PREFACE

The Encyclopedia of Smart Materials (ESM) contains the writings, thoughts, and work of many of the world's foremost people (scientists, educators, chemists, engineers, laboratory and innovative practitioners) who work in the field of smart materials. The authors discuss theory, fundamentals, fabrication, processing, application, applications and uses of these very special, and in some instances rare, materials.

The term "smart structure" and "smart materials" are much used and abused.

Consideration of the lexicology of the English language should provide some guidelines, although engineers often forget the dictionary and evolve a language of their own. Here is what the abbreviated Oxford English Dictionary says:

- *Smart*: severe enough to cause pain, sharp, vigorous, lively, brisk . . . clever, ingenious, showing quick wit or ingenuity . . . selfishly clever to the verge of dishonesty;
- *Material*: matter from which a thing is made;
- *Structure*: material configured to do mechanical work . . . a thing constructed, complex whole.

The concept of "smart" or "intelligent" materials, systems, and structures has been around for many years. A great deal of progress has been made recently in the development of structures that continuously and actively monitor and optimize themselves and their performance through emulating biological systems with their adaptive capabilities and integrated designs. The field of smart materials is multidisciplinary and interdisciplinary, and there are a number of enabling technologies—materials, control, information processing, sensing, actuation, and damping—and system integration across a wide range of industrial applications.

The diverse technologies that make up the field of smart materials and structures are at varying stages of commercialization. Piezoelectric and electrostrictive ceramics, piezoelectric polymers, and fiber-optic sensor systems are well-established commercial technologies, whereas micro-machined electromechanical systems (MEMS), magnetostrictive materials, shape memory alloys (SMA) and polymers, and conductive polymers are in the early stages of commercialization. The next wave of smart technologies will likely see the wider introduction of chromogenic materials and systems, electro- and magneto-rheological fluids, and biometric polymers and gels.

Piezoelectric transducers are widely used in automotive, aerospace, and other industries to measure vibration and shock, including monitoring of machinery such as pumps and turbomachinery, and noise and vibration control. MEMS sensors are starting to be used where they offer advantages over current technologies, particularly for static or low frequency measurements. Fiber-optic systems are increasingly being used in hazardous or difficult

environments, such as at high temperatures or in corrosive atmospheres.

Automotive companies are investigating the use of smart materials to control vehicles in panels, such as damping vibration in roof panels, engine mounts, etc. Aerospace applications include the testing of aircraft and satellites for the strenuous environments in which they are used, both in the design phase and in use, as well as for actuators or devices to react to or control vibrations, or to change the shape of structures.

In civil engineering, especially in earthquake-prone areas, a number of projects are under way to investigate the use of materials such as active composites to allow support systems of bridges (and the like) to handle such shocks without catastrophic failure. These materials can be used in many structures that have to withstand severe stresses, such as offshore oil rigs, bridges, flyovers, and many types of buildings.

The ESM will serve the rapidly expanding demand for information on technological developments of smart materials and devices. In addition to information for manufacturers and assemblers of smart materials, components, systems, and structures, ESM is aimed at managers responsible for technology development, research projects, R&D programs, business development, and strategic planning in the various industries that are considering these technologies. These industries, as well as aerospace and automotive industries, include mass transit, marine, computer-related and other electronic equipment, as well as industrial equipment (including rotating machinery, consumer goods, civil engineering, and medical applications).

Smart material and system developments are diversified and have covered many fields, from medical and biological to electronic and mechanical. For example, a manufacturer of spinal implants and prosthetic components has produced a prosthetic device that dramatically improves the mobility of leg amputees by closely recreating a natural gait.

Scientists and doctors have engineered for amputees a solution with controllable magneto-rheological (MR) technology to significantly improve stability, gait balance, and energy efficiency for amputees. Combining electronics and software, the MR-enabled responsiveness of the device is 20 times faster than that of the prior state-of-the-art devices, and therefore allows the closest neural human reaction time of movement for the user. The newly designed prosthetic device therefore more closely mimics the process of natural thought and locomotion than earlier prosthetic designs.

Another example is the single-axis accelerometer/sensor technology, now available in the very low-profile, surface-mount LCC-8 package. This ceramic package allows users to surface-mount the state-of-the-art MEMS-based sensors. Through utilization of this standard packaging profile, one is now able to use the lowest

profile, smallest surface-mountable accelerometer/sensor currently available. This sensor/accelerometer product technology offers on-chip mixed signal processing, MEMS sensor, and full flexibility in circuit integration on a single chip. Features of the sensor itself include continuous self-test as well as both ratiometric and absolute output. Other sensor attributes include high long-term reliability resulting from no moving parts, which eliminates striction and tap-sensitive/sticky quality issues.

Application areas include automotive, computer devices, gaming, industrial control, event detection, as well as medical and home appliances. In high-speed trains traveling at 200 km/h, a droning or rumbling is often heard by passengers. Tiny imperfections in the roundness of the wheels generate vibrations in the train that are the source of this noise. In addition to increasing the noise level, these imperfect wheels lead to accelerated material fatigue. An effective countermeasure is the use of actively controlled dampers. Here a mechanical concept—a specific counterweight combined with an adjustable spring and a powerful force-actuator—is coupled with electronic components. Simulations show what weights should be applied at which points on the wheel to optimally offset the vibrations. Sensors detect the degree of vibration, which varies with the train's speed. The electronic regulator then adjusts the tension in the springs and precisely synchronizes the timing and the location of the counter-vibration as needed. Undesirable vibration energy is diffused, and the wheel rolls quietly and smoothly. In this way, wear on the wheels is considerably reduced.

The prospects of minimized material fatigue, a higher level of travel comfort for passengers, and lower noise emissions are compelling reasons for continuing this development.

Novel composite materials discovered by researchers exhibit dramatically high levels of magneto-resistance, and have the potential to significantly increase the performance of magnetic sensors used in a wide variety of important technologies, as well as dramatically increase data storage in magnetic disk drives. The newly developed extraordinary magnetoresistance (EMR) materials can be applied in the read heads of disk drives, which, together with the write heads and disk materials, determine the overall capacity, speed, and efficiency of magnetic recording and storage devices. EMR composite materials will be able to respond up to 1000 times faster than the materials used in conventional read heads, thus significantly advancing magnetic storage technology and bringing the industry closer to its long-range target of a disk drive that will store a terabit (1000 gigabits) of data per square inch.

The new materials are composites of nonmagnetic, semiconducting, and metallic components, and exhibit an EMR at room temperature of the order of 1,000,000% at high fields. More importantly, the new materials give high values of room-temperature magnetoresistance at low and moderate fields. Embedding a highly conducting metal, such as gold, into a thin disc of a nonmagnetic semiconductor, such as indium antimonide, boosts the magnetoresistance, and offers a number of other advantages. These include very high thermal stability, the potential for much

lower manufacturing costs, and operation at speeds up to 1000 times higher than sensors fabricated from magnetic materials.

Envisioned are numerous other applications of EMR sensors in areas such as consumer electronics, wireless telephones, and automobiles, which utilize magnetic sensors in their products. Future EMR sensors will deliver dramatically greater sensitivity, and will be considerably less expensive to produce.

Another recent development is an infrared (IR) gas sensor based on MEMS manufacturing techniques. The MEMS IR gas SensorChip will be sensitive enough to compete with larger, more complex gas sensors, but inexpensive enough to penetrate mass-market applications. MEMS technology should simplify the construction of IR gas sensors by integrating all the active functions onto a single integrated circuit.

Tiny electronic devices called “smart dust,” which are designed to capture large amounts of data about their surroundings while floating in the air, have been developed. The project could lead to wide array of applications, from following enemy troop movements and detecting missiles before launch to detecting toxic chemicals in the environments and monitoring weather patterns. The “Smart Dust” project aims to create massively distributed sensor networks, consisting of hundreds to many thousands of sensor nodes, and one or more interrogators to query the network and read out sensor data. The sensor nodes will be completely autonomous, and quite small. Each node will contain a sensor, electronics, power supply, and communication hardware, all in a volume of 1 mm³.

The idea behind “smart dust” is to pack sophisticated sensors, tiny computers, and wireless communications onto minuscule “motes” of silicon that are light enough to remain suspended in air for hours at a time. As the motes drift on the wind, they can monitor the environment for light, sound, temperature, chemical composition, and a wide range of other information, and transmit the data back to a distant base station. Each mote of smart dust is composed of a number of MEMS, wired together to form a simple computer. Each mote contains a solar cell to generate power, sensors that can be programmed to look for specific information, a tiny computer that can store the information and sort out which data are worth reporting, and a communicator that enables the mote to be interrogated by the base unit. The goals are to explore the fundamental limits to the size of autonomous sensor platforms, and the new applications which become possible when autonomous sensors can be made on a millimeter scale.

Laser light can quickly and accurately flex fluid-swollen plastics called polymer gels. These potential polymer muscles could be used to power robot arms, because they expand and contract when stimulated by heat or certain chemicals. Gel/laser combinations could find applications ranging from actuators to sensors, and precisely targeted laser light could allow very specific shape changes. Polymer gels have been made to shrink and swell in a fraction of a second. Targeting laser light at the center of a cylinder made of *N*-isopropylacrylamide pinches together the tube's edges to form a dumb-bell shape. The cylinder

returns to its original shape when the laser is switched off. This movement is possible because in polymer gels, the attractive and repulsive forces between neighboring molecules are finely balanced. Small chemical and physical changes can disrupt this balance, making the whole polymer to violently expand or collapse. Also it has been shown that radiation forces from focused laser light disturb this delicate equilibrium, and induce a reversible phase transition. Repeated cycling did not change the thresholds of shrinkage and expansion; also, the shrinking is not caused by temperature increases accompanying the laser radiation.

The field of smart materials offers enormous potential for rapid introduction and implementation in a wide range

of end-user sectors industries. Not only are the organizations involved in research and preliminary development keen to grow their markets in order to capitalize on their R&D investment, but other technologically aware companies are alerted to new business opportunities for their own products and skillsets.

The readers of this ESM will appreciate the efforts of a multitude of researchers, academia, and industry people who have contributed to this endeavor. The editor is thankful to Dr. James Harvey and Mr. Arthur Biderman for their initial efforts in getting the project off the ground and moving the program.

Mel Schwartz

Table of Contents

Preface	vii
Actuators to Architecture	
Actuators, Piezoelectric Ceramic, Functional Gradient	1
Introduction	1
Actuators	1
Piezoelectric Ceramics	2
Functionally Graded Materials	7
Summary	1
Acknowledgments	14
Bibliography	15
Adaptive Composite Systems: Modeling and Applications	16
Introduction	16
Actuators and Sensors	16
Adaptive Composite Modeling	18
Applications	20
Concluding Remarks	25
Bibliography	25
Adaptive Systems, Rotary Wing Applications	28
Introduction	28
Active / Passive Control of Structural Response	29
Passive / Active Control of Damping	30
Trailing Edge Flaps	32
Servoflap	34
Active Twist	35
Modeling	37
Future Directions	39
Bibliography	40
Aircraft Control, Applications of Smart Structures	42
Introduction	42
Smart Structures for Flight in Nature	43
General Remarks on Aspects of Aircraft Design	44
Traditional Active or Adaptive Aircraft Control Concepts	44
The Range of Active Structures and Materials Applications in Aeronautics	45
Aircraft Structures	45
Smart Materials for Active Structures	47
The Role of Aeroelasticity	47
Overview of Smart Structural Concepts for Aircraft Control	50
Quality of the Deformations	54
Achievable Amount of Deformation and Effectiveness of Different Active Aeroelastic Concepts	55
Need for Analyzing and Optimizing the Design of Active Structural Concepts	56
Summary, Conclusions, and Predictions	57
Bibliography	58

INTRODUCTION

Actuators and materials play a key role in developing advanced precision engineering. The breakthroughs in this field are closely related to the development of various types of actuators and related materials. The successes of piezoelectric ceramics and ceramic actuators have. For instance, the propagating-wave type ultrasonic motor that produces precise rotational displacements has been used in autofocusing movie cameras and VCRs (1). Multimorph ceramic actuators prepared from electrostrictive $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$ (PMN) ceramics are used as deformable mirrors to correct image distortions from atmospheric effects (2). The likelihood that the range of applications and demand for actuators will grow actively and has stimulated intensive research on piezoelectric ceramics. Functionally graded materials (FGMs) are a new class of composites that contain a continuous, or discontinuous, gradient in composition and microstructure. Such gradients can be tailored to meet specific needs while providing the best use of composite components. Furthermore, FGM technology is also a novel interfacial technology for solving the problems of the sharp interface between two dissimilar materials. In recent years, significant advances in developing FGMs have been achieved. In this paper, we introduce and summarize the recent progress in piezoelectric ceramic actuators and review recent applications of FGMs in piezoelectric ceramic devices.

ACTUATORS

Background

Microelectromechanical and intelligent materials systems have received much attention because of their great scientific significance and promising potential applications in automation, micromanipulation, and medical technology. However, most applications require a source of mechanical power, microscale motors and actuators, that provide the effect of "muscles" to make things happen. To date, several different physical mechanisms such as electrostatic and magnetostatic forces, phase changes (shape memory alloys and electro-rheological fluids), piezoelectric/electrostrictive strains, magnetostriction, and thermal stresses have been explored as potential actuation sources.

Each kind of actuator has its own advantages and drawbacks, so their selection and optimization should be determined by the requirements of the application.

Ceramic Actuators

Piezoelectric/electrostrictive ceramics are widely used in many different types of sensing-actuating devices. This is particularly true for the whole family of micro- and macro-piezoelectric ceramic actuators. Various types of ceramic actuators have been developed for different applications. From a structural point of view, ceramic actuators are classified as unimorph, bimorph, Moonie, Cymbal, and Rainbow monomorph benders (3–7). The bimorph bender consists of two thin ceramic elements (poled in opposite directions) that sandwich a thin metal shim, whereas the unimorph is simply on a thin ceramic element bonded to a thin metal plate. Although unimorph and bimorph structures have been successfully applied to many devices during the past forty years, their inability to extend the force-displacement envelope of performance has generated a search for new actuator technologies. The Moonie bender has crescent-shaped, shallow cavities on the interior surface of end caps bonded to a conventionally electroded piezoelectric ceramic disk (5). The metal end caps are mechanical transformers for converting and amplifying the lateral motion of the ceramic into a large axial displacement normal to the end caps. Both the $d_{31}(=d_{32})$ and d_{33} coefficients of a piezoelectric ceramic contribute to the axial displacement of the composite. The advantages of the Moonie include (1) a factor of 10 enhancement of the longitudinal displacement, (2) an unusually large d_{33} coefficient that exceeds 2500 pC/N, and (3) an enhanced hydrostatic response. Recent improvements in the basic Moonie design have resulted in an element named "Cymbal" (6), a device that possesses more flexible end caps that result in higher displacement. Moonie and Cymbal composites have several promising applications, such as transceivers for fish finders, positional actuators, and highly sensitive accelerometers.

Another device developed to increase the force-displacement performance of a piezoelectric actuator is the rainbow (7), a monolithic monomorph that is produced from a conventional, high-lead piezoelectric ceramic disk that has one surface reduced to a nonpiezoelectric phase by a high-temperature, chemical reduction reaction. Thermal stresses induced on cooling from the reduction temperature, due to the different thermal expansion coefficients of the reduced and unreduced layers, cause the ceramic disk to deform with high axial displacements and sustain moderate pressure. The axial displacements achieved when driven by an external electric field can be as high as 0.25 mm (for a 32-mm diameter \times 0.5-mm thick wafer), while sustaining loads of 1 kg. Displacements larger than 1 mm can be achieved by using wafers (32 mm in diameter) thinner than 0.25 mm when operating in a saddle

mode. Prototypes of rainbow pumps, sensors, actuator arrays, and optical deflectors have been demonstrated, but commercial products have not yet been produced (8).

The photostrictive actuator is another type of bimorph application. The photostrictive behavior is results from a combined photovoltaic effect and a piezoelectric effect. PZT ceramics doped with slight additives of niobium and tungsten exhibit a large photostrictive effect when irradiated by violet light. A photostrictive PLZT bimorph has been used to demonstrate the prototype of a photodriven relay for a remote microwalking device, and a photophone for the future is also envisioned (9).

There is also increasing interest in electrostrictive ceramic actuators (10) because electrostrictive ceramics do not contain ferroelectric domains, so that they can return to their original dimensions immediately, when the external electric field is reduced to zero. Therefore, the advantages of an electrostrictive actuator are the near absence of hysteresis and lack of aging behavior. However, because the electrostrictive effect is a second-order phenomenon of electromechanical coupling, it is usually necessary to apply a high voltage to achieve moderate deformation. However, a particularly large longitudinal electrostrictive strain as high as 0.1% has been achieved in PMN-based relaxor materials (11–13) just above their Curie temperature. To decrease the applied voltage, a considerable effort is now being devoted to developing multilayered actuators, which have the advantages of low operating voltage, large generated forces and displacements, quick response, and low energy consumption (10).

Composite Actuators

Piezoelectric/electrostrictive ceramics, magnetostrictive materials, and ferroelastic shape memory alloys (SMA) are all used for actuators. However, different classes of ceramic actuators require somewhat different materials. In general, an ideal actuating material should exhibit a large stroke, high recovery force, and superior dynamic response. Shape memory alloys display large strokes and forces but have an inferior dynamic response and low efficiency. Ferroelectric ceramics exhibit excellent dynamic response (of the order of microseconds), but their displacements are quite small (of the order of a few micrometers) due to their small strain magnitude ($<10^{-3}$). By combining ferroelastic shape memory alloys with piezoelectric, or magnetostrictive, materials, hybrid smart heterostructures can be fabricated, which may have the optimum characteristics of both materials. Recently much work has been done to explore the technical feasibility of smart thin film heterostructures by depositing piezoelectric thin films (PZT) on SMA substrates using techniques such as sol-gel, spin-on coating, and pulse laser deposition (14,15). However, cracking of ferroelectric thin films and the low interfacial bonding and dynamic coupling of dissimilar components are crucial problems to be solved before hybrid composites can be employed as actuators in for smart structures. To feature the diverse characteristics, various kinds of smart hybrid composites will be designed for actuating applications by incorporating these smart materials appropriately together.

It is clear that the application field of ceramic actuators is remarkably wide. However, some issues of reliability and

durability still need to be solved before ceramic actuators can become general-purpose commercialized products, especially for ferroelectric ceramic actuators. It is very desirable to develop new fatigue methodology and fracture mechanics to predict actuator dynamic response and lifetime, to assess actuator reliability, and to implement them in control methodology. The main issues in constitutive behavior are coupled field effects, modeling of phase transformations, twinning, and domain switching (in the finite strain regime). Good understanding of fatigue and fracture behavior at the microlevel and understanding interfacial failure mechanisms (active–passive and active–active) and the mechanics of hybrid active materials is the rational approach to designing actuators. As the relentless drive of electronic devices toward miniaturization, multifunction, and integration continues, the issues of optimizing the size and location of actuators based on control theory, structural response, and desired adaptability should be addressed. Thus, ceramic actuators will need to be smarter and smarter as the applications demand.

PIEZOELECTRIC CERAMICS

Background

Piezoelectricity in solids is based on the internal structures of materials. For simplicity, here, consider only a single crystal that has a defined chemical composition and consists of ions (atoms that have positive or negative charges) that are constrained to occupy positions in a specific repeating relationship to each other, thus building up the structure of the crystal lattice. The smallest repeating unit of the lattice is called the unit cell, and the specific symmetry possessed by the unit cell determines whether piezoelectricity can exist in the crystal. Among the 32 point groups, 21 classes are noncentrosymmetric (a necessary condition for piezoelectricity), and only 20 of these are piezoelectric. One class, although it lacks a center of symmetry, is not piezoelectric because of other combined symmetry elements. Furthermore, for those materials that are piezoelectric but not ferroelectric (i.e., they do not possess spontaneous polarization), the stress itself is the only means by which dipoles are generated. The piezoelectric effect is linear and reversible, and the magnitude of the polarization depends on the magnitude of the stress, the sign of the charge produced depends on the types of stresses such as tensile or compressive (16). A ferroelectric material is one that undergoes a phase transition from a high-temperature phase that behaves as ordinary dielectrics (so that an applied electric field induces an electric polarization, which goes to zero when the field is removed) to a low-temperature phase that has spontaneous polarization whose direction can be switched by an applied field. Therefore, all ferroelectric materials possess piezoelectricity. The piezoelectric effect in ferroelectric ceramics is realized by a poling process, in which an external electric field can orient the ferroelectric domains within the grains and thus produce a ceramic material that acts similarly to a single crystal that possesses both ferroelectric and piezoelectric properties. Before poling, ferroelectric ceramics do not possess any piezoelectric properties due to the random

Figure 1. (a) Unit cell of ABO₃ perovskite, (b) oxygen octahedra, and (c) 180° polarization reversal for two of the six possible polarization states produced by displacement of the central cation in the tetragonal plane.

orientations of the ferroelectric domains in the ceramics. The first piezoelectric ceramic was BaTiO₃ developed commercially in the 1940s; it has an unusually high dielectric constant due to its ferroelectric (permanent internal dipole moment) nature and thus ushered in a new class of ferroelectrics of the ABO₃ perovskite structure. A typical ABO₃ unit cell is shown in Fig. 1a. As an example, the BaTiO₃ unit cell consists of a corner-linked network of oxygen octahedra where Ti⁴⁺ ions occupy B sites within the octahedral cage and the Ba²⁺ ions are situated in the interstices (A site) created by the linked octahedra, as shown in Fig. 1b. Below the Curie temperature, there is a structural distortion to a lower symmetry phase accompanied by a shift off-center of the small cation (Ti⁴⁺) along the *c* axis, as shown in Fig. 1c. The spontaneous polarization derives largely from the electric dipole moment created by this shift. Displacement of Ti⁴⁺ occurs along the *c* axis in a tetragonal structure, although it should be understood that it can also occur along the orthogonal *a* or *b* axes as well. The views of “polarization up” and “polarization down” (representing 180° polarization reversal) show two of the six possible permanent polarization positions. New ferroelectric ceramic materials were surveyed and led to the development of Pb(Zr,Ti)O₃ in the 1950s (17), it became the main industrial product in piezoelectric ceramic materials in the following 10 years. The phase diagram of the PZT pseudobinary is shown in Fig. 2, where the *T_c* line is the boundary between the cubic paraelectric phase and the ferroelectric phases. A significant feature in Fig. 2 is the morphotropic phase boundary (MPB), which divides the

region of the ferroelectric phase into two parts: a tetragonal phase region (on the Ti-rich side) and a rhombohedral phase region (on the Zr-rich side). In the PZT system at room temperature, the MPB occurs close to Zr/Ti = 53/47. An MPB represents an abrupt structural change (involving fractional atom shifts, but no change in near neighbors) in composition at a constant temperature within a solid solution. Usually, it occurs because of the instability of one phase (such as the ferroelectric tetragonal phase) to the other (ferroelectric rhombohedral phase) at a critical composition where two phases are energetically very similar but elastically different. Note that the dielectric constant and the piezoelectric and electromechanical behavior attain maxima, whereas the elastic constants tend to be softer in the vicinity of the MPB composition, as shown in Fig. 3. Similar phenomena are also observed in ternary solid solutions such as PLZT, and this feature is exploited in many commercial compositions because of the high property coefficients and unique structural characteristics of MPB compositions. Many have speculated concerning the reasons for the maximum in coupling at the MPB (18). Polycrystalline materials that have random grain orientation belong to the ∞ ∞ *m* Curie group and show no piezoelectricity before poling because of the random orientations of the dipoles. The poled ferroelectric ceramics belong to the Curie group of ∞ *m*, and the net residual spontaneous polarization has a component in the direction of the poling field, which is optimized in terms of the poling electric field and the poling temperature. Although piezoelectricity was first observed in single crystals, polycrystalline

piezoelectric ceramics now represent the primary commercial piezoelectric material for actuators and sensors in intelligent systems and smart structures.

Dielectric and Piezoelectric Parameters

Piezoelectric ceramics are evaluated by the piezoelectric coupling factor κ (e.g., κ_{33} , κ_{31} , and κ_p), mechanical quality

Figure 3. Dielectric constant κ and electromechanical coupling factor κ_p for the PbZrO_3 - PbTiO_3 piezoelectric ceramic system.

factor (Q_m), frequency constant (N_l), and piezoelectric coefficients, such as the d and g coefficients that describe the interaction between the mechanical and electrical behavior of piezoelectric ceramics. The effective electromechanical coupling coefficient κ_{eff} describes the ability of the ceramic transducer to convert one form of energy to another, as defined by the equations

$$\kappa_{\text{eff}}^2 = \frac{\text{mechanical energy converted to electrical energy}}{\text{input mechanical energy}}, \quad (1)$$

or

$$\kappa_{\text{eff}}^2 = \frac{\text{electrical energy converted to mechanical energy}}{\text{input electrical energy}}. \quad (2)$$

This parameter is a function in equations for electrical/mechanical energy conversion efficiency in actuators, in bandwidth and insertion loss in transducers and signal processing devices, and in the location and spacing of critical frequencies of resonators.

The effective coupling coefficient κ_{eff} is related to the values of f_m and f_n and can be described as

$$\kappa_{\text{eff}}^2 \approx \frac{f_n^2 - f_m^2}{f_n^2}. \quad (3)$$

Values for f_m and f_n are readily measured by using a suitable bridge. The approximations in Eq. (3) are good, provided that the Q_m value for the resonator is high enough, for example, greater than 100.

The planar coupling coefficient κ_p is related to the parallel and series resonant frequency by

$$\frac{\kappa_p^2}{1 - \kappa_p^2} = f \left(J_0, J_1, \nu \frac{f_p - f_s}{f_s} \right), \quad (4)$$

where J_0 and J_1 are Bessel functions and ν is Poisson's ratio. κ_{31} can also be calculated from

$$k_{31}^2 = \frac{1 - \nu}{2} k_p^2. \quad (5)$$

The mechanical quality factor Q_m that represents the degree of mechanical loss of a piezoelectric resonator at resonance is defined as

$$Q_m = 2\pi \frac{\text{stored mechanical energy at resonance}}{\text{mechanical dissipated energy per resonant cycle}}. \quad (6)$$

Q_m can be obtained from the following equation:

$$Q_m = \frac{f_p^2}{2\pi f_s |Z_m| (C_0 + C_1) (f_p^2 - f_s^2)}, \quad (7)$$

where $|Z_m|$ is the minimum impedance at resonance and C_0 and C_1 are the capacitance shown in Fig. 4a, respectively.

Figure 4. (a) Equivalent circuit for a piezoelectric specimen vibrating close to its fundamental resonance; (b) the equivalent series components of the impedance of (a); (c) characteristic frequencies of the equivalent circuit, the differences between f_m , f_s , and f_r , and between f_a , f_p , and f_n are exaggerated.

The frequency constant N_l is defined by the following equation:

$$N_l = l \times f_r = \frac{1}{2} \sqrt{\frac{Y}{\rho}} \quad (8)$$

where l is the length of a piezoelectric ceramic thin plate, f_r is the resonant frequency in the length direction, Y is Young's modulus, and ρ is the density.

These values of the piezoelectric properties of a material can be derived from the resonant behavior of suitably shaped specimens subjected to a sinusoidally varying electric field. To a first approximation, the behavior of the piezoelectric specimen close to its fundamental resonance can be represented by an equivalent circuit, as shown in Fig. 4a, b. The frequency response of the circuit is shown in Fig. 4c, in which various characteristic frequencies are identified. The functions f_r and f_a are the resonant and antiresonant frequencies when the reactance of the circuit is zero ($X_e = 0$); f_s is the frequency at which the series arm has zero reactance ($X_1 = 0$); f_p is the frequency when the resistive component R_e is at a maximum; f_m and f_n are, respectively, the frequencies for the minimum and maximum impedance Z of the circuit as a whole. Piezoelectric vibrators that have electrodes covering their two flat faces are used to measure the properties of piezoelectric ceramics. A more common geometry is a thin disk of diameter d electroded over both faces and poled perpendicularly to the faces. The resonance in these disk-shaped specimens is focused on a radial mode excited through the piezoelectric effect across the thickness of the disk. The details for determining piezoelectric coefficients can be found in IRE standards on piezoelectric crystals: measurements of piezoelectric ceramics [Proc. IRE 49(7); 1161–1169 (1961)].

Compositions and Properties

To meet stringent requirements for specific applications, piezoelectric ceramics under different doping conditions and hence, possessing different characteristics, have been

developed for various applications. The techniques for modifying piezoelectric ceramics include element substitution and doping. In general, the term “element substitution” implies that cations in the perovskite lattice, for example, Pb^{2+} , Zr^{4+} , and Ti^{4+} , are replaced partially by other cations that have the same chemical valence and ionic radii similar to those of the replaced ions. The new substituent cation usually occupies the same position as the replaced cation in the perovskite lattice, and thus a substitutional solid solution is formed; the term “doping” implies that some ions whose chemical valences differ from those of the original ions in the lattice, or some compounds that have the chemical formulas, $A^+B^5+O_3$ and $A^{3+}B^{3+}O_3$ are added to PZT ceramics. From a global perspective, there are essentially four types of compositional modifiers (19). The first type comprises higher covalent substitutions (donor dopants) on A and/or B sites (such as La^{3+} replacing Pb^{2+} or Nb^{5+} replacing Zr^{4+} or Ti^{4+}) to counteract the natural p-type conductivity of PZT and, thus, increase the electrical resistivity of the materials by at least three orders of magnitude. The donors are usually compensated for by the formation of A-site vacancies. The donor-doped PZT piezoelectric ceramics are usually called “soft” piezoelectric ceramics, meaning that they are easily depoled and driven nonlinear. Their main features include square hysteresis loops, low coercive fields, high remanent polarization, high dielectric constants and dielectric loss, maximum coupling factors, high mechanical compliance, and reduced aging.

The second modified type consists of lower valent substitutions (acceptor dopants) on A and/or B sites (such as Fe^{3+} replacing Zr^{4+} or Ti^{4+}). These are compensated for by the formation of oxygen vacancies. Acceptor-doped PZT piezoelectric ceramics are usually called “hard” piezoelectric ceramics because of their much enhanced linearity and high drive. Their main features are poorly developed hysteresis loops, lower dielectric constants and dielectric loss, lower compliances, and higher aging rates.

The third modified type is composed of isovalent substitutions on A and/or B sites (such as Ba^{2+} or Sr^{2+} replacing Pb^{2+} or Sn^{4+} replacing Zr^{4+} or Ti^{4+}). Such isovalent

substitutions usually broaden the temperature-dependent properties, increase the dielectric permittivity, and reduce the Curie temperature, but cause no significant change in coupling coefficient, aging rate, volume resistivity, or low amplitude mechanical or dielectric loss.

The last types of compositional modifiers are more difficult to classify and are called “thermally variable”. They can exist in more than a single valence state and at more than one type of ionic site. The feature of piezoelectric ceramics doped with variable valence additives is much improved temperature and time stability of the resonant frequency. These materials are typically used in electric wave filters or resonators where high temperature and time stability of the resonant frequency are required.

Fabrication Processes

The fabrication processes for piezoelectric ceramics are similar to those used for electronic ceramics. Sequential processes involve weighing the starting materials, mixing, preliminary calcination, milling, shape forming, removing all organic constituents, sintering, formulating electrodes, poling, measuring properties, testing, and packing. Poling is the most critical step in the total fabrication process. The poling process is necessary to induce piezoelectric properties in polycrystalline ferroelectric ceramics because ceramic bodies are generally macroscopically isotropic in the “as-sintered” condition. The poling process can be carried out by immersing the specimens in transformer oil at a temperature of 100–150 °C, while applying a static electric field of 2.5–4.5 MV/m in a desired direction for a period of 10–20 minutes to align the ferroelectric domains. In the poled condition, the ferroelectric ceramics exhibit spontaneous polarization and have a component in the direction of the applied field. To obtain the best piezoelectric properties, the temperature and applied static voltage must be optimized in the poling process. The poling temperature is limited by the leakage current, which can cause an increase in the internal temperature that leads to thermal breakdown, whereas the electric field is limited by the breakdown strength of the ceramic. Higher fields can be used if they are applied as a succession of short pulses. In another poling method, called corona poling, high voltages of the order of 10^4 V are applied either to a single needle or an array of needles; their tips are located a few millimeters from the ceramic surface, and the opposite surface of the ceramic is grounded to develop a high electric field in the ceramics. The corona poling method has many advantages over conventional poling, such as the capability of continuous poling for mass production and the use of samples that have larger surface areas. Furthermore, it diminishes the risk of electrical breakdown because the poling charge cannot be quickly channeled to a “weak spot,” as it could be when using metallic electrodes. This method has been successfully used for poling piezoelectric ceramic–polymer composites such as PZT-epoxy (20). The alignment of the ferroelectric domains in the direction of the poled field is never complete in poled ceramics. However, depending on the type of crystal structure involved, the degree of poling can be quite high and ranges from 83% for the tetragonal phase, to 86% for the rhombohedral phase, and to 91% for the orthorhombic phase. The degree of poling also increases in

ascending order from polycrystalline ferroelectric ceramics, to poled ferroelectric ceramics, to single-crystal ferroelectrics, and to single-domain single crystals.

Applications of Piezoelectric Ceramics

Both direct and inverse piezoelectric effects can be used for applications of piezoelectric ceramics. In general, the use of the direct piezoelectric effect can generate a high voltage by applying a compressive stresses, whereas using the converse piezoelectric effect, small displacements can be generated by applying an electric field to a ceramic piece. Similarly, vibrations can be produced by applying an alternating field to a ceramic piece and can be detected by amplifying the field generated by vibrations incident on the ceramic. The flexor transducer, which consists of two piezoelectric ceramic thin plates poled in opposite directions, is used in gramophone pick-ups and ultrasonic accelerometers. Filters and other devices can be made to generate surface waves at frequencies that exceed 1GHz, and ultrasonic motors provide an opportunity to illustrate many important concepts.

