibration	Random Vibration	Thermal Cycles
1. Power on			$n_1/N_1 = 0.035$
2. Taxi		$n_2/N_2 = 0.001$	
3. Take-off		$n_3/N_3 = 0.203$	$n_3/N_3 = 0.047$
4. Climb		$n_4/N_4 = 0.097$	$n_4/N_4 = 0.022$
5. Attack	$n_5/N_5 = 0.091$	$n_5/N_5 = 0.191$	$n_5/N_5 = 0.033$
6. Return home		$n_6/N_6 = 0.009$	
7. Power off			$n_7/N_7 = 0.045$
$\sum \frac{n_i}{N_i}$	0.091	0.501	0.182

frequency f_n , and the Q value:

$$G_{rms} = \sqrt{\frac{\pi}{2} \text{psd } f_n Q} \tag{29}$$

The maximum allowable dynamic displacement Z_{max} for the PCB can still be shown by Eq. (22) for random vibration. The PCB fatigue life for random vibration is now expected to be about 20 million stress cycles. Because the maximum random displacement is based upon the $3\text{-}\sigma$ value, Eq. (8) must be multiplied by 3. Now Eqs. (8) and (22) can be combined with Eqs. (9a) and (29) to obtain the *minimum* desired PCB natural frequency for a component fatigue life of about 20 million stress cycles:

$$f_d = \left[\frac{VChr \sqrt{\frac{\pi}{2} (\text{psd}) L}}{UB} \right]^{0.80} \tag{30}$$

(*minimum*; desired PCB natural frequency),

where

$$V = 0.744 \text{ metric (29.4 English)}$$

$$U = 8.90 \times 10^{-7} \text{ metric (} 2.20 \times 10^{-4} \text{ English)}$$

$$\text{psd} = G^2/\text{Hz, power spectral density input, metric (English)}$$

Sample Problem—Finding the Minimum Desired PCB Natural Frequency

Use the same physical dimensions for the PCB, as shown in the sine vibrational sample problem following Eq. (23), except use a PCB length of 0.228 m (9.0 in), parallel to the component length, and a random vibrational psd input of 0.10 G^2/Hz in the area of the PCB natural frequency. This results in a minimum desired natural frequency of about 178 Hz.

Determine the Approximate Fatigue Life of the Component on the PCB

$$\text{Life} = \frac{20 \times 10^6 \text{ cycles}}{\frac{178 \text{ cycles}}{\text{s}} \times \frac{3600 \text{ s}}{\text{h}}} = 31.2 \text{ h to failure} \tag{31}$$

Determine the Response of the PCB to the Previous Random Vibration

Substitute the previous information into Eq. (29) as follows:

$$G_{rms} = \sqrt{\frac{\pi}{2} (0.10)(178)\sqrt{178}} = 19.3 \text{ rms} \tag{32}$$

Find the Maximum Expected Acceleration G Level for the PCB

The maximum acceleration level expected is three times the rms, which will be

$$\text{Max } G = 3(19.3) = 57.9 \text{ G} \tag{33}$$

Find the Maximum Expected Displacement for the PCB

The maximum displacement expected for the PCB can be obtained from Eq. (8), which results in a dynamic displacement of 4.54×10^{-4} m (0.0179 in).

MINER'S CUMULATIVE DAMAGE FOR ESTIMATING FATIGUE LIFE

Miner's cumulative damage theory states that every time a structure experiences a stress cycle, part of its life is used up. This is shown as a series of ratios where the actual number of stress cycles (n) is divided by the number of cycles required to produce a failure (N) for many different stress environments. When the total of all of the ratios equals one, all of the life will be used up, so the structure will fail. Miner's method can be used to add up all of the damage accumulated in sine vibrational, random vibrational, shock, acoustic noise, and thermal cycling environments. Miner's damage ratio R_n is (1,2)

$$R_n = \frac{n_1}{N_1} + \frac{n_2}{N_2} + \frac{n_3}{N_3} + \frac{n_4}{N_4} + \frac{n_5}{N_5} + \dots = 1.0 \text{ for failure} \tag{34}$$

Sample Problem: Estimating the Fatigue Life of the Lead Wires on an Aircraft Electronic Component Subjected to Gunfire Sine Vibration, Flight Random Vibration, and Flight Thermal Cycling Environments

The attack uses the Gatling gun which generates a sine type of vibration. Anytime the engines are running, the system experiences random vibration. Anytime there is a

significant power change there is a significant temperature change, which is considered a thermal cycle.

Fatigue failures are difficult to predict because of the typically wide scatter in the fatigue life test data available. To ensure the reliability of the electronic systems in a military aircraft, it is good policy to include a scatter factor, or safety factor, in the design and analysis of these systems. Therefore, a scatter factor of 2.0 will be used to evaluate the fatigue life for the electronics. The normal design life for a military aircraft is about 10 years or 10,000 flying hours. Using a scatter factor of 2.0, the fatigue life of this electronic system will be designed for an operational time of 20,000 hours.

$$R_n = 0.091 + 0.501 + 0.182 = 0.774 \quad (35)$$

The cumulative damage ratio is less than 1.0, so the electronic design is acceptable.

VIBRATIONAL DAMPING, DESIGN CONSIDERATIONS

MICHAEL DRAKE
University of Dayton Research
Dayton, OH

INTRODUCTION

This article discusses the phases of a damping design effort. The basic steps in a damping design effort are identical for either a passive or active damping concept. The steps in this general approach are summarized in Table 1. The first four steps in this design process ensure that the designer completely defines the problem to be solved. During these steps, the designer verifies that the problem is the result of a resonant vibration, defines the vibrational characteristics of the structure under consideration, defines the environmental conditions in which the structure operates, and defines the level of damping required to solve the problem. These parameters are obviously needed because an effective design for the candidate damping concept (either active or passive) depends on the level of damping required, the frequency and mode shape, and the operational temperature range of the vibrating system. Based on these parameters, the problem is completely defined, and the

designer can make a logical choice of appropriate damping concepts to be evaluated that lead to the final design (1–3).

Although this design approach identifies individual steps, these steps are not independent. A successful damping design project is a systems engineering problem and must be solved using a concurrent engineering process. Most unsuccessfully damping designs are the direct result of not addressing all of the critical issues in a timely manner. The following paragraphs detail the critical tasks contained in each of the process steps and present examples from actual case histories of the way various issues were addressed.

DYNAMIC PROBLEM IDENTIFICATION

The proper initial step in solving any problem always is first completely defining the problem. This fact holds true when attempting to solve a vibration-induced problem by using damping technology. Therefore, the first step in this damping design approach is to substantiate that the problem to be solved results from structural resonance. If the vibration problem is not due to structural resonance, then a damping design will not be effective.

In a new structural system design, the designer must obtain the anticipated force input or excitatory environment for the system and correlate the frequency content of this information with the results of a natural frequency analysis of the structure (4). If there are natural frequencies within the frequency band of the excitation expected, the designer has identified the potential for dynamics problems. These dynamic problems must be evaluated to determine if the vibrations will keep the system from fulfilling the intended purpose.

If a problem develops in an existing part, the designer might choose one of the following approaches to identify the problem.