The ultrasonic motor is based on the concept of driving a rotor by mechanical vibration excited on a stator via the piezoelectric effect. The rotor is in contact with the stator, and the driving force is the frictional force between the rotor and stator, in contrast to conventional electric motors that are based on electromagnetic conversion. The elliptical trajectory of the surface points of a stator is used to generate a rotational, or translational, motion in the rotor or slider. These elliptical motions may be generated either by exciting both longitudinal and bending vibrations of a beam or longitudinal and torsional vibrations. The unique features of ultrasonic motors are high output torque, quick response, large holding torque without energy dissipation, and operation free of a magnetic field. Many types of ultrasonic motors have been proposed that can be classified by the type of elliptical particle motion created in the stator. Here, we introduce only two types of ultrasonic motors: the standing-wave type and the traveling-wave type.

The standing-wave type is sometimes referred to as a vibratory-coupler type, or a “woodpecker” type; a vibratory piece is connected to a piezoelectric driver, and the tip portion generates flat elliptical movement. The vibratory piece is attached to a rotor, or slider, and provides intermittent rotational torque, or thrust. In general, the standing-wave type is highly efficient, but lack of control in both clockwise and counterclockwise directions is still a problem. In comparison, a wave in the traveling-wave type motor is excited by piezoelectric elements bonded to the stator. The traveling wave is obtained by superimposing two standing natural flexural waves equal in amplitude, but differ in phase by 90° , both spatially and temporally. The temporal difference is obtained by using one wave generated by the voltage $U_0 \sin(\omega t)$ and the other by $U_0 \cos(\omega t)$; the spatial phase difference results from the $3\lambda/4$ and $\lambda/4$ gaps between the two poled segments, as shown in Fig. 5. By propagating the traveling elastic wave induced by the thin piezoelectric ring, a ring-type slider in contact with the “rippled” surface of the elastic body bonded onto the piezoelectric elements is driven in both rotational directions by exchanging the sine and cosine voltage inputs. Another advantage of this motor

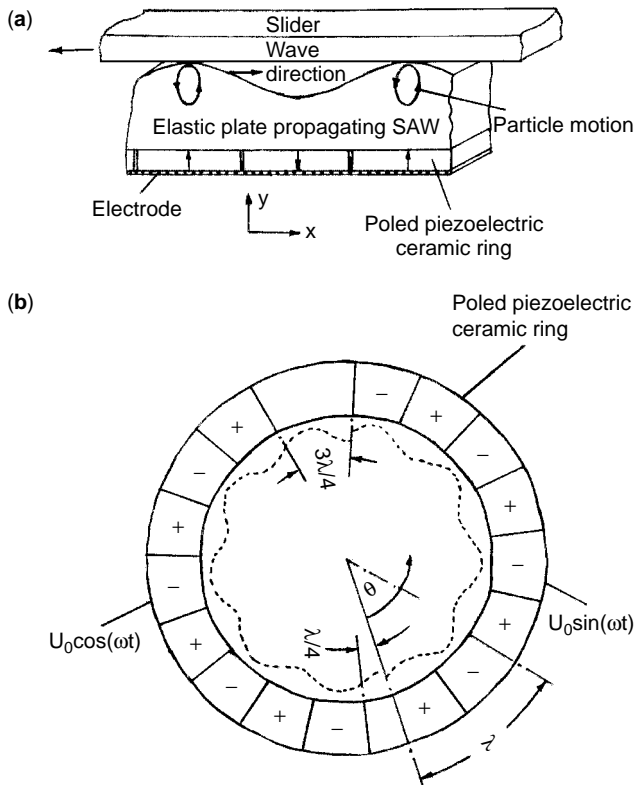

Figure 5. Operating principle of the ultrasonic rotary motor. (a) Side view, (b) plan view showing the poled segments and driving scheme.

is its thin design that makes it suitable for installation in analog instruments (21).

Future Trends in Piezoelectric Ceramics

Presently, PZT-based piezoelectric ceramics are leading materials for use in piezoelectric transducers, but recent concerns for the environment, safety, and health have prompted increasing research activity into Pb-free piezoelectric materials. To meet the extremely diverse applications, hybrid piezoelectric composites made by combining piezoelectric ceramics with other advanced materials are urgently required. Piezoelectric composites have some unique properties and functions such as improved dynamic response, high sensitivity to weak hydrostatic waves, damage resistance and control, which can be used to tailor or tune the overall performance of a smart structural system. Numerous efforts and exploratory approaches have been made to develop piezoelectric composites of piezoelectric ceramic and metal, piezoelectric ceramic and polymer, and piezoelectric ceramic and shape memory alloy (22–24), which represent a significant potential for advanced composites for smart systems. Numerical modeling and computer simulations of piezoelectric composites, in conjunction with some efforts in experimental characterization, will lead to the optimization of technical factors, such as structural design, geometry, processing parameters, and material selection, and in turn the improvement of the overall performance of piezoelectric composites. A major issue in piezoelectric composites is the creation of stresses, permanent strains, and cracks owing to a mismatch in thermal expansion and other physical properties of dissimilar

components in composites. To solve these problems, it is necessary to develop functionally graded composites that have gradients in composition, microstructure, and properties through one or more layers. Such an approach offers a number of advantages over the traditional methods of tailoring the compliance of composite materials, or structural elements, and opens up new horizons for novel applications.

FUNCTIONALLY GRADED MATERIALS

Background

Composite materials have been widely used for applications ranging from sporting and recreational accessories to advanced aerospace structural and engine components. Traditionally, the compositions and microstructures of composite materials are statistically homogenous, and have no significant spatial variations in properties. The development of space airplanes for the twenty-first century poses enormous technical problems, particularly for materials of superior heat resistance. The usual ceramic composites that combine a ceramic matrix and a dispersed phase are not expected to withstand the severe space environment or the high thermal stresses generated by the extreme temperature gradient experienced during reentry from space. Thus, materials that have superior stress relaxation, superior oxidation, thermal shock resistance, and other related characteristics are highly desirable. To meet these specific requirements, the concept of functionally graded materials (FGMs) has been proposed (25). By definition, FGMs are used to produce components that

feature engineered gradual transitions in microstructure and/or composition, whose presence is motivated by functional performance requirements that vary with location within the part. FGMs meet these requirements in a manner that optimizes the overall performance of the component. Thus, FGMs have grown to become one of the major current themes in structural materials research. They have also received considerable attention in a variety of nonstructural applications, where gradients in composition are deliberately introduced to optimize some physical properties and in areas where issues of mismatched material properties exist. The potential benefits derived from this new class of materials have led to increasing research activity in their design, processing, and applications.

Characterization

Functionally graded materials are composed of two or more phases, that are fabricated so that their compositions vary in some spatial direction and are characterized by nonlinear one-, two- or three-dimensional gradients that result in graded properties. They are distinguished from traditional composites by gradients of composition, phase distribution, porosity, grain size and texture, and particles or fiber reinforcement. From the viewpoint of their applications, FGMs can be classified as functionally graded coatings, functionally graded joints, and functionally graded materials, per se. Such a classification provides a good model for theoretical approaches and related numerical calculations for residual stress analyses (26). However, there is no significant difference in the structure and properties of the gradient volume among these FGM patterns. In contrast, based on their compositions, FGMs can be also classified as metal–ceramic, metal–metal, ceramic–ceramic, etc. The porosity, grain size and texture, or the gradient distribution (one-, two-, and three-dimensional) can also be used to classify FGMs. Note that the so-called back properties (e.g., modulus, thermal conductivity, electrical resistance, and specific heat) of FGMs (as for other materials) depend essentially on chemical composition rather than the structure, whereas the structurally sensitive properties such as strength, fracture toughness, and optical and magnetic characteristics depend on both crystal and microstructure. This observation should be considered when designing and analyzing gradient components because the structure of the final materials may affect both the desired properties and other incidental properties. Thus, the ultimate goal of FGM development is to fabricate components that have a predetermined concentration profile that best achieves the desired purpose for the material, and maintains other properties within limits that ensure acceptable performance.

Processing Methods

Several different physical and chemical methods are used to prepare FGMs (27,28). Each method has its own advantages and drawbacks, so it is difficult to predict a best-fit single method that will satisfy most of the requirements and technical limitations of the whole FGM spectrum. One of the potential answers may be optimal combination of

several methods. This combination will differ for each system, depending on the properties of the component materials.

The starting materials can be gases, liquids, or solids. If the starting materials are vapors, all CVD and PVD processes are available in principle. Compositional gradients can be easily obtained by continuously adjusting the ratios of the reactants in the mixture. The vapor method is one of the easiest ways to control the concentrations of phases being dispersed, but it is mainly suitable for obtaining compositional gradients in a thin film, or plate, across the material thickness.

Using liquids as starting materials, spraying is quite effective in achieving a graded structure. The major advantages of spraying are its flexibility and high deposition rates. Furthermore, plasma spraying can provide the possibility of coating a device that has complex shapes. Graded compositions can be obtained by adjusting the spray composition discretely or continuously. FGMs based on YSZ/Ni–Cr have been successfully prepared by this method (29).

Using solids, powder metallurgy or ceramic sintering are ideally suitable for fabricating FGMs because of the close microstructural control and versatility inherent in these techniques; they are widely used in industry because of the simple equipment and cost-efficient technology. Sizable and bulk functionally graded materials that have complex structures can be produced by this method, and transition phases in the thickness direction can be tailored from less than 1 mm to several centimeters, if desired. Several approaches have been proposed and tested to obtain a green body that has compositional gradients. The simplest is compositional distribution in a stepwise form, for example, many layers stacked in a block, which is then compacted and sintered to form FGMs (30). Another method uses centrifugal force, combined with gravity. The powder mixture is fed into the center of a centrifuge, from which it is projected toward the outer wall. The powder gradually forms a ring that has a through-thickness gradient (31). Self-propagating, high-temperature synthesis (SHS) is also a simple method that consists of simultaneous synthesis and forming (32, 33). The rapid propagation of a combustion reaction and low energy requirements limit elemental diffusion and allow one to conserve the graded composition designed in the green body. The SHS method is suitable for fabricating FGMs from components that have different high melting points and are chemically unreactive. The thin-sheet lamination method is a wet process, in which sheets that have different volume fractions are piled and pressed to form a graded green body and then sintered.

Other methods for producing functional or structural gradients such as sedimentation processes and magnetron sputtering have also been investigated. They have been used for gradient and multilayered thin coatings, but their application ranges are very limited. In general, the requirements and technical limitations of the whole FGM spectrum are quite diverse, so the methods for fabricating FGMs need to be versatile, but further work is needed to facilitate the transfer of production to industrial practice.

Modeling and Design

During the past 10 years, a variety of models have been established to describe the response of FGMs to thermal and mechanical loads, the chemical compatibility and degradation of interfacial layers, thermally activated diffusion, thermal stability, fabrication, and measurement of processing and/or service-induced residual stresses. Models developed for the spatial distribution of composition have been examined, followed by models developed for various aspects of FGM behavior and models for design and performance.

Models for Spatial Distribution of Composition. FGM models generally require an assumption for the spatial distribution of their constituent phases. For instance, consider an FGM that consists of two constituents denoted 1 and 2, respectively. Assume that the geometry is one-dimensional in the x direction, the direction of the functional gradient. A simple equation (34) describes the compositional gradient as

$$f_1(x) = \left(\frac{x_2 - x}{x_2 - x_1} \right)^n, \quad (9)$$

where $f_1(x)$ is the local volume fraction of phase 1 as a continuous function (the volume fraction of phase 2 is $1 - f_1(x)$ if the material is fully dense), x_1 and x_2 are the border regions of pure phase 1 and 2, respectively, and n is a variable functionally graded index, whose magnitude determines the curvature of $f_1(x)$. The curvature can be made concave upward, or downward, to a greater or lesser degree by selecting a proper functionally graded index n . Another approach to modeling the spatial distribution of composition is to select $f_1(x)$ varying discontinuously in a finite number of steps across the functionally graded direction. This would be appropriate to describe a multilayered FGM where the composition of each layer differs from one layer to the next. Based on knowledge of $f_1(x)$ and other information (such as the composition-dependent microstructure), one can determine the corresponding x dependence of effective values for evaluating physical properties such as thermal conductivity, Young's modulus, and the coefficient of thermal expansion. These, in turn, can be used to calculate the distributions of stress and temperature. The temperature distribution $T(x)$ under steady-state conditions can be determined by the equation (34),

$$\lambda(x) \frac{dT(x)}{dx} = \text{constant}, \quad (10)$$

where $\lambda(x)$ is the thermal conductivity. The solution to this equation is subject to appropriate boundary conditions. The determination of $f_1(x)$ is related to the design, whereas the calculation of $T(x)$ is related to the performance as well as fabrication. However, the calculation of $T(x)$ may indicate a need to revise the current $f_1(x)$, if the evaluated thermal stress has an excessively high value.

Systems Approach to FGM Modeling. A useful approach developed for the overall modeling of FGM processing, called the inverse design procedure, is based on the

properties of a homogenous composite material that has a certain composition ratio, materials and design databases, and known rules of mixture (35). Such an approach has been widely used in calculating the optimum compositional distribution for a material. The flow chart of the inverse design procedure is illustrated in Fig. 6. Here, the structure and the boundary conditions are specified initially. Then, several combinations of materials are assumed along with different assumptions for the spatially dependent mixture ratio. The distributions of stress and temperature can be calculated for these various combinations, and the calculations are repeated until optimum conditions are obtained. Based on these calculations, a FGM that excels in offering thermal relaxation can be prepared by various methods. Another system-based approach to the optimization process, used by Tanaka et al. (36), consists of the following sequence of steps: (1) select the initial compositions properly; (2) carry out a preliminary analysis of nonstationary heat conduction and thermal stress; (3) examine the design (failure) criteria at each step; (4) if the design criteria are violated, calculate a quantity known as the thermal stress sensitivity increment; (5) find the optimum composition profile that satisfies the design criteria; (6) repeat the analysis of nonstationary heat conduction, and thermal stress using the optimum composition profile determined; (7) if the design criteria are violated at another step, return to step (4). Note that these system-type approaches to FGM design are just ordered sequences of steps carried out to ensure that the resultant material performs adequately in its intended application.

Models Developed for Behavior of FGM. To use FGMs practically, performance tests should be established that include local evaluation of the microstructure and material properties to reveal the performance of the designed structure and property distributions and evaluation of the overall performance of FGM properties. To understand the performance of the FGM better, some models for describing the behavior of FGMs have been developed. A modified micromechanical model (37) is presented for the response of functionally graded metal–matrix composites subjected to thermal gradients. In this model, the actual microstructural details are explicitly coupled with the microstructure of the composite, which is particularly well suited for predicting the response to thermal gradients of thin-walled metal–matrix composites that have a finite number of large-diameter fibers in the thickness direction. A non-destructive method for detecting and evaluating the distribution of elastic parameters in the graded direction of an FGM by using ultrasonic waves has also been developed (38). The principle is based on the reflection of an impulse response. The acoustic impedance (defined as the product of density times the speed of sound) profile is first determined by ultrasonic waves, and then the profile of elastic modulus is evaluated using the equation (38)

$$V = \frac{E}{\rho(1 - \nu^2)} \quad (11)$$

where V is the speed of sound, ρ is the density, and ν Poisson's ratio. This method has been successfully used in

Figure 6. Flow chart of the inverse design of functionally gradient materials.

Ni-ZrO₂ FGMs to evaluate the accuracy of the design. A finite element model developed by Miller et al. (39) was intended to be a guide for both the design and fabrication of NiAl-Al₂O₃ FGMs. This model was applied to estimate residual stress as a function of the structure of the materials and the effects of thermal recycling. A coupled thermoelastic model is also being developed to study the thermal shock response of a metal/ceramic FGM to abrupt heating (40). Modeling studies of FGMs are clearly an essential ingredient to attaining the successful performance and have shed light on the future directions, but much work in modeling remains (41).

Applications of FGMs

The initial goal in developing FGMs was to obtain thermal barrier materials usable in space structures and fusion reactors and also in future space-plane systems. However, a

variety of nonstructural FGMs whose compositional gradients were introduced deliberately to optimize physical properties, such as electrical, magnetic and optical properties, have been developed recently (42–50). By controlling the compositional gradient in the radial direction, an optical fiber that has a graded refractive index can be prepared (48). Such graded index materials possess unique and useful optical properties that cannot be achieved by conventional optical materials, which have a constant refractive index. By this method, very low optical loss can be achieved in a wide wavelength range from the infrared to the ultraviolet spectrum (48). An important technological issue in nuclear power generation is the development of reactor core materials that have superlong lifetimes, high temperature strength, and high resistance to deformation and irradiation damage (51). The development of an FGM-type nuclear furnace is highly desired for this application. In optoelectronic devices, graded semiconducting layer

of InGaAs sandwiched between GaAs and InGaAs layers of fixed composition are used to increase the mean spacing of misfit dislocations and to control the density, and spatial distribution of threading dislocations (52). Furthermore, FGMs such as FGM semiconductors or superconductors that have gradients of quantum characteristics have been developed (50). Recently the application of FGMs in electronics is also increasing rapidly (50).

Piezoelectric Ceramic Materials. Recent trends in manufacturing electronic components are moving toward improved lightness, high density, and miniaturization. Therefore, electronic components that can be integrated with substrates or coating-materials and two- and/or three-dimensional composite components are strongly needed. The FGM technique is very suitable for fabricating such electronic components. By controlling the graded compositions between the component and substrate, the problems of spallation of components from the substrate can be effectively reduced and the stability of the electronic components can be greatly improved. PZT piezoelectric ceramics are widely used in electronic components, such as ultrasonic vibrators and ceramic filters (4,19). To improve the temperature stability of the piezoelectric and its dielectric properties, a third component that has a perovskite structure is usually incorporated into PZT to adjust the distributions of piezoelectric and dielectric properties and to increase the lifetime of the piezoelectric components (53–55). Piezoelectric bimorph benders are typical solid-state actuators that are composed of two piezoelectric ceramic strips bonded together by bonding agent (usually by epoxy resin) and fixed at one end to form a cantilever structure (4,10). The major problem of the device is that the bonding agent between the two oppositely poled piezoelectric ceramic strips may crack or peel off at low temperatures and may creep at a high temperature. Such problems may lead to deterioration of the electric-field induced displacement characteristics and reduced reliability and lifetime of the piezoelectric devices. To overcome these problems, a new type of piezoelectric actuator that has a sandwich structure has been recently developed, where the bonding agent is replaced by a FGM interlayer. The schematic structure of the FGM actuator is illustrated in Fig. 7a. The functional gradients of piezoelectric and dielectric properties vary in opposition to each other across the thickness of the FGM actuator, as shown in Fig. 7b. Thus, the FGM actuator acts like a monomorph-type piezoelectric device without a bonding agent and has improved durability and reliability in high-temperature operation. The compositions of the piezoelectric layer (that have high piezoelectric activity and low dielectric properties) and the dielectric layer (that has low piezoelectric activity and high dielectric properties) may be chosen by referring to the electrical property database of the $\text{Pb}(\text{Ni}_{1/3}\text{Nb}_{2/3})\text{O}_3\text{--PbZrO}_3\text{--PbTiO}_3$ (PNN–PZ–PT) ternary system. Because lattice parameters of the perovskite structure and the sintered characteristics of PNN are similar to those of PZT, they have better structural compatibility. By suitably selecting the compositions of the piezoelectric and dielectric layers, an FGM actuator can be prepared by powder metallurgy or ceramic sintering (56,57). The compositional and microstructural gradients

Figure 7. (a) Schematic structure of a functionally graded piezoelectric ceramic actuator. A: dielectric layer, B: piezoelectric layer, C: sandwich, D: electrode, E: applied electric field, and P: polarization; (b) variations of piezoelectric activity and dielectric activity across the thickness of the actuator.

across the section of the FGM actuator are shown in Figs. 8 and 9, respectively, and the related bending displacement of the FGM piezoelectric actuator is shown in Fig. 10.

Other types of monomorph piezoelectric ceramic actuators that have graded electrical resistivity across the thickness, as shown in Fig. 11, are fabricated by tape casting (58) or by uniaxially pressing two layers of different resistivities (59); graded resistivity is achieved by doping PZT ceramics with a gradual dopant concentration. Such gradual dopant concentration and resistivity gradients attained within a monolithic piezoelectric ceramic bar could result in a uniform stress gradient when a thickness poled monomorph is driven by an external electric field. This prevents a steep stress peak that is caused by a sharp poling gradient in a conventional bimorph. Then, significant increases in lifetime and reliability can be achieved. The application of an external electric field causes a monolithic ceramic bar to bend due to the differential strains induced

Figure 8. (a) General SEM observation on the morphologies of grains across the section of the FGM actuator; (b), (c), and (d) high magnification SEM images of regions A, AB, and B indicated in Fig. 8a. The grain sizes in the A, AB, and B regions are 10, 6, and 4 μm, respectively.

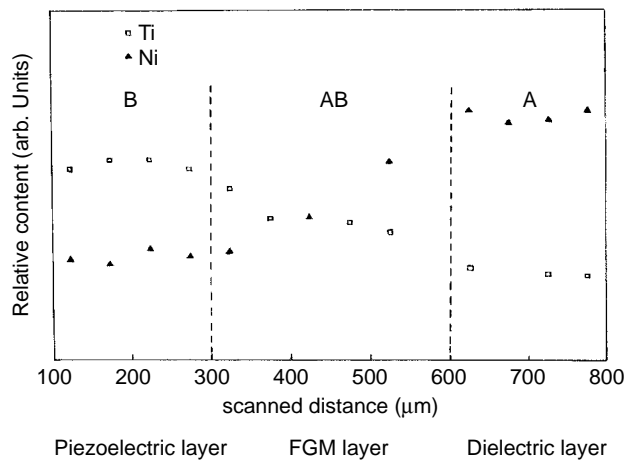

Figure 9. Typical compositional distributions of Ti and Ni elements across a section of the FGM actuator.

Figure 11. Schematic diagram of the field distribution and the structure of a monomorph that has graded electrical resistivity across its thickness.

by the piezoelectric effect. A monomorph that is initially unpoled PZT-5A on one side and PZT-5A modified by 2 mol% zinc borate on the other side shows a $28 \mu\text{m}/\text{cm}$ deflection in an external electric field of $5 \text{ kV}/\text{cm}$ (58). Chatterjee et al. also developed a multilayered rainbow type actuator that has graded piezoelectric properties across the thickness (60). Theoretical analyses of out-of-plane displacement and stress fields in such FGM piezoelectric actuator have been carried out by using a modified classical lamination theory (61). The results show that the linear profile has the best performance in higher out-of-plane displacement and moderate stress field and the concave displacement gave a larger out-of-plane displacement, but at the cost of higher stresses. It is possible to optimize the material property gradient profile within an FGM to provide out-of-plane displacements higher than those of standard piezoelectric bimorphs and still maintain moderate stress levels. The governing equations for a piezoelectric plate that has general symmetry and thickness-graded material properties are deduced from the three-dimensional equations of linear piezoelectricity by Mindlin's general procedure of series expansion (62). Recently, a more sophisticated model for calculating the bending behavior of FGM piezoelectric actuators that have arbitrary graded piezoelectric properties was proposed by T Hauke et al. (63). Based on their model, it seems possible to build bending actuators that have strongly reduced or vanishing internal mechanical stress induced by using a FGM. Some modeling results were verified experimentally by BaTiO_3 -based FGM piezoelectric actuators using different model structures.

Pyroelectric Ceramic Materials. In recent years, graded ferroelectrics have become of interest due to their unique properties (64–66) and the rapid development of ferroelectric-based heterostructures [e.g., ferroelectric semiconductor structures (67) and ferroelectric superconductor structures (68)]. For example, it has been demonstrated that a graded ferroelectric thin film can exhibit a large dc polarization offset. The sign of the offset is

determined by the direction of the composition gradient (64). Such an offset, reportedly, depends strongly on temperature and thus, can be used in pyroelectric detectors (66). The composition gradient can be tuned and tailored to produce properties that meet the designated requirements of practical applications, and many more efficient sensors, actuators, and energy converters are possible. Unlike in a simple structure of ferroelectric laminates, the polarization gradient in graded ferroelectric devices skews the potential wells to lower energy to favor populating the polarization states with lower energy and breaks the symmetry of the graded material, resulting in a self-poling effect. The “built-in” difference in free energy across a graded ferroelectric device is schematically shown in Fig.12, which can be likened to the “built-in” barrier potential of a p-n junction in semiconductor devices. The polarization gradient can be achieved in a variety of ways because the polarization of ferroelectric materials is a function of temperature, mechanical strain, and composition. Recently, several graded thin films, such as $(\text{Ba}_{1-x}\text{Sr}_x)\text{TiO}_3$ (BST) (66, 69, 70), PZT (71), $(\text{Pb,Ca})\text{TiO}_3$ (72–74), and $\text{Pb}_{1-3y/2}\text{La}_y(\text{Zr}_{0.4}\text{Ti}_{0.6})\text{O}_3$ (PLZT) (75), whose compositional gradients are normal to the

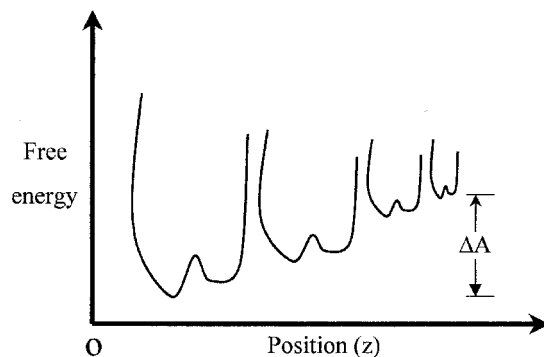

Figure 12. A graded potential well for electrons in a graded ferroelectric device skewed by its graded polarization below the lowest Curie temperature of the graded device.

growth surface, have been prepared by different methods. Such functionally graded devices exhibit several features, including broadening of the dielectric permittivity versus temperature plot, polarization offsets dependent on the direction of the compositional gradient, and electric field dependence of that offset, as shown in Fig. 13. A modified Slater model (76) was applied to explain these phenomena, in which the energy function for a ferroelectric material is characterized by

$$\xi = k_0(T - T_c)x^2 + Bx^4, \quad (12)$$

where x is the ion displacement relative to a central charge, T and T_c are the absolute and Curie temperatures, respectively, and k_0 and B are characteristic functions of temperature as well. Such a potential implies a

ferroelectric state when the temperature falls below the critical temperature T_c . When $T < T_c$, an energy extreme exists at $x = 0$ and also at

$$x = \pm \sqrt{\frac{k_0(T_c - T)}{2B}}. \quad (13)$$

The latter corresponds to the two spontaneous polarization states of ferroelectric dipoles. The self-poling phenomenon (“up” and “down” polarization hysteresis) is observed in graded ferroelectric thin films; however, its origin is still unclear, even though some legitimate interpretations have been proposed, including charge injection at the electrodes, nonuniformities in the thin film structures due to asymmetries in the growth process, leakage currents, and electrical breakdown of the films. Functionally graded ferroelectric thin films offers a significant approach to finding a method that combines the advantages of low-cost thin film processing with the high sensitivity of bulk ceramic and single-crystal materials. The unique properties observed in FGM ferroelectric materials may lead to new ferroelectric device applications; however, these unique properties have not been fully studied and are not well understood. The development of FGM ferroelectric thin films is still in its initial stage, so many problems remain unsolved and technical challenges lie ahead.

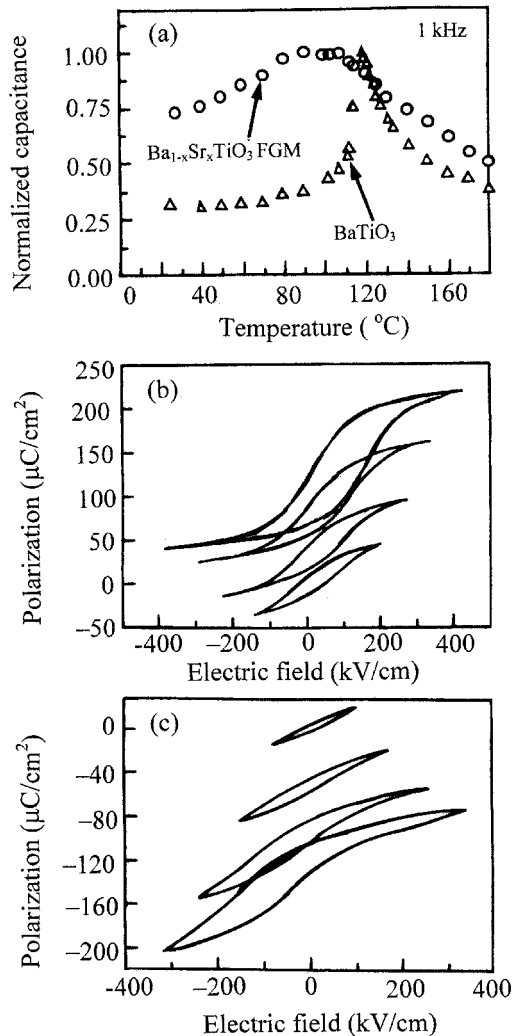

Figure 13. (a) Broad temperature dependence of the capacitance of a graded Ba_{1-x}Sr_xTiO₃ thin film at $x = 0, 0.47, 0.54, 0.70, 1.0$, compared with a single layer of BaTiO₃ thin film; (b) positive polarization offsets in upgraded (Pb,Ca)/TiO₃ thin films; (c) negative polarization in downgraded (Pb,Ca)/TiO₃ thin films. The magnitude of the offsets shown in Fig. 13b, c depends strongly on the driving electric field.

SUMMARY

In this article, we initially discussed current piezoelectric ceramic actuators and then focused on introducing piezoelectric ceramics, including the general characteristics, compositions, fabrication, and applications of piezoelectric ceramics, and finally reviewed the recent progress of FGMs and their applications in piezoelectric ceramic devices. FGMs, as a relatively new technology for solving the major problems and the development of the sharp interfaces at the joint of two dissimilar materials appear to have proven their worth in a variety of applications. Combinations of FGM technology with intelligent systems can be used to tailor, or tune, the overall performance of smart structural systems. It has been shown that the combination of theories, experiments, and computational simulations (such as neural network and fuzzy inference simulations) is an effective approach to developing FGMs. Because a completely or partially graded structure can be formed in any material and component, application of the FGM concept is virtually unlimited. The materials science developed in the twentieth century was based mainly on homogeneous material systems. It is likely that the twenty-first century will see the development of new materials science and technology for nonhomogeneous materials and systems that have optimized structures, like FGMs.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the helpful conversations with our colleagues at Nanjing University and Shanghai University (Jiading Campus). The authors thank Professor C.L.Choy of Hong Kong Polytechnic

University for his helpful comments on the manuscript. This work is supported by the National Natural Science Foundation of China, Nanjing University Talent Development Foundation, and a grant for a State Key Program for Basic Research of China.

ADAPTIVE COMPOSITE SYSTEMS: MODELING AND APPLICATIONS

A. SULEMAN

Instituto Superior Técnico
Lisbon, Portugal

INTRODUCTION

In the past decade, technological developments in materials and computer sciences have evolved to the point where their synergistic combination have culminated in a new field of multidisciplinary research in adaptation. The

advances in material sciences have provided a comprehensive and theoretical framework for implementing multifunctionality in materials, and the development of high speed digital computers has permitted transforming that framework into methodologies for practical design and production. The concept is elementary: a highly integrated sensor system provides data on the structural environment to a processing and control system which in turn signals integrated actuators to modify the structural properties appropriately.

Multifunctional materials embedded in adaptive composite systems have presented exceptional promise in engineering design problems that require solutions in active vibration suppression, shape control, and noise attenuation. Piezoelectric materials, shape memory alloys, and magnetostrictive materials are the three most recognized types. These materials develop strains or displacements when exposed to electric, thermal, and magnetic fields, respectively.

ACTUATORS AND SENSORS

Actuation Technology

When a **shape memory** alloy is heated above a critical temperature, the material recovers its original predeformed shape. The most common commercially available shape memory alloy is Nitinol. This alloy is very ductile and can be deformed easily. In addition, it also has good strength and strain rate, it is corrosion resistant, and it is stable at high temperature. A limited number of efforts aimed at using shape memory alloys as actuators in composite structures have been made. Recent studies include the work by Boyd and Lagoudas (1) in developing a micromechanical model for shape memory composites, and Sullivan (2), who developed a model to predict shape memory composite behavior. Other significant theoretical studies on modeling systems that contain shape memory alloys include the works by Liang and Rogers (3), Feng and Li (4), and Graesser and Cozzarelli (5). Research on using shape memory alloys in active structural control include the works by Baz et al. (6), Ikegami et al. (7), and Maclean et al. (8).

Magnetostrictive materials change dimensions when placed in a magnetic field. Terfenol-D is the most popular commercially available magnetostrictive material. Recent research on magnetostrictive materials shows that they provide strokes significantly larger than their electromechanical counterparts; however, they tend to be difficult to implement in structural systems (9). Work on composites that incorporate magnetostrictive materials include the unimorphs by Honda et al. (10) and the microcomposite systems by Bi and Anjanappa (11).

Piezoelectric materials present two distinct characteristics: the “direct” piezoelectric effect occurs when a piezoelectric material subjected to a mechanical stress becomes electrically charged. Thus, these devices can be used to detect strain, movement, force, pressure, or vibration by developing appropriate electrical responses. The “converse” piezoelectric effect occurs when the piezoelectric material becomes strained when placed in an electric

field. The ability to induce strain can be used to generate a movement, force, pressure, or vibration by applying a suitable electric field. The most popular commercial piezoelectric materials are lead zirconate titanate (PZT) and polyvinylidene fluoride (PVDF). The potential of applying piezoelectric materials as distributed actuators in composite structures has resulted in several significant studies. Suleman and Venkayya (12) modeled a simple composite plate structure of piezoelectric layers using classical lamination theory; however, the first reported studies on adaptive composites include the works by Bailey and Hubbard (13), Crawley and de Luis (14), Leibowitz and Vinson (15), and Wang and Rogers (16).

The electrostrictive phenomenon is a nonlinear property that exists in all dielectric materials. When an electric field is applied across an electrostrictive material, the positive and negative ions are displaced, and a strain is induced in the material. The resulting strain is proportional to the square of the applied electric field and is independent of the applied electric field's polarity. Because the strain is proportional to the square of the electric field, the strain is always positive. This is analogous to the magnetostrictive behavior described earlier. The most popular electrostrictive material is lead magnesium niobate (PMN); however, this material is still not widely available commercially. These materials generally offer higher electrically induced strain with lower hysteresis than piezoelectric materials, due to nonlinearities; however, constitutive models for electrostrictors are not as mature as models for piezoelectrics. Hom and Shankar (17) formulated a fully coupled constitutive model for electrostrictive ceramic materials. Electrostrictive materials used as distributed actuator elements in adaptive composites have not been reported in the literature.

Magneto- and electrorheological fluids are multiphase materials that consist of a dispersion of polarizable particles in a carrier oil, and they exhibit the properties of a typical viscoelastic material. The use of electrorheological materials for vibration damping has been the subject of considerable research because these materials exhibit fast, reversible, and controllable changes in behavior. However, despite advances in sensing and controls, fundamental rheological research applied to vibration damping has lagged behind. Specifically, essential information on material-based structural reliability and controllability is still needed to implement such systems successfully.

Typically, the performance of an actuator is evaluated in terms of the following characteristics: displacement (the ability of the actuator to displace an object), force generation (the amount of force the actuator can produce), hysteresis (the degree of reproducibility in positioning operations), response time (how quickly an actuator can start the actuation process), bandwidth (the range of frequencies in which the actuator can operate effectively), temperature range of operation, repeatability and precision of the actuator, power required to drive the actuator, mass of actuator material required for a given displacement; and cost. Table 1 presents the general characteristics of commercially available actuators (18).

The piezoelectric PZT provides the potential for the greatest force handling capability. PZT also operates across

Table 1. Actuator Technology Assessment

	Nitinol	Terfenol-D	PZT
Energy	Heat	Magnetic field	Electric field
Hysteresis	High	Low	Low
Bandwidth	Low	Moderate	High
Accuracy	Poor	High	High
Response time	Low	Fast	Very fast
Power use	High	Moderate	Moderate
Maturity	New	New	Established

the highest bandwidth of the microactuators and has among the highest displacements. Electrostrictive PMN possesses the lowest hysteresis of any of the actuator materials. However, the temperature operating limits for PMN would require special insulation. Although PZT is preferred for most applications, future commercial applications may favor direct replacement of PZT with PMN because of its superior hysteresis efficiency.

The shape memory material, Nitinol, produces the greatest displacements but the weakest force of the actuators under consideration. This material is very ductile and consequently does not support as much force as other actuator materials. However, it does give it the advantage of being easily shaped into different actuator geometry. It is less desirable from the point of view of precision and economy of design due to its power consumption, accuracy, and hysteresis characteristics. It can also be observed that Terfenol-D and PZT compare very closely in these general characteristics. For deformation of thin structural elements, the most widely used multifunctional materials to date have been piezoelectric actuators. Piezoelectrics have higher bandwidths than are possible in shape memory alloys, they are more compact than magnetostrictive devices, and they are bidirectional by nature, unlike electrostrictive materials.

Sensing Technology

Optical fibers make excellent strain sensors because they are immune to electromagnetic interference. Optical fibers can be bonded to the surface of a structure or embedded directly into the structure. There are many types of optical fiber sensors. The more useful fiber-optic strain sensors uses the intrinsic properties of the optical fiber. In an intrinsic fiber measurement, one or more of the optical field parameters, which include frequency, wavelength, phase, mode index, polarization, index of refraction, and attenuation coefficient, are affected by the environment.

Piezoelectric sensors tend to operate best in dynamic situations because the induced charge imbalances created by straining the material dissipate with time. How quickly this occurs depends on the material's capacitance, resistivity, and output loading. Force transducers use piezoelectric elements to produce an electrical output that is proportional to the applied force. The force transducer is mounted in series with the force transmission path to expose the piezoelectric element directly to the forces that are to be measured. Because the piezoelectric is preloaded, the force sensor can measure both tensile and compressive

Table 2. Sensor Technology Assessment

forces. High stiffness ensures high resonant frequency, and it will have a minimum effect on the structural integrity.

In the case of sensors, the technologies considered for adaptive composites must withstand the composite manufacturing process. Embedding issues make Nitinol a questionable choice. If the shape memory alloy had to be electrically insulated from the conductive composite, it would complicate the composite manufacturing process and increase the cost significantly.

The performance of any sensor can be evaluated in terms of sensitivity (amount of signal that a sensor produces for a given change in the variable), the length across which the measurement is made, bandwidth (the frequency range over which the sensor remains effective), response time (the speed at which the sensor can respond to a change in the variable), the temperature range across which the sensor can operate, repeatability and precision of the actuator, weight, and cost. Table 2 presents a relative assessment of the sensor types considered suitable for embedding in adaptive composite systems.

The temperature range is critical for an adaptive composite system because it is anticipated that sensors may be embedded and would therefore undergo the composite curing process. Embedding would be feasible for fiber optic sensors but not as desirable for PZT strain sensors. From the point of view of assembly and handling, strain gauges or even PZT are favored because of the availability of knowledge and experience with these techniques.

ADAPTIVE COMPOSITE MODELING

This section presents the recent advances and trends in finite-element modeling of adaptive composite systems, and emphasizes particularly the development of finite-element models for adaptive composites. Benjeddou (19) presented an excellent survey of finite-element developments in piezoelectric elements. Electromechanical coupling is the major feature added by a piezoelectric material to standard structural finite-element modeling.

For the last two decades, there has been increased research activity in finite-element modeling of adaptive composites. The primary interest has been in the analysis of piezoelectrically actuated composites, and early investigations were devoted to three-dimensional electromechanical elements. Among the reported studies, Tzou and Tseng (20) used variational methods to model finite-element piezoelectric solids. Ha et al. (21) developed an eight-node, three-dimensional, composite brick, finite-element for modeling the dynamic and static response of laminated composites that contain distributed piezoelectric ceramics

subjected to mechanical and electrical loading. The electrical potential is taken as a nodal degree of freedom that leads to an element that has four degrees of freedom per node. These models using three-dimensional finite elements can give accurate results by setting computationally expensive refined meshes that have acceptable aspect ratios. Classical plate theories have been proposed to analyze rectangular piezoelectric plates (22–25). Other plate formulations include the work reported by Chandrashekhara and Agarwal (26), who used a finite-element formulation based on first-order shear deformation theory to model the behavior of laminated composite plates that have integrated piezoelectric sensors and actuators. The model developed does not introduce voltage as an additional degree of freedom. Tzou and Ye (27) presented a laminated quadratic C^0 piezoelectric triangular shell finite-element using the layerwise constant shear angle theory that accounts for a constant approximation of the nonlinear cross-sectional warping applied to piezoelectric laminated systems. A model that contains an actuator element, an adhesive interfacial element, and an eight-node isoparametric plate element was developed by Lin et al. (28). An analytic solution is also derived and results are compared with the finite-element model. Chattopadhyay and Seeley (29) used a finite-element model based on a refined higher order theory to analyze piezoelectric materials surface bounded or embedded in composite laminates. The displacement field accounts for transverse shear stresses through the thickness and satisfies the boundary conditions at the free surfaces. Through numerical examples, they showed that the refined theory captures important higher order effects that are not modeled by the classical laminate theory. Recently, models using higher order theories for piezoelectric laminates can be found in Reddy and Mitchell (30) and Jonnalagadda et al. (31), among others.

Very few composite shell elements that have electromechanical properties have been reported in the literature. A four-noded shell element that extends the shallow shell shear deformation theory has been proposed, using an equivalent single-layer model for a three-layer shell (32). An eight-noded quadrilateral shell element (33) that has no electrical degrees of freedom using the 3-D degenerated shell theory has also been proposed, where the piezoelectric effect was treated as an initial strain problem. An axisymmetric three-node triangular shell element has also been developed to study mooney transducers (34). A 12-noded degenerated 3-D shell element that has a layerwise constant shear angle has been formulated (35). However, more research is required to understand and quantify the influence of the curvature on the piezoelectric actuators and sensors. Suleman and Venkayya (12) reported on an efficient finite-element formulation for vibration control of a laminated composite plate/shell that uses piezoelectric sensors and actuators. By modeling the plate and the sensor/actuator system with the four-noded, bilinear, Mindlin plate element, the problems associated with the solid element are eliminated, and modeling the plate and the sensor/actuator system with the four-noded, bilinear, Mindlin plate element considerably reduces the problem size.

Finite-Element Formulation

To derive the equations of motion for laminated composite structures (plate or shell) that have piezoelectrically coupled electromechanical properties, recall the generalized form of Hamilton's principle,

$$\delta \int_{t_1}^{t_2} (T - \Pi + W_e) dt = 0, \quad (1)$$

where T is the kinetic energy, P is the potential energy, and W_e is the work done by the electrical field. The kinetic and potential energies can be written in the form

$$\begin{aligned} T &= \int_V \frac{1}{2} \rho \dot{u}^T \dot{u} dV, \\ \Pi &= \int_V \frac{1}{2} \bar{S}^c{}^T \bar{T}^c dV, \end{aligned} \quad (2)$$

where \bar{S}^c and \bar{T}^c are the generalized electric strain and stress vectors. The work done by the electrical forces can be written as

$$W_e = \int_{V_p} \frac{1}{2} \bar{S}^e{}^T \bar{T}^e dV_p, \quad (3)$$

where \bar{S}^e is a vector of electrical field (potential/length), \bar{T}^e is a vector of electrical displacement (charge/area), and V_p is the volume pertaining to the piezoelectric material.

Constitutive Relationships

To apply piezoelectric materials in adaptive composite systems, the properties are defined relative to the poling direction through the thickness, and the material is approximately isotropic in the other two directions. In matrix form, the equations governing these material properties can be written as

$$\bar{T}^e = \mathbf{e}^T \bar{S}^c + \varepsilon \bar{S}^e, \quad (4)$$

$$\bar{T}^c = \mathbf{c}^T \bar{S}^c - e \bar{S}^e, \quad (5)$$

where \mathbf{e} is the dielectric permittivity matrix, ε is the dielectric matrix at constant mechanical strain, and \mathbf{c} is the matrix of elastic coefficients at constant electrical field strength.

Strain–Displacement Relationships

The strain–displacement relationships for an electromechanical composite element are based on the Mindlin first-order shear deformation theory. The matrix that relates the generalized strains to the displacements and rotations

can be written in the form

$$\bar{S}^c = \begin{bmatrix} \frac{\partial}{\partial x} & 0 & \frac{1}{R_{xx}} & 0 & 0 \\ 0 & \frac{\partial}{\partial y} & \frac{1}{R_{yy}} & 0 & 0 \\ \frac{\partial}{\partial y} & \frac{\partial}{\partial x} & \frac{2}{R_{xy}} & 0 & 0 \\ 0 & 0 & 0 & 0 & z \frac{\partial}{\partial x} \\ 0 & 0 & 0 & z \frac{\partial}{\partial y} & 0 \\ 0 & 0 & 0 & z \frac{\partial}{\partial x} & z \frac{\partial}{\partial x} \\ 0 & 0 & \frac{\partial}{\partial x} & 0 & 1 \\ 0 & 0 & \frac{\partial}{\partial y} & 1 & 0 \end{bmatrix} \begin{Bmatrix} u \\ v \\ w \\ \theta_x \\ \theta_y \end{Bmatrix}. \quad (6)$$

Electric Field Potential Relationships

For a laminated plate/shell that contains piezoelectric layers/patches polarized along the transverse axis, the in-plane electric fields vanish. The electric field potential relationships are $\bar{S}^e = -\nabla \bar{\phi}$, where $\bar{\phi}$ is the vector of potential degrees of freedom. It is assumed that these are constant throughout the plane of the piezoelectric patch/layer and vary linearly through the thickness. Thus $S_i^e = \frac{1}{t_{pi}} \phi_i$, where t_{pi} is the thickness of the i th piezoelectric layer/patch.

Substituting for the generalized stress and strain expressions in Eq. (1) gives the mass, elastic, and electrical stiffness matrices. For the entire structure, using the standard assembly technique for the finite-element method and applying the appropriate boundary conditions, we obtain the complete equations of motion for a piezoelectrically actuated adaptive composite structure:

$$\begin{bmatrix} M_{cc} & 0 \\ 0 & 0 \end{bmatrix} \begin{Bmatrix} \bar{U}_c \\ \bar{U}_e \end{Bmatrix} + \overbrace{\begin{bmatrix} K_{cc} & 0 \\ 0 & 0 \end{bmatrix}}^{\text{elastic}} \begin{Bmatrix} \bar{U}_c \\ \bar{U}_e \end{Bmatrix} + \overbrace{\begin{bmatrix} 0 & K_{ce} \\ K_{ec} & K_{ee} \end{bmatrix}}^{\text{electric}} \begin{Bmatrix} \bar{U}_c \\ \bar{U}_e \end{Bmatrix} = 0 \quad (7)$$

To avoid shear locking in thin structural elements, a reduced order integration technique is used to evaluate the shear stiffness term. For the actuation mechanism, the structure is given applied voltages on the layers/patches, and the static deformation is given by $\bar{U}^c = -K_{cc}^{-1} K_{ce} \bar{U}^e$. The sensing mechanism is governed by the equation $\bar{U}^e = -K_{ee}^{-1} K_{ec} \bar{U}^c$.

Finite-element techniques have also been developed for other active materials, such as electrostrictive (36,37), and magnetostrictive (38–40) systems. Boundary finite-element techniques have also been proposed for piezoelectric solids (41,42). However, most of the research activity

has been devoted to developing models for piezoelectric-based adaptive structural systems. It can be concluded that although relative maturity has been reached, there is a lack of curved two-dimensional and active constrained layer damping shell finite elements and some quadratic elements that save electric degrees-of-freedom representation.

APPLICATIONS

The application of adaptive composite systems in structural systems is vast and diverse. The literature indicates that applications of adaptive composite structures have been devoted mostly to dynamics and control analysis of adaptive beams and plates. Other applications include analysis of the thermal effect on active materials (43,44), noise suppression (45–47), composite delamination (48), precise position control (49), topology optimization (50), panel flutter suppression (51), and structural health monitoring and self-repair (52–55).

In this article, design problems in aircraft structures that require active solutions using adaptive composites to suppress vibration and control shape are presented. Adaptive composite solutions to vertical tail buffeting suppression, supersonic panel flutter envelope extension, and aeroacoustic noise suppression are discussed.

Vertical Tail Buffeting Suppression

The primary passive solutions to dynamic aeroelastic problems are increased stiffness and mass balance, and these were used as early as 1922. They still comprise the basic passive means of improving the response and stability of an aircraft. Increased stiffness has come to include composite tailoring which can greatly alter the stability characteristics of a given wing. Aeroelastic tailoring has made airplane configurations, such as a forward swept wing, feasible. Recently, aeroelastic tailoring has been used to enhance the performance of controllers. By the 1950s, the concept of active control to improve the aeroelastic performance of wings had emerged. One of the first aeroelastic control experiments began in 1972 in NASA Langley Research Center's Transonic Dynamics Tunnel (56,57). The model was a clipped delta wing that had a leading edge and a trailing edge actuator. Since that time, control experiments using flap actuators have studied a variety of control design techniques and objectives. The Active Flexible Wing (AFW) project used the flexibility of the wing in conjunction with active controls to provide greater maneuverability. Multifunctional control systems were also investigated in the AFW project. In addition to flutter suppression experiments, there have also been gust alleviation experiments.

Until now, the unifying factor of the previous work was that the actuators were all aerodynamic control surfaces. One of the reasons for these actuators is that they already exist on current aircraft. The development of aeroelastic control has evolved in the last couple of decades, a new actuation concept has emerged for structural control, and this is direct strain actuation. Direct strain actuators include materials such as piezoelectric ceramics and shape memory alloys. Piezoelectrics have several advantages

over hydraulic actuators because they have a higher frequency bandwidth of operation and because they act directly in the structure by straining it.

The DARPA/USAF Wright Laboratory program was to design, build, and test wind tunnel models to quantify performance improvements that could be achieved by incorporating smart materials such as PZTs for actuation and sensing systems in aircraft wings. The Smart Wing program performed wind tunnel tests at the NASA Langley Transonic Dynamic Tunnel to demonstrate the use of smart actuator systems in a realistically modeled aircraft operating environment. The wind tunnel test quantified aerodynamic improvements of two concepts: the use of embedded SMA wires in the trailing edge to provide a smooth variable contoured control surface and SMA torque tubes built into the wing structure that enabled the wing to be twisted or torqued.

Several active vibration suppression concepts have been investigated by a program shared between Daimler-Benz Aerospace Military Aircraft (DASA), Daimler-Benz Forschung (DBF), and Deutsche Forschungsanstalt für Luft- und Raumfahrt (DLR); two concepts using aerodynamic control surfaces and two concepts using piezoelectric components. In the DASA concept, a thin surface of piezoactuators is set out to flatten the dynamic portion of the combined static and dynamic maximum bending moment loading case directly in the shell structure. The second piezo concept by DLR involves preloaded PZT block actuators at structural fixtures. Both piezoelectric strategies were aimed at straight open-loop performance related to concept weight penalty and input electric power.

The shape control of a flexible wing structure has a great potential for improving the aerodynamic lifting-surface performance. Significant reductions in the shock-induced drag can be achieved by small adaptive modifications to the wing cross-sectional profile. The results presented here are the experimental wind tunnel results obtained to suppress buffeting actively by using piezoelectric actuators to control the shape of the wing camber. Two methodologies are presented and compared. One uses the piezoelectric actuators in the traditional way, placing them at the root to generate bending moments that compensate for the mechanical vibration along the span of the wing. The other method consists of using the piezoelectrics to achieve airfoil camber shape control to control lift, so that the change of lift can be used to generate the same type of moments and hopefully result in using fewer piezoactuators and less energy.

The plate wing motion was controlled by six piezoceramic actuators bonded on the surfaces at the wing mount root portion and two shape control actuators near the wing tip. The piezo wafer sensors were located at the wing mount root, and the signal was sent to a digital signal processor through filters. The control signal was sent to power amplifiers. The amplified signal drove the piezoceramic actuators and attenuated vibration at the wing mount. This signal also drove the shape control actuators. A control law was designed based on a discrete system model.

Photographs of the test model system are presented in Fig. 1a. The dimensions were determined on the basis of the wind tunnel size, blowing air velocity, and the limitations

Figure 1. (a) The experimental test article that has surface-bonded piezoelectric actuators; (b) first three modal frequencies and shapes used in the controller design.

of the piezoceramic actuators. Structurally, it was aimed at having a fairly flexible wing that had low bending and torsion mode frequencies.

Six piezoceramic sensor patches (1.5' long; 1.00' wide; 0.0075' thick) are bonded to the top and bottom of the plate near the root. The actuators are divided in two groups, those to produce moments, two pairs near the leading edge and one near the trailing edge, all near the root to maximize the bending moment. The other group, which is responsible for the camber shape control, is located near the wing tip to change the wing camber and produce favorable changes in lift. A finite-element modal analysis was performed to generate natural frequencies and model shapes (Fig. 1b).

The experimental setup is based on a DSP state-of-the-art laboratory facility created for testing and validating the theoretical models and applying of active control design. A rigid plate was placed at the upstream end of the test section. The wake from this obstacle was used to generate buffeting flow. The position of this object was easily adjusted so that the resulting wake impinged on the model mounted downstream. Using the control law gain set to the desired value, the tunnel speed was increased to and then held constant at a preselected value. Buffet response measurements were made at a velocity of 5.5 m/s. The output signal from the PZT sensor was routed to a transfer function analyzer that was used to calculate the autocorrelation function of the response signal.

With respect to the gust alleviation tests, a special flap was mounted upstream of the model to deflect the flow so that a vertical wind component would appear (20% of the wind tunnel velocity). The wind tunnel speed was

maintained at 5 m/s, and the flap would change its incidence at 2.5 Hz, creating a vertical gust of 1 m/s that excited the bending on the wing. Maintaining the gust at this frequency and turning on the controller, the amplitude decreased considerably.

An appreciable buffeting reduction has been obtained, especially when using airfoil shape control, which combined with the root actuators to decrease the average buffeting amplitude from 32 to 47.5% (Table 3). The airfoil shape control also decreased the frequency of the vibration by 34%. The airfoil shape control has presented a feasible engineering design solution where the piezoelectric shape control actuators are used to create favorable changes in lift characteristics.

Supersonic Panel Flutter

Panel flutter is a self-excited, dynamic instability of thin plate or shell-like structural components of flight vehicles. It is a supersonic/hypersonic aeroelastic phenomenon that is often encountered in the operation of high-speed aircraft and missiles. The mode of failure for panel flutter is fatigue due to limit-cycle oscillations. Therefore, to increase the critical dynamic pressure or to suppress the limit-cycle oscillations is an important design consideration. Conventional design is to increase the panel stiffness, which in turn, may result in additional weight.

Many researchers have investigated the supersonic panel flutter suppression problem. Dowell (58) gave a comprehensive overview of panel flutter, and Olson (59) and Bismarck-Nasr (60) presented applications of the finite-element method to linear flutter problems for isotropic

Table 3. Active Wing Shape Control (Buffeting Suppression)

	Bending Control Only		Bending + Shape Control	
	Average Amplitude	Frequency	Average Amplitude	Frequency
Control law off	585 mm	1 Hz	620 mm	1 Hz
Control law on	395 mm	0.9 Hz	325 mm	0.66 Hz
Improvement	32%	10%	47.5%	34%

materials. Lee and Cho (61) and Liaw (62) investigated the use of composite panels in flutter problems due to stringent performance requirements in high-speed aircraft. Lee and Lee (63) performed supersonic flutter analysis of anisotropic panels taking into consideration the effects of panel geometry, boundary conditions, lamination scheme, flow directions, and thermal effects. Gray and Mei (64) conducted research on various theoretical considerations and analytical methods for investigating of nonlinear panel flutter. Zhou et al. (65) extended this work to include finite-element methods. Scott and Weishaar (66) proposed a linear panel flutter control using piezoelectric actuators and sensors. Paige et al. (67) extended this study to include anisotropic composites. Xue and Mei (68) studied the feasibility of applying shape memory alloys in linear panel suppression.

The flutter velocity of panels, or similarly the critical dynamic pressure, can be increased by making piezoelectric actuators induce in-plane tensile forces that alter the effective stiffness of the panel. The same voltage is applied to the top and bottom piezoelectric layers, resulting in uniform compression or tension in the plate.

Consider a case #1 where the patches cover only the center 6% of the plate area (Fig. 2). Here, the mass increases by 17% due to the addition of the piezo patches to the base structure. Obviously, the effective stiffness also increases. It was observed that the critical dynamic pressure increased from 267×10^3 to 323×10^3 N/m², an improvement of 27%. Note that this increase is solely due to the bonding of the piezo patches to the top and bottom surfaces of the aluminum panel. Subsequently, the piezo

patches were actuated with a voltage of 400 V and, in this instance, a further increase of 42% was attained, relative to the case where no voltage was applied. The effective stiffness was increased by attaching of the piezo patches in the first instance, and a further increase was obtained by actuating the piezos with an applied voltage.

Next, the performance of a patch that covered 25% of the plate area was assessed (configuration #2). Here, a substantial increase in mass was observed (69%). The addition of piezo patches with no voltage applied resulted in an increase of 92% in dynamic pressure. Further application of 400 V across each layer resulted in a smaller further improvement in dynamic pressure to 645×10^3 N/m², or 32% relative to the 0 V case. Thus, it is noted that an increase in the size of the piezo patches and/or actuating power does not necessarily result in better performance. In fact, the 25% patch configuration performed worse than the 6% patch case. Apparently, the larger piezo patch configuration resulted in a relatively much larger mass increase that offset the benefits of increased actuation capability.

Three more patch configurations were analyzed to probe this matter further. Let us call these configurations #3, #4, and #5. In configuration #3, five piezo patches are placed in a star-shaped form, resulting in a mass increase of 86%. The flutter dynamic pressure in the presence of an applied voltage of 400 V exhibits poor performance, a mere 5% increase in value relative to the no applied voltage case. In other words, a larger actuation capability, followed by a much larger mass increase, resulted in negligible improvement. For configuration #4, where four piezoelectric patches were arranged in a cross, the mass increased by 69%. The resultant critical dynamic pressure increased by 8% to 684×10^3 N/m² due to an applied voltage of 400 V. Finally, configuration #5, where the piezo patches were arranged along the perimeter of a square at the center of the plate, exhibited an increase of 20% in dynamic pressure and an increase of 52% in mass. Thus, in configuration #5, better performance was attained in the presence of a relatively smaller increase in mass, whereas in configuration #3, poor performance was exhibited with and mass increased.

Another aspect that draws attention is the fact that the 25% central patch configuration and the number #4 configuration provide a similar mass increase (69%). However, the 25% central patch configuration resulted in a 32% improvement in dynamic pressure, whereas the actuation in configuration #4 exhibited a poor 8% improvement. The performance parameters of interest are the added mass to stiffness ratio and the shape, size, and location of the piezoelectric patches on the adaptive composite structure.

Figure 2. Critical dynamic pressure for five different piezoelectric actuator configurations.

Fuselage Noise Attenuation

During the last few years, there has been an increased understanding of the mechanisms involved in aircraft interior noise and the transmission paths from the sources to the cabin interior. Progress has been made in reducing interior noise levels, especially for propeller driven aircraft, when traditional passive noise control methods are supplemented by recent advances in active noise control. The technical advances have not always translated into large reductions in interior noise levels, but they have enabled existing sound levels to be maintained despite increases in the acoustic power generated by the sources. Because weight is at a high premium, optimization of airplane soundproofing is a design challenge.

Most aircraft use passive methods exclusively to control interior noise. The general concept of cabin soundproofing has remained constant for years, but design changes have occurred, particularly in more efficient treatments. The basic noise control treatment consists of one or more layers of porous material, an intervening sheet of heavy limp material, and a covering impervious trim (69). Stiffening the structure tends to incur a substantial weight penalty. Broadband passive damping is not useful because the response is primarily forced, rather than resonant. Narrowband damping using tuned vibration absorbers has yielded 10-dB reductions (70), but the problem is limited by the difficulty of keeping them tuned in a varying environment.

Active noise suppression methods include control of either the acoustic field or the structural vibration. There have already been flight tests using active control of the internal sound field that have provided significant reductions in noise levels (71). However, the many microphones and speakers required to obtain this performance create a moderate weight penalty and some difficulty in locating bulky speakers in the passenger compartment.

The first documented research on acoustic modeling was reported by Foxwell and Franklin (72) and later, Warburton (73) considered the effects of an acoustic field on the vibrations of a cylindrical shell. The use of finite-elements in acoustics was first suggested by Gladwell (74) who considered some simple one- and two-dimensional problems. Craggs (75) presented a model for studying sound transmission between enclosures that allowed for flanking as well as direct sound transmission.

The concept of controlling structural vibration to reduce transmitted noise is not new. Previous analytical and experimental work established that interior noise in aircraft is directly coupled to fuselage vibration (76–81). This observation implies that if the fuselage vibration can be reduced, then the associated interior noise levels should fall everywhere in the interior space, that is, global attenuation would be achieved. Piezoelectric actuators are well suited for this problem due to their high bandwidth. Jones and Fuller (82) used piezoelectric actuators bonded to an aircraft fuselage and obtained acceptable authority over internal noise using microphone feedback, indicating that the required actuator strength is feasible.

Jayachandran and Sun (83) studied the potential use of shallow, spherical-shell actuators, made of piezoelectric materials supported on a flexible foundation along

the edge. The actuators were modeled analytically and the effects of curvature, mount stiffness, mass, and other parameters on the natural frequencies, linear stroke, and volume velocity were studied. Shields et al. (84) investigated sound radiation from a plate into an acoustic cavity controlled by patches of active piezoelectric-damping composites. Yoon et al. (85) used the fact that anisotropy and the shape of a distributed piezopolymer actuator have coupling effects with vibration modes of structure to control the sound transmission actively through composite structures. Shen and Sun (86), on the other hand, compared the performance of acoustic microphones and strain induced by distributed piezoelectric actuators. A uniform cylindrical shell is used as a simplified model of a section of fuselage.

The referenced numerical investigations in noise attenuation concentrated on either flat plate or simple analytical models to represent adaptive composite structures. Other investigations more specifically implemented for aircraft components do not account for the effects of curvature of the fuselage to evaluate actuator performance properly (87–89). These models require refined meshes to capture the physics of the curved fuselage panel accurately. The model proposed in this investigation consists of a shell-type adaptive composite finite element that has electromechanical properties. The acoustic cavity model is based on a solid brick element.

The results presented in this section are based on finite-element computer simulations aimed at predicting the effectiveness of using piezoelectric actuators as passive control devices to attenuate the transmission of sound through an aircraft fuselage. A relatively simple model comprised of a finite, adaptive composite cylinder that has bonded piezoelectric patches was chosen to represent the aircraft fuselage. The properties of the cylinder material and its dimensions were selected to represent a typical aircraft fuselage and these values were obtained from Thomas et al. (90). The cylinder is 16 m long, and the propeller plane is at a distance of 3.5 meters along the axis of the cylinder. The diameter is 1.3 meters. The objective is to provide a quantitative measure of the actuating capabilities of the piezoelectric patches in internal noise attenuation applications (Fig. 3a).

Simulations were carried out at a frequency close to the blade passage frequency at 90 Hz. Forty acoustic and structural modes were used to model the dynamics of the coupled acoustic-structural system. Numerical results are obtained for the following geometric and material properties for the piezoactuators: $E_p = 63$ GPa, $\rho_p = 7650$ kg/m³, $\nu_p = 0.3$, $d_{31} = d_{32} = -180 \times 10^{-12}$ m/V, $L_p^z = 0.6$ m, $L_p^\theta = 0.6$ m, and $h_p = 1$ mm. It is assumed that the actuators are perfectly bonded to the aluminum fuselage shell structure. A constant voltage of 300 V was applied to each actuator patch.

The finite-element mesh for the structural-acoustic coupled system is shown in Fig. 3b. Two actuator configurations were selected to study the noise suppressing capabilities of the actuator geometry (Fig. 3c). It was observed that the response in the low-frequency range is very low because no modes are excited in this frequency range. Figure 3d presents the noise reduction attained

Figure 3. (a) Passive actuation mechanism for interior noise attenuation; (b) finite-element mesh for the aircraft fuselage and cavity with 16 elements along the fuselage length; (c) piezoelectric actuator configuration in chess and line layouts; and (d) noise reduction in the interior of the fuselage for both actuation configurations.

in the interior of the fuselage as determined from the numerical simulations at 90 Hz. It can be observed that it is possible to attain noise reduction levels of the order of 10–15 dB for the frequency simulated in this study. The results presented are compared to those with no actuation in the presence of the piezoelectric actuators. The effect of adding the actuators in the dynamics of the coupled system was taken into account. Noise reduction levels of the order of 17% were attained for the chess-type actuator pattern, and for the line-type configuration, the noise reduction levels obtained were of the order of 22%. This demonstrates that the actuator layout is an important design parameter in applying piezoelectric devices for noise suppression, as was observed in the panel flutter suppression problem.

The results presented here are simply intended to demonstrate the feasibility of applying piezoelectric actuators passively to suppress noise in the interior of closed acoustic cavities such as the interior of an aircraft fuselage. The design concept is based on the effect of stiffening the structure by actuating of the piezoactuators.

CONCLUDING REMARKS

An overview of the state of the art in adaptive composite systems design and applications has been presented. This area of research has been commonly known as the field of smart structures. Two key technological developments

have combined to establish the potential feasibility of smart/adaptive structures. The first is the development of multifunctional materials (materials science) and their use in devices such as distributed actuators and sensors (mechanical engineering). The second development in the field of computer science and electrical engineering, is the advent of ever faster and compact computers, new control algorithms, and signal processing technologies.

The adaptive structures design concepts presented here are feasible engineering solutions to problems that require active vibration suppression and shape control in aircraft structures. However, for the adaptive composite systems to see widespread commercial applications, lighter multifunctional materials, new manufacturing techniques, and cost reduction will have to be integrated into the design process. There is also a need to link the engineered solutions to the market needs. Materials supply is not a viable commercialization position because synthesis and assembly will ultimately address the design, shaping, and functional issues of adaptive materials and structures. Only vertical integration of the manufacturing process will ensure that materials science research will be directly connected to design, implementation, and production of adaptive composite systems.

The multidisciplinary nature of the field of adaptive composite systems requires a complex and sophisticated effort for the transition from research to full implementation and commercialization. Figure 4 depicts technologies and other aspects of research that must be addressed to enable adaptation of structural composite structures and systems.