When a component cracked, a crack analysis should be run to verify that the crack is a high cycle fatigue failure. An instrumented operational test of the component should also be run to identify the frequencies and vibrational levels of the problem. Operational deflection patterns also can be defined to support the identification of the mode shapes encountered. This operational test can be run using strain gauges or accelerometers for measurements. The use of thermocouples enables one to obtain peak vibrational levels and corresponding temperature data, as well as maximum operating temperature data.

If the problem under consideration is a high-noise radiative problem, an operating evaluation should be done to determine both the frequencies and magnitudes of the noise being radiated and the source of radiation (5). An unacceptable vibrational level environment problem should be attacked in the same basic manner as the noise problem.

As a result of these investigations, the designer has determined the operating dynamic cause of the problem and the resonant frequencies that are developing the high dynamic response.

Table 1. General Approach Steps

Step Number	Description
1	Verify that the problem is resonant vibration induced
2	Complete dynamic analysis of the system determining resonant frequencies, mode shapes, and system damping
3	Define the environmental conditions in which the system operates
4	Define the system damping required to eliminate the problem
5	Select the appropriate damping concept and basic damping configuration
6	Develop the required design from the data collected
7	Prototype the design and complete laboratory verification tests
8	Develop tooling and manufacturing methods and complete field validation tests

DYNAMIC CHARACTERISTICS

A successful damping design is developed from a complete understanding of the dynamic behavior of the structural system and the component to be damped. Generally, a frequency range across which dynamic information is needed is defined from the analysis completed during the first step. The dynamic range can be defined from operational testing or can be determined from knowledge of the system under consideration. For example, problems such as a component where the excitation forces are known to be engine-order related, low frequency excitation from road roughness to the suspension system, or acoustic excitation to aircraft fuselage components due to jet engine exhaust all enable rapid determination of the excitatory frequency range. Once a frequency range is defined for the problem, a complete dynamic structural characterization must be completed. One must accurately determine all of the resonant frequencies, corresponding structural mode shapes, and inherent modal damping values that occur in the required frequency range. This data can be obtained analytically or experimentally.

If a prototype is available in the early structural design stages, the optimum solution for data acquisition is experimental analysis of the prototype structure used to refine analytical models. These models are then used for further component damping design evaluation (6).

Often, when a damping application is used as a redesign approach, the necessary dynamic characterization can be acquired efficiently by using modern experimental methods. Experimental methods can quickly determine the data needed for a highly complex structural system; however, measurements on operating systems can often be extremely difficult and costly.

The Fourier analyzer is a powerful experimental tool available to do the experimental work; however, holographic methods for determining mode shapes and standard sine sweep methods for resonant frequencies and modal damping values are extremely useful (7–9). The designer must choose the most expedient method for developing the required data.

ENVIRONMENTAL DEFINITION

A major data point needed in the quest for an optimally designed damping application is the operational environment that the design will see. This data, at first thought,

might seem to be a rather simple task, but the importance of accurate information cannot be overstressed. This data must cover the entire life of the damping concept from fabrication through operation.

A broad-brush approach to temperature, such as the standard temperature range of -65 to 250°F for operation of many aircraft components, is not the answer. This range may be the maximum range seen by the component; however, it will not generally be necessary to provide high damping across this entire range. The engineer must determine the specific temperature range across which the damage is occurring and design his application for that range while maintaining a total awareness of the required survivability temperature range. Time-related recordings of vibration and temperature data from operating tests are used to determine the temperature range across which damaging vibrational levels occur. Operating tests can also supply the necessary maximum temperature limits to be used in the design. If temperature data from a large number of different operating tests are available, a statistical study of the data will reveal the temperature range in which the majority of operating time is spent. An example of this type of data is shown in Fig. 1 illustrating minimum and maximum temperatures along with the percentage of total operating time spent in each temperature range. It is easy to see the value of this type of data, particularly if vibrational level and temperature data cannot be simultaneously obtained for operating conditions.

In the early stages of system design, complete operating temperature data may not be available. Then, data from

Figure 1. Percentage of flight time spent in various temperature ranges during 500 flight hours.

similar systems should be reviewed, and the best estimates of temperature should be developed and used in the design procedure.

Temperature is not the only environmental factor that must be considered. The engineer must know if the application will come in contact with contaminants such as salt water, gasoline, jet engine fuel, hydraulic fluid, or any other substance that might affect the performance or longevity of the candidate damping concepts (10,11).

When the damping concept will be integrated into the structural system and installed during the structural system manufacturing process, the damping concept components must be able to survive manufacturing processing, including temperatures, pressures, and processing.

REQUIRED DAMPING INCREASE

The remaining question to be answered before a damping design can be started is "How much damping is needed to eliminate the problem?" In the "fix-it" damping business, the general approach found in the literature is to design an optimum damping system and test it in service. If the failures are eliminated, the problem is solved. In reality, the designer wants the minimum value of system damping that will eliminate the vibrational problem. If the damped design accomplishes just the minimum required damping using an optimum damping system, the design also should be optimized from the standpoints of weight, size, and cost.

The method for determining the minimum required system damping depends on the problem to be solved. The inherent system damping has been determined from the dynamic characterization. The corresponding vibrational problem (high dynamic stress, noise level radiated, high dynamic amplitude response, etc.) is directly related to the inherent damping. Quick calculations can be made to determine the required increase in system damping to eliminate the vibrational problem. Basically, if a 20% decrease of system response is needed, then the system damping needs to be increased 20%. If an analytical model has been developed, an analysis can be conducted to verify the value of system damping needed to eliminate the vibrational problem.

Table 2 presents values of typical system and material damping for various structural systems and structural materials (4).

DAMPING CONCEPT SELECTION AND APPLICATION DESIGN

Until this point, the primary function of the designer has been to develop an accurate and complete definition of the resonant vibrational problem. Now, it becomes a simple matter to determine which resonant modes of the component are creating the vibrational problem. This information defines the frequencies that need to be damped, the corresponding mode shapes, and the undamped modal loss factors. The required level of damping and the environmental conditions complete the data required to start defining appropriate damping concepts and analyzing the effectiveness of the concepts.

Table 2. Typical Damping Values at Room Temperature

Systems/Materials	Loss Factor
Welded metal structure	0.001 to 0.0001
Bolted metal structure	0.01 to 0.001
Aluminum	0.0001
Brass, bronze	0.001
Beryllium	0.002
Copper	0.002
Glass	0.002 (0.3 to 1.5 at elevated temperatures)
Lead	0.5–0.002
Magnesium	0.0001
Plexiglas™	0.03
Sand	0.6–0.1
Steel	0.0001
Iron	0.0006
Tin	0.002
Wood, fiberboard	0.02
Wood, oak, fir	0.008–0.01
Wood, plywood	0.01
Zinc	0.0003

Often, the temperature range for effective damping and the survivability temperature limits are evaluated first. If the survival temperature is above 400°F, most organic passive damping materials and many of the piezoelectric materials are eliminated from consideration. Therefore, if you had a requirement for damping in the 100°–300°F range and a survival temperature of 600°F, most constrained layer and free layer damping materials and piezoelectric materials would be ruled out.

The next consideration is the mode shapes of the resonant frequencies that must be damped. Free-layer and constrained-layer passive damping concepts and induced strain actuation active damping concepts are effective for damping "plate-like" modes that have large areas of bending deformation. Highly localized strain distribution will negate the effectiveness of these damping concepts. An example of the localized strain condition is discussed in (12). The high-cycle fatigue cracks initiated in the corner areas on the antenna are shown in Fig. 2. For the mode generating the failure, all of the strain was concentrated in the corners, and the rest of the cone area was moving in a rigid body motion. As a result, layered passive concepts and piezoelectric induced strain active concepts were not applicable. The displacements of the mount were such that a displacement-sensitive concept such as a passive tuned damper or an active reaction mass concept could eliminate the problem. In this case, a passive design was used.

Figure 2. Cross section of the antenna base showing high strain areas.

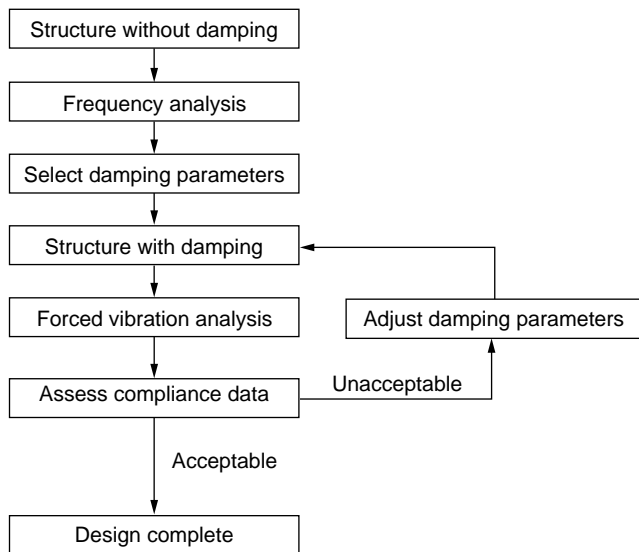

Figure 3. Basic damping design flow chart.

From the environmental conditions and the dynamic characteristics, the designer can choose the appropriate classes of damping concepts for the starting point to design the specific application for the structure under investigation. The basic principles of passive and active damping concepts and analysis methods are given in (13–18).

Various design analysis methods are often appropriate for problems; however, a successful design can be developed only after all of the basic information discussed previously is obtained. A design flow chart appropriate for any of the design analysis techniques is given in Fig. 3. The dynamic and temperature data are the inputs, and the output is the structural loss factor. The process loops through the design analysis step until the proper loss factor is achieved.

Note also that any successful design must use concurrent engineering principles and consider, from the beginning, the manufacturing methods that will be used to integrate the damping concept into the structural system and the maintenance processes for the damping concept.

PROTOTYPE FABRICATION AND LABORATORY VERIFICATION

Once the design is complete, the next step is to fabricate the design prototype and verify the design in the laboratory. The fabrication processes used for the prototype should be scalable to production processes, whenever possible. These processes must not degrade the function of the damping concept in any way.

Generally, the laboratory test setup is some scaled version of the total structural system. The primary consideration in the laboratory test is that the test article has the same dynamic characteristics as the full structural system and that the laboratory test environment simulates the critical operating conditions.

The laboratory validation test results should verify the analytical method used to develop the design. Any variation in the comparison of the test results and the model results should be evaluated and the test or the model, whichever is found in error, modified. After satisfactory comparisons are obtained, critical analysis for the field evaluation test should be conducted.

PRODUCTION TOOLING AND FIELD VALIDATION

Production tooling and processes should be refined from the process used to fabricate and install the prototype damping system. All lessons learned from the laboratory testing should be applied to the field test effort.

Figure 4. Y966 damping material properties as a function of temperature.

SUMMARY

Restating the importance of the problem definition is appropriate at this point. Inaccurate temperature range data will eliminate any beneficial effects of the damping concept. For passive systems, this effect can be seen in Fig. 4 (dynamic properties of 3M Y-966) where a temperature shift of 100°F causes a significant reduction in the material loss factor. If the survival temperature limits are incorrect, the damping concept may well provide the necessary reduction in the vibration levels, but the concept will be destroyed by the first overtemperature condition (19). Guesses at temperature data will invariably lead to failure of the damping design.

The other major area where accurate data are necessary is the dynamic characteristics of the structural system under investigation. Placing a strain-sensitive damping concept on a portion of the structure which is not undergoing significant strain for a particular mode is as ineffective as placing a displacement-sensitive concept on a node line of the mode that you wish to control.

As in any design project, successful results require accurate information upon which to base the design. Operational data and dynamic characteristics are the two prime factors that must be meticulously defined to obtain good damping design results.

INTRODUCTION

The term Smart Window was introduced in the mid 1980s by Claes Granqvist to describe optically switchable electrochromic glazings. These devices exemplify the fundamental characteristic of all “smart windows”: controllable variation in the optical transmittance of the window. The variation in optical transmittance of electrochromic smart windows occurs through the simultaneous injection of electrons and ions (usually H^+ or Li^+ ions) into an electrochromic material such as WO_3 . In WO_3 , this leads to the development of either a broad absorption band or a reflection edge (depending on the details of the material preparation) that leads to a low transmittance state. The process is (ideally!) reversible; extraction of the ions and electrons returns the material to a transparent state. The control of the process is accomplished by applying a small voltage (1–2 V) (or passing a small current) that controls ion injection and extraction. Since the initial discovery of electrochromism in thin film WO_3 by Deb (1) in 1969, an enormous amount of research has been directed toward the goal of large area switchable windows for architectural applications. This initially focused on electrochromic systems that covered a wide range of materials and device structures. However, during the 1980s and subsequently, several alternate optical switching systems were developed that fall into the general category of smart windows. These include other electrically activated systems such as suspended particle devices (2) and phase dispersed liquid crystals (3), temperature controlled switchable devices such as thermochromic (4) and thermotropic devices (5), and recently developed gasochromic devices that are controlled by using reducing or oxidizing gas mixtures in a window unit (5).

ARCHITECTURAL GLAZING APPLICATIONS FOR SMART WINDOWS

The potential reductions in heating, cooling, and lighting energy use that can result from using switchable glazings in buildings has provided the impetus for the majority of this research. More than 675 U.S. patents have been filed in this field since 1976. It is now well established that reduced energy consumption of up to 50% is possible from the use of electrochromic glazings in commercial buildings, and

savings of 20–30% are obtainable in most climatic conditions. This is also the primary application for thermochromic and thermotropic windows that change transmittance as a function of temperature and therefore can reduce transmittance of infrared radiation (i.e., heat) when the temperature is high. However, some of the other “smart” windows, such as the polymer dispersed liquid crystal (PDLC) devices, do not provide significant energy savings but are used as privacy screens. To understand the role of switching in a smart window, it is necessary to understand the nature of glazings and the way the optical properties of a window affect its performance and utility.