ADAPTIVE SYSTEMS, ROTARY WING APPLICATIONS

ADITI CHATTOPADHYAY
JOHN RAJADAS
Arizona State University
Tempe, AZ

INTRODUCTION

Research and development of smart materials and smart structural systems has been actively pursued during the last decade. Smart materials are defined as materials that can adapt to external stimuli, such as load or environment. The control capabilities of the material can be enhanced by material composition, processing, defect or microstructure, and conditioning to adapt to various levels of stimuli. When these special types of materials are integrated into the structure, both the sensing and the actuating mechanisms become integral parts of the structure through induced strain actuation. The technological applications of this class of materials span a wide range. Today, a large variety of materials and techniques exist (piezoceramics, magnetostrictives, electrostrictives, electrorheological fluids, shape-memory alloys and fiber optics) that serve as sensors and actuators in smart structures. A material that is subjected to a mechanical load and accumulates an electric charge is said to have piezoelectric properties. Conversely, when the piezoelectric material is subjected to an applied electrical field, it induces strain. Thus, piezoelectric materials can be used as active vibrational dampers for structures where they act as both sensors and actuators. When placed in discrete locations on a structure, these materials can sense movement and can control that motion via localized strains. The strain is either compressive or tensile depending on the polarity of the applied electric field. Although these materials generate very low strain, they cover a wide range of actuating frequency and therefore have more practical applications. Although piezoelectric materials are relatively linear and bipolar, they exhibit hysteresis. Magnetostriction is the change in any dimension of a magnetic material caused by applying an external field. These materials are monopolar and nonlinear and exhibit hysteresis. At room temperature and higher, rare-earth transition-metal compounds such as Terfenol-D offer considerable promise as materials for magnetomechanical actuators. These materials generate low strains and moderate forces across a broad frequency range. However, these actuators are often bulky. Electrostrictive materials are similar in characteristics to piezoelectrics and have slightly better strain capability but high sensitivity to temperature. These materials are also monopolar and nonlinear but exhibit negligible hysteresis. Electrorheological (ER) fluids consist of a suspension of fine semiconducting particles in a dielectric liquid that solidifies in a sufficiently large electric field. More precisely, the particles align themselves and thereby form columns that connect the two electrodes. The viscosity of the fluid clearly undergoes dramatic changes as this process takes place, and this effect has been used in a variety

of studies to suppress vibrations by increasing damping. The very short response time of these fluids represents a very important feature from the standpoint of vibrational control. Fiber optics are increasingly becoming popular because like piezoceramics, they can be easily integrated into composite structures. Shape-memory alloys (SMA) operate via a martensitic phase transformation and its subsequent reversal. The shape-memory effect is driven by cooling and heating cycles. It is characterized by recoverable strains as high as 10% and can generate a significant restoring force. The most common commercially available SMA is Nitinol™.

An intelligent or smart structure is generally considered an integrated system of structure, sensors, actuators, and a control module. Currently, there is a great deal of interest in applying smart structure technology to various physical systems. Active vibration, noise, aeroelastic stability, damping, shape control, health monitoring, process monitoring, and damage and delamination detection are a few examples. A significant amount of the early development was devoted to application to space-related systems. Recently, studies have also been conducted to investigate using this concept to improve fixed wing performance. During the last decade, significant research efforts have also been directed toward applying these concepts to rotary wing aircraft which is the topic of this article. A review of the applications of smart materials and structures in aeronautical systems is presented in (1). The potential for improving performance, handling qualities in stall, and increasing fatigue life is discussed. Actuators that use smart materials require relatively slow-acting shape and shape-distribution changes in this respect. A similar review is made of applications for improving aeroelastic divergence, flutter instabilities, and tail buffeting on fixed-wing aircraft and reducing vibrations, improving external acoustics, and providing flight controls for rotary wing aircraft—all of these require a high-frequency response.

Vibration and noise are two long-standing problems that have limited the expansion of military and commercial applications of rotorcraft. Helicopters are particularly susceptible to high vibratory loads compared to fixed wing aircraft due to the high unsteady load and complex aerodynamic environment in which the rotor must operate and the existence of the complex structural, aerodynamic, and dynamic coupling. The structural flexibilities in the rotor blade, lead to vibration and control problems during operation (especially at high operating speeds) even though lightweight and stiff advanced materials such as composites and ceramics may be regularly used to build them. Alleviating rotor noise and vibration presents a major challenge to the aviation engineering community and is essential for increased survivability, reliability, and maintainability of rotorcraft. The flexibility of the rotor system in rotary wing aircraft makes it possible to impose changes in shape, mechanical properties and stress-strain fields upon it. The use of smart structures will allow tailoring the imposed changes according to the conditions sensed by the rotor. Most importantly, by using distributed sensors and actuators, control can be achieved across a much broader bandwidth than by using a swash plate control system which is limited to n/rev for an n -bladed rotor.

Recently, a significant amount of research has been conducted to control vibration using both active and passive methods. Passive techniques, such as nonstructural tuning masses and additional stiffening members, can help reduce vibrational amplitudes. However, such techniques are subject to significant weight penalties. Active vibrational suppression techniques offer definite advantages compared to conventional methods because of reduced weight penalties. An early study of different techniques for controlling rotary wing vibration by using smart structures was done (2).

Friedmann and Millott (3) present a concise review of the state of the art for vibrational reduction in rotorcraft by using active controls. The principal approaches presented for vibrational reduction in helicopters are higher harmonic control (HHC) and individual blade control (IBC). In HHC, time-dependent pitch control is introduced into the nonrotating frame through the swash plate. In the IBC approach, each blade is individually controlled in the rotating frame. Although the HHC method has been successful in reducing hub vibration, a similar reduction in airframe vibrational levels is not always possible because conventional HHC methods employ a single frequency of the form $n\Omega$. Other factors, including mechanical complexity and weight penalty, also limit its application. In addition, if the hub moves as a result of a dynamic rotor-airframe coupling, its filtering characteristics for frequencies other than n/rev are severely degraded, this makes the HHC scheme ineffective. In the IBC approach, control laws are synthesized independently and are aimed at minimizing the modal contribution of each blade to the overall rotor vibration. Therefore, vibrations due to manufacturing variability among the blades can be addressed effectively. The procedure is not restricted by the $(n + 1)\Omega$ phenomenon specific to the swash plate and hence can be more effective in addressing airframe vibrations due to rotor-airframe coupling.

A major improvement in helicopter performance can be achieved by implementing active rotor control technology. Smart material actuator technology for operation "on the blade" is now becoming available and promises to overcome the size, weight, and complexity of hydraulic and electric on-rotor actuation which should alleviate the problem. Blade actuation by smart materials offers the chance for an electrical system integrated into the blade itself. A study of different blade actuating systems shows that, in principle, there is a possibility of achieving this goal. A significant amount of research has been conducted by using induced strain actuation for improved IBC. These include using distributed induced strain actuation for active/passive control of structural response for improved vibratory response, an actively controlled flap located on the blade for possible noise and vibration reduction, actuator driven servoflaps, an active twist concept for controlling vibration and noise, and novel active/passive damping treatments for increased modal damping. Unfortunately, the development of high force/high deflection actuators, the most critical issue in all of these applications, has not been addressed adequately and still remains a topic of future research. Finally, in all applications involving smart materials, accurate modeling of the material response and the integrated smart

structural response is important because control authority can be significantly mispredicted if inaccurate theories are used. In the following sections, the current state of the art in improving rotor vibratory response and aeromechanical characteristics is reviewed. Advantages and disadvantages of these techniques are discussed. Numerical results from feasibility studies are summarized, and accomplishments already achieved and the goals to be pursued in the near future are discussed.

ACTIVE/PASSIVE CONTROL OF STRUCTURAL RESPONSE

Both the first elastic flatwise bending (second for hingeless rotors) and the first elastic torsion modes of a single blade require special attention in vibrational control. Theoretical investigations supported by wind tunnel and flight tests confirmed that these modes are responsible for the larger amplitude loads at $3/\text{rev}$ in four-blade hingeless rotors. IBC, based on a collocated actuator-sensor arrangement along the blade and tailored to act specifically on the bending and the torsional modes, is expected to reduce further the overall dynamic response of helicopters. Induced strain actuation using both active and passive control has been investigated by several researchers. Nitzsche and Breitbach (4,5) investigated the feasibility of employing adaptive material to build sensors and actuators for attenuating the higher harmonic loads of the helicopter rotor based on the individual blade control (IBC) concept. The results indicate that the adaptive material has enough power in a number of applications to accomplish the task without saturating the applied electrical field. Individual blade control of bearingless composite helicopter rotors aimed at vibrational attenuation by using adaptive structures is presented by Nitzsche (6). A periodic model-following regulator was developed in the frequency domain to approximate the aeroelastic response of a single blade in forward flight to its hover characteristics. Two control strategies are investigated: a robust one using distributed control and a cost-efficient one using lumped control. Selective linearization of the periodic system at determined frequencies is demonstrated in both cases. Active and passive control of the aeroelastic response of helicopter rotors was achieved by using smart materials to tailor the blade root flexibility (7). An individual blade controller designed to attenuate the aeroelastic response of helicopter rotors in forward flight by tailoring the blade root attachment conditions was developed. A feasibility analysis indicates that the open-loop controller that incorporates both passive and active designs is energy efficient and may be realized by available adaptive structures. A thin-walled cantilever beam is used to model a helicopter blade (8,9). The integrated distributed actuator design methodology was based on the converse piezoelectric effect and aimed at actively control of the vertical and lateral eigen vibrational characteristics of the beam.

A helicopter rotor system that employs an adaptive rotor blade was developed (10). The unique feature of this system is the replacement of the traditional swash-plate-based collective control by adaptive rotor blades that generate lift by using active camber control based on a

shape-memory alloy. A control scheme that allows a smooth variation of camber changes was developed. However, appropriate heating and cooling schemes necessary in active SMA are not discussed.

An adaptive nonlinear neural network control algorithm that can be used for smart structure actuators and sensors to control the shape and suppress the vibrations of flexible beams was developed (11). The algorithm couples an explicitly model-based adaptive component that employs time-varying estimates of the beam's material properties and an adaptive neural network, learning in real time, which is used to estimate the additional actuator moments needed to offset the effects of periodic external disturbances. Experimental results for a thin beam that has bonded piezoceramic sensors and actuators demonstrate the algorithm's ability to track desired bending profiles and reject vibrations caused by external disturbances and to maintain this performance despite changes in the material properties of the structure or in the properties of the external disturbance. The development of one-dimensional pure bending, coupled bending and extension, and combined bending, extension, and torsion models of isotropic beams that use induced-strain actuation is discussed (12). An adhesive layer of finite thickness between the crystal and beam is included to incorporate shear lag effects. Experimental tests evaluated the accuracy and limitations of the models. The bending and coupled bending and extension models show acceptable correlation with static test results, whereas the combined extension, bending, torsional model indicates the need for model refinement.

Chattopadhyay et al. (13) investigated the reduction of vibratory loads at a rotor hub using smart materials and closed-loop control. A comprehensive composite theory was used to model the smart box beam. The theory, which is based on a refined displacement field, is a three-dimensional model that approximates the elasticity solution, so that the beam's cross-sectional properties are not reduced to one-dimensional beam parameters. The finite-state, induced-flow model is used for predicting the dynamic loads. Significant reductions in the amplitudes of dynamic hub loads are shown by using closed-loop control. Detailed parametric studies assessed the influence of number of actuators and their locations in vibratory hub load reduction.

All of this work suggests that distributed induced strain actuation for IBC is a promising concept. However, the lack of appropriate rotating blade actuating systems is a major barrier that needs to be overcome before the impact of these concepts can be truly realized in the area of vibration and noise control. The limited output capability of the materials and the dynamic operating environment must be fully addressed and resolved to take advantage of this technology.

PASSIVE/ACTIVE CONTROL OF DAMPING

Both airframes and rotors are prone to vibratory motions that can become severe when conditions of resonance, limit cycle, chaos, or aeromechanical instability are approached. Current advanced rotor designs tend toward hingeless and bearingless rotors to reduce life-cycle costs, improve hub

designs, and achieve superior handling qualities. Due to stress and weight considerations, advanced rotors are designed as soft in-plane rotors. These rotor systems are susceptible to aeromechanical instabilities such as air and ground resonance due to the interaction of a poorly damped regressing lag mode and the body mode. The introduction of damping into the system may alleviate aeroelastic flutter, reduce gust loading, increase fatigue life expectancy of rotor blades, improve maneuverability and handling, and diminish interior noise levels. In conventional articulated rotors, these instabilities are usually mitigated by using hydraulic dampers. But hingeless and bearingless helicopter rotor designs have elastomeric lag dampers. Elastomeric dampers have received a significant amount of attention for damping in helicopter design due to the variety of advantages they exhibit over conventional dampers. A new technology called Fluidlastic[®] which combines fluids and bonded elastomeric elements to provide unique dynamic performance in solving vibrational control and damping problems in helicopters was introduced (14). The fluids add a viscous component to the energy dissipation mechanism in the dampers. These devices accommodate all relative motion by flexing the elastomer, which eliminates dynamic seals and achieves a long, predictable service life. Incorporation of the fluid facilitates the design of devices that have a much broader range of dynamic characteristics than can be achieved by elastomers alone. Substantial energy dissipation, as required in lead-lag dampers, can be provided. Large inertial forces that have little damping, as required in tuned vibrational absorbers and pylon isolators, can also be achieved. However, elastomeric dampers are sensitive to temperature, exhibit significant loss of damping at extreme temperatures, and it has been known that they cause limit cycle oscillations in rotor blades. They are expensive and are susceptible to fatigue. These dampers also exhibit complex nonlinear behaviors that introduce additional modeling issues. As a result, a variety of alternatives to auxiliary lag dampers are currently under consideration. The elimination of lag dampers would further simplify the hub and reduce weight, aerodynamic drag, and maintenance costs. However, the design of a damperless, aeromechanically stable configuration is a true challenge. Several concepts have shown some promise, but no generally accepted solution has evolved for eliminating lag dampers (15,16).

Recently, new concepts for enhancing structural damping characteristics were introduced in the study of adaptive structures. Such active damping techniques, based on combinations of viscoelastic, magnetic, and/or piezoelectric materials, magnetorheological (MR) fluids, shunted electric circuits, and active nonlinear control strategies, have emerged as candidates for improving structural performance and reliability. A numerical study of electrorheological (ER) dampers (17) used two models, the Newtonian and the Bingham plastic models, to characterize ER fluid behavior. Damping performance of two damper configurations, the moving electrode and the fixed electrode, were studied and the effects of electrode gap sizes, the field strength, and the ER fluid model were quantified. The study provides a basis for designing ER-fluid based dampers. Magnetorheological fluid dampers are

attractive candidates for augmenting lag mode damping in helicopter rotors, where additional damping is required to avert instabilities during specific flight conditions. MR fluids change properties dramatically as a magnetic field is applied. This active damping component presents an advantage over passive elastomeric and fluid–elastomeric dampers. The feasibility of using MR fluid-based dampers for lag damping augmentation in helicopters was explored by Marathe et al. (18). An analytical study to examine the influence of MR lag dampers on rotor aeroelasticity was carried out by integrating a MR damper model and a rotor aeromechanical model. Two different control schemes are presented, the on-off scheme and the feedback linearization scheme. The two control schemes are compared for lag transient response in ground resonance and their ability to reduce damper load in forward flight. The study examines damper sizing, as related to the magnetic field saturation limits and lag perturbation amplitudes, to produce the desired damping. It is shown that a MR damper whose size is comparable to an elastomeric damper can provide sufficient damping for ground resonance stabilization and can significantly reduce periodic damper loads by judiciously choosing an operating scheme. An extensive comparative study of fluid–elastomeric and MR dampers was done (19). The MR dampers were tested when the magnetic field was turned off (off condition) and when it was turned on (on condition). The dampers were tested individually and in pairs, under different preloads, and under conditions of single and dual frequency excitation. The fluid–elastomeric and MR (off) damper behavior was linear, whereas the MR (on) behavior was nonlinear and the stiffness and damping varied as the displacement amplitude changed.

The concept of active constrained layer (ACL) damping treatment in reducing vibrational and augmenting stability has also been investigated. An ACL system consists of a viscoelastic damping layer sandwiched between an active piezoelectric layer and the host structure. The piezoelectric layers have sensing and control capabilities that actively tune the shear of the viscoelastic layer according to the structural response. Using such active/passive control capabilities, the energy dissipation mechanism of the viscoelastic layer is enhanced, and the damping characteristics of the host structure can be improved. Thus, the ACL configurations capitalize synergistically on both passive and active techniques. The merits of ACL for suppressing vibration of flat plates are discussed in (20–22). The primary concern in ACL configuration is the fact that the viscoelastic layer reduces the actuating ability of the piezoelectric layer. An enhanced active constrained Layer (EACL) concept was introduced by Liao and Wang (23,24) to improve the active action transmissibility of ACL by introducing edge elements. The edge elements are modeled as equivalent springs mounted at the boundaries of the piezoelectric layer. The viscoelastic layer model becomes the current active constrained layer system model as the stiffness of the edge elements approaches zero. Some important characteristics of enhanced active constrained layer damping (EACL) treatments for vibrational controls are addressed in (23). Analysis indicates that the edge elements can significantly improve the active action transmissibility of the current active constrained layer

damping treatment. The authors suggest that although the edge elements slightly reduce viscoelastic material passive damping, the EACL still has significant damping from the viscoelastic material (24). However, debonding of the edge elements, which are made of aluminum and are bonded to the piezoelectric and viscoelastic layers still needs attention before these treatments can be effective in practical applications.

Limited efforts have been reported in using these novel damping treatments to improve helicopter aeromechanical stability. Badre-Alam et al. (25) developed a simplified beam model that uses an enhanced active constrained layer (EACL) damping treatment to represent the flexbeams of soft in-plane bearingless main rotors. The goal was to demonstrate the feasibility of using such damping treatment to improve lag mode damping and aeromechanical stability. A derivative controller based on the flexbeam tip transverse velocity was used in this study. Design optimization was studied to understand the influence of various design parameters, such as viscoelastic layer thickness, PZT actuator thickness, and edge element stiffness, on PZT actuator electrical field levels, induced axial stress levels, and available lag damping. All of this work used a constrained layer treatment that covered the entire beam surface. It is well known that segmentation of the active constraining layer can effectively increase passive damping in low-frequency vibrational modes by increasing the number of high shear regions. The use of segmented constrained layer (SCL) damping for improved rotor aeromechanical stability was recently addressed by Chattopadhyay et al. (26–28). The rotor blade load-carrying member was modeled by using a composite box beam of arbitrary wall thickness. The SCLs were bonded to the upper and lower surfaces of the box beam to provide passive damping. A finite element model based on a hybrid displacement theory was used to capture the transverse shear effects accurately in the composite primary structure and in the viscoelastic and piezoelectric layers within the SCL. Detailed numerical studies assessed the influence of the number of actuators and their locations on aeromechanical stability. Ground and air resonance analysis models were implemented in the rotor blade built around the composite box beam by using segmented SCLs. Results indicate that surface-bonded SCLs significantly increase rotor lead-lag regressive modal damping in the coupled rotor-body system (26). A hybrid optimization procedure was also used (27) to address the complex design problem of properly placing actuators along the blade spar as well as to determine the optimal ply stacking sequence of the host structure for improved modal damping. Active control, using SCLs was addressed in (28). For rotary wing applications, the controller must be designed to deal with the time-variant characteristics of the dynamic model due to rotor rotation. A transformation matrix was introduced to transform the time variant problem to a time invariant problem. A linear quadratic Gaussian (LQG) controller was designed for the transformed system on the basis of the available measurement output. Numerical studies showed that the control system was effective in improving helicopter aeromechanical stability across a wide range of operating speeds (28).

TRAILING EDGE FLAPS

Smart structure activated trailing edge flaps can actively alter the aerodynamic loads on rotor blades. Using a suitable feedback control law, such actuators could be used to counter the vibrations induced by periodic aerodynamic loading on the blades, eliminate the bandwidth constraints, and reduce the weight penalties of previous actuating methods. The flaps are actuated by piezostack, bimorph, or magnetostrictive actuators. It is, however, still unclear if there is a single actuating mechanism that addresses both noise and vibrational reduction and still has enough control authority to act as an extra control effector in its own right. The uncertainties about the actuating mechanism, the precise amount of flap deflection available, and the accuracy of current constitutive models of the actuators lead to significant difficulties in analyzing the potential of the concept for helicopter applications. Today, the available materials are not quite ready for real "smart" applications. The preferred materials, such as piezoceramics, have tensile strength that is too low and very low active strains.

The feasibility of using piezoelectric materials as integrated actuators for a trailing edge helicopter blade flap was first demonstrated by Spangler and Hall (29). A model of the dynamic behavior of this actuator was developed for a fixed airfoil section using an aeroelastic Rayleigh–Ritz procedure. A set of scaling laws for the dynamic similarity between scaled test articles and representative full-scale blades was developed and experimental tests were done to verify actuator feasibility and effectiveness. The results include the amplitude response of the flap angle to the applied electric field as well as the lift and moment on the airfoil due to flap deflection. A feasible blade actuating system for individual blade control is now a hinged flap at the outer third of a rotor blade (30). This flap can be controlled by a smart (piezoelectric) actuator. Initial analysis shows that such a system will work as desired. Vibrational reduction in a four-bladed helicopter rotor using an actively controlled flap located on the blade was studied by Millott and Friedmann (31). This study examined the influence of using a more sophisticated fully flexible blade model on the potential of active flap control for reducing vibrations. A deterministic feedback controller was implemented to reduce the 4/rev hub loads. Trend studies show that the torsional stiffness of the blade and the spanwise location of the active flap are important parameters. A time-domain simulation of the helicopter response to control was carried out to investigate the validity of the quasi-static frequency domain approach to formulating control strategies.

Samak and Chopra (32) developed electromechanical actuators based on the concept of mechanical amplification using piezo and electrostrictive stacks as drivers to achieve high force and high displacement actuation. Two different actuators were developed. The first, using a piezostack, actuates a "Flaperon," which consists of a small movable surface to trip the boundary layer that is located on the top surface of a wing model using a NACA0012 airfoil. The second actuator, using an electrostrictive stack as a driver, was designed to move a leading edge droop flap hinged

at the 25% chord of a wing model using a VR-12 airfoil. Experiments to evaluate the actuators were conducted. The dynamic response of the actuators across a 33 Hz frequency range showed that 7 lb of actuator force was obtainable in both cases; the flaperon actuator produced 15 mils of dynamic displacement at 15 Hz, and the droop flap actuator produced about 6 mils of displacement at 16 Hz. A helicopter trailing edge flap using piezostack actuators was also designed and tested by Spencer and Chopra (33). A flap actuator was constructed from two piezoelectric stacks arranged in series, and mechanical amplification was provided through a hinged arm. A test model using NACA0012 airfoil was constructed, and the flap performance of the model was tested in no-load conditions. An analytical model was formulated to calculate the predicted flap deflection using quasi-steady-state aerodynamics. The model showed that the high force piezoelectric stacks maintained flap deflection across a wide range of free-stream velocities.

A parametric design of a plain trailing edge flap system was studied for a typical helicopter (34). The results show that plain flaps are effective in implementing multi-cyclic control. Significant reductions in fixed system 4/rev hub loads are predicted. The effects of variations in flap length, spanwise location, chord, and aerodynamic effectiveness could be largely offset by compensating adjustments to the flap commands. A comprehensive aeroelastic analysis was done to investigate plain trailing edge flaps for vibrational control (35). Results of the analysis are compared with experimental wind tunnel data and that of another comprehensive analysis. Correlation between predicted and measured frequencies and forward flight trim control predictions are good. Significant discrepancies are observed in 3/rev in-plane bending. Using a trailing edge flap moving $\pm 4^\circ$ at 5/rev, the analysis overpredicts the 5/rev flatwise bending moments due to the flap motion, whereas the blade torsional moment is predicted fairly well. Varying the phase angle of the flap motion had a significant effect on the blade 4/rev flatwise and in-plane bending loads.

A new actuating mechanism for a smart rotor that has an active trailing edge flap uses a piezo-activated composite bending–torsion coupled beam as an actuator (36). Spanwise variation in the beam layup and piezoceramic element phasing maximize the twist response and minimize the bending response. The surface-bonded piezoceramic elements are excited to induce spanwise and chordwise bending of the beam, which results in an induced twist via structural coupling. The composite beam has an outboard integral flap, and the flap deflection corresponds to the tip twist of the beam. Two one-eighth scale model rotor blades that used the actuator beam were hover tested at various rotor speeds and collective settings to evaluate the performance of the flap drive system. The actuator beam was excited at various frequencies and rms voltages, and 4/rev peak-to-peak flap deflections of 3–4° were achieved at an operating speed of 900 rpm. Two active rotor blade concepts were developed using a piezo-induced bending–torsion coupled composite actuator beam (37). The first is an active moving blade, and the second is a rotor blade that has an active linear twist. A spanwise variation in the beam layup and piezoceramic element phasing maximizes the twist

response and minimizes the bending response. Two operational one-eighth Froude scale model rotor blades that have a 90% main blade section and 5 and 10% span active tips were used for hover testing. In the controllable twist configuration, a nonrotating twist amplitude of 0.8° is achieved at $100V_{\text{rms}}$ and 75Hz. In hover, at 875 rpm, this reduces to 0.5° at 5/rev. The actuating power per blade is estimated at 1.2% of the hover power required at 8° collective. In the moving blade tip configuration, a nonrotating deflection amplitude of 1.7° is achieved at $100V_{\text{rms}}$. Nonrotating dynamic tests show resonant amplification for all frequencies up to 5/rev. The deflection at $120V_{\text{rms}}$ increases from a low frequency 2.25° to 3.5° at 4/rev, and for $90V_{\text{rms}}$, the low-frequency deflection amplitude of 1.5° doubles to 3.0° at 5/rev.

Koratkar and Chopra (38) reported on the analysis and testing of a Froude scaled rotor model that uses piezoceramic-bimorph actuated trailing-edge flaps. Piezoceramic benders mounted into the spar of the blade actuate the flap, and a rod-cusp mechanism is used to amplify the actuator tip displacement. An analytical model was developed by coupling an unsteady-state aerodynamic model for the flap hinge moment and a structural finite element beam model for the piezoceramic bender. Two operational one-eighth (Froude) scale rotor models that had piezo-bimorph actuated trailing-edge flaps were tested. Flap deflections of $\pm 6^\circ$ (4/rev excitation) were achieved in hover at the Froude scaled operating speed of 900 rpm. Flap authority of 10% for the rotor thrust was achieved at 4° collective for a 4/rev excitation. The analytical model was used to design a Mach scaled rotor model that had piezo-bimorph actuated trailing-edge flaps. The analysis indicates that two side by side, tapered, eight-layered bimorphs excited by a bias voltage (2:1 amplification) can generate flap deflections of $\pm 6^\circ$ at the Mach scaled operating speed of 2100 rpm. An active rotor blade that can be flown in two different configurations (with a moving blade tip or as a controllable twist blade) was designed and tested (39). The inboard 90% of the blade that uses a bending-torsion coupled actuator located in the spar is common to both blade types. The actuator (both blades) is a piezo-induced bending-torsion coupled composite beam. Two operational one-eighth scale model rotor blades were used for hover testing. In the controllable twist configuration, a nonrotating twist amplitude of 0.8° is achieved at 100V and 75Hz. In hover, at 875 rpm, this reduces to 0.5° at 5/rev. The actuating power per blade is estimated at 1.2% of the hover power required at 8° collective. In the moving blade tip configuration, a nonrotating deflection amplitude of 1.7° is achieved at 100V. Nonrotating dynamic tests show resonant amplification for all frequencies up to 5/rev. The deflection at $120V_{\text{rms}}$ increases from a low frequency 2.25° to 3.5° at 4/rev, and for $90V_{\text{rms}}$, the low-frequency deflection amplitude of 1.5° doubles to 3.0° at 5/rev. The rotor blades that had nonactivated moving tips were successfully flown in hover at 900 rpm and collective settings from $4-8^\circ$.

Advances in developing a Froude scaled helicopter rotor model featured a trailing-edge flap driven by piezoceramic bimorph actuators for active vibration suppression (40). Dynamic performance of the actuator and the actuator-flap

assembly were examined. A beam model of the piezo bimorph, including rotor moment effects was formulated to illustrate better the physical mechanisms that affect the system in a rotating environment. An analytic model and validation tests of Froude and Mach scaled rotors featured piezoelectric bender actuated trailing-edge flaps for active vibrational suppression (41). A finite element structural formulation in conjunction with time domain unsteady-state aerodynamics was used to develop the rotor blade and bender-flap coupled response in hover. A two-bladed Froude scaled rotor that used piezobender actuation was tested to investigate the feasibility of piezobender actuation and validate the analytic model. Flap deflections of ± 4 to $\pm 8^\circ$ for 1 to 5/rev bender excitation were achieved at the Froude scaled operating speed of 900 rpm. The trailing-edge flap activation resulted in a 10% variation in the rotor thrust levels at 6° collective pitch. The analytic model shows good correlation with experimental flap deflections and oscillatory hub loads for different rotor speeds and collective settings. Two Mach scaled rotor blades using piezo-bender actuation were also designed and tested. An eight-layered, tapered bender was used, and the bender performance was improved by selectively applying large electric fields in the direction of polarization to individual piezoceramic elements.

Lee and Chopra (42) developed an actuator for a trailing-edge flap on a full-scale helicopter rotor blade using a high performance piezoelectric stack device. The actuator was designed and constructed using two identical piezostacks that were selected from commercially available actuators. An analytical model was formulated by using quasi-steady-state aerodynamics to calculate the aerodynamic requirement of the flap actuator. A new amplification device that used a double-lever mechanism was also designed. An amplification factor of 19.4 was obtained experimentally under nonrotating conditions. The flap actuator can achieve the required flap deflections for active vibrational control. A systematic approach was used to design an active trailing-edge flap actuator for helicopter vibrational suppression (43). The prototype actuator was developed by using two piezostacks that had a double-lever amplification mechanism. An extended piezostack testing methodology, including both high preload and dc/ac excitation, was used to evaluate the performance of the piezostacks. The measured actuation stroke at 600 g of centrifugal loading included more than 90% of nonrotating actuating capability. Koratkar and Chopra (44,45) reported on the development of a Mach scaled rotor model that uses piezoelectric bender actuated trailing-edge flaps for individual blade control of helicopter vibration. An analytic model was developed for the coupled actuator-flap-rotor dynamic response in hover and was validated by using experimental data obtained from a Froude scaled rotor that had piezo bender actuated trailing-edge flaps. Future work in this area will involve designing, fabricating, and testing two Mach scaled rotor blades using piezo bender actuation.

A full scale demonstration system to provide active control of noise and vibrations as well as inflight blade tracking for the MD-900 helicopter was conceptually sized and designed (46). Active control is achieved via a trailing-edge flap and trim tab, both driven by on-blade smart material

actuators. Fulton and Ormiston (47) studied a trailing-edge control surface (elevons) used to generate local aerodynamic lift and pitching moments. A two-blade, hingeless rotor that used 10% chord on-blade elevons driven by piezoceramic bimorph actuators was tested in forward flight for advance ratios from 0.1 to 0.3 at low to moderate thrust coefficients. The fundamental dynamic response characteristics and the effectiveness of elevon control in reducing blade vibratory loads were studied. Deflections of $+1-5^\circ$ at a nominal rotor speed of 760 rpm were achieved, and nonlinear actuator response characteristics were evaluated. Aeroelastic and structural dynamic responses were evaluated across a wide range of rotor speeds using sine sweep excitation of the elevon up to 100 Hz. Preliminary experimental results include actuator effectiveness, the effects of low Reynolds number on elevon pitch moments, elevon control reversal, and the variation of flap bending mode responses to rotor speed and elevon excitation.

A new, robust individual blade control (IBC) control methodology for vibrational suppression using a piezo-actuated trailing-edge flap was explored (48). The controller uses a neural network, learning in real time, to cancel the effects of periodic aerodynamic loads on the blades adaptively, greatly attenuating the resulting vibrations. Complete proof of the stability and convergence of the proposed neurocontrol strategy is provided, and numerical simulation results for a one-eighth Froude scale blade model demonstrate that the controller can virtually eliminate blade vibration from a wide variety of unknown, periodic, disturbance sources. An innovative approach to vibration reduction in rotorcraft that consists of modeling the smart actuating mechanism by using a simple low-order linear model that matches test data (with an associated variation or uncertainty) was introduced by Sahasrabudhe et al. (49). The model is used along with a helicopter flight dynamic model to optimize flap sizing and placement for minimum fixed frame vibration. The effectiveness of the flap in reducing interaxis coupling and as a redundant control for primary actuator failure was analyzed. Straub and Charles (50) studied a bearingless rotor that had trailing-edge flaps for active control of rotor aerodynamics and dynamics. The flaps are controlled by piezoelectric actuators installed in the blade. Two aeroelastic codes are used to explore the aerodynamics and dynamics of this rotor. Results show that a simple but efficient code may be used to predict rotor response and conduct concept development and active control law development. An advanced code must be used to obtain more accurate loads and to study the coupled blade/flap dynamics and stability.

A numerical study to evaluate the aeroelastic steady-state response of a hingeless rotor blade that used trailing-edge flap controls was conducted by Yillikci (51). A new aerodynamic environment due to flap control is formulated on the basis of Theodorsen's unsteady-state oscillating airfoil aerodynamics representation, including unsteady-state trailing-edge flap motions. Aeroelastic responses of elastic rotor blades that have flap and pitch controls were compared, and the responses of different blade configurations that had variable chord and flap geometries were analyzed. Control flap actuation using the magnetostrictive material Terfenol-D was studied by designing a minimum

weight actuator, subject to a set of actuation and stress constraints (52). The resulting device can reduce vibration by more than 90% under cruise conditions.