Physics of Windows

Common to all applications of glazing materials is the need for transmission of light, and in most applications, reflectivity is also very important. To quantify the light transmission properties, the transmittance and reflectance spectra, $T(\lambda)$ and $R(\lambda)$ can be measured and used to define several different average transmittance and reflectance quantities. The most important of these are the solar and visible transmittance and reflectance:

$$T_{\text{sol}} = \frac{\int_0^{\infty} T(\lambda)\varphi_{\text{sol}}(\lambda)d\lambda}{\int_0^{\infty} \varphi_{\text{sol}}(\lambda)d\lambda}, \quad (1)$$

$$R_{\text{sol}} = \frac{\int_0^{\infty} R(\lambda)\varphi_{\text{sol}}(\lambda)d\lambda}{\int_0^{\infty} \varphi_{\text{sol}}(\lambda)d\lambda},$$

$$T_{\text{vis}} = \frac{\int_{370}^{770} T(\lambda)\varphi_{\text{vis}}(\lambda)d\lambda}{\int_{370}^{770} \varphi_{\text{vis}}(\lambda)d\lambda}, \quad (2)$$

$$R_{\text{vis}} = \frac{\int_{370}^{770} R(\lambda)\varphi_{\text{vis}}(\lambda)d\lambda}{\int_{370}^{770} \varphi_{\text{vis}}(\lambda)d\lambda},$$

where φ_{sol} and φ_{vis} are the solar spectrum and visible response of the human eye, respectively. Usually, the air mass 1.5 solar spectrum is used to define the solar averages, although it is not necessarily the most appropriate at all locations, and there can be significant differences between different solar spectra (6). The difference in the spectral ranges for φ_{sol} , φ_{vis} , illustrated in Fig. 1, immediately gives rise to the concept of spectral selectivity, which is central to many advanced window glazing systems. This refers to the ability of a window to transmit, for example, visible radiation (high T_{vis}) but to reflect heat (low T_{sol} and high R_{sol}). This is fully explained in Granqvist (7). Therefore,

Figure 1. The three components related to the ambient radiation environment which need to be considered for designing windows. The three distinct spectral regions correspond to the wavelengths $0.3 < \lambda < 2.5 \mu\text{m}$ [solar radiation— $\varphi_{\text{sol}}(\lambda)$], $\lambda > 3 \mu\text{m}$ (thermal IR), not shown here, and $0.37 < \lambda < 0.77 \mu\text{m}$ corresponding to the visible response of the human eye, $\varphi_{\text{vis}}(\lambda)$.

the selectivity $T_{\text{vis}}/T_{\text{sol}}$, which has a maximum value of approximately two, can be used as a figure of merit for glazings. Another important optical quantity is the solar absorption, $A_{\text{sol}} = 1 - T_{\text{sol}} - R_{\text{sol}}$. A window that absorbs solar radiation strongly will heat up considerably, and this heat can be transmitted into the building, negating the reduction in insolation that results from low solar transmittance (8).

Although these are the basic quantities of interest, there are several derived quantities, such as the total solar energy transmittance (6) that are commonly used to classify window glazings. The key parameters of interest in switchable glazings are the change in the visible and solar transmittance between the two states of the window. The values usually quoted are the normal-normal transmittance and reflectance, that is, the fraction of an incident beam normally incident on the window that is specularly transmitted. The spectral response typical of different types of smart windows is illustrated in Fig. 2.

Figure 2. Schematic illustration of the different types of switching of transmitted radiation that are possible using different switchable window systems.

Most windows are designed to have low diffuse scattering, but many of the smart windows available or in development switch between a specularly transmitting and reflecting state and a diffusely transmitting and reflecting state. In this case, the normal-hemispherical or sometimes the hemispherical-hemispherical transmittance and reflectance are quoted.

Even for the purposes of minimizing energy use in buildings, there is no single figure of merit for smart windows that can be used to identify the optimum smart window. In general, the important characteristics and those quoted in this work where they are available, are the selectivity, defined before, and the contrast ratio, or amount of switching, in both the visible and solar spectral ranges: $T_{\text{vis}}^{\text{clear}}/T_{\text{vis}}^{\text{colored}}$, and $T_{\text{sol}}^{\text{clear}}/T_{\text{sol}}^{\text{colored}}$, respectively. The contrast ratio is frequently quoted as the change in optical density, $\Delta\text{OD} = \log_{10}(T_{\text{vis}}^{\text{clear}}/T_{\text{vis}}^{\text{colored}})$. A complete description of window behavior involves the variation of the selectivity or contrast function of the switching parameter, schematically illustrated for several different devices in Fig. 3. Some authors prefer to use the g factor or total solar energy transmittance (TSET) rather than the solar transmittance because this includes the effects of thermal conduction through the window and secondary heat gains that arise from absorption in the glazing (6). A good single number that is frequently used to rate a smart window is the ratio of the maximum visible transmittance to the minimum value of total solar energy transmittance ($T_{\text{vis}}^{\text{clear}}/T_{\text{sol}}^{\text{colored}}$). Another approach to defining the performance of smart windows in buildings is the energy cost for a building when different types of windows are used. Selkowitz and Lampert (9) introduced this concept through a graph that compares the cooling and lighting costs (the costs most

Figure 3. affected by advanced glazing in commercial buildings) for different types of switchable glazings.

Other important aspects of windows and the materials used to make windows are durability (10), cost (11), color (12), and haze, or the amount of radiation which is diffusely transmitted (13).

SURVEY OF SMART WINDOWS

The principal smart window systems are summarized in Table 1 (2–5, 14–18). This table shows the switching mechanism, the method by which this mechanism is operated, whether the device exhibits memory, and the type of spectral response (selectivity and contrast) that occurs. The table also includes a control parameter that in most cases is the same as the operational switching parameter. However, in the context used here, the control parameter is one that can be measured and provides a degree of control over the optical state of the device. This is extremely important for practical applications of smart windows where it is essential to control the state of a device and to be able to switch the device. As can be seen in Fig. 3, of the electrically activated devices, the inorganic electrochromic devices provide the most linear response with respect to the control parameter, which in this case is injected charge density.

Electrochromic Smart Windows

Electrochromic materials undergo a change in their optical properties when an electrical potential difference is applied. A wide range of both organic and inorganic materials exhibit electrochromism. Inorganic electrochromic materials, most commonly transition-metal oxides, change from a clear to a colored state when ions and electrons are inserted into their lattice, under the application of a small dc voltage, that leads to optical absorption. Extraction of these ions and electrons is effected by a reversal of the electrical field and the material returns to the clear state. Organic electrochromic materials involve stoichiometric redox couples, where the oxidized and reduced forms have different colors. Therefore, the application of an electrical potential sufficient to change the oxidation state of the material causes a color change.

Inorganic Electrochromic Smart Windows. Many inorganic electrochromic materials may be produced in thin films on transparent electrically conducting substrates, thereby allowing their use in window fabrication. Tungsten trioxide (WO_3) the most commonly used inorganic electrochromic material is the compound in which electrochromism was first observed. Tungsten oxide can be colored by injecting electrons and small ions, including H^+ , Na^+ , K^+ and Li^+ , as schematically illustrated in the reaction scheme in Eq. (3a). Insertion of lithium and electrons into the tungsten trioxide structure (intercalation) forms the tungsten bronze Li_xWO_3 [reversible for $0 < x < 0.4$ (19)] which has a deep blue color. To fabricate an electrochromic device, a source of ions and electrons is required. The most common device structure used for inorganic electrochromic devices is illustrated in Fig. 4. There are a number of variants of this device structure that have different components, and this is discussed

Figure 4. A schematic illustration of the structure of a typical inorganic electrochromic device that shows the five-layer structure.

later. The most widely used counterelectrode materials are cerium–titanium oxide ($\text{CeO}_2\text{--TiO}_2$) (20), vanadium oxide (V_2O_5) (21), and derivatives. The complementary reaction at the counterelectrode in a $\text{WO}_3\text{--V}_2\text{O}_5$ device is illustrated in Eq. (3b), where Li^+ is the mobile ionic species (22):

The change in optical density is usually proportional to the charge density injected into the electrode (23,24), and the coloration efficiency, $\text{CE} = \Delta\text{QD}/Q_n$, is frequently used to characterize the performance of a film or device. A typical coloration efficiency for WO_3 -based electrochromics is between 55 and 70 mC/cm^2 at $\lambda = 700 \text{ nm}$ (25).

The electrochromic material usually changes its optical constants by developing an absorption band (26) or by increasing the effective free electron density in the material (27). These give rise to optical changes known as “absorption modulation” and “reflectance modulation” (7), respectively, according to whether the change in transmittance results from an increase in optical absorption or reflectance. Reflectance modulation is the preferable optical change for glazing materials because these materials do not absorb radiation significantly in the colored state, minimizing secondary heat gain and reducing the TSET value of the window. The specific behavior depends on the microstructure of the material; crystalline WO_3 films exhibit reflectance modulation, and amorphous WO_3 films show absorption modulation. The coloration efficiency spectra in Fig. 5 illustrate the change in the absorption characteristics of sputtered WO_3 as the deposition temperature is increased. Despite the better performance that can be obtained from reflectance modulation, the majority of prototype devices produced to date use absorption modulation.

Devices based on inorganic electrochromics are usually spectrally selective to some degree (Type B behavior in Fig. 2), and it is possible to modulate the solar transmittance of the window strongly and still maintain moderate visible transmittance, thus allowing significant daylighting in a building. This makes WO_3 an excellent candidate for smart windows where low solar transmittance is a major requirement and daylighting is a direct advantage.

Figure 5. The spectral coloration efficiency that is directly proportional to change in optical density in sputtered WO_3 . This shows the development of an absorption band in WO_3 during ion injection. Note the shift in the absorption band peak position as the substrate temperature increases and the film becomes more crystalline, representing the change from absorption to reflection modulation.

Organic Electrochromic Smart Windows. The absorption coefficients of organic electrochromic materials are generally extremely high compared to those of inorganic materials, so it is possible to produce devices that undergo drastic optical changes that involve very intense colors. The majority of organic electrochromic materials are conducting polymers. Some of these organic materials, such as polyaniline, have different colors for various oxidation states, so it is possible to achieve multiple coloration by stepwise oxidation or reduction (28). The transmittance of organic electrochromic materials depends on the specific compound; however, most of these materials switch primarily in the visible region and show little modulation of solar transmittance compared to inorganic systems (Type D spectral behavior). This makes organic electrochromics less suitable than inorganic electrochromics for smart window applications.

The most widely studied family of organic electrochromic materials is the viologens, which are currently used in a commercial, variable reflectance mirror for automobile rear view mirrors (Gentex Corporation). In this application, it is free from many of the problems associated with solar/UV degradation that occur in architectural glazing applications of smart windows. Polyaniline is a promising candidate for organic electrochromic smart windows due to its high stability and ability to undergo multiple color changes (28,29).

Thermochromic Devices

Thermochromic materials change their optical properties when heated and return to the original state when cooled to the initial temperature (30). The most widely studied inorganic thermochromic material and the best

candidate for large area thermochromic smart window applications is VO_2 and various doped forms of VO_2 (15). This material undergoes a metal-insulator phase transition at 68°C and exhibits metallic properties at high temperature and associated infrared reflectivity, as shown in Fig. 6a. The visible part of the spectrum is largely unaffected by the transition (Type C spectral behavior), so the principal change that occurs at switching is in solar transmittance. The visible transmittance decreases slightly, but there is a moderately strong absorption band in the visible spectrum in the low-temperature insulating state which means that visible transmittance is relatively low in both states.

The major area of research in developing large area smart windows that are useful for energy control in buildings is developing materials that have higher visible transmittance and, most importantly, a transition temperature close to room temperature. This means that windows will switch to a low transmittance state to prevent overheating in the building. Both of these areas have been the subject of considerable research, and numerous

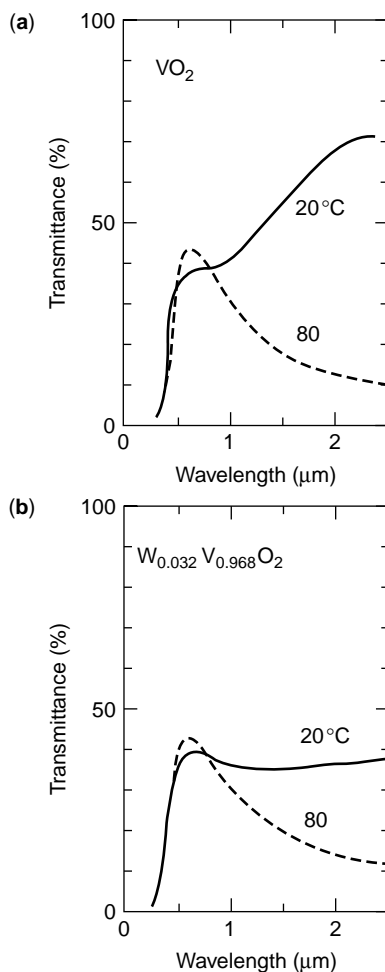

Figure 6. The transmittance of (a) VO_2 and (b) W -doped VO_2 at temperatures above (80°C) and below (20°C) the thermochromic transition. The spectra are type C in both cases (see Fig. 2). Reprinted from Sobhan et al. (15), with permission from Elsevier Science.

efforts have been made to dope VO_2 with various elements to achieve these goals. Fluorination of VO_2 (4) increases visible transmittance from 27 to 35% (in the low-temperature state) but also reduces the effect of switching; a change in solar transmittance from 44 to 40% occurs at the transition. However, the efforts to reduce the transition temperature have been much more successful; significant reduction in the thermochromic transition temperature from 68°C to approximately 10°C has been achieved for $\text{W}_{0.032}\text{V}_{0.968}\text{O}_2$ (15,31). This is illustrated in Fig. 6b.

Apart from the relatively poor spectral selectivity and contrast ratio of thermochromic devices, the inability to control the state of thermochromic devices independently makes it difficult to envisage wide ranging applications as smart windows.