C-blocks are midrange piezoelectric actuators that show promise for use in dynamic applications, such as noise and vibrational control. They can be combined in series or parallel to generate tailorable performance and exploit the advantages of bender and stack architectures. An analytical model of an individual C-block actuator was developed, and the possible configurations for achieving improved force and deflection characteristics were investigated (53). The use of C-block actuators in trailing-edge flap control was addressed (54). It was found that several C-blocks, attached in series and in parallel configurations were necessary to achieve the required amount of lift authority. Although important issues such as power requirements were not investigated, this study shows that it is possible to attach the C-block actuators directly to the trailing-edge flap and thereby avoid the need for excessive hinge moments caused by other types of actuating mechanisms. A more recent effort in using C-block actuators is discussed in (55). Planar structural actuation that uses anisotropic, active materials is addressed by Bent et al. (56). The mechanisms for creating anisotropic actuators and the impact of anisotropy at the individual lamina level and at the laminated structural level are discussed. Models for laminated structures were developed using an augmented classical laminated theory and incorporating induced stress terms to accommodate anisotropic actuator materials. Four anisotropic actuators that have different material anisotropies were compared. A laminate incorporating piezoelectric fiber composite actuators was manufactured and tested.

SERVOFLAP

Although a vast amount of research based on the IBC concept has been reported, direct use of piezoelectric devices is still infeasible due to excessive power requirements and lack of sufficient induced strain for adequate control. For this reason, research efforts have been directed toward servoflap designs to suppress aeroelastic instabilities. Though greater efficiency has been reported, servoflap concepts increase the complexity of rotor designs and involve expensive aeroelastic computations. Giurgiutiu et al. (57) investigated the engineering feasibility of induced strain actuators for active vibrational control. Rotor blade vibrational reduction based on higher harmonic control-individual blade control (HHC-IBC) principles is a possible area for applying the induced strain actuator (ISA). Recent theoretical and experimental work on achieving HHC-IBC through conventional and ISA means has been reviewed. A benchmark specification for a tentative HHC-IBC device based on the aerodynamic servoflap principle operated through an ISA was developed. Preliminary studies based on force, stroke, energy, and output power requirements show that available ISA stacks coupled with an optimally designed displacement amplifier might meet the benchmark specifications. Straub (58) investigated the feasibility of using smart materials for primary and

active control on the AH-64 helicopter. The results suggest that embedded actuator concepts, that is, pitch, twist, and camber control, were not practical. Servoflap control using hinged control surfaces driven by discrete actuators emerged as the most suitable candidate for smart material actuation. Preliminary data show that rotor control using smart materials might be feasible if a combination of smart materials is used and the rotor design is driven toward low control loads and motions.

The basic concepts for analyzing, designing, and experimenting on induced-strain actuators for rotor blade aeroelastic vibrational control are presented in (59). A trailing-edge servoflap actuated by a hydraulically amplified, large-displacement, induced-strain actuator is considered. The principle of high-power induced-strain actuation and the energy and energy density of several commercially available induced-strain actuators and results from static and dynamic tests on a full scale model are presented. Prechtl and Hall (60) describe a servoflap that uses a piezoelectric bender to deflect a trailing-edge flap for a helicopter rotor blade. The design uses a new flexure mechanism to connect the piezoelectric bender to the control surface. The efficiency of the bender was improved by tapering its thickness over its length. The authority of the actuator was also increased by implementing a nonlinear circuit to control the applied electric field; this allowed a greater range of actuator voltages.

An analytically developed smart material actuator that employed ETREMA TERFENOL-D[®] to demonstrate its effectiveness for helicopter rotor servoflap control was introduced by Ghorayeb et al. (61). The design enables control of the rotor blade flap by an actuator embedded in the blade itself. A series of loading conditions characterized by an additive process of steady-state, cyclic, and active control functions were considered for sustained flight. Optimization of the overall system gave rise to a system gain of 3.7 for sustained motion. Magnetostrictive actuators used in conjunction with an extension-torsion coupled composite tube were studied for actuating a rotor blade trailing-edge flap to control helicopter vibration actively (62). Thin-walled beam analysis based on the Vlasov theory was used to predict the axial force-induced twist and extension in the composite tube. Tests of the magnetostrictive actuator/composite tube systems showed good correlation between measured and predicted twist values.

A flap-operated, individual blade control (IBC) system for reducing vibration in the Army UH-60A helicopter is described (63). An alternative actuating technology using magnetostrictive materials was adapted. The advantages of the design include all-electric operation, simplicity, reliability, low mass, low voltage, and insensitivity to centripetal acceleration. The actuator requirements are derived for 17% chord width flaps integrated into the outer half-span of the trailing edge. Four flaps per blade for improved control effectiveness using opposing actuation, particularly for the first flatwise bending mode which has a node in the blade region under control, were used. An optimized magnetostrictive actuator was developed using Terfenol-D[®], material. The impact of magnetostrictive flap actuators on the development of practical IBC systems for

reducing vibration is discussed. Straub and Merkley (64) presented the results of a study to define conceptually an on-blade smart material actuator for primary and active control of a servoflap rotor. For a previously developed hybrid actuator concept, the design of the cyclic and active (high speed) control actuator and the feasibility of the collective (low speed) actuator and stroke multiplier were investigated. Sizing of actuator components based on AH-64 servoflap requirements shows that collective control using shape-memory alloys is well within the capability of the material. Cyclic and active control using magnetostrictive material leads to a reduced maneuver envelope due to weight and volume constraints.

Teves et al. (65) introduced an active control technology in the rotating system that uses pitch link actuators and results in the first flying four-bladed helicopter whose blades are individually controlled. To reduce the number of free control parameters, the blade control technology was tested in the harmonic mode. Recently, the design of large stroke, electromechanical actuators to power a trailing-edge servoflap system for feedback control of helicopter rotor vibration, acoustics, and aerodynamic performance was addressed by Prechtl and Hall (66). A new high-efficiency discrete actuator, the X-frame actuator, is described.

ACTIVE TWIST

A smart rotor that actively controls blade twist by using embedded piezoceramic elements as sensors and actuators to minimize rotor vibrations was developed (67). A one-eighth Froude-scale, bearingless helicopter rotor model that uses banks of torsional actuators capable of manipulating blade twist at frequencies from 5 to 100 Hz was tested for vibrational suppression capability. Experimental results show that tip twist amplitudes of the order of 0.5° are attainable in forward flight by the current actuator configurations. Test results also show that partial reduction of vibration is possible. Open-loop phase shift control of blade twist in the first four rotor harmonics produced measured changes in rotor thrust up to 9% of the steady-state values that resulted in 3 and 8% reductions in rotor pitching and rolling moments, respectively. Results from hover tests of a one-eighth dynamically scaled (Froude scale) helicopter model that had embedded piezoceramic elements (vibrational suppression) were reported (68). The twist performance of several rotor blade configurations as investigated using accelerometers embedded in the blade tip. A dynamically scaled (Froude scale) helicopter rotor blade was developed that has embedded piezoceramic elements as sensors and actuators to control blade vibrations (69). Each blade of a bearingless rotor model has banks of piezoelectric actuators embedded in the top and bottom surfaces at $\pm 45^\circ$ angles with respect to the beam axis. A twist distribution along the blade span is achieved by in-phase excitation of the top and bottom actuators at equal potentials, and a bending distribution is achieved by out-of-phase excitation. A uniform strain beam theory was formulated to predict analytically the static bending and torsional response of composite rectangular beams that have piezoelectric actuators embedded. Parameters such as bond thickness,

actuator skew angle, and actuator spacing were investigated by experiments and then validated by theory. The static bending and torsional response of the rotor blades was experimentally measured and correlated with theory. The viability of a vibrational reduction system based on piezoactuation of blade twist was investigated.

The structural and aerodynamic characteristics of a new class of active flight control surface were developed (70). The control surface uses a symmetrical, subsonic aerodynamic shell that is supported at the quarter-chord by a main spar and actively pitched by an adaptive torqueplate. Details of the structural mechanics of the torqueplate and several actuator elements, an interdigitated electrode (IDE) and constrained directionally attached piezoelectric (CDAP) elements are presented. An experimental torqueplate specimen constructed from PSI-5A-S2 piezoceramic shows high torsional deflections and stiffness as well as excellent correlation with theory. An active moving blade tip for a smart rotor that is torsionally actuated via a piezo-induced bending-torsion coupled composite beam is presented (91). A novel spanwise variation in the beam layout and piezoceramic element phasing is used to maximize the twist response and minimize the bending response. The bending results in an induced twist via structural coupling, and this twist deflects the moving tip. A variety of tests were conducted using a proof-of-concept actuator beam.

An interdigitated electrode piezoelectric in fiber composite (IDEPEC) method uses smart materials to achieve main spar twist (72). Active materials are embedded in the composite plies of rotor blades actuated by applied electrical fields. Active twist for a one-sixteenth scale CH-47 rotor blade is demonstrated, and a preliminary design for a one-sixth scale blade is presented. The benefits of actively twisting the main rotor spar are demonstrated, and the influence that active twist may have on rotor design constraints and traditional ground rules is illustrated. Overall system performance, including economic merit, weight, and power consumption for this method of actuation is evaluated, and the feasibility of applying this process to rotorcraft is discussed. An active blade designed for controlling rotor vibrations and noise was introduced (73). Active fiber composites were integrated within the composite rotor blade spar to induce shear stresses, which results in a distributed twisting moment along the blade. The design of an active blade model based on a one-sixth Mach scale Chinook CH-47D is reviewed. The requirements for the active fiber composites subjected to 160 kt., 3 g maneuver loads and the experimentally determined actuator capabilities are reviewed. The testing of a half-span active blade test article is described. Twist actuation performance is compared with model predictions. An analytical effort to examine the effectiveness of embedded piezoelectric active fiber composite laminae for alleviating adverse vibratory loads on helicopter rotor blades in high-speed, high-thrust forward flight conditions is detailed (74). Structural and piezoelectric actuating properties for a conceptual full-scale active fiber composite rotor blade were developed using a classical laminated plate theory approach. The out-of-plane bending and torsional dynamic responses of the active fiber composite blade, both with and without piezoelectric twist control, are calculated by using an aeroelastic

analysis code. The dynamic stall-limited maximum rotor thrust versus forward flight speed trends for the active fiber composite blade are compared with those of a baseline, conventional rotor blade structure. The maximum stall-limited rotor thrust using active blade twisting is approximately 5–10% greater than that achievable by using a conventional passive blade structure. A corresponding 10–15% increase in dynamic stall-limited forward flight speed is also shown when the active fiber composite blades are used. Torsional load buildup due to dynamic stall effects is delayed by 4% in rotor thrust and 10% in forward flight speed.

The vibratory load reduction at the rotor hub by using smart materials and closed-loop control was investigated by Chattopadhyay et al. (75). The principal load-carrying member in the blade is represented by a composite box beam, of arbitrary thickness, that has surface-bonded, self-sensing piezoelectric actuators. A comprehensive shear deformation theory was used to model the smart box beam. An integrated procedure for rotor vibratory load analysis was developed by coupling an unsteady aerodynamic model with the rotor blade dynamic model based on the smart composite box beam theory. The dynamic deformations of the blade in all three directions, flap, lead-lag, and torsion, were included in the analysis. The results showed significant reductions in the amplitudes of rotor dynamic loads by using closed-loop control. Aeroelastic modeling procedures used in the design of a piezoelectric controllable twist helicopter rotor are described (76). Two aeroelastic analytical methods were developed for active twist rotor studies and were used in designing the wind tunnel model blade. The first procedure uses a simple flap-torsion dynamic representation of the active twist blade and is intended for rapid and efficient control law and design optimization studies. The second technique employs a commercially available comprehensive rotor analysis package and is used for more detailed analytical studies. Analytical predictions of hovering light-twist actuating frequency responses are presented. Forward flight fixed system $n\Omega$ vibration suppression capabilities of the model active twist rotor system are also presented. Frequency responses predicted by using both analytical procedures agree qualitatively for all design cases considered; the best correlation results when uniform blade properties are assumed. The development of the active twist rotor for hub vibration and noise reduction studies is described (77). The rotor blade is integrally twisted by direct strain actuation by distributing embedded piezoelectric fiber composites along the span of the blade. The development of the analytical framework for this type of active blade is presented. The requirements for the prototype blade and the final design results are also presented. Active rotor blade tips offer an alternative approach for main rotor active vibrational control. The tips are actively pitched via a piezodriven bending-torsion coupled actuator beam that runs down the length of the blade. A near Mach scale rotor model design (tip Mach = 0.47) that has adaptive blade tips was reported (78).

A new type of flightworthy solid-state adaptive rotor system uses directionally attached piezoelectric (DAP) torqueplates to control Hiller servopaddles (79). The servopaddles change the rotor disk tilt and thereby induce

changes in forces and moments for flight control. The servopaddles were constructed from PZT-5H piezoceramic actuator sheets bonded symmetrically at 45° . An aluminum substrate and a high temperature cure was used for pre-compression. The classical laminate theory (CLT) along with strip theory aerodynamics and inertial relations was used in analytical modeling. Because rotor moments are proportional to servopaddle deflections at a fixed rotational speed, it was possible to cancel them out by balancing an aeroelastic coupling between the center of mass, the aerodynamic center, and the elastic axis. Bench testing of the rotor system showed good agreement between theory and experiment. The design and testing of a one-twelfth scale solid-state adaptive rotor for helicopter flight control via active pitch manipulation is described (80). The pitch angle is adjusted by using piezoceramic directionally attached piezoelectric (DAP) torqueplates mounted between the rotor shaft and the blade root. Analytical models based on classical laminated plate theory for steady torqueplate deflection are presented and verified using the solid-state adaptive rotor test article (Froude scaled).

MODELING

The presence of a sensor and actuator introduces discontinuities in both the geometric and material properties of a structure. Accurate and validated modeling techniques are also necessary to account for the presence of multiple and interacting failure modes. The efficient implementation of smart materials requires developing accurate analytical models that incorporate their unique properties and the discrete nature of their positions in the structure. Important issues that need to be addressed include: (1) a transducer model for smart materials that addresses the coupling effects or interactions among all possible fields, electrical, mechanical, and thermal; (2) a constitutive model that addresses the application of large induced strain when driven by a high electrical field, that is, a hysteresis model; (3) in a composite primary structure, a laminated smart structure model that efficiently predicts transverse shear effects accurately; and (4) modeling the presence of defects to predict the life of the structure accurately. Although, a significant amount of research effort has been directed to using smart materials for rotary wing control, all of the issues of basic modeling have not yet been fully resolved.

In the process of modeling rotor blades that use induced strain actuators, composite box beams can be used to model the principal load-carrying member in the blade. These simplified reduced-order models can be designed to meet the stiffness, mass, and twist distributions of a reference blade. The use of these models offers physical insight and reduces the computational time requirement, compared to the detailed finite element model. Therefore, they can be used efficiently within an optimization framework. Composite box beam analysis has been investigated by a number of researchers. Chandra et al. (81) developed a formulation for a composite thin-walled box beam that has distributed actuators. The results of the static analysis were correlated with experimental data.

Chattopadhyay and Seeley (82) developed a rotating composite box beam model that has embedded actuators and sensors, and results were obtained by developing a formal optimization technique. Chen and Chopra (83,84) used a one-dimensional, uniform strain model in their investigation of using distributed piezo actuators to twist the blade actively. Later, they refined the one-dimensional uniform strain theory to include closely spaced actuator interactive effects, based on a block-force assumption, and developed a Bernoulli–Euler plate theory to predict the static response of smart composite beams (85).

In all of this work involving box beams that have embedded actuators and sensors, the analysis was based on the classical laminate theory (CLT), thereby neglecting out-of-plane stresses and strains. The need for modeling transverse shear deformation in composites has been well documented. Transverse shear effects increase as laminate thickness and material anisotropy increase. In modeling composite laminates that have distributed sensors and actuators, it is important to have a general framework for evaluating the transverse shear effects accurately. Full three-dimensional analyses can accurately predict displacements and stresses, even at a local level, but are too computationally expensive to be used for practical analysis of aerospace structures. First-order shear deformation theories that use shear correction factors have been used by some researchers to analyze composites that use embedded adaptive materials (86). The dynamical modeling of rotating blades carrying a tip mass and surface-bonded piezoelectric actuators is addressed in (87). The blade is modeled as a thin-walled beam, including anisotropy and secondary warping. Transverse shear is included using shear correction factors. Layerwise theory was used in to ascertain the level of model complexity necessary to represent piezoelectric actuation of beam structures accurately (88). A refined hybrid plate theory that combines the layerwise theory and an equivalent single-layer theory with linear piezoelectricity was developed by Mitchell and Reddy to model smart composite laminates (89).

Several researchers have shown that the higher order theory can accurately describe transverse shear deformation in composites without being computationally prohibitive. Chattopadhyay et al. developed a higher order theory for modeling smart composite structures (90–92). In modeling plates of arbitrary thickness and surface-bonded self-sensing piezoelectric actuators, it was shown that the first natural frequency is highly overestimated by the classical theory, especially for thicker plates, whereas the first-order and the higher order theories agree well. Larger differences between the theories were observed in the second bending mode. Even the first-order theory, it was shown, overpredicts these frequencies (90). These results indicate that it is necessary to include an accurate description of the transverse shear stresses, which are important in composites due to the large ratio between Young's moduli and shear moduli. Because a helicopter rotor blade is very flexible, shear deformation plays an important role. Therefore, an accurate description of the displacement field is necessary. The higher order theory was extended by Chattopadhyay et al. (92) to model a composite box beam that has surface-bonded piezoelectric actuators and

sensors. The new theory, based on a refined higher order displacement field of an eccentric plate, is a three-dimensional model, which approximates the elasticity solution so that the box beam's cross-sectional properties are not reduced to one-dimensional beam parameters. Both in-plane and out-of-plane warping are included automatically in the formulation.

Coupling of thermal, piezoelectric, and mechanical fields plays an important role in analyzing smart structures. However, these issues are ignored in most applications. In most of the work, a one-way coupling that considers only the effect of a known field on another field is used. For example, it is assumed that the piezoelectric field can be calculated directly from the applied voltage, which is then introduced in the unknown displacement field as an induced strain. However, piezoelectric actuation changes the strain field during active control of the structure, and the new strain field, in return, also affects piezoelectric distributions. This is referred to as "two-way" interaction/coupling. Two-way coupling between piezoelectric and mechanical fields was included in the hybrid plate theory developed by Mitchell and Reddy (89). The piezothermoelastic behavior of composite plates was addressed by Tauchert (93) using CLT and by Lee and Saravanos using layerwise theory (94). In this work, a known thermal field was used to study the effect on mechanical and piezoelectric fields. The interactions between thermal and mechanical fields and between thermal and piezoelectric fields were ignored. Recently, a coupled thermal–piezoelectric–mechanical (t–p–m) model was developed by Chattopadhyay et al. to address the two-way coupling of smart composites (95,96). As shown in their work, coupling affects plate deformation and can lead to mispredicting the control authority of smart composite plates.

In all of this work, the material is usually assumed perfect and is not debonded or delaminated. Seeley and Chattopadhyay addressed debonded in piezoelectric actuators, which causes significant reductions in control authority (97). Recently Chattopadhyay et al. developed a more general framework for modeling adaptive composite beams and plates that have delaminations in the primary structure by using a refined third-order displacement field (91).

The applications of piezoelectric materials in smart structures are based mostly on a linear piezoelectric model. This implies both low electrical fields and low mechanical strains. However, to obtain greater actuating authority and increased induced strain for practical applications, an electric field is required, whose magnitude exceeds the limit of linear piezoelectric constitutive relationships. Piezoelectric actuators exhibit only mild nonlinear response at low voltage levels, but it is well known that the response can be profoundly nonlinear at high field strength (98). The behavior of piezoelectric actuators under high applied voltage was studied by Tiersten using a theory linear in displacement gradients but cubic in electric field (99). Chattopadhyay et al. (92) used the experimental results of Crawley and Lazarus (98) to develop an analytical model of the nonlinear effect. In this model, the coupling coefficients also depend on the actual strain in the actuator. The benefit of this model is that the final governing equations remain linear.

Piezoceramics exhibit constitutive nonlinearity involving hysteresis due to the variation in polarization if the magnitude of the applied electric field is higher than that of the coercive electric field. In addition, hysteretic behavior is also related to mechanical loading. Different hysteretic loops are observed as mechanical stresses vary. Several phenomenological theories have been proposed during the last two decades to match experimental results to assumptions motivated by certain piezoelectric characteristics (100,101). These theories are not completely satisfactory due to weak physical modeling or difficulties in adapting the models to accommodate varying operating conditions. Issues such as the crystal structure and interactions between the crystallites, the unique crystallite orientation distributions due to polarization switching, and stress and strain states are neglected in these models. A phenomenological hysteretic model based on a simplified piezoelectric microstructure was recently developed by Zhou and Chattopadhyay (102). The internal constraint of 180° and 90° polarization switching was considered. The energy losses due to orientation switching and the inclusions in piezoelectric materials were modeled. The three-dimensional stress state was addressed by using a new form of Gibbs free energy. The research yielded an explicit form of the constitutive relationships governing hysteresis.

The applications of SMA controllers result from their large constrained recovery despite their slow response time and high energy requirement, compared to piezoelectric materials. Birman (103) published a comprehensive review of work in the areas of SMA constitutive modeling and applications. A good overview of shape-memory alloy characteristics and applications was recently presented by Otsuka and Wayman (104). Lagoudas and Bo (105) studied the use of more than one active material by modeling piezoelectric and SMA layers in a composite laminate. Hebda and White (106) investigated SMA transformation behavior within an elastomeric matrix and concentrated on the two-way shape memory effect (TWSME). Epps and Chandra (107) embedded SMA wires in a composite beam to tuning the beam actively. A thermomechanical model under multiple nonproportional loading cycles was reported by Lagoudas et al. (108).

Simple classical Euler–Bernoulli beam theories or classical laminate theories have been used in most applications of SMA fibers. The SMA fibers were heated by applying electrical current using some control device, and it was assumed that the heat would not affect the composite. This important effect was addressed by Turner et al. (109) who observed significant changes in the properties, and natural frequencies of laminates by including the thermal effect. However, the model was macromechanical, so that it depends only on measuring fundamental engineering properties. In embedded SMA actuators, the large load transfer over a thin shear layer exacerbates the problem of debonding and, even using improved composite design and fabrication, debonding is expected at some point during the useful life of an active composite. Therefore, modeling must account for incipient damage to enable designing damage-tolerant active composites. Therefore, although significant research has been reported in modeling that uses SMA fibers, a critical gap must be bridged between

micromechanics and structural lamination theories. The strain energy absorption of SMA and the performance of SMA hybrid composites for augmenting damping in rotary wing structures have not yet been fully explored. Several issues require further investigation to make these concepts useful in rotorcraft application.

Several modeling approaches that describe the behavior of elastomeric materials used in helicopter rotor lag dampers are examined and evaluated in (110). Two of the models are then used in a simulation of a helicopter rotor startup, and the simulation results are compared to each other as well as to flight test data. The simple models (complex modulus models) that predict damper energy dissipation well are inadequate for predicting forced response. Elastomeric and Fluidlastic(R) damper activities at Boeing Helicopters and issues that must be considered in designing and analyzing such systems are discussed in (111). Bench tests were performed on various damper configurations to understand their dynamic characteristics.

FUTURE DIRECTIONS

Smart materials and composite structures have demonstrated a huge potential for enhancing the performance, reliability, and agility of rotary wing aircraft. Significant advances have been made in piezoelectric, electrostrictive, and magnetostrictive materials; shape-memory alloys; and active fiber composites. However, practically implementing of these proposed schemes still requires substantial research in a number of areas. The following is a brief description of some suggested research directions.

Multifunctional Systems

Multifunctionality will be a cornerstone of future military platforms and structures, and it is envisioned that these systems will have sensors and control systems of the order of tens of thousands. The excellent strength, stiffness, and low weight of heterogeneous materials and their extensive tailorability make them the material of choice for many present and future Army applications. Integration with arrays of distributed actuators, sensors, and microelectromechanical systems (MEMS) can lead to the development of new generations of efficient multifunctional systems. These information technology devices that are fabricated from active materials are self-contained data processors and embedded components of control devices. They can potentially be used for a multitude of rotary wing applications, including vibrational and noise control, detection and active mitigation of structural damage, and stability augmentation. The control and optimal distribution of these types of devices still remains a major concern. Data fusion techniques are also needed to optimize the number of embedded devices, their distribution, and material behavior within the system, so that crucial mission information is efficiently processed and maintained. Furthermore, the reliability of these embedded devices, not as stand-alone devices, but as integrated subsystems within systems that may comprise combinations of heterogeneous materials, such as resin and metal matrix composites,

high-strength laminated metals, toughened ceramics, and functionally graded materials must be addressed. New actuating materials and control systems that have the desired strain and frequency responses are needed so that these devices, which can range in size from the micro- to the mesoscale, can be easily integrated within larger scale heterogeneous host structures for tailored applications. Finally, research in developing a multidisciplinary analytical computational and experimental framework is necessary for designing and optimizing such systems.

Health Monitoring

Structural damage of heterogeneous systems can occur during production or field operations. Cyclic loading, excessive vibrations, and low velocity and/or high velocity impacts can cause structural damage in a rotary wing environment. Inability to detect damage in heterogeneous structures that may comprise combinations of composites, ceramics, and metals is a factor that limits their use in practice. Therefore, the development of integrated health monitoring and inspection capabilities is a vital research issue. The application of active materials to the development of novel sensing techniques and the ability to interpret sensor signals effectively and accurately in nearly real time are fundamental for improving the reliability of physical systems. Sensors based on active material can revolutionize health monitoring, damage detection, and non-destructive evaluation. However, this potential can be ensured only by deploying ultrareliable sensing techniques. Advances in the development of microsystems have made it possible for microsystems to be the enabling technology in developing viable health monitoring strategies for complex composite structures. Miniaturized sensory devices could be incorporated into heterogeneous structures to signal the presence, location, and extent of local and global failure modes, such as fiber breakage, fiber pull-out, delamination, and large matrix structural cracking. This requires interdisciplinary approaches that integrate research activities focused on sensors, actuators, signal processing and interpretation, structural modeling, system integration, electronics, and computational techniques.

Given the complexity of studying damage phenomena in solids, it may be necessary to incorporate a hierarchy of analytical networks and achieve structures that have large sensory array capabilities to ensure structural integrity and reliability based on continuous and dependable structural health monitoring, status inspection, and damage detection with minimal human intervention/involvement. Because practical structures are often subjected to impact loads and high strain rates that cause large nonlinear deformation and failure, the physical modeling of heterogeneous structures that contain integrated microdevices must be addressed. Investigation of physical models for nonconservative and nonlinear structural and sensor/actuator response and robust hierarchical control system models for fault-tolerant design of distributed embedded devices will be important. Appropriate numerical and analytical techniques and optimization procedures also need to be developed. The precision and reliability of the health monitoring system strongly rely on the accuracy

and analysis that relate sensor measurements to physical changes due to fracture initiation and progression. It would be desirable to integrate sensors and actuators based on active material, the structural components, the power supply, and the localized control circuit into a single unit.

Enhanced Structural Damping

Successfully incorporating advanced, active damping schemes and/or treatments into rotary wing aircraft would lead to a more comfortable ride, quieter interiors for greater crew and passenger comfort, safer flight due to enhanced rotor stability, more economical operation because of extended fatigue life of airframe and rotor blades, and improved maneuverability. Therefore, developing a more effective and economical structural damping approach that can adjust its mechanical properties to appropriate specifications will be beneficial in designing future rotorcraft systems. Because currently used damping models are fragmented and ad hoc, they must be generalized to become useful in design and analysis. Although recent research has demonstrated the feasibility of tailoring damping methodologies on a small scale, their synthesis on a practical scale is still not proven. Innovative approaches to modeling damping, compatible with current finite element codes, and the introduction of damping mechanisms into a structure are needed for vibrational suppression, noise reduction, increased system performance, extended service life, and lower maintenance costs. Thus, fundamental research is required to devise actuating schemes, develop, and validate experimentally new modeling methods and controller designs for damping mechanisms. The control issues in this initiative are on the frontier of distributed nonlinear control. These issues range from structural modeling of control elements, through coupling and feedback to the elements of the system, to the study of the overall dynamics of the control system. Improving the performance of active vibrational suppression systems by using nonlinear approaches and subsequently exploring the new design space holds the promise of higher energy dissipation capabilities, more robustness, and adaptability to changing demands and diminished requirements from resources and infrastructure. However, a number of hurdles in system concept definition, nonlinear systems modeling, and design need to be addressed.

Improved Actuators

Much progress has been made recently in using active materials in actuator design for damping and/or induced strain. However, successful application of such actuators will depend upon their cost and ease of system integration and retrofitting. Therefore, innovative concepts to address issues in the development of design tools, methodology, modeling, simulation, prototyping, and real-time software/hardware implementation are necessary for a number of designs of actuators based on active materials. Low-cost, high-bandwidth, high-authority (force/displacement characteristics), innovative actuators for both military and commercial applications need to be developed, and the associated driving electronics and control systems must also be addressed.

Aerodynamic Control

The application of smart materials, intelligent systems and control logic concepts to aerodynamic problems has been very limited, primarily because of the lack of knowledge and understanding of the way these techniques might best be used in aerodynamic flow control. There is a real need for better understanding of the fluid physics and fluid mechanisms that will become available from using advanced materials and intelligence technologies. Although major improvements in aerodynamic performance and control from using unsteady flow control techniques seem feasible, their use will depend upon developing techniques to create the flow interactions that govern the manner in which these new flow control ideas are implemented. Much better understanding must be established concerning the benefits and difficulties of using the various advanced actuators that are needed to create physical interaction with flow. Research activity in this area might combine concepts derived from the areas of adaptive structures, MEMS devices, control theory, modeling and numerical analysis techniques, and other relevant technologies to evaluate the various possible actuators for such applications.

AIRCRAFT CONTROL, APPLICATIONS OF SMART STRUCTURES

JOHANNES SCHWEIGER

Muenchen, Germany

INTRODUCTION

Probably the most famous photograph in aviation, (Fig. 1) depicts the first successful manned powered flight on 17 December 1903 by the Wright brothers. It also shows the first successful airplane that had an active structure. The Wright brothers' design must definitely be called smart in many aspects and design features. They were among the first pioneers in aviation who had realized that uncoupled control about all three vehicle axes was required. They had done systematic experimental aerodynamic research to achieve the maximum possible aerodynamic performance. And they had learned how to design and manufacture lightweight structures in their bicycle shop. Their solution for adequate roll control of the airplane, moreover, was more than one century ahead of the state of the art in aviation technology. As we are approaching the centennial celebrations of this remarkable event, no single airplane exists yet that uses a smart structural concept to control the flight of the vehicle.

Rather than fighting the low torsional stiffness of their braced biplane wing design, they used this characteristic positively. By the sideways motions of the pilot, who lay on a sliding cradle, the wires attached to the cradle twisted the wing tips in opposite directions, thus producing the desired aerodynamic loads to roll the airplane. Figure 2 from Orville Wright's book (1) demonstrated this principle, which is also a very good example of the importance of integrated or multidisciplinary design concepts, especially in aeronautics. Unfortunately, this knowledge was lost and forgotten over the years, mainly because of more expert knowledge in single disciplines and more formal and

Figure 1. First flight of Wright Flyer I on 17 Dec. 1903 (available as a postcard).

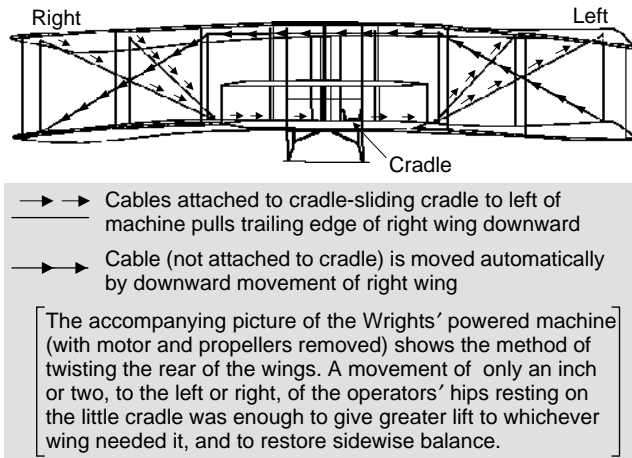

Figure 2. Active structural concept of the Wright Flyer I for roll control [adopted from (1)].

bureaucratic processes in designing new airplanes. Only in recent years, some prophets in aerospace are trying to spread the news about this old idea again and develop some new ones. Weisshaar (2), for example, in 1986, cited the success of the Wright Flyer as a good example of the need for integrated design methods. The Wright Flyer also demonstrates that smart aircraft structures do not necessarily rely only on advanced active materials.

Even earlier than that, active structural concepts were studied. Alois Wolfmüller (1864–1948), the producer of the world's first motorcycle, bought the No. 2 model of the production glider "Normal-Segelapparat" (normal soaring apparatus) from Otto Lilienthal in 1894 (3). Both aviation pioneers were communicating about improvements in performance and maneuverability by controlling the air loads through flexible wing twist. Wolfmüller tried to improve performance by introducing a flexible hinge in the wings to modulate aerodynamic control forces by flexible deformations.

Today, aircraft control is achieved by control surfaces attached to the main aerodynamic surfaces. These devices—aileron, elevator, and rudder—create the required forces and moments to control the motion of the aircraft about all three axes in space. Depending on the size and speed of the aircraft, these surfaces are actuated manually or by hydraulic systems. If the Wright brothers had used separate ailerons to roll the airplane, the additional structural weight might have been too much for the available power from the engine.

The idea of active or smart structures to control air vehicles is as old as the earliest known attempts to fly in heavier-than-air machines. Early attempts by humankind to fly were usually based on efforts to understand and copy the flight of birds. Besides the difficulty in controlling an unstable flying vehicle, which requires to day's high computing power or the complex neural network of animals to control their muscular systems, it is even more difficult to sense and actuate the dynamic motions of continuously deforming, flexible aerodynamic surfaces.