Thermotropic Devices

Thermotropic devices, originally classed with thermochromic devices in the literature (32,33), also change their optical properties as temperature increases. However, the mechanism of the change is sufficiently different from typical inorganic thermochromic materials that they are now recognized as a different class of material. Thermotropic materials change between a specularly transmitting transparent state to a white, diffusely reflecting state as their temperature rises. The change is reversible. This change occurs through a phase separation that occurs in the materials at elevated temperatures that transforms the material from a homogeneous optical material to a heterogeneous, two-phase material at high temperature. The size of the particles of the two phases leads principally to backscattering of incident radiation (16).

There are two main types of thermotropic materials: hydrogels and polymer blends. Both systems have a similar device structure, as illustrated in Fig. 7. In both cases, the materials form homogeneous transparent mixtures at low temperatures, in which the two components are bound

together at a molecular or molecular cluster (macromolecular) level. The bonding is usually hydrogen bonding, and these bonds can be broken as the temperature increases from room temperature. Once the bonds break, the materials separate into distinct domains of different refractive index and cause scattering. If the particle size is appropriate (close to the wavelength of light across the solar spectral range), then strong scattering occurs.

Hydrogels. This is one class of thermotropic materials; the thermotropic material CloudGel, commercially available from Suntek, is of this type. As the name suggests, a hydrogel is a water/polymer mixture. Another example of these materials is the TALD hydrogel, which is a mixture of colloidal particles of a polyether/water mixture, embedded in a carboxyvinyl polymer and water gel (16). The colloidal particles are soluble in the gel at room temperature and below, but as the temperature increases, water is expelled from the colloidal particles, and the polyether particles become denser and increase their refractive index.

The switching temperature of hydrogels can be varied between 5 and 60°C by changing the proportions of the components. The materials switch across a reasonably wide temperature range, as illustrated in Fig. 8. The size of the particles in the phase-separated state and the thickness of the hydrogel layer (typically 1 mm) ensure that the majority of the radiation is backscattered by multiple scattering in the high-temperature state (see Fig. 8). This means that these thermotropic materials have good potential as energy efficient windows.

Polymer Blends. Polymer blends of thermotropic materials have the advantage of not containing liquid water. An example of a polymer blend hydrogel is a high refractive index (1.585) cross-linked matrix of polystyrol and polyhydroxyethyl methacrylate that has a second, low refractive index (1.45) phase of polypropylene oxide interpenetrating the matrix. At low temperatures, the lower refractive index

Figure 7. The structure of a thermotropic laminate. In the low-temperature state (a), the device is fully transparent, but in the high-temperature state (b), the thermotropic state separates into discrete particles, and the layer becomes scattering.

Figure 8. The normal-hemispherical reflectance of a thermotropic hydrogel laminate at a range of temperatures below (30°C) and above (>35°C) the thermotropic transition temperature. The spectra are type B and demonstrate a high degree of selectivity.

component is hydrogen bonded to the matrix. At higher temperatures, these bonds break, and the polypropylene oxide component forms small inclusions in the matrix that lead to scattering. The size of the scattering particles and the transition temperature depend on the proportions of the two components and the degree of cross-linking of the matrix.

Applications. The principal factors that constrain the application of thermotropic devices are the inability to control the device transmittance independently and the scattering state at high temperatures. The latter means that thermotropic devices are unlikely to be used in view windows, but they have applications in skylights and for overheating protection on brick facades. These applications have been extensively investigated (16), and large area windows can be routinely produced.

Polymer Dispersed Liquid Crystal Devices

There are many classes of liquid crystals. Most liquid crystals consist of thin, needle-like or rod-shaped organic molecules that exhibit significant ordering properties. There are several classes of electro-optic devices that can be formed using liquid crystals, but only two classes—guest–host systems and polymer dispersed liquid crystals (PDLC)—have been extensively investigated for use in smart windows. Lampert (34) provides an excellent introduction to the physics of liquid crystals, and Basturk and Grupp (35) and Montgomery (3) provide good reviews of the basics of both types of liquid crystal devices.

The principal liquid crystal devices currently available are PDLC devices, which are commercially available from 3M under the name “Privacy Film.” This device consists of a PDLC film sandwiched between ITO-coated sheets of glass, as illustrated in Fig. 9. The PDLC film consists of spherical liquid crystal droplets embedded in a polymer matrix. The typical droplet diameter is about $1\ \mu\text{m}$ or less, of the same order of magnitude as light wavelengths. When a voltage is applied to the ITO electrodes, the liquid crystal molecules are oriented in the field direction, resulting in index matching between the droplets and the matrix, and thus high transmittance for light propagating parallel to the applied field. When the field is switched off, the liquid crystal molecules reorient randomly; the (unmatched) value of the extraordinary refractive index also becomes effective and causes scattering at the droplet surfaces, and the film appears milky.

Figure 9. The structure of a PDLC device. Unlike an electrochromic device, it is not a conducting device, and switching depends on the electrical field across the PDLC layer.

Figure 10. Normal-hemispherical transmittance spectra for a PDLC device at applied voltages of 0, 10, 20, 30 and 100 V. The device is opaque (in the sense that images cannot be perceived through the device in the off state (0V), but it still transmits significant energy. Reproduced with permission of Dr. Arne Roos.

Although PDLC devices act very effectively as privacy screens and have essentially zero specular transmittance in the zero voltage state and good transmittance but some diffuse scattering in the “on” state, the devices are not particularly effective for energy conservation because the majority of the scattered radiation is forward scattered. This is illustrated in Fig. 10, which shows total transmittance (including diffuse transmittance). The device is totally opaque in the “off” state (0V), but the total transmittance is still substantial. Another drawback of PDLC devices and all liquid crystal systems is the lack of memory in the devices. This is intrinsic to liquid crystal systems because the alignment of liquid crystal molecules is caused by dipolar polarization in the applied field. The curves in Fig. 10 also show the highly nonlinear behavior of switching as voltage is applied, which is the control parameter in Fig. 10 for the PDLC device.

Suspended Particle Devices

Suspended particle devices, also termed “light valves,” consist of a suspension of fine particles that are strongly absorbing in the “off” state (no applied voltage), but which can be aligned by applying an electrical field, leading to a transparent “on” state. The device requires constraining the suspension between conducting electrodes; in the large area devices currently being commercialized by Hankuk Glass, these are deposited on a PET film, which is then laminated to glass (2). The suspended particles are usually needle-shaped particles of polyiodides or parathite approximately $1\ \mu\text{m}$ long that are suspended in an organic liquid (32). In current devices, methods have been developed to encapsulate microdroplets that contain the suspended particles in a polymer matrix. The device structure is essentially identical to the PDLC device (Fig. 9), and the suspended particle layer replaces the PDLC layer.

In the absence of an applied electrical field, the particles are randomly arranged and absorb incident radiation. The absorption in all states (from zero applied voltage to the

promising, however; one gasochromic smart window 1.1×0.6 m has been cycled 10,000 times, and there was no significant reduction in its performance (18).

ELECTROCHROMIC SMART WINDOWS

As noted in the second section one of the most promising candidates for a future commercial smart windows is an electrochromic glazing based on inorganic electrochromic materials. Inorganic electrochromic smart windows are also the closest to commercial production for large area architectural applications and have substantial potential for reducing building energy use. Hence, the discussion following is based on windows made from inorganic materials, in particular, tungsten oxide.

The method of window control is also very important. To optimize energy performance, it is essential to be able to set specific optical states independent of temperature and irradiance incident on the window. The lifetime of electrochromic films and entire devices can be reduced by using improper control methods (41).

Various different types of electrochromic material and window testing and control (42) have been used: constant voltage control, trapezoidal voltage waveform (10), cyclic voltammetry (triangular voltage waveform) (43), and constant current control (44). There have also been many theoretical analyses of the charge injection and extraction processes. It is widely recognized that the coloration process is based on double injection of ions and electrons that form tungsten bronze M_xWO_3 (22). There are various theories regarding the mechanisms that limit the coloration current. They include the presence of a barrier at the ion injecting interface (electrolyte/ WO_3 interface) (22,45), diffusion limited motion of ions within the electrochromic films (46,47), and the series resistance of the cell (48,49). Impedance spectroscopy has been used by a number of authors recently to study ion injection kinetics in electrochromics (50,51), and this holds some promise as a useful tool for analyzing the degradation of smart windows in operation.

Electrochromic Smart Window Structures

The basic multilayer electrochromic device structure is shown in Fig. 4. There are two electrodes in all electrochromic devices to enable electron flow, an active electrochromic layer, and an ion storage and/or ion conducting layer to allow ions to move into and out of the active layer. It is possible to classify various electrochromic devices according to the structure and materials used to achieve ion injection and extraction in a device. There are three principal generic device types, which are all essentially the same as that shown in Fig. 4, but use different approaches to the ion transport and ion storage layers. The materials used in these devices are discussed in more detail later.

Type 1—Ion Conducting Layer and Passive Counterelectrode. The most widely used device structure has an ion transport layer (also called the electrolyte layer) between the working electrode and an ion storage

electrode (which is also called the counterelectrode). The fundamental requirement of the ion storage layer is charge capacity—the amount of charge (number of ions) that can reversibly be stored in the layer. The charge capacity is normalized to the electrode area and is measured in mC/cm^2 . The charge capacity of the ion storage electrode should be in excess of the charge required for sufficient coloration of the working electrode. Typical values are from 15–30 mC/cm^2 . It is also essential to achieve high transparency of the counterelectrode, which often conflicts with the requirement for high charge capacity. Another requirement for the ion storage layer in this structure is low coloration efficiency. A good ion storage electrode should have very large charge capacity and be optically passive. Two examples of devices of this type are the prototype commercial window produced by Sustainable Technologies Australia (STA) and the commercially available window produced by Flabeg (Pilkington). These devices incorporate a modified WO_3 electrochromic electrode, a V_2O_5 -based counterelectrode, and a lithium-doped cross-linked polymer electrolyte. STA uses sol-gel deposition of the electrodes, whereas Flabeg uses vacuum deposition. Spectra of the colored and bleached states of the STA device are shown in Fig. 12.

Type 2—Combined Ion Conducting Layer and Counterelectrode. In the second approach to device design, charge delivery and charge storage are realized in one layer. This is the ion conducting layer, which contains a dispersed redox couples; thus in the deintercalated state, ions are stored in the electrolyte. An example of this type of device is based on WO_3 as the working electrode and a solid polymer electrolyte that contains lithium polyorganodisulfide redox salts (52). These devices have the advantage of simplicity of manufacture and require deposition of one less layer than Type 1 devices. In addition, the redox salts are generally optically passive, so the charge capacity of the counter electrode is not an issue. However, the redox reaction occurs only at the surface of the layer, and

Figure 12. Transmittance spectra for colored and bleached states of an STA electrochromic device. The selectivity in both states is shown on the graph, indicating the increase in selectivity in the colored state. The dynamic range for the device is $T_{sol} = 51.5\%$ to $T_{sol} = 20.6\%$, and the injected charge is $10 mC/cm^2$.

transport of the electrons across the polymer layer from the TEC on the counterelectrode side of the device can limit the device.

Type 3—Ion Transport Layer and Complementary Counterelectrode. The third device structure is very similar to the first type because there are separate ion transport and counterelectrode layers. However, the counterelectrode is an electrochromic material which is complementary to the working electrode, that is, it is an anodically coloring electrochromic material that darkens upon extraction of ions from the counterelectrode and bleaches upon injection of ions (53). In this way, both electrodes contribute to the coloration of the electrochromic device and enhance the overall performance of the device. This type of device has the advantage that it requires less overall charge transport to achieve the same level of coloration as a type 1 device. Hence, the charge capacity requirements of the electrodes are lower than those of type 1 devices. A device of this type has been developed by the Asahi Glass Company (Japan). This device has the following structure: glass/TEC (200 nm)/NiO_x (500 nm)/Ta₂O₅ (500 nm)/WO₃ (500 nm)/TEC (500 nm)/adhesive film (250 μm)/glass. The spectral response of this device is shown in Fig. 13 at four different levels of charge injection. Note that the change in optical density per unit charge is significantly larger for this device than for the STA device of type 1 (see Figs. 3 and 12) due to the coloration of both the working electrode (WO₃) and the counterelectrode (NiO_x).

Materials Used in Electrochromic Devices

Electrochromic Materials. Tungsten oxide is currently the most commonly used inorganic electrochromic material. Coloration during ion insertion (H⁺, Li⁺, Na⁺, and K⁺) and bleaching on ion extraction is termed cathodic coloration. In an electrochromic smart window, thin film electrodes must be in contact with the working and counterelectrodes, and an electrolyte is required for ion transport. Use of electrochromic materials in window fabrication necessitates the transparency of all components, and

these constraints limit the number of materials suitable for electrochromic device fabrication.

Numerous metal oxides are suitable for use as the electrochromic layer in smart windows; a detailed discussion of electrochromism in these materials is given in Granqvist (54). The most widely studied electrochromic materials are WO₃ and doped WO₃, where the dopant is another transition-metal oxide such as TiO₂ or MoO₃. Tungsten oxide films are commonly prepared by thermal evaporation and sputtering, but CVD (chemical vapor deposition), spray deposition, anodization, and sol-gel deposition have also been used. A detailed discussion of these deposition techniques and their effects on the properties of the deposited materials is given in Granqvist (54), Bell and Matthews (55), and references therein. On the basis of the amount of charge which can be inserted, the coloration efficiency and the transmittance change of the film, the electrochromic performance of WO₃ deposited by most techniques is similar; the most important effect is increased crystallinity in films sputtered onto heated substrates (above approximately 350°C) or in sol-gel deposited films heat treated at temperatures of 350–400°C after deposition. This increase in crystallinity is usually accompanied by an increase in reflectance modulation in films.

Other inorganic electrochromic systems that have received significant attention are NiO, TiO₂, IrO₂, Nb₂O₅, and more recently, SnO₂ and Pr₂O₃. A variety of techniques has been used to deposit all of these coatings, but none of these materials shows the electrochromic efficiency of WO₃.