In most of these efforts, the pilot was supposed to actuate birdlike aerodynamic surfaces to produce the required

lift force, create the forward thrust, stabilize the vehicle, and apply the necessary control inputs in time. For a multitude of reasons, all of these early efforts were doomed to failure from the beginning:

- very limited knowledge of the laws of aerodynamics and flight mechanics;
- insufficient load capacity of the available materials, only primitive manufacturing techniques, and only a rudimentary understanding of structural mechanics;
- not enough sustained power output from the human body to produce the required thrust or lack of engines that had sufficient power density;
- efforts in trying to copy structural design principles from nature did not take into account the scaling laws of physics; the resulting designs were too heavy, too fragile, or too flexible; and
- and, in most cases, also the very complex efforts required to stabilize and control a flying vehicle without natural stability.

Only in recent years, after almost one century since the first successful powered flight, was it possible to design, build, and fly vehicles powered by the human body for the sole purpose of winning trophies.

For these reasons, the first successes in aviation were possible only by using design concepts for almost "rigid" surfaces and natural stability of the vehicles. Nevertheless, a major contribution to the success of the Wright brothers was their "Smart Structures" flight control system for the roll axis. They were among the first pioneers in aviation who had realized that uncoupled control about all three vehicle axes was required. They had done systematic experimental aerodynamic research to achieve maximum possible aerodynamic performance. They had a combustion engine that had sufficient energy density available "just in time," and they had learned how to design and manufacture lightweight structures in their bicycle shop.

SMART STRUCTURES FOR FLIGHT IN NATURE

Although complete plants do not fly, they have to withstand aerodynamic loads by using proper aeroelastic reactions, and sometimes their existence relies on their aerodynamic performance. The seeds of some plants are optimized in shape for long distance flight and mass distribution by millions of generations in a genetic optimization process. The interest in micro air vehicles in recent years has increased aerodynamic research efforts in this area (4). Although not for free flight, the leaves of trees and their stems are built to withstand strong winds. The joints between leaves and branches must have the right amount of flexibility in bending and torsion to reduce aerodynamic loads and at the same time avoid excessive unsteady loads from flutter.

More interesting for aircraft applications of smart structures is the flight of animals. As mentioned before, early aviators tried to learn from birds. However, the required knowledge about the physics of flight was missing in these early attempts. The complex interactions of steady

Figure 3. “Structural” design concept for dragonflies.

and unsteady aerodynamic forces and the active motions and passive deformations of wings and feathers are still not completely understood today. We are only now beginning to understand the functions and importance of the individual components for the efficiency of animal flight. Pendleton (5) gives some good examples from the prehistoric flying saurian to modern birds that have feathers.

But even more astonishing are the achievements in the art of flying for another species. Insects show by far the widest variety and most advanced structural concepts of active and passive control. An ordinary fly can land and take off from the tip of your nose or from the ceiling of a room. Dragonflies like that shown in Fig. 3 use a combination of passive mass balance to prevent flutter at the wing tips and an advanced structural design that has stiff chitin “spar” elements to support the membrane skins and flexible hinges of resilium to adjust the shape for all flight conditions.

The variety and large number flying members in the family of insects has been attributed to their ability to fly, which offers advantages of reaching and conquering new territories more easily.

In the context of formal optimization methods in aeronautics, genetic algorithms became fashionable in recent years. The question in the context of technical products is, can we really wait as long as in nature to get better products? Or should we continue to rely on gradient based methods, which can be seen as targeted “artificial genetic manipulations” similar to the “biological engineering” approaches of today?

GENERAL REMARKS ON ASPECTS OF AIRCRAFT DESIGN

One reason that we have not seen more progress in the application of smart structures in aeronautics may be the lack of understanding of the interactions between the different classical disciplines in aircraft design and between these disciplines and the specialists from the smart materials area for each others’ needs and capabilities.

To assess the possibilities of smart structure applications for aircraft control, it is advisable to look at some aspects of aircraft design first. The structural engineer is

usually concerned with the strength of a design for critical conditions and may be surprised in some cases, how relatively small deformations of the structure can have severe impacts on the aerodynamic performance or on maneuverability. The aerodynamic and flight control engineers want the structure “as rigid as possible,” but at the same time want different shapes for different flight conditions. These requirements may attract the smart structure specialists to make the design deformable and at the same time meet tight requirements for the external shape in changing flight conditions. This requires a look at the stiffness of the structure from the viewpoint of strength, as well as at the additional internal loads created by active deformations. And finally, aeroelastic aspects like flutter stability and effectiveness of deformed aerodynamic surfaces have to be considered.

An aircraft design is always a compromise for the aerodynamic engineer between different flight conditions: a small flat wing for cruising with low drag at high speed and a large, cambered wing for take-off and landing at low speed. This can be met partially by extendable control surfaces attached to a fixed surface by complex kinematic systems. On the other hand, the complexity of these systems increases the structural weight. Therefore, it looks attractive to replace these mechanisms and integrate their functions into one actively deformable structure. To consider such options, it is necessary to look at basic structural design requirements for aircraft wings. They have to carry loads from 2.5 to 9.0 times the total weight of the airplane. And they must be strong enough in torsion to keep the aerodynamic shape and transmit the loads from control surfaces. To achieve this at an acceptable structural weight, sophisticated lightweight design concepts were developed during the first half century of manned aviation. Besides improvements in materials and manufacturing, lightweight design by shape—within the prescribed aerodynamic shape is the main principle.

Simplified, this principle leads to the placement of material on the external shape of the airfoil and to closed cross sections of maximum area. This provides maximum strength for a fixed amount of material. At the same time, this structure also has maximum stiffness. This fact must be kept in mind when active deformable structural concepts are considered for airframe components.

TRADITIONAL ACTIVE OR ADAPTIVE AIRCRAFT CONTROL CONCEPTS

One kind of active aircraft control concept was developed and demonstrated in the early 1980s: artificial stabilization of an airplane’s flight path by fast motions of the control surfaces, commanded by a digital flight control system. Today, this system helps to reduce trim drag and increase the agility of all modern fighter aircraft by avoiding negative contributions from a stabilizer surface to the total lift force to establish natural static stability.

Most airplanes have wings adaptive by additional deployable surfaces like slats at the leading edge or Fowler flaps at the trailing edge to provide additional lift for take-off and landing or to provide clean flow conditions

for extreme maneuvers. The resulting effects are usually a combination of increased wing surface, increased camber, and accelerated air flow. These concepts are well described in most aerodynamic text books (6), where more sophisticated and exotic concepts like telescope wings can also be found. Variable wing sweep is rather common for combat aircraft, among them the American F-111. The Mission Adaptive Wing (MAW) demonstrator version of this aircraft used a complex mechanical system to adjust the wing camber for changing flight conditions (5). However, this system proved too complex and heavy for applications on production aircraft.

Enhancement of active flutter stability by control surface deflections to create unsteady aerodynamic damping forces was also demonstrated in the 1970s (7). There are two main reasons that we do not see them on today's airplanes:

- flutter within the flight envelope in failure of the system is considered too critical;
- the performance of these systems was not very good because of the loss of static aeroelastic effectiveness of the control surfaces as airspeed increased; it is typically close to zero for ailerons mounted near the wing tip at the trailing edge.

The last point also applies to the effectiveness of maneuver load alleviation systems by symmetrical deflected outboard aileron surfaces.

THE RANGE OF ACTIVE STRUCTURES AND MATERIALS APPLICATIONS IN AERONAUTICS

Besides aircraft control, including load alleviation, aerodynamic performance improvement by shape, and static aeroelastic applications for maneuverability and static stability enhancement, which will be the main points of the following sections, the following main additional applications in aeronautics are being addressed by theoretical and experimental research:

Health monitoring. Because piezoelectric materials can serve as actuators and sensors as well, these materials can be used to monitor changing static or dynamic internal loading conditions that result from airplane maneuvers or from failures in the structure. Although these functions have been widely discussed in the literature for two decades, the author knows of no application to a production airplane to date.

Vibration control. This application can be subdivided into two categories:

- to treat local or global vibrations of structural components. This was also the first flight test demonstration of piezo materials applied to a skin panel affected by engine noise of the Rockwell B-1B bomber (8).
- to reduce vibrational levels on equipment that is mounted internally or externally on the aircraft structure. This can be done to support the integrity of the equipment or to improve

the performance of equipment acting as sensor systems. Because rather small deformations and forces have to be handled here, the most promising and near term applications of smart materials on airplanes in this area were already predicted in the survey paper by Crowe and Sater (9).

Active flutter suppression. A lot of research has been dedicated to this task. The NASA wind tunnel test program "Piezoelectric Aeroelastic Response Tailoring Investigation"(PARTI) (10) demonstrated this technology. Applications to real aircraft are rather unlikely because of the previously mentioned safety aspects. Panel flutter as a special case for the instability of individual skin panels at supersonic speed is also addressed in many publications. The required effort for installing and controlling active devices is inappropriate compared to a simple structural reinforcement of critical panels.

Acoustic noise reduction. Several research projects are dealing with cabin noise reduction, especially for turboprop airplanes.

AIRCRAFT STRUCTURES

Definition of a Structure

To design active structural systems for airplane control, it is necessary to understand the functions of the structure, the requirements that define its properties, and the reasons that existing aircraft structures are built in a specific way.

The main functions of the airframe are

- to bear and carry the loads acting on the vehicle;
- to provide space and support for engines, equipment, payload, and fuel; and
- to satisfy the tight rigidity and smoothness required by aerodynamics for the external shape.

In other words, the external shape of the vehicle is defined by aerodynamic performance requirements, and the structure has to meet these requirements within this shape at minimum weight. This requires carefully combining the shape and load-carrying purpose of the individual structural elements with the best available material for this purpose. Early designs used fabric to collect the aerodynamic pressure loads on a wing surface and transfer them to the fuselage through a wooden framework supported by thin wires. As soon as it was discovered that the aerodynamic drag of these wires is 100 times higher than that of a carefully designed airfoil of the same thickness, design efforts concentrated on cantilevered wings where the loads could be completely transferred internally. Aluminum skins paved the way for modern monocoque airframes, where the main loads are carried by a monolithic shell structure which needs mainly only the internal structure to maintain the shape. The shape of this shell provides highest resistance against bending and torsion loads at minimum weight.

Rigidity of Wing Structures

Considering active deformations of a wing structure, it is useful to look at the differences in the possible passive deformations under different loading conditions. The lift force is the largest component of the aerodynamic forces. It corresponds to multiples of the total weight of the airplane, 2.5 times for transport aircraft and currently up to 9 times for fighters. At the same time, the external shape of a wing has the smallest dimension in its height and the largest in a spanwise direction. This means that the structure needs the largest cross sections of its skins on the upper and lower surfaces. Therefore, to deform a wing in bending actively would be difficult but not impossible. However, the bending deformation of an unswept wing has no impact on the aerodynamic characteristics or loading conditions. Only swept wings are sensitive in this respect. Swept forward, bending increases the local aerodynamic angle of attack in the streamwise direction, as indicated in Fig. 4. This increases the bending moment and causes structural divergence at a flight speed, called the divergence speed, which depends on the bending stiffness and geometric properties of the wing. The same effect reduces the bending moment on a swept-back wing under load, which acts as a passive load alleviation system. But to control these deformations actively by internal forces would mean stretching and compressing the skins in the spanwise direction—a rather difficult task.

The aerodynamic drag forces that act in the streamwise direction are smaller than the lift forces by a factor of 10. At the same time, the shape of the airfoil creates a high static moment of resistance in this direction. For these reasons, the loads in this direction need no special attention in the structural design. An active deformation would be both very difficult and meaningless.

Torsional loads on a wing can be very high, depending on the chordwise center of pressure locations and on additional forces from deflected control surfaces. A center of pressure in front of the fictive elastic axis through the wing cross sections causes torsional divergence at a certain flight speed, and a center of pressure too far behind the elastic axis twists the wing against the desired angle

of attack or control surface deflection. Therefore, the wing torsional deformation is very sensitive to the loads acting on the wing, to the spanwise lift distribution which is important in the aerodynamic drag, and to the effectiveness of the control surfaces. As mentioned before, a closed torque box that has a maximum cross section is desirable for the structural designer. But the possibility of adjusting torsional flexibility would also allow several options for active control of aerodynamic performance, load distribution, and control effectiveness. This active control by internal forces could theoretically be achieved by active materials in the skins or by an internal torque device fixed at the wing root and attached to the wing tip. Such a device, based on a shape memory alloy, has already been demonstrated on a wind-tunnel model (4). For practical applications, the parameters that define the torsional stiffness of a structure that has a closed cross section, should be kept in mind. Torsional stiffness is proportional to the square of the complete cross-sectional area and linearly proportional to the average thickness of the skin. This demonstrates how difficult it would be to modify the stiffness by changes in the skins or by an internal torque tube that has a smaller cross section.

The most often mentioned application of active structures for aircraft application is camber control and the integration of control surface functions into the main surface by camber control. This would mean a high chordwise bending deformation of the wing box. As mentioned before for spanwise bending, the skins would have to be stretched and compressed considerably, but in this case based on a smaller reference length and a smaller moment arm. For this reason, we do not see chordwise bending deformations on conventional wings under load. Aeroelastic tailoring, addressed later, by adjusting the carbon fiber plies in thickness and direction to meet desired deformation characteristics, was also addressing camber control in the 1970s and 1980s as one specific option. Because of the previously mentioned constraints, there has been no application of this passive aeroelastic control feature on a realistic wing design.

Structures and Mechanisms

To a certain extent, the main functions of structures and mechanisms are opposite: a structure must provide rigidity, and a mechanism must provide large defined motions between parts. If active structures are considered, both functions must be integrated into the structure, the performance of this system should be better, and the total weight should be lower compared to a conventional design. This shows the difficulty of developing active structures for aircraft control.

Therefore, the intention of making the structure more flexible to allow deformations is a contradiction. Hinges are required to allow deformations without producing internal forces. If this function is desired within the structure, the structure has to become more flexible in distinct small regions. But this attempt will create high internal loads in regions that have small cross sections, and the desired deformations for aircraft control functions will produce a high number of load cycles.

Figure 4. Bending deformation of swept wings and impacts on the aerodynamic angle-of-attack.

Figure 5. A/C performance improvements from materials.

Passive Materials for Aircraft Structures

Lightweight aircraft structures are obtained by optimal shape and the best suitable materials for the load levels and type of loading. Figure 5 shows the achievements produced in aircraft design by new materials. Unfortunately for active structural concepts, today's high performance composite materials are stiffer than previous aluminum structures. Therefore, it is a mistake for some active aircraft structures researchers to talk about "highly flexible" composite structures for their designs. On the other hand, today's skepticism about future applications of smart materials may be as wrong as the statement in one of the earliest textbooks on aircraft structures, where the author states that metal will never be used on aircraft structures, because its density is too high compared to wood (11). Obviously, the author was only considering iron at that time.

The figure also indicates the typical performance trends for new technologies. When they are introduced, they are inferior to the best available state-of-the-art technology at the time. The book, 'The Innovator's Dilemma,' by Clayton M. Christensen (12) describes this trend for several new, disruptive technologies. First applications are typical on low-cost, low-performance products.

Typical Load Requirements for Aircraft Structures

A typical fighter aircraft has to be designed to carry a load nine times its own weight. Applied to a car that has an empty weight of 1 metric ton plus a $\frac{1}{2}$ ton payload, this would mean an external load of 14.5 tons! The wings for a transport aircraft have to carry 2.5 times the total weight. This shows that airplane structures have to be strong, which means that they are also rather stiff. The upper and lower skins of the torque box have a typical thickness of the order of 10 to 20 millimeters, compared to the body of a car that is less than 1 millimeter thick.

SMART MATERIALS FOR ACTIVE STRUCTURES

Smart materials for active structures applications are mainly interesting because of their high energy density. On the other hand, their strain or stroke capacity is rather limited, compared with other materials for aircraft structures and with other actuators. And they are rather heavy. Probably the most complete survey paper on this topic entitled "Smart aircraft structures" by Crowe and Sater (9) was presented in 1997 at the AGARD Symposium on

Future Aerospace Technology in the Services of the Alliance. It classifies the different concepts and gives an overview on recent and ongoing research activities. It also predicts future applications in real systems that have different purposes and for different classes of airplanes.

So far, piezoelectric materials and shape memory alloys (SMA) are addressed mainly for potential applications. Whereas piezos are usually applied as patches in multiple layers, distributed over the surface, or as concentrated stack actuators, SMAs have been investigated mainly as wires or torque tubes for active deformation of aerodynamic surfaces. To date, the results achieved are not very promising for aircraft control by active structures. For this purpose, which means large static deformations in a rather short time, piezo materials respond fast enough, but their stroke is very limited. SMAs, on the other hand, could provide larger deformations and higher forces but are not fast enough for flight control inputs, and their thermal energy supply issues are rather complex within the airframe and aircraft environment.

Because of these limitations, the Defense Advanced Research Projects Agency (DARPA) launched an ambitious research program in 1999, called "Compact Hybrid Actuators" (CHAP), to multiply the stroke and force output of current actuators by a factor of 10.

THE ROLE OF AEROELASTICITY

The Reputation of Aeroelasticity

Some years after the Wright brothers' success using their active wing, designers began to fear the flexibility of the structure. The famous MIT Lester B. Gardner Lecture "History of Aeroelasticity" by Raymond L. Bisplinghoff (13) quotes many of the early incidents involving aeroelastic phenomena and the famous comment from Theodore von Kármán "Some fear flutter because they do not understand it, and some fear it because they do." Also quoted from a review paper on aeroelastic tailoring by T. A. Weisshaar (2): "As a result, aeroelasticity helped the phrase "stiffness penalty" to enter into the design engineer's language. Aeroelasticity became, in a manner of speaking, a four-letter word....it deserves substantial credit for the widespread belief that the only good structure is a rigid structure." The role of aeroelasticity in aviation is depicted in Fig. 6. It shows the impact on aircraft performance over the years,

Figure 6. The impact of aeroelasticity on aircraft performance.

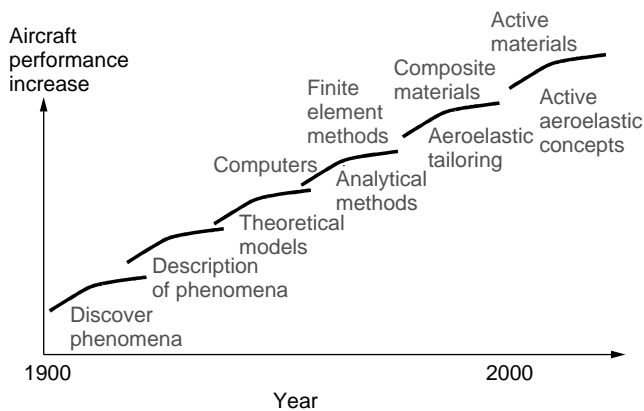

Figure 7. Relationship between aircraft performance, advances in aeroelasticity, and external stimuli.

caused mainly by increasing speed. But the upper dot in 1903 also indicates that aeroelasticity can act positively, if properly used and understood today and on faster airplanes. Smart structural concepts will help to reverse this negative trend of aeroelastic impact on aircraft performance.

Similar to Fig. 5, the progress in aeronautics can also be connected to the progress in aeroelasticity and related external stimuli and events, as shown in Fig. 7.

Aeroelastic Effects

Because of the difficulty in describing aeroelastic effects by using proper theoretical models that involve a good description of the structure, its flexibility, and structural dynamic characteristics, as well as its steady and unsteady aerodynamic properties, solutions were limited in the early years of aviation to selected cases that had only a few degrees of freedom. More general solutions required the storage space and short computing time of modern computers. The aeroelastic triangle, (Fig. 8), cited the first time by Collar (14) in 1946, describes the involved types of forces in the different aeroelastic phenomena. Looking at these forces and interactions, it becomes obvious that smart structures for aeronautical applications will have a close relationship to aeroelasticity in most cases.

Figure 8. Aeroelastic triangle.

Static Aeroelasticity. No inertial forces are involved, by definition, in static aeroelastic effects. This is true for aileron reversal, an effect, where the rolling moment due to a control surface deflection changes sign at a certain flight speed due to opposite deformation of the fixed surface in front of the control surface. This effect has to be avoided within the flight envelope of the aircraft to avoid disturbing the pilot when he moves the stick to roll the airplane.

If the Wright Brothers had used conventional ailerons on their first airplanes, they might have experienced aileron reversal because of the low torsional stiffness of their wings, even at very low speeds. On the other hand, the Wright brothers' main competitor, Samuel P. Langley, was very likely less fortunate in using his Aerodrome designs because of insufficient aeroelastic stability (13) after scaling up the successful smaller unmanned vehicle to larger dimensions.

It is not sufficient to avoid aileron reversal in fighter airplanes. Even under the worst flight conditions, a high roll rate must be achieved to provide high agility. This is usually done by reinforcing the wing structure because the basic static design of a fighter wing yields rolling moment effectiveness slightly above or even below zero under the worst flight conditions. The basic design of the American F-18 had to be revised after delivery of the first batch of production aircraft. An additional weight of 200 lb per wing side was added to the Israel Lavi lightweight fighter to provide sufficient roll power. In addition to the loss of roll power, the adverse deformation of the control surface requires larger control surface deflections, which result in higher hinge moments and require stronger actuators. The difficulty of predicting the most effective distribution of additional stiffness for improved roll effectiveness, especially in conjunction with the introduction of modern composite materials that have highly anisotropic stiffness properties in airframe design, inspired the development of formal mathematical structural optimization methods (15).

Aileron reversal usually has the most severe static aeroelastic impact on aerodynamic forces and moments. But all other aerodynamic performance or control characteristics of an airplane are affected as well by static aeroelastic deformations and aerodynamic load redistributions, to a more or less severe degree. Weisshaar (16), for example, mentions the excessive trim drag due to aeroelastic wing deformations on the delta wing of a supersonic transport aircraft.

Roll control improvement by active concepts was and still is the most often studied application of active concepts for static aeroelastic phenomena in aircraft. Although active structures or materials are not involved, the Active Aeroelastic Wing project (17), or Active Flexible Wing project, as it was called before, is currently on the way to flight test trials in 2001 on a modified F-18. This concept originates in several theoretical studies and wind tunnel demonstrations in the 1980s. A summary of these activities was presented in a special edition of the *Journal of Aircraft* in 1995 (18). Figure 9 depicts the wind tunnel model installed in the Transonic Dynamics Tunnel at the NASA-Langley Research Center.

Losses of static aeroelastic effectiveness in lateral stability and rudder yawing moment are well-known design drivers for vertical tails. Surprisingly, almost nobody has

Active flexible wing model mounted in the langley TDT

Figure 9. Active aeroelastic wing model mounted in the NASA Transonic Dynamics Wind Tunnel (from the Internet).

looked so far into smart structural concepts to obtain better designs. Sensburg (19) suggested a smart passive solution, called the diverging tail, achieved by aeroelastic tailoring of the composite skins and modifying the fin root attachment to a single point aft position to achieve higher yawing moments compared to a rigid structure.

Aeroelastic divergence was the most severe instability for early monowing airplanes. If the wing main spar is located too far behind the local aerodynamic center of pressure (at 25% chord), a lack of torsional stiffness causes the wing structure to diverge and break at a certain speed. As Anthony Fokker describes in his book (20), sufficient strength of the design had already been demonstrated by proof load and flight tests for his D-VIII, (Fig. 10), when regulations called for a reinforced rear spar that has strength proportional to the front spar. This redistribution of stiffness caused torsional divergence under flight loads. This example also demonstrates the potential effects

and impacts of applying smart structures to an airplane structure.

The introduction of high-strength composite materials that had the possibility of creating bending-torsion coupling effects from anisotropic material properties caused a renaissance of the forward swept wing in the late seventies (2), this had been ruled out before for higher sweep angles because of the bending-torsion divergence, as depicted in Fig. 4.

Static aeroelasticity also includes all effects on aerodynamic load distributions, the effectiveness of active load alleviation systems by control surfaces, and flexibility effects on aerodynamic performance. In this case, the variable inertial loads from the payload or fuel on structural deformations have to be considered simultaneously.

Dynamic Aeroelasticity. Flutter is the best known dynamic aeroelastic stability problem. It belongs to the category of self-excited oscillatory systems. In this case, any small external disturbance from a control surface command or atmospheric turbulence that excites the eigenmodes of the structure, creates additional unsteady aerodynamic forces at the same time. Depending on the mass and stiffness distribution and on the phase angles between the vibrational modes involved, aerodynamic forces dampen the oscillations or enforce them in the case of flutter.

Active control for enhancing flutter stability by aerodynamic control surfaces was fashionable in the late 1970s (21). In this case, the effectiveness of the system depends on the static aeroelastic effectiveness of the activated control surfaces. Mainly because of safety aspects, but also because of limited effectiveness, none of these systems has entered service so far. Active control by active structural devices was a popular research topic in recent years (10), but, for the same reasons, it is doubtful that we will ever see applications.

Panel flutter is a special case, where only individual skin elements of the structure (panels) are affected. This usually happens at low supersonic speeds, and only

Front spar Rear spar

Figure 10. Fokker D-VIII monoplaner, where aeroelastic divergence caused several fatal accidents after reinforcement of the rear spar (modified by author, photo from the Internet).

structural elements that have low static load levels, like fairings, can usually be affected. Active control by smart materials is possible, but there are no considerable impacts on aircraft effectiveness.

Buffeting is forced vibration where turbulent flow generated by one aerodynamic surface excites this surface itself or another surface located in the turbulent flow region. Here also, aerodynamic control surfaces located on the affected part can be used to counteract the vibrations. Compared to flutter, the aerodynamic effectiveness of these surfaces is additionally reduced because of the turbulent flow conditions. Active structural systems are more effective in this case. For this reason and because the required active deformations are small, the first large-scale active structural application in aircraft dealt with the buffeting problem of fighter aircraft vertical tails under extreme maneuver conditions. After several theoretical (22) and small-scale experimental studies (23), full-scale ground tests were performed in a joint Australian–Canadian–USA research program (24) on an F-18 and in a German program for a simplified fin structure of the Eurofighter (25). In both cases, piezoelectric material was used.

Aeroelastic Tailoring and Structural Optimization

Weisshaar (26) was one of the first researchers who tried to give aeroelasticity a better reputation when modern fiber-reinforced composite materials that had highly anisotropic directional stiffness were considered for primary aircraft structures. They provided the possibility of tailoring the materials' directional stiffness within the composite lay-up to meet desired deformation characteristics for improved aeroelastic performance. Together with formal mathematical optimization methods for the structural design, this approach allowed minimizing the impact of aeroelasticity.

Any improvement of a technical system is often referred to as an optimization. In structural design, this expression is mainly used today for formal analytical and numerical methods. Some years after the introduction of finite element methods (FEM) for analyzing aircraft structures, the first attempts were made to use these tools in an automated design process. Although the structural weight is usually used as the objective function for optimization, the major advantage of these tools is the fulfillment of aeroelastic constraints, not the weight saving. Other than static strength requirements, which can be met by adjusting the dimensions of the individual finite elements, the sensitivities of the elements to aeroelastic constraints cannot be expressed so easily. The option of tailoring the composite material's properties by individual ply orientations and different layer thicknesses for the individual orientations required and inspired the development of numerical methods (27).

OVERVIEW OF SMART STRUCTURAL CONCEPTS FOR AIRCRAFT CONTROL

Classification of Concepts

Active structural concepts for aircraft control can be subdivided into these categories:

- the purpose of the active system,
- the types of devices to activate the structure.

In the first case, the intended concepts are aiming at improving

- control effectiveness,
- aerodynamic drag reduction by adaptive shape,
- load alleviation by adaptive deformation, and
- stabilizer effectiveness for trim and static stability.

As mentioned earlier, the majority of the concepts aim to improve roll control power because it usually has the highest sensitivity to structural deformations.

A classification by actuation devices can be given by

- activation of a passive structure by conventional or novel aerodynamic control surfaces,
- active structural elements, and
- actuators or connecting elements that have adaptive stiffness between structural components.

An additional classification can be made by

- concepts, where aeroelastic effects are intentionally used, and
- concepts without special aeroelastic considerations.

As far as aeroelasticity is addressed by concepts, the intended improvements aim at the high-speed part of the flight envelope, where aeroelastic effects become more important. When aeroelastic effects are exploited in a positive sense, this also means that active aeroelastic effects can usually be used beneficially only at higher speeds. An exception is shown later.

Fictitious Control Surface Concepts

To evaluate the potential benefits of smart structural concepts, as well as the required energy to activate them, it is useful to start with a “virtual concept,” assuming that the intended structural deformation is created by any device. Khot, Eastep, and Kolonay (28) call this the “fictitious control surface” concept. They investigated the aeroelastic loss of roll control power for a conventional trailing edge control surface and then tried to retwist the wing by supplying the same amount of strain energy that was created by the aileron deflection. The main purpose of this effort was analytical evaluation of the energy required to maintain a constant roll rate as dynamic pressure increases. The result, however, an increase in energy versus dynamic pressure at the same gradient as the reduction of effectiveness, may be misleading. The achievable rolling moment from a deformation depends on the position, where the deformation is initiated by an internal force or by a control surface deflection. Similarly to a rigid wing, where a trailing edge surface is much more effective than a leading edge surface, there are more or less effective regions on a flexible wing, where a deflection

of a control surface or a deformation of the structure by internal forces results in different rolling moments and requires different efforts to create the deflection or deformation.

Variable Shear Stiffness Spar Concept

Similarly to the fictitious control surface, a study by Griffin and Hopkins (29) used a “fictitious” variable stiffness spar concept to modulate the rolling moment effectiveness of a generic F-16 wing model. They assumed a small outboard trailing edge control surface on an analytical F-16 wing model for roll control, which would operate in a conventional mode at low dynamic pressures, and the negative “postreversal” effectiveness could be enhanced by turning the spar web shear stiffness off at high dynamic pressures. This concept was explained simply by “link elements” attached to the upper and lower spar caps by bolts and removable pins. The basic principle of this concept was also experimentally verified by an aeroelastic wind tunnel model for an unswept, rectangular wing that had removable spars (30). Unfortunately, no reference was found to show that more technical smart structural solutions were ever investigated for this concept.

Innovative Control Effector Program

In the Innovative Control Effector (ICE) program from NASA-Langley (31,32), the positions and required amount of small, “fictitious control surfaces” were determined by a genetic optimization process for an advanced “blended wing-body” configuration. These “control effectors” are elements of the surface grid in the analytical aerodynamic model that create the “virtual” shape change. See (31) for an excellent overview of all research activities within the NASA “Morphing Program.”

Active Flow Control Actuators

Synthetic jet actuators were also developed and tested as a part of the NASA Morphing Program (31). This device is based on a piezoelectrically driven diaphragm, which sucks and blows air through a small orifice. It was originally developed for cavity noise control. The power output needs to be multiplied to use it for aircraft control, where much higher forces are required.

Innovative Aerodynamic Control Surface Concepts

Although there are no active structural components involved, these concepts can also be considered “smart structures.” In this case, the active deformation of the structure is actuated by aerodynamic control surfaces. The January/February 1995 edition of the *Journal of Aircraft* (33) was a special issue, dedicated to the U.S. “Active Flexible Wing Program,” which started in 1985 and later turned into the “Active Aeroelastic Wing Program.” This basic idea was improving roll effectiveness for a fighter aircraft wing by combining two leading edge and two trailing edge control surfaces, which could also be operated beyond reversal speed. This concept was demonstrated on an aeroelastic wind tunnel model by tests that started in 1986. After

Figure 11. Active aeroelastic wing demonstrator aircraft [from (5)].

theoretical studies on F-16 and F-18 wings, reported by Pendleton (5,17,34), the F-18, depicted in Fig. 11, was selected as the candidate for flight test demonstrations, that are expected to start in 2001. For this purpose, the wing structure was returned into the original stiffness version, which had shown aileron reversal in early flight tests.

Flick and Love (35) studied wing geometry sensitivities for potential improvements from active aeroelastic concepts based on a combination of leading and trailing edge surfaces. The results shown in Fig. 12 (5) indicate only very small advantages for low aspect ratio wings. The theoretical studies of a generic wing model of the Eurofighter wing by the first author, however, also resulted in large improvements for this configuration, as can be seen in Fig. 6. Active aeroelastic concept research by TsAGI in Russia already demonstrated impressive improvements in flight tests. In addition to using leading edge control surfaces to improve roll performance, a small control surface was also mounted at the tip launcher. Figure 13 from (36) shows the achievable improvement compared to the trailing edge aileron only. Note the size of the special surface compared with a conventional aileron.

For high aspect ratio transport aircraft wings, especially in combination with a winglet, similar devices could be used for roll control and also for adaptive induced drag reduction, or load alleviation, as indicated in Fig. 14 for a concept, called active wing tip control (AWTC) by Schweiger and Sensburg (37). In this case, the winglet root provides sufficient space and structural rigidity to integrate the control device and its actuation system. In flutter stability, the forward positions of the masses increase the flutter stability, which is reduced by the aft position of the winglet.

Of course, the static aeroelastic effectiveness of a control surface is also important for dynamic applications like flutter suppression or load alleviation for buffeting of vertical tails. This fact is very often forgotten in favor of optimizing the control laws.

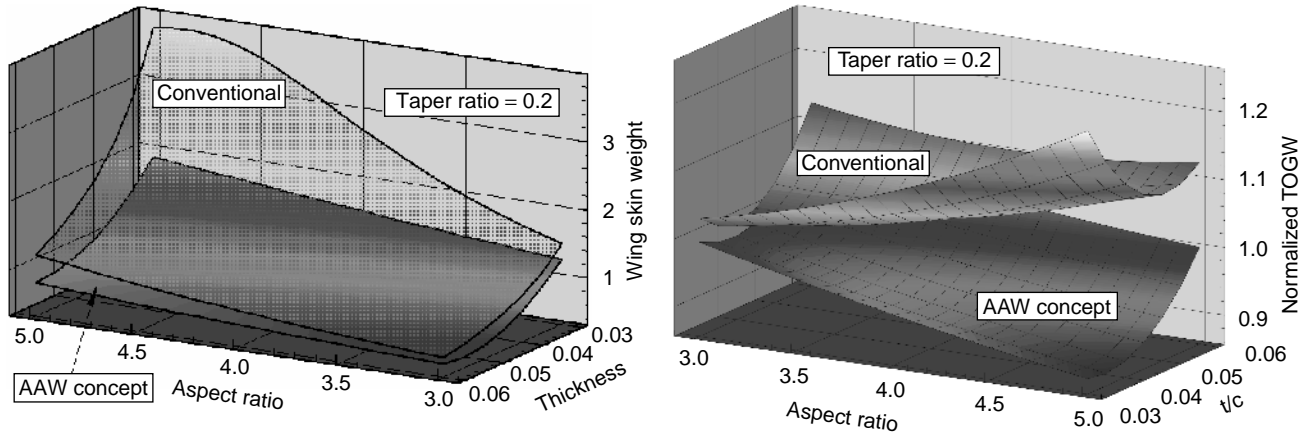

Figure 12. AAW technology advantages and wing geometry sensitivities for lightweight fighter wings [results from (35) figures from (5)]

Active Structures and Materials Concepts

Dynamic applications for flutter suppression (10) or buffetting load alleviation (38,39) by piezoelectric material were demonstrated on wind tunnel models and in full-scale ground tests. The involved mass and complexity, mainly for the electric amplifiers, precludes practical applications at the moment. For dynamic applications, however, a semi-active solution using shunted piezos (40) that have very little energy demand is an interesting option.

The use of piezoelectric materials for static deformations is limited by the small strain capacity, as well as by the stiffness of the basic structure. Because of these facts, some researchers realized rather early that it is not advisable to integrate the active material directly into the load-carrying skins. To achieve large deflections, it is necessary to amplify the active material's stroke and to uncouple the to-be-deformed (soft) part of the passive structure from the (rigid) main load-carrying part. Because this usually causes a severe "strength penalty" for the main

structures of conventional airplanes, practical applications are limited to unusual configurations like small UAVs or missiles (41). As an example, Barrett (42) developed such a device, where the external shell of a missile fin is twisted by a PZT bender element.

Compared to piezoelectric materials, which respond very fast, shape memory alloys (SMA) are rather slow, but they can produce high forces. This precludes applications for the speed of flight control motions or higher and allows only adaptation to very slow processes like the pre-described trajectory of a transport airplane and the parallel reduction of fuel mass.

Two typical applications of SMAs were investigated in the DARPA/AFRL/NASA Smart Wing Program (5,31), a SMA torque tube to twist the wing of a 16% scale wind tunnel model of a generic fighter aircraft and SMA wires to actuate the hingeless trailing edge control surfaces. The ratio between the torque tube cross section and the wing torque box cross section should be kept in mind. To replace conventional control surfaces, efforts to create deformation of a realistic structure still need to be addressed. And,

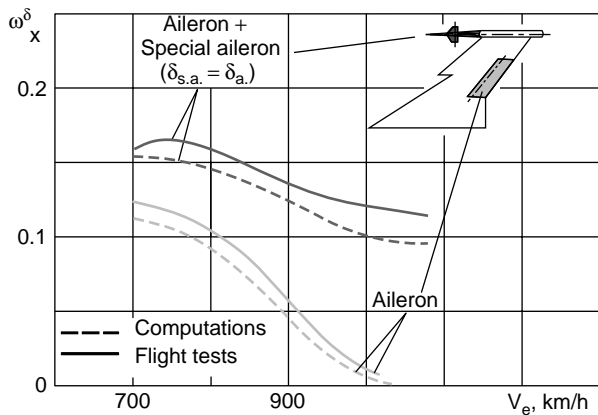

Figure 13. AAW technology in Russia: Flight test results and comparison with analysis for a special wing tip aileron [results adapted from (36)].

Active Wing Tip Control Device

- for:
- Drag reduction
- Increased roll control
- Load alleviation

Figure 14. Advantages of an active wing tip control device on a transport aircraft wing.

Figure 15. Comparison of rolling moment effectiveness for conventional and conformal trailing edge control surface [from (5)].

what is even more important than the limitations of actuation speed, aeroelastic aspects should be kept in mind from the beginning to evaluate and optimize the effectiveness of such concepts. As depicted in Fig. 15 (5), the effectiveness of the conformal trailing edge control surface is better than the conventional control surface a low speed but gets worse as dynamic pressure increases. As mentioned in this reference, such concepts are not developed to replace existing systems but to demonstrate the capabilities of active materials. If this is the case, realistic applications still need to be discovered.

Smart materials applications on small RPVs are currently investigated at the Smart Materials Lab of the Portuguese Air Force together with the Instituto Superior Técnico in Lisbon (43).

Other Innovative Structural Concepts

Because of the limited stroke of active materials and the inherent stiffness of a minimum weight aircraft structure, some researchers try to amplify the stroke by sophisticated

kinematic systems and enable larger deformations more easily by “artificially” reducing the structural stiffness. So far, all of these concepts show the following disadvantages:

- high complexity for the actuation system,
- higher energy demand compared with the actuation of conventional control surfaces,
- additional internal loads in the structure from the forced deformation,
- additional structural weight from the reduced strength,
- reduced static aeroelastic effectiveness because of additional flexibility in the rear wing area, and
- reduced aeroelastic stability (flutter) from the reduced stiffness.

As one example, such systems are described by Monner, et al. (44). That paper summarizes active structural research by the German aerospace research establishment DLR on an Airbus type transport aircraft wing.

An old idea, the pneumatic airplane, as depicted in Fig. 16, may be useful, if applied to small UAVs (for storage), or, on larger airplanes to selected structural elements, like spar webs, to adjust the shape by variable pneumatic stiffness to control the aeroelastic load redistribution.

Adaptive All-Movable Aerodynamic Surfaces

Adaptive rotational attachment or actuation stiffness for all-movable aerodynamic surfaces can be seen as a special class of active aeroelastic structural concepts. If properly designed, this concept will also provide superior effectiveness compared to a rigid structure at low speeds. Other active aeroelastic concepts show their advantages only as speed increases, in the same way as negative aeroelastic effects increase.

As an example, a fixed root vertical tail can be made more effective, if the structure is tailored so that the elastic axis is located behind the aerodynamic center of pressure. This wash-in effect, for example, increases the lateral stability compared to a conventional design on a swept-back vertical tail, as depicted in Fig. 17. The so-called diverging tail (19) has improved effectiveness but also experiences higher bending moments.

Figure 16. Goodyear Inflatoplane (1950s) (from the Internet).

Figure 17. Aerodynamic load distribution for different design approaches on a vertical tail.

Instead of tailoring the structure, which essentially always creates a (minimized) weight increase, the tail can be designed as a reduced size all-movable surface. The location of the spigot axis is used to tailor the wash-in effect, and the attachment stiffness is adjusted to the desired effectiveness. This also allows obtaining the required effectiveness at low speeds using a smaller tail. As described in (45), the proper shape of the surface in conjunction with the spigot axis location also enhances flutter stability.

Figure 18 depicts the effectiveness of different spigot axis locations at different Mach numbers (and dynamic pressure) using variable stiffness.

The crucial element of the all-movable surface using adaptive attachment stiffness is the attachment/actuation

component. This can, for example, be a mechanical spring that has variable stiffness and a conventional hydraulic actuator or, as a more advanced system, a hybrid actuator using smart material elements, such as magnetorheological fluids. The objective of the current DARPA program “Compact Hybrid Actuators” is to develop such components at high energy density and 10 times the stroke of current systems.

Of course, such systems can also be used for horizontal stabilizers or outboard wing sections. Compared to a horizontal tailplane, where the fuselage flexibility causes losses of aeroelastic effectiveness, a forward surface can exploit additional benefits from the fuselage flexibility.

QUALITY OF THE DEFORMATIONS

The amount of internal energy required for the desired deformations depends strongly on the static aeroelastic effectiveness involved. As depicted in Fig. 19, the aerodynamic loads can either deform the structure in the wrong direction and require additional efforts to compensate for the deformations caused by external loads, or the internal, initial deformation is used so that the desired deformations are only triggered and the major amount of energy required is supplied by the air at no cost. In the first case, the required deformation generated by internal forces already creates a high level of internal strain in the structure, resulting in reinforcement and extra structural weight. In the second case, the required internal actuation forces and the strain levels are much smaller. For a favorable solution, the design process must reduce the total load level of the structure in the “design case,” thus reducing the total weight required for the structure and actuation system

Actuator position and stiffness variation for aeroelastic effectiveness vs. dynamic pressure

Figure 18. Achievable aeroelastic effectiveness using variable attachment stiffness for different locations of the spigot axis.

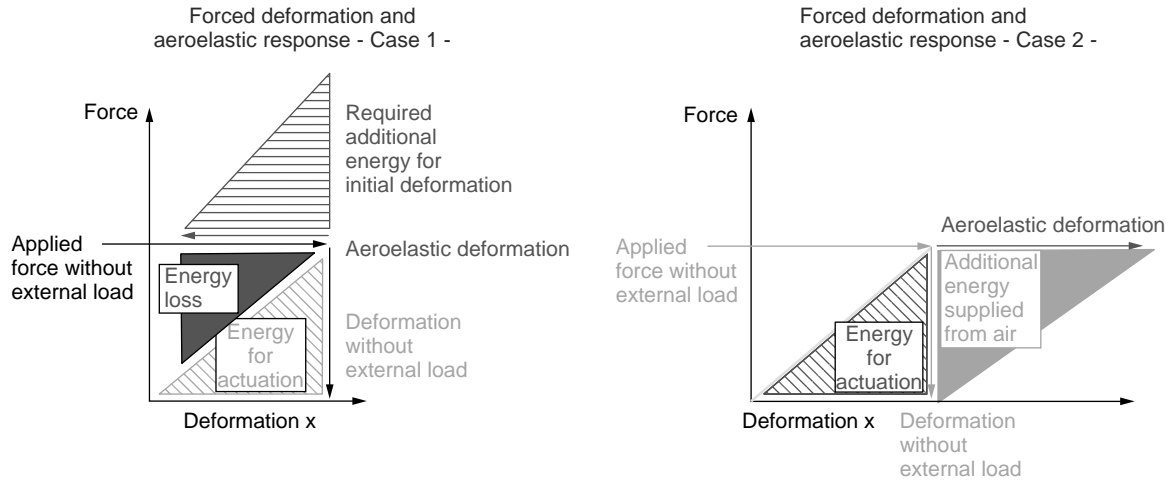

Figure 19. Forced structural deformation and aeroelastic response of different design approaches.

compared to a conventional design, as indicated in Fig. 20, and achieving better performance.

The effort required and the results achievable for a specific type of deformation depend strongly on the typical properties of the wing structure, which in most cases can be described as a beam. First of all, lift forces create bending deformations in the direction of the lift force. Because drag forces are much smaller (1/10) and because of the shape of the airfoil, in-plane bending deformations can be neglected. Depending on the chordwise location of the resulting lift force relative to the beam (torque box) shear center location, it is possible to twist the wing. This can, for example, be used to reduce the bending deformation. Because of the high stiffness of a modern wing in a chordwise section and because of the resulting aerodynamic pressure distribution that usually acts in one direction, a chordwise bending deformation (camber) is very difficult to achieve by internal or external forces. This is also true for a reduced thickness rear section of a wing, for example, to replace a deflected control surface.

ACHIEVABLE AMOUNT OF DEFORMATION AND EFFECTIVENESS OF DIFFERENT ACTIVE AEROELASTIC CONCEPTS

Classical active aeroelastic concepts rely on the adaptive use of aerodynamic control surfaces and their aeroelastic effectiveness under various flight conditions. In conventional designs, the aeroelastic effect is more pronounced as airspeed increases, as demonstrated in Fig. 21 for potential losses and gains.

Conventional active aeroelastic concepts exploit the increasing effectiveness in the upper half of this figure, as well as the recovering effectiveness of a conventional aileron beyond the reversal speed. A combined operation of leading and trailing edge surface results in an achievable roll rate, as indicated in Fig. 22.

To exploit aeroelastic effects more beneficially, increasing the aeroelastic sensitivity of the design in a wider range of the flight envelope is required. This can be achieved,

Figure 20. Performance of active structural concepts in weight and performance.

Figure 21. Typical range of aeroelastic effectiveness.

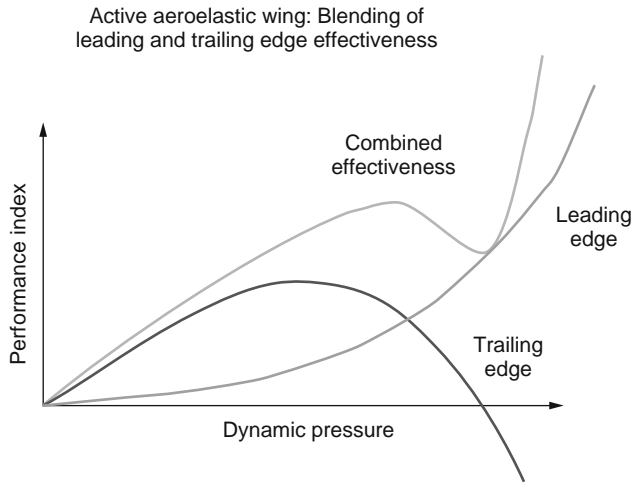

Figure 22. Achievable roll performance by combining leading and trailing edges.

for example, by an all-movable aerodynamic surface that has adaptive rotational attachment stiffness. This also provides high effectiveness at low speeds, and excessive loads from diverging components or flutter instabilities at high speeds can be avoided.

The usable aeroelastic effectiveness for conventional concepts is rather limited between take-off and cruise speed. Aileron reversal usually occurs between the cruise speed and limit speed, and too high an effectiveness of leading edge surfaces must be avoided at the limit speed. On the other hand, adaptive all-movable concepts can provide high effectiveness at all speeds and avoid excessive loads at the high end of the speed envelope, as indicated in Figs. 23 and 24. This means, for example, that a stabilizer surface can be built smaller than would be required by “rigid” aerodynamic low-speed performance.

NEED FOR ANALYZING AND OPTIMIZING THE DESIGN OF ACTIVE STRUCTURAL CONCEPTS

Of course, active materials and structural components, together with the stimulating forces, need a correct

Figure 23. Aeroelastic effectiveness of conventional and adaptive-all-movable active aeroelastic concepts.

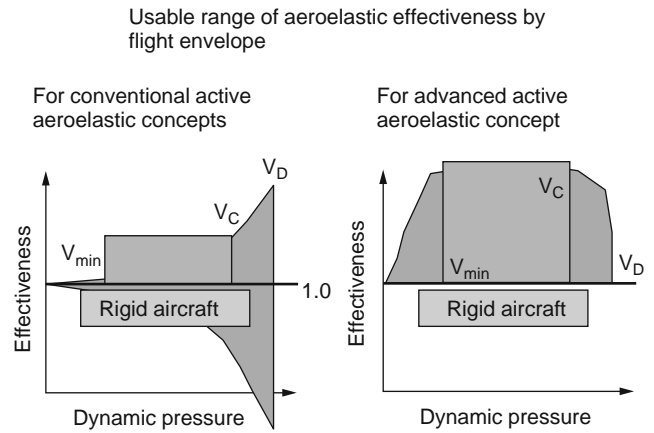

Figure 24. Usable range of aeroelastic effectiveness for conventional and advanced active aeroelastic concepts.

description in theoretical structural or multidisciplinary analysis and optimization (MDO) models and methods. Once this is provided, the actively deforming structure needs another approach for static aeroelastic analysis. The deflections of selected control surfaces of an aircraft that has conventional control surfaces can be prescribed for aeroelastic analysis. For an actively deformed structure, initial deformations without external loads first need to be determined, for example, by static analysis.

As described before, the deformations achievable in conjunction with the distribution of external aerodynamic loads are essential for the effectiveness of active structural concepts for aircraft control. This requires efficient tools and methods for simultaneous, multidisciplinary analytical design. The best design involves optimizing

- external shape,
- arranging the passive structure (topology),
- sizing the passive structure,
- placing and sizing the active elements, and
- a control concept for the active components.

The aims of this approach are the optimum result for the objective function (minimum weight, aerodynamic performance), fulfillment of all constraints like strength, and also optimization of additional objectives, such as minimum energy. As depicted in Fig. 25 for the optimization of a passive structure that has different constraints for the required rolling moment effectiveness, the energy required to actuate the control surface can be considerably reduced, even if the required (low) roll rate is already met.

MDO does not mean combining single discipline analytic tools by formal computing processes. It means first a good understanding of what is going on. This is essential for a conventional design. Only from this understanding can the creative design of an active concept start.

It is also very important to choose the proper analytic methods for individual disciplines. Usually, not the highest level of accuracy is suitable for the simulation of important effects for other disciplines. This also refers to refining the analytic models, where local details are usually not

Figure 25. Optimization of the rolling moment and hinge moment of a trailing edge aileron of a low aspect ratio fighter wing.

interesting for interactions. It is more important to keep the models as versatile as possible for changes in the design concepts and to allow the simulation as many variants as possible. This also means an efficient process for generating models, including the knowledge of the user for this process. Fully automated model generators can create terrible results, if the user cannot interpret or understand the modeling process.

Any improvement in a technical system is often referred to as an optimization. In structural design today, this expression is mainly used for formal analytic and numerical methods. Some years after the introduction of finite element methods (FEM) for analyzing aircraft structures, the first attempts were made to use these tools in an automated design process. Although the structural weight is usually used as the objective function for optimization, the major advantage of these tools is the fulfillment of aeroelastic constraints, not the weight saving. Other than static strength requirements, which can be met by adjusting the dimensions of individual finite elements, the sensitivities of the elements to aeroelastic constraints cannot be expressed so easily.

In the world of aerodynamics, the design of the required twist and camber distribution for a desired lift at minimum drag is also an optimization task. Assuming that minimum drag is achieved by an elliptical lift distribution along the wingspan, this task can be solved by a closed formal solution and potential flow theory. More sophisticated numerical methods are required for the 2-D airfoil design or for Euler and Navier–Stokes CFD methods, which are now maturing for practical use in aircraft design.

Formal optimization methods have been used for conceptual aircraft design for many years. Here, quantities such as direct operating costs (DOC) can be expressed by rather simple equations, and the structural weight can be derived from empirical data. Formal methods such as optimum control theory are also available for designing the flight control system.

So, one might think that these individual optimization tasks could easily be combined into one global aircraft optimization process. The reasons that this task is not so

simple is the different natures of the design variables of individual disciplines and their cross sensitivities with other disciplines. The expression multidisciplinary optimization (MDO) summarizes all activities in this area, which have intensified in recent years. It must be admitted that today most existing tools and methods in this area are still single discipline optimization tasks that have multidisciplinary constraints.

To design and analyze active aeroelastic aircraft concepts, especially when they are based on active materials or other active structural members, new quantities are required to describe their interaction with the structure, the flight control system, and the resulting aeroelastic effects.

SUMMARY, CONCLUSIONS, AND PREDICTIONS

In the same way as it was wrong in the past to demand that an aircraft design to be as rigid as possible, it's wrong now to demand a design that is as flexible as possible.

It is sometimes said that smart structural concepts can completely replace conventional control surfaces. But this looks very unrealistic, at least at the moment. The major difficulties for successful application are the limited deformation capacity of active materials, as well as their strain allowables, which are usually below those of the passive structure. However, this can be resolved by proper design of the interface between the passive and active structures. But the essential difficulties are the stiffness and strain limitations of the passive structure itself. It cannot be expected that the material of the passive structure just needs to be replaced by more flexible materials without an excessive weight penalty. It is also not correct to believe that an active aeroelastic concept becomes more effective, if the flexibility of the structure is increased. Aeroelastic effectiveness depends on proper aeroelastic design, which needs certain rigidity of a structure to produce the desired loads. A very flexible structure would also not be desirable from the standpoints of aerodynamic shape, stability of the flight control system, and transmission of static loads.

Because large control surface deflections are required at low speeds, where aeroelastic effects on a fixed surface are small, it is more realistic to use conventional control surfaces for this part of the flight envelope and use active aeroelastic deformations only at higher speeds. This would still save weight on the control surfaces and their actuation system due to the reduced loads and actuation power requirements.

To produce usable deformations of the structure also at low speeds, all-movable aerodynamic surfaces that have a variable attachment stiffness are an interesting option. This concept relies on development efforts for active devices that have a wide range of adjustable stiffness.

The reasons that we have not seen more progress to date in successfully demonstrating smart structural concepts in aeronautics may be that

- specialists in aircraft design do not know enough about the achievements in the area of smart materials and structures, and
- smart materials and actuation system specialists, who try to find and demonstrate applications in

aeronautics, do not know or care enough about real-world conditions for airplane structures.

What we need is more awareness on both sides, as well as stronger efforts to learn from each other and work together.

Although there are strong doubts about useful applications of smart structures for aircraft control, it should always be remembered how often leading experts have been wrong in the past in their predictions, in many cases even on their own inventions. Norman R. Augustine quotes some of them in his famous book "Augustine's Laws" (46):

- "The [flying] machines will eventually be fast; they will be used in sport but they should not be thought of as commercial carriers." – Octave Chanute, aviation pioneer, 1910.
- "The energy produced by the breaking down of the atom is a very poor kind of thing. Anyone who expects a source of power from the transformation of these atoms is talking moonshine. – Ernest Rutherford, physicist, ca. 1910.
- "Fooling around with alternative currents is just a waste of time. Nobody will use it, ever. It's too dangerous ... it could kill a man as quick as a bolt of lightning. Direct current is safe." – Thomas Edison, inventor, ca. 1880.

Also quoted by Augustine (46), the eminent scientist Niels Bohr remarked: "Prediction is very difficult, especially about the future."

At the moment it looks more realistic that new hybrid, concentrated active devices, positioned between a passive but properly aeroelastically tailored main aerodynamic surface and the corresponding control surfaces are showing the like. Hopefully this article will inspire useful applications of smart structures and prevent some unnecessary research.

ARCHITECTURE

D. MICHELLE ADDINGTON
 DANIEL S. SCHODEK
 Harvard University
 Cambridge, MA

INTRODUCTION

An inextricable link has existed historically between a building's characteristics—form, appearance, and function—and the characteristics of the different materials that were available and suitable for construction. As exemplified by historical building traditions in stone and wood, early architects sought to understand intuitively the intrinsic physical behavior of commonly available materials to exploit their properties in designing and constructing buildings. Conversely, later innovations in the type and availability of materials strongly impacted the development of new architectural forms as architects began to respond to changing societal demands and new building functions emerged. This trend is illustrated by the development of steel in the nineteenth century and the related emergence of long-span and high-rise building forms. Today, architects are beginning to look forward to using the developments in smart materials to bring new solutions to long-standing problems and also to exploit the potential of smart materials in developing new building functions, forms, and responses. The wide variety of smart materials available has great potential for use within the field, but, in this area, their applications remain only marginally explored.

MATERIAL CONSIDERATIONS IN ARCHITECTURE

Unlike materials used for specific applications or products such as in refractory linings or engine blocks that are fundamentally chosen on the basis of performance criteria and cost, the choice of materials for architectural use has always been based on very different types of criteria. Performance and cost obviously play a role, but the final selection is often based on appearance and aesthetics, ease of constructability in terms of labor skill, local or regional availability, as well as the material used in nearby existing buildings. The multimodal nature of the selection process coupled with the wide-ranging array of building types, uses, and locales has resulted in a material palette that encompasses all of the major material classes.

TRADITIONAL MATERIAL CLASSIFICATIONS IN ARCHITECTURE

The Construction Specification Institute (or CSI) devised a classification system in 1948 that is used throughout the architectural design and building construction industries. The classification system is bipartite: the first half is devoted to the broad classes of materials typically used in buildings, including paint, laminate, and concrete, and the second half categorizes standard building components such as doors, windows, and insulation. The emphasis in both major groupings is on application, not on fundamental behavior or properties. For example, in Division 6 the characteristics of wood are discussed in relationship to their relevance to the intended application: the grade of wood suitable for load-bearing roof structures or the type of wood suitable for finish flooring.

The CSI index serves as a template for communication among architects, contractors, fabricators, and suppliers. After the preliminary design of a building is completed and approved, architects prepare construction documents (known as CDs) that will serve as the “instructions” for constructing the building. Accompanying each set of CDs are the “Construction Specifications”: a textual document that defines each building element documented in the CDs and specifies the material or component. The Construction Specifications serve as a binding contract that construction professionals and contractors must follow. Trade associations and manufacturers of building products routinely write their material and product specifications in CSI format to streamline the specification process for architects, and many architectural firms maintain an internal set of Construction Specifications that is used as the baseline for all of their projects.

TRADITIONAL TECHNOLOGY CLASSIFICATION IN ARCHITECTURE

The CSI index also categorizes the technologies used in architectural design and construction. Unlike the standard technology classifications used in engineering sciences that categorize according to process and product, the CSI specifications categorize by system. As in the CSI

material classes, the focus of the technology classes is also on application. The technologies are divided into two major groups: the first is devoted to building operational systems such as HVAC, lighting, and plumbing systems, and the second is devoted to building construction systems such as structural, drainage, and vertical circulation systems. The specifications for the building operational systems are almost entirely supplied by manufacturers.

PROPOSED CLASSIFICATION SYSTEM FOR SMART MATERIALS

The introduction of smart materials into architecture poses a challenge to the normative classification system. A smart material may be considered as a replacement for a conventional material in many components and applications, but most smart materials have inherent “active” behaviors, and, as such, are also potentially applicable as technologies. For example, electrochromic glass can be simultaneously a glazing material, a window, a curtain wall system, a lighting control system, or an automated shading system. The product would then fall into many separate categories, rendering it particularly difficult for the architect to take into consideration the multimodal character and performance of the material. Furthermore, many smart materials are introducing unprecedented technologies into the field of design, and are also making more commonplace many technologies, such as sensors, which previously had only limited application in highly specialized functions. Table 1 describes a proposed organization in which smart materials establish a sequential relationship between materials and technologies. The proposed organization also maintains the fundamental focus on application of the traditional classification system.

TAXONOMY OF SMART MATERIALS

Four fundamental characteristics are particularly relevant in distinguishing a smart material from the traditional materials used in architecture: (1) capability of property change (2) capability for energy exchange, (3) discrete size/location, and (4) reversibility. These characteristics can potentially be exploited either to optimize a material property to match transient input conditions better or to optimize certain behaviors to maintain steady-state conditions in the environment.

Smart Material Characteristics

Property Change. The class of smart materials that has the greatest volume of potential applications in architecture is the property-changing class. These materials undergo a change in a property or properties—chemical, thermal, mechanical, magnetic, optical, or electrical—in response to a change in the conditions of the material’s environment. The conditions of the environment may be ambient or may be produced via a direct energy input. Included in this class are all color-changing materials, such as thermochromics, electrochromics, and photochromics, in which the intrinsic surface property of the molecular spectral absorptivity of visible electromagnetic radiation is modified by an environmental change (incident solar radiation, surface temperature) or an energy input to the material (current, voltage).

Energy Exchange. The next class of materials predicted to have a large penetration into architecture is the energy-exchanging class. These materials, which can also be called “first law” materials, change an input energy into another form to produce an output energy in accordance with the first law of thermodynamics. Although the energy

Table 1. Proposed Classification System for Smart Materials and Systems

Category	Fundamental Material Characteristics	Fundamental System Behaviors
Traditional materials: Natural materials (stone, wood) Fabricated materials (steel, aluminum, concrete)	Materials have given properties and are “acted upon”	Materials have no or limited intrinsic active response capability but can have good performance properties
High performance materials: Polymers, composites	Material properties are designed for specific purposes	
Smart materials: Property-changing and energy-exchanging materials	Properties are designed to respond intelligently to varying external conditions or stimuli	Smart materials have active responses to external stimuli and can serve as sensors and actuators
Intelligent components: Smart assemblies, polyvalent walls	Behaviors are designed to respond intelligently to varying external conditions or stimuli in discrete locations	Complex behaviors can be designed to respond intelligently and directly to multimodal demands
Intelligent environments	Environments have designed interactive behaviors and intelligent response—materials and systems “act upon” the environment	Intelligent environments consist of complex assemblies that often combine traditional materials with smart materials and components whose interactive characteristics are enabled via a computational domain

converting efficiency of smart materials such as photovoltaics and thermoelectrics is typically much less than those of conventional energy conversion technologies, the potential utility of the energy is much greater. For example, the direct relationship between input energy and output energy renders many of the energy-exchanging smart materials, including piezoelectrics, pyroelectrics and photovoltaics, excellent environmental sensors. The form of the output energy can further add direct actuating capabilities such as those currently demonstrated by electrostrictives, chemoluminescents and conducting polymers.

Reversibility/Directionality. Some of the materials in the two previous classes also exhibit the characteristic of either reversibility or bidirectionality. Many of the electricity converting materials can reverse their input and output energy forms. For example, some piezoelectric materials can produce a current from an applied strain or can deform from an applied current. Materials that have a bidirectional property change or energy-exchange behavior can often allow further exploitation of their transient change rather than only of the input and output energies and/or properties. The energy absorption characteristics of phase changing materials can be used either to stabilize an environment or to release energy to the environment, depending on the direction in which the phase change is taking place. The bidirectional nature of shape-memory alloys can be exploited to produce multiple or switchable outputs, allowing the material to replace components composed of many parts.

Size/Location. Regardless of the class of smart material, one of the most fundamental characteristics that differentiates smart materials from traditional materials is the discrete size and direct action of the material. The elimination or reduction in secondary transduction networks, additional components, and, in some cases, even packaging and power connections allows minimizing the size of the active part of the material. A component or element composed of a smart material can be much smaller than a similar construction using traditional materials and also will require less infrastructural support. The resulting component can then be deployed in the most efficacious location. The smaller size coupled with the directness of the property change or energy exchange renders these materials particularly effective as sensors: they are less likely to interfere with the environment that they are measuring, and they are less likely to require calibration.

Relevant Properties and Behaviors

Architectural materials are generally deployed in very large quantities, and building systems tend to be highly integrated into the building to maintain homogeneous interior conditions. Materials and systems must also withstand very large ranges of transient exterior conditions. The combination of these two general requirements tends to result in buildings of high thermal and mechanical inertia. Therefore, even though the typical building uses

several different materials for many functions, there are only a few areas in which the characteristics of smart materials can be useful. The transient environmental conditions experienced by most buildings often results in oversizing systems to accommodate the full range of the exterior environmental swing. The swings may be instantaneous, as in the case of wind, diurnal, or seasonal. These conditions include those that affect both heat transfer and daylight transmission through the building envelope (also known as the building façade or exterior skin) as well as those that create dynamic loading on the building's structural support system. For the building envelope, the property-changing class of smart materials has the most potential application, whereas the energy-exchanging class is already finding application in building structural systems.

Buildings consume two-thirds of the electrical energy generated in the United States, and the majority of that electrical energy is used to support the building's ambient environmental systems, primarily lighting and HVAC (heating, ventilating, and air conditioning) systems. The intent of these systems is to effect a desired state in the interior. That state may be defined by a specified illuminance level or by an optimum temperature and relative humidity. Because conditions are generally maintained at a steady state, the primary need is for more efficacious control. Energy-exchanging materials have potential application as discrete sources, particularly for lighting delivery systems, and also as secondary energy supply sources. The most significant applications of smart materials in buildings, however, has been and will continue to be as sensors and actuators for the control systems of these ambient environmental systems.

Smart Material Mapping

The material properties and/or characteristics that are most relevant to architectural requirements are mapped in Table 2 against examples of smart material applications.

CATEGORIES OF APPLICATIONS

One of the major difficulties in incorporating smart materials into architectural design is the recognition that very few materials and systems are under single environmental influences. For example, the use of a smart material to control conductive heat transfer through the building envelope may adversely impact daylight transmission. Furthermore, because most systems in a building are highly integrated, it is difficult to optimize performance without impacting the other systems or disrupting control system balancing. As an example, many ambient lighting systems include plenum returns through the luminaires (lighting fixtures) that make it particularly difficult to decouple HVAC from lighting systems. The following discussion establishes four major categories of applications for smart materials and takes into account the material/behavior mapping described in Table 2 but also considers the complex systems that are affected. The four categories—glazing materials, lighting systems, energy systems, and

Table 2. Mapping of Smart Materials to Architectural Needs

Architectural Need	Relevant Material Characteristic	Smart Material Application
Control of solar radiation transmitting through the building envelope	Spectral absorptivity/transmission of envelope material	Electrochromics Photochromics Liquid crystal displays Suspended particle panels
	Relative position of envelope material	Louver control systems <ul style="list-style-type: none"> • exterior radiation sensors (photovoltaics) • interior daylight sensors (photoelectrics) • controls (shape-memory alloys)
Control of conductive heat transfer through the building envelope	Thermal conductivity of envelope material	Thermotropics Phase change materials
Control of interior heat generation	Heat capacity of interior material	Phase change materials
	Relative location of heat source	Fiber-optic systems Thermoelectrics Photoluminescents Light-emitting diodes
Secondary energy supply systems	Lumen/watt energy conversion ratio	Photovoltaics
Optimization of lighting systems	Conversion of ambient energy to electrical energy	
	Daylight sensing Illuminance measurements Occupancy sensing Relative location of source	Photovoltaics Photoelectrics Fiber optics Electroluminescents
Optimization of HVAC systems	Temperature sensing Humidity sensing Occupancy sensing CO ₂ and chemical detection Relative location of source and/or sink	Pyroelectrics Hygrometers Photoelectrics Biosensors Thermoelectrics Phase change materials
	Euler buckling Inertial damping	Piezoelectric Magnetorheological Electrorheological Shape-memory alloys Fiber optics
Control of structural vibration	Strain sensing	

monitoring/control systems—are also intended to be consistent with the more normative and identifiable classification systems of architecture.