Counterelectrode Materials. NiO and V₂O₅ have been extensively studied as potential counterelectrode materials for electrochromic devices (54); CeO₂-TiO₂, and more recently CeO₂-ZrO₂, were extensively studied in the past few years (20). NiO is particularly attractive because it colors anodically (on the extraction of ions) and hence complements both the coloration and bleaching of the cathodically coloring WO₃ layer (53). (see previous discussion). V₂O₅ has excellent charge capacity and can be produced relatively easily using sol-gel deposition (21), but it has the disadvantage of an absorption edge that encroaches into the visible region of the spectrum and results in a yellowish coloration in the films (56). Initially (up to the early 1990s), sputtering and evaporation dominated the deposition of electrochromics, but sol-gel deposition is becoming very widespread, except for NiO, although there has been one report of sol-gel deposited NiO (57).

Ion Transport Layer. The function of the electrolyte layer is to allow ions to travel between the working and counterelectrodes; hence, it is ionically conducting. Low electronic conductivity of the electrolyte layer is advantageous because it reduces the internal leakage current in a device and allows devices to stay colored for long periods of time without the need for an external power source.

Electrolytes used in electrochromic smart windows can be classified as either polymeric or superionic conductors. Polymeric electrolytes are prepared as liquids that contain some dissolved lithium salt, and are then used to

Figure 13. Transmittance spectra of an Asahi electrochromic device in the bleached state and for three colored states, where 5 mC/cm², 10 mC/cm² and 15 mC/cm² are injected into the WO₃ layer at a constant potential of 1.5 V.

lamine the working and counterelectrode layers together. Therefore, the polymer allows ionic conduction and gives the device its mechanical strength. Superionic conductors such as M- β -Alumina (where M is a monovalent metal such as Li, Na, or K) allow ions to move through the host lattice of alumina. These electrolytes are advantageous because they are not prone to damage by factors such as UV irradiation and can be deposited directly onto the electrochromic layer; however, they may have nonzero electrical conductivity which leads to reduced memory in the colored state. The Asahi device which uses Ta₂O₅ as an ion conducting layer has poor memory compared to devices that use polymer-based electrolytes (e.g., the STA device discussed previously) (14).

Transparent Electronic Conductors. The transparent electrical conductors in most electrochromic devices are thin films of metal oxides such as indium-doped tin oxide (SnO₂:In or ITO) and fluorine-doped tin oxide (SnO₂:F or FTO). These materials are commercially available precoated onto glass substrates by spray pyrolysis methods (58). Some electrochromic devices use conducting polymeric layers such as ITO-PET (ITO coated onto polyethylene terephthalate) as the transparent electrical conductors, which allows fabrication of polymeric solid-state electrochromic devices (59).

Control of Electrochromic Smart Windows

The application of electrochromic smart windows in architectural glazings requires that the devices perform tens of thousands of switching cycles during a period of 20–30 years and undergo minimal degradation in optical performance. The lifetime of a smart window is measured in the number of coloration/bleaching cycles, when the transmittance in each cycle is modulated between specified maximum and minimum values. However, the transmittance of the window, particularly of an installed window, is not easily accessible. As illustrated in Fig. 3, the optical density of an electrochromic window has a one-to-one (and very nearly linear) relationship to injected charge density. This relationship is also almost independent of temperature (Fig. 14), so a good switching algorithm for electrochromic smart windows can be based on charge control. When considered as an electrochemical system, an electrochromic device is very similar to a rechargeable battery. The energy in the battery is stored and released by reversible redox reactions. In electrochromic devices, these reactions result in optical changes. The durability of batteries has been investigated extensively during the last 50 years, and several empirical relationships between the lifetime and operational parameters have been found (60). In particular, it is found that battery lifetime is inversely proportional to the operational current, so the switching current must be small enough to provide a long lifetime.

In the design of a control algorithm for electrochromic windows, two fundamental limits that restrict fast switching of the window must be considered:

- Thermodynamic limit (overvoltage)—the voltage must be maintained below the potential at which destructive side reaction(s) occur; and

Figure 14. Electrochromic device performance at 50°C (+) and 18°C (x). The solid lines represent the device voltage, and the dashed lines the relative transmittance of the device. The operational parameters in both cycles are current density = 0.1 mA/cm², $Q_{in} = 13$ mC/cm²; $Q_{out} = -13$ mC/cm²; preset switching voltages are $V_{max} = 1.8$ V, $V_{min} = -0.7$ V. Note that at 50°C, the voltage does not reach V_{max} . The high-temperature cycle period is shorter and lower voltages are required; however, the transmittance change in the two cycles is almost identical.

- Kinetic limit (excessive charging current)—large currents cause irreversible cation trapping on the surface of the film (44) due to charge “pile-up” at the surface. This is usually caused by slow cation diffusion into the electrochromic layer.

Of course, if the voltage is too small, the desirable electrochromic reaction can never occur, and if the charging current is too small, the switching time of the window is unacceptably long. Therefore, both current and voltage need to be maintained within fixed limits to achieve optimum device lifetime, and charge is used as an independent parameter to control the optical state of the device.

Both thermodynamic (redox potentials) and kinetic (resistance, diffusion coefficients) properties of electrochromic window are temperature dependent; thus, they generally require adjustments in switching parameters for changing environmental conditions. For example, a constant applied voltage will not provide a constant contrast ratio at different temperatures due to the dependence of the film potential on temperature. At high temperatures, a voltage suitable for low temperature could exceed the potential of side reactions (thermodynamic limit) and will lead to higher currents and possible kinetic device failure.

Typical cycles of an electrochromic window at 50 and 18°C are presented in Fig. 14. The charge intercalated into the working electrode is the same in both cycles; therefore, the changes in optical transmittance are almost identical. The charging current density is also identical at the two temperatures; however at 50°C, the window required significantly lower coloring voltage because diffusion coefficients and electrolyte conductance increase with

temperature. The control algorithm implemented to produce these results includes constant current charging until the injected charge exceeds a given value Q_{in} . If the voltage exceeds a predetermined safe value V_{max} , the system automatically switches to a constant voltage mode. In the bleaching part of a cycle the extracted charge shall not exceed Q_{out} , and voltage shall be lower in magnitude than a predetermined maximum bleaching voltage V_{min} . Methods for controlling electrochromic devices by using these techniques are described in patents (61,62), and the theoretical background is outlined in Bell et al. (41,44).

FUTURE DIRECTIONS

Commercially available smart windows enabling energy control in buildings are now available (63). There are still significant questions about the durability of such windows, and the major research efforts in the immediate future will be to improve window durability during cycling. The advantage of electrochromic windows in terms of independent control of the optical state (using injected charge density) is actually a disadvantage in this context because it allows overdriving the device, whereas gasochromic and thermally switched devices are intrinsically self-limiting in switching the windows. However, other durability issues exist for these devices.

Two issues need to be addressed to improve the performance of smart windows in architectural glazing applications: the development of truly reflective smart window devices (like crystalline electrochromic materials, thermotropic glazings, and some of the recently discovered gasochromic materials) that are fully specular and (relatively) color-neutral; and control of the thermal emittance of glazings. The latter will broaden the range of climates in which smart windows can be useful and will also open up a new range of nonarchitectural applications.