Glazing Materials

Whether serving as windows or as glass curtain walls, glazing materials are extensively used on the building envelope. Originally incorporated and developed during the twentieth century for aesthetic reasons, the current use of glazing materials also considers the delivery of daylight into the building's interior. The majority of developments in high-performance glazing materials have focused on thermal characteristics—spectral selectivity to reduce radiant transmission to the interior or low emissivity to reduce radiant loss to the exterior. Glazing introduces the problematic condition in which, depending on the exterior environmental conditions, performance criteria that have been optimized for one set of conditions may be undesirable in a matter of hours or even moments later. The ideal glazing material would be switchable—managing the radiant transmission between exterior to interior to transmit solar radiation when the envelope is conducting heat out

(typical winter daytime condition) and reflect solar radiation when the envelope is conducting heat into the building (typical summer daytime condition). Photochromics, thermochromics and thermotropics have been proposed as switchable glazing materials, although only thermotropics are currently being developed commercially for this application. The basic operation of these materials is that either high incident solar radiation (photochromic) or high exterior temperature (thermochromic or thermotropic) produces a property change in the material that increases its opacity, thereby reducing radiant transmission to the interior. When incident solar radiation lessens or when the exterior temperature drops, the material reverts to a more transparent quality, allowing more solar radiation to transmit to the interior.

There are numerous circumstances, however, for which this type of switching is neither desirable nor useful. Direct solar radiation into the building can create overheated zones in particular locations, even in the dead of winter. Winter sun altitude is also much lower, thereby significantly increasing the potential for glare if solar radiation is not controlled. During the summer, reducing the radiant transmission may increase the need for

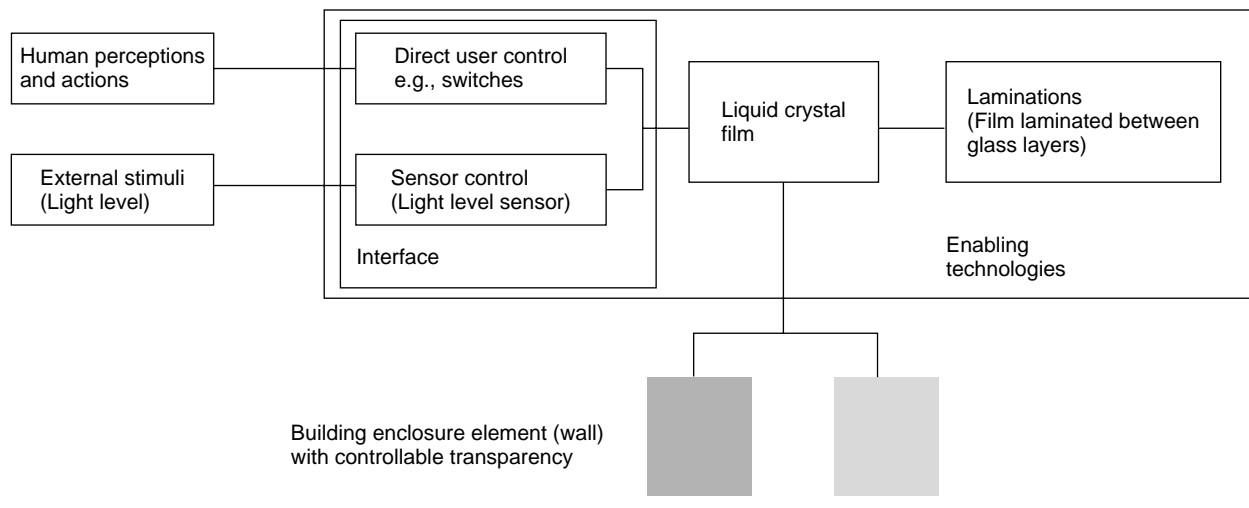

Figure 1. Typical current use of a smart material in architecture. Only a single behavior is controlled.

interior lighting systems and, because all electrically generated light has a lower lumen/watt ratio than daylight, might exacerbate the building's internal heat gains. As a result, the majority of efforts to develop smart glazing have focused on the electrically activated chromogenics—electrochromics, liquid crystal panels, and suspended particle panels (see Fig. 1). By using an electrical input to control transparency, these materials can be more easily incorporated into the control schemes for energy management systems and/or lighting control systems. The optimum balance among lighting needs, heating/cooling requirements, and occupant comfort can be determined, and the transparency can be adjusted to meet these demands in highly transient conditions.

Lighting Systems

Most high efficiency lighting systems—fluorescent, HID (high intensity discharge)—are relatively unsuitable for low-level lighting or task lighting. Furthermore, the typical ambient lighting system requires enormous infrastructure for support: electronic control systems, ballasts, integrated cooling, light diffusers/distributors (often part of the luminaire or lighting fixture). The efficiency and economics of these systems drop as the overall lighting requirements become smaller or more discrete. Ambient systems are also difficult to dim and to focus, so that very low-efficiency incandescent/halogen systems are still widely used for task or discrete lighting requirements. The low efficiency of the typical lighting system results in producing a substantial amount of heat and can be responsible for as much as 30% of a commercial building's cooling load. The development of fiber-optic lighting systems allows decoupling the delivered light from the primary energy conversion processes for generating light. This has the dual advantage of allowing light delivery to any location in a building, which is much more efficacious than using ambient lighting systems to deliver light, as well as removing the heat source from the occupied space. Current applications for fiber-optic systems

include many museums and retail display areas, where the removal of the heat source can profoundly improve the environmental conditions of the objects under display and the discrete nature of the light allows better highlighting and focusing.

Ambient lighting systems are generally designed to provide a standard illuminance level throughout a space at a specified height (usually three feet above the floor). The human eye, however, responds to the relative luminance contrast between surfaces in the field of vision. A lighting level of 100 footcandles may be too low for reading if the surrounding surfaces provide little contrast and may be too high if the surfaces provide high contrast. The division of light into smaller and more discrete sources allows optimizing contrast within the field of vision. Furthermore, the design of lighting for managing contrast enables using lower levels of lighting. Sources produced by the various luminescents—chemo, photo, electro—are starting to find application in architectural interiors, particularly as emergency lighting systems, because they have low and in some cases no input power requirements. LED (light-emitting diode) systems are also being developed as low energy lighting delivery systems. The latest developments in polymer LED technology have produced lighting fixtures that have precise color control. They provide excellent color rendition and also allow for color variation—features that are difficult to achieve in standard lighting systems.

Energy Systems

The majority of buildings in the United States are connected to a utility grid and as such have little need for primary energy conversion on-site. There are numerous circumstances, however, where secondary energy conversion can be quite useful, including back-up power generation, peak demand control, and discrete power for remote needs. For these situations, photovoltaic energy systems are increasingly becoming popular because they can be

readily deployed on roofs or integrated directly into the building envelope to take advantage of the incident solar radiation. Two other developments in smart materials hold greater promise for managing energy needs within a building. The large interior heat loads of most buildings coupled with a diurnal exterior temperature swing has encouraged investigation into thermal mass systems for maximum exploitation of a building's thermal inertia. Although theoretically sound, thermal mass systems have three major problems: (1) very slow response time, (2) the inability to switch off the phenomenon when it is not desirable, and (3) the large embodied energy required to provide the necessary mass of material. Phase change materials offer the advantages of thermal mass and very few of its disadvantages. The materials can be tuned to particular temperatures and can have very rapid responses. Much less mass is required, and therefore, the materials can be packaged and distributed throughout the building much more efficiently and strategically. By layering phase change materials and other smart materials, such as electrochromics or thermotropics, there may be a potential to add switching capability that allows activating or deactivating of the inertial behavior of the materials.

The removal of heat generated in a building is becoming an increasing concern as point loads from lighting, computers, and other electrical equipment escalate. Ambient HVAC systems do not distinguish between human-generated and equipment-generated cooling needs. The ability to manage and remove the heat generated by a point load without affecting the ambient environmental system could improve the operation of the ambient system and significantly reduce the energy requirements. Thermoelectrics are currently being explored for their potential to manage point loads discretely. Already serving as heat sinks in the majority of microprocessor cooling packages, thermoelectrics could be incorporated into integrated cooling for many other types of point sources. Although the devices are not practical for cooling air directly because of their low coefficient of performance (COP), they are ideal for managing the conjugate heat transfer that is characteristic of most nonhuman heat sources encountered in a building.

Monitoring and Control Systems

The increasing push to reduce the energy used by building HVAC systems has led to tighter buildings to reduce infiltration and to larger resets for the control equipment. This combination of an impermeable building envelope and more variable interior conditions has led to an increase in occupant complaints and indoor air quality problems. Many of the strategies intended to reduce energy can impact human health adversely, and much discussion of the appropriate compromise between the two requirements continues. One solution that holds promise is DCV, or "demand controlled ventilation." DCV adjusts interior ventilation depending on the presence of occupants; it reduces ventilation when no occupants are in a room or zone and increases ventilation as more occupants enter. Because the

human need for fresh air is linked to activity, simple occupancy sensors are not enough. The level of carbon dioxide in a room has been proposed as a good surrogate for the amount of fresh air needed in a space, but many concerns have arisen in regard to other chemical contamination, such as finish material outgassing, that is not connected to occupancy. Chemical sensing for building monitoring has previously been too expensive to incorporate and too slow to be useful. New developments in smart sensors for environmental monitoring, particularly biosensors, hold great promise for optimizing the controls of ambient HVAC systems.

The need to control various kinds of motions and, in particular, vibrations in a structure appears in many forms. At the level of the whole building structure, excitations resulting from seismic or wind forces can result in damage to both primary structural systems and nonstructural elements. User discomfort can also result. Many pieces of delicate equipment in buildings also need to be protected from external vibrations by using similar strategies. Alternatively, many pieces of equipment used in buildings can produce unwanted vibrations that can propagate through buildings. In response to these needs, methods of mitigating structural damage have been proposed that seek to control overall structural responses via controllable smart damping mechanisms used throughout a structure. Several smart base isolation systems for mitigating structural damage in buildings exposed to seismic excitations have also been proposed. These dampers are based on various electro- or magnetorheological fluids or piezoelectric phenomena. Piezoelectric sensors and actuators, for example, have been tested for use in vibrational control of steel frame structures for semiconductor manufacturing facilities.

Active control can be used to modify the behavior of specific structural elements by stiffening or strengthening them. Structures can adaptively modify their stiffness properties, so that they are either stiff or flexible as needed. In one project, microstrain sensors coupled with piezoceramic actuators were used to control linear buckling, thereby increasing the buckling load of the column several-fold.

Several new technologies provide capabilities for damage detection in structures. Various kinds of optical-fiber sensors have been developed for monitoring damage in materials as diverse as concrete and fiber-reinforced plastic composite laminate structures. Optical fibers are usually embedded in the material. Strain levels can be measured via wavelength shifts and other techniques. Crack development in structures made of concrete, for example, has been monitored via optical-fiber sensors, and special distributed systems have been developed for use in the structural health monitoring of high-performance yachts. Distributed fiber-optic systems have also been proposed for leak detection in site applications involving infrastructure systems. Other site-related structural applications include using optical-fiber sensors for ground strain measurement in seismically active areas. Other applications where smart materials serve as sensors include the use of embedded temperature sensors in carbon-fiber structures.

FUTURE DESIGN APPROACHES IN ARCHITECTURE

The previous sections have outlined and discussed smart materials in conjunction with needs currently defined in architecture. In some cases, smart materials have been proposed as replacements for conventional materials, and in other cases, smart materials have been proposed for improving the functionality of standard building systems. All of these developments can be positioned into the third category titled “Smart materials” in Table 1. The impact of incorporating these materials into standard architectural practice will be significant, particularly in regard to energy use and building performance, but far more interesting potentials derive from reconsidering smart materials as fundamental conceptual elements in design rather than only as improvements to existing elements.

As architectural design has always traditionally involved integrated systems and materials—the building envelope construction depends on the building’s structural system, the building’s HVAC system depends on the envelope construction—then the greatest potential may come from using smart materials to *dis-integrate* certain components, behaviors, or environments within the building. A smart component would be one that functions intelligently without infrastructural support and also will not disrupt the performance of surrounding systems. An example of a smart component might be a luminaire that can sense relative luminances within a visual field and self-adjust its focus, dimming capacity, and position.

Several different smart materials would be involved in the development of this component, including sensors and actuators, electroluminescents or LEDS, and perhaps even shape-memory alloys. A smart assembly would operate at the next level of functionality beyond the smart component. There are many “high-tech” assemblies currently used in architecture. These assemblies integrate several types of components and technologies to achieve multiple functions. For example, many of the most advanced envelope systems incorporate mechanical shading systems, thermal and ventilation control systems, and multiple layers of glass into a highly integrated assembly intended to preserve view without incurring energy penalties. A smart assembly would be designed to manifest the same behaviors, but do so in the most strategic manner (see Fig. 2). Shading could be accomplished at the micron or molecular level by using smart materials, and thermal control could take place discretely and transiently by selective placement of phase change materials and thermoelectrics. The smart assembly would maximize functionality and minimize the number of components.

Many development activities have been focused on proposals for “smart rooms” (see Fig. 3). Most of these proposals accept the building as a traditional structure and seek to insert certain technologies into a room to add increased functionality. Ubiquitous computing, teleconferencing, smart boards, voice and gesture recognition systems, and wireless communication systems are among the many smart technologies being developed for incorporation

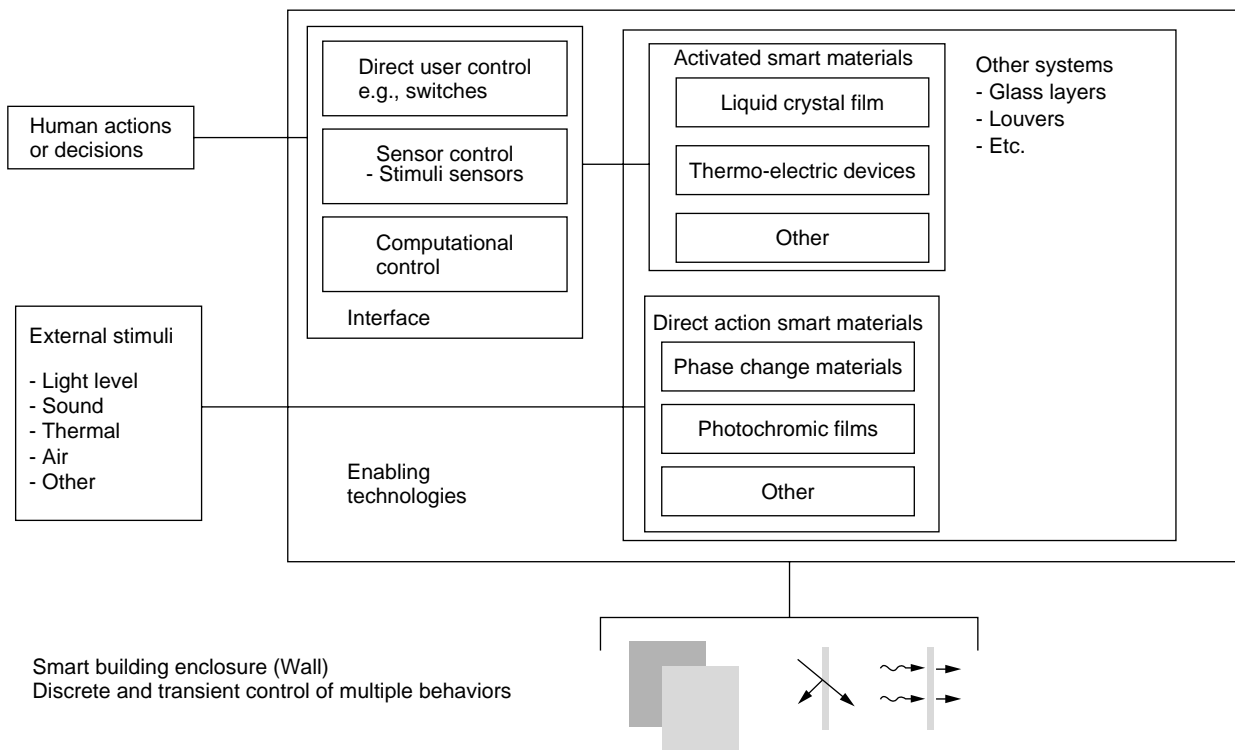

Figure 2. Control of multiple behaviors via smart building assemblies.

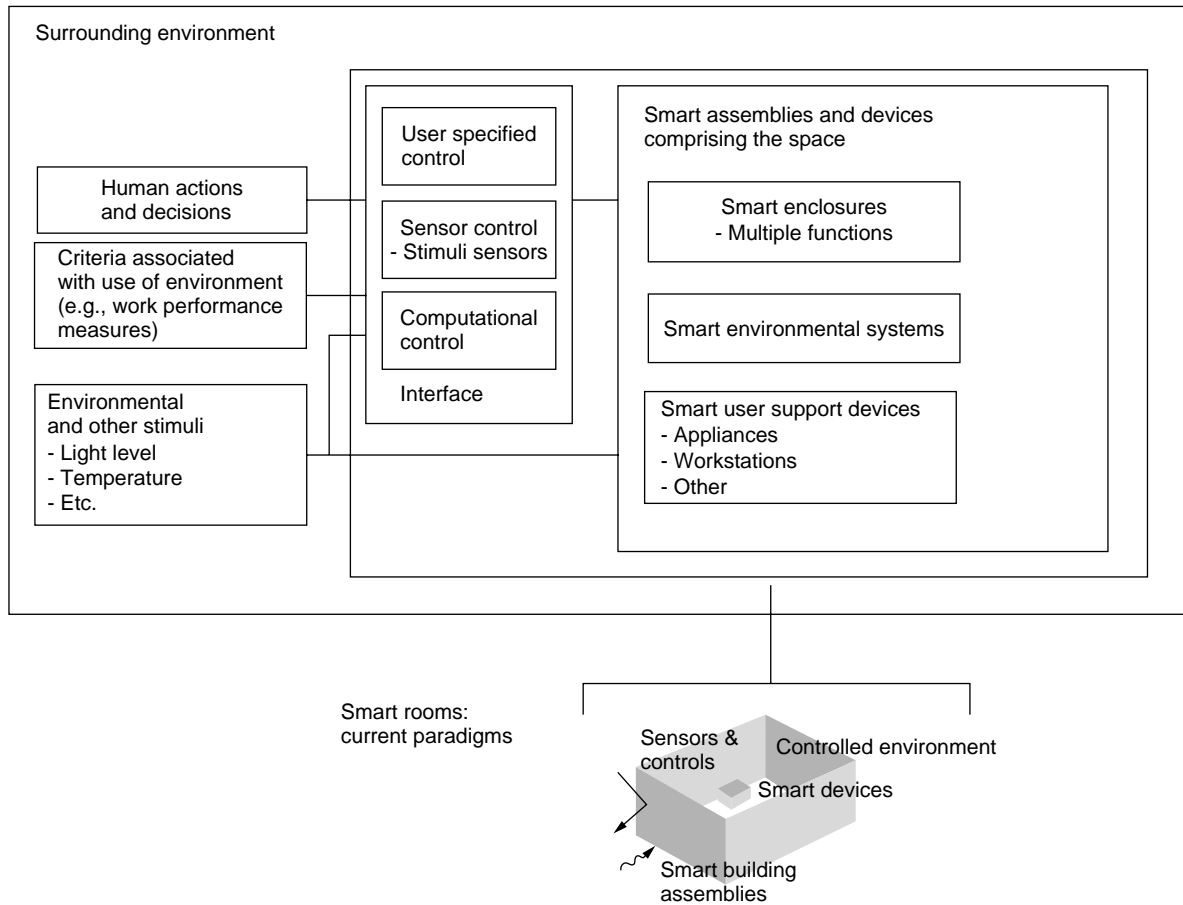

Figure 3. Smart rooms: In the current paradigm of a smart room, new smart devices are added to increase functionalities. The controlling interface is visibly and operationally present.

Figure 4. Smart rooms—future paradigms: The interface will disappear to the user.

into buildings. A more interesting and provocative question might be, “What would a room or building of the future be like if we could exploit smart materials and technologies to redesign the environment?” Smarter structures and construction materials might allow significant reductions in the size of the static building components—buildings could become thinner, lighter, and more flexible. The energy intensive ambient systems in buildings could be reduced or even eliminated if we allowed full interactivity between the occupant and the environmental behavior (see Fig. 4). Ambient lighting systems could be replaced by discrete sources that respond to the viewer. HVAC systems could be minimized if only the zone around an occupant were conditioned. Fundamentally, actions could be discrete and direct—the minimum necessary at the point and time for maximum effect.

BATTERY APPLICATIONS

ARUMUGAM MANTHIRAM
The University of Texas at Austin
Austin, TX

INTRODUCTION

Batteries are the major power sources for portable electronic devices and toys. They are also used in automobiles for starting, lighting, and ignition (SLI batteries). At present, the worldwide battery market exceeds \$30 billion per year. Rapid technological advances and miniaturization in electronics have created an ever-increasing demand for compact, lightweight batteries. For example, popular portable electronic devices such as cellular phones, laptop computers, and camcorders require batteries of high energy density. Additionally, a need for more efficient use of available energy resources as well as air-quality control have created enormous interest in electric vehicles. For example, the major automobile manufacturers around the globe are engaged in developing advanced batteries for electric vehicles in response to increased environmental regulations and legislative mandates. The advanced and high energy density batteries have become possible due to the discovery and development of smart materials and processes. This article, after providing a brief introduction to the basic electrochemical concepts and the principles involved in batteries, presents the materials and electrochemical aspects of high energy density (lithium-ion) batteries.

ELECTROCHEMICAL CONCEPTS

A battery is an electrochemical cell that converts the chemical energy of a reaction directly into electrical energy. This section covers briefly the fundamental principles of electrochemical cells. For more detailed information, readers are referred to several excellent texts available in the literature (1–4).

Electrochemical Cells

Figure 1 shows a schematic of an electrochemical cell that consists of three components: an anode or negative electrode, a cathode or positive electrode, and an electrolyte or ionic conductor. During the electrochemical reaction, the anode M is oxidized and it gives up electrons to the external circuit:

and the cathode X accepts the electrons from the external circuit and is reduced:

The electrolyte, on the other hand, acts as a medium for charge transfer between the anode and cathode as ions inside the cell. The overall cell reaction is given by adding the two half-cell reactions (1) and (2):

The amount of electricity that passes through an electrochemical cell is related by the Faraday law to the masses of reactants involved and products formed. If a current of I amperes flows in the circuit for a time of t seconds, then the amount of charge Q transferred across any interface in the cell is equal to It coulombs. Now, in accordance with the Faraday law, the number of moles N_m of the reactants M or X [see Eqs. (1) and (2)] consumed by the passage of It coulombs is given by

$$N_m = \frac{It}{nN_{Ae}}, \quad (4)$$

where n , N_A , and e are, respectively, the number of electrons given up or accepted by each M or X, Avogadro's number, and the charge on an electron. The product N_{Ae} is called the Faraday constant F , which is equal to $96,487 \text{ C mol}^{-1}$, and Eq. (4) can be reduced to

$$N_m = \frac{It}{nF}. \quad (5)$$

Consequently, the theoretical capacity Q of the electrode is given by

$$Q = It = nFN_m. \quad (6)$$

One gram-equivalent weight of an electrode, for example, theoretically has a capacity of $96,487 \text{ C}$ or 26.8 Ah . Gram-equivalent weight is defined as the atomic or molecular weight in grams divided by the number of electrons n involved in the reaction.

Thermodynamics of Electrochemical Cells

The driving force for an electrochemical cell to deliver electrical energy to an external circuit is the decrease in the standard free energy ΔG° of the cell reaction [Eq. (3)]. The free energy ΔG° is related to the standard cell potential E° by

$$\Delta G^\circ = -nFE^\circ, \quad (7)$$

where n and F are, respectively, the number of electrons involved in the reaction and the Faraday constant. The cell potential E° is the difference between the electrode potentials of the cathode and anode. The values of E° for various electrochemical couples are given in terms of standard reduction/oxidation potentials in textbooks and handbooks

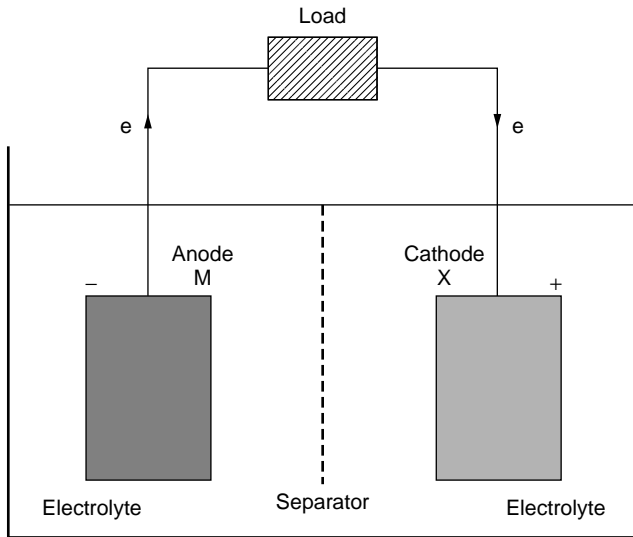

Figure 1. Schematic of an electrochemical cell.

(5,6). A positive value of E° means that the cell reaction occurs spontaneously. The standard potential E° is the equilibrium potential when all of the cell components are in their standard states. For example, the solution species have unit molar activities, the gases have pressures of 1 atmosphere, and the solid phases are in their most stable form in their standard states. For conditions other than the standard state, the cell potential E is given by the Nernst equation,

$$E = E^\circ - \frac{RT}{nF} \ln \frac{a_{M^{n+}} a_{X^{n-}}}{a_M a_X}, \quad (8)$$

where R is the gas constant, T is the absolute temperature, and $a_{M^{n+}}$, $a_{X^{n-}}$, a_M , and a_X are the activities of the products and reactants involved in cell reaction (3). At room temperature $T = 298$ K, the Nernst equation can be simplified to

$$E = E^\circ - \frac{0.0591}{n} \log \frac{a_{M^{n+}} a_{X^{n-}}}{a_M a_X}. \quad (9)$$

The cell potential also depends on the temperature and pressure. The dependences are related to the thermodynamic quantities by

$$\left(\frac{\partial E}{\partial T} \right)_P = \frac{\Delta S}{nF} \quad (10)$$

and

$$\left(\frac{\partial E}{\partial P} \right)_T = -\frac{\Delta V}{nF}, \quad (11)$$

where ΔS is the entropy change and ΔV is the volume change. Thus, the measurement of the cell potential can be used to determine thermodynamic quantities such as ΔG , ΔS , enthalpy change ΔH , and equilibrium constants.

Polarization Losses in Electrochemical Cells

The amount of electrical energy that an electrochemical cell can deliver is related to the free energy change of the cell reaction [Eq. (7)]. However, when a current I is passed through the cell, part of the energy is lost as waste heat due to polarization losses in the cell. The polarization loss can be classified into three types: activation polarization, concentration polarization, and ohmic polarization. Activation polarization is related to the kinetics of electrode reactions. Concentration polarization is related to the concentration differences of the reactants and products at the electrode surfaces and in the bulk as a result of mass transfer. Ohmic polarization, usually referred to as internal IR drop, is related to the internal impedance of the cell, which is a sum of the ionic resistance of the electrolyte and the electronic resistance of the electrodes.

The different polarization losses are indicated schematically in Fig. 2 as a function of operating current (2). The operating (measured) cell voltage E_{op} is given by

$$E_{op} = E_{oc} - \eta, \quad (12)$$

where E_{oc} is the open-circuit voltage and η is the overvoltage from polarization. The overvoltage η is a measure of the deviation of the cell voltage E_{op} from the equilibrium open-circuit voltage E_{oc} . The overvoltage η from the three different polarizations is given by

$$\eta = \eta_a + \eta_c + IR_i, \quad (13)$$

where η_a is the activation polarization at the anode and cathode, η_c is the concentration polarization at the anode and cathode, I is the load or operating current, and R_i is the internal resistance of the cell. The degree of polarization increases and the measured cell voltage E_{op} decreases as current increases. Therefore, the cell will operate close to the open-circuit voltage E_{oc} and deliver most of the expected energy only at very low operating currents. Obviously, the

Figure 2. Variation of cell voltage with operating current illustrating polarization losses: (a) ohmic polarization, (b) activation polarization, and (c) concentration polarization.

intrinsic properties of the electrodes and electrolytes as well as the engineering design of the cell will influence the polarization losses and hence the performance and efficiency of electrochemical cells.

BATTERIES

Performance Parameters

As mentioned in the previous section, a battery is an electrochemical device that converts stored chemical energy directly into electrical energy. The performance characteristics of a battery are assessed in terms of several parameters discussed later (1–3). The cell voltage E_{op} is the difference between the electrode potentials of the cathode E_c and anode E_a :

$$E_{op} = E_c - E_a. \quad (14)$$

Although the theoretical capacity Q of a cell or half-cell is given by Eq. (6), it is often convenient to calculate the specific capacity Q_{sp} for purposes of comparison. The specific capacity Q_{sp} is obtained by dividing the capacity Q of the cell or half-cell by the mass m or volume V of the cell or half-cell and is usually expressed in terms of Ah/kg or Ah/L:

$$Q_{sp} = \frac{Q}{m}, \quad (15)$$

or

$$Q_{sp} = \frac{Q}{V}. \quad (16)$$

The available energy ε of a cell is given by the product of the cell capacity Q and the average operating voltage E_{op} and again is usually given in terms of either gravimetric energy density (specific energy ε_{sp}) in Wh/kg or volumetric energy density in Wh/L:

$$\varepsilon_{sp} = Q_{sp} E_{op}. \quad (17)$$

The power P delivered by the cell is given by the product of the current I flowing and the associated cell voltage E_{op} and is generally given in terms of gravimetric power density (specific power P_{sp}) in W/kg or volumetric power density in W/L:

$$P_{sp} = I_{sp} E_{op} \quad (18)$$

where I_{sp} is the current density (current per unit weight or volume).

The discharge characteristic of a battery is another important parameter, which is given in terms of a plot of cell voltage versus capacity. The discharge profile and the final capacity obtainable depend on the current density I_{sp} used. Figure 3 compares the discharge profiles for various current densities. A useful way of defining the influence of current density on discharge curves is in terms of C

Figure 3. Discharge profiles at various C rates that illustrate the influence of current density.

rates:

$$C = \frac{I_d}{Q_n}, \quad (19)$$

where I_d and Q_n are, respectively, discharge current and nominal capacity. For example, a C rate of τ implies that the nominal capacity of the cell is delivered in $1/\tau$ hours under the specified current density. In an ideal battery, the discharge voltage drops sharply to zero when the chemical reaction reaches completion and the stored energy is fully consumed (Fig. 3). The discharge curves deviate from the ideal curve as the discharge rate (or current density) increases due to the polarization losses discussed in the previous section.

Coulometric and energy efficiencies and cycle life of secondary (rechargeable) batteries are some additional important parameters. Coulometric efficiency q_c is defined as

$$q_c = \frac{Q_d}{Q_c}, \quad (20)$$

where Q_d and Q_c are, respectively, the discharge and charge capacities. The reciprocal of the coulometric efficiency is the charging factor f :

$$f = \frac{1}{q_c}. \quad (21)$$

Energy efficiency q_E is defined as

$$q_E = q_c \frac{E_d}{E_c}, \quad (22)$$

where E_d and E_c are, respectively, the average discharge and charge voltages. A $q_C < 1$ implies the occurrence of unwanted side reactions that produce heat during the charging process. Intrinsic cell materials characteristics, cell engineering, and cell operating conditions such as current density and temperature can all influence q_C . A $q_E < q_C$ implies a deviation of the discharge and charge curves

Figure 4. Schematic energy diagram of a cell that has an open circuit.

from the open-circuit voltage profile. Again, polarization losses arising from materials characteristics, cell engineering, and operating conditions can influence q_E .

The cycle life of a battery is the number of times it can be charged and discharged repeatedly before the cell capacity falls below a limiting value. Generally, the limiting value is set around 70 to 80% of the nominal capacity. The cycle life depends on the reversible characteristics (structural and chemical stability) of the electrode materials, cell engineering, and operating conditions such as temperature, current density, and depth of discharge.

Design Considerations

The equilibrium cell voltage E_{oc} and the capacity Q of a battery are determined by the intrinsic properties of the electrode materials. The cell voltage can be maximized by choosing anode materials that have a smaller work function ϕ_a and cathode materials that have a larger work function ϕ_c . In other words, the anode should be a good reducing agent that has a large negative reduction potential, and the cathode should be a good oxidizing agent that has a large positive reduction potential. A schematic energy diagram of an open circuit is shown in Fig. 4. The open-circuit voltage E_{oc} of the cell is given by

$$E_{oc} = \frac{\phi_c - \phi_a}{e} \quad (23)$$

or by the difference between the electrode potentials of the cathode and anode [Eq. (14)]. Thermodynamic stability considerations also require that the Fermi energies E_F of the cathode and anode lie within the band gap E_g of the electrolyte, as shown in Fig. 4, so that no unwanted reduction or oxidation of the electrolyte occurs. This implies a limitation of

$$\phi_c - \phi_a < E_g. \quad (24)$$

Alkali and alkaline-earth metals that have a smaller ϕ_a or a larger negative reduction potential are attractive anodes, and higher valent transition-metal compounds that have a larger ϕ_c or larger positive reduction potentials are attractive cathodes to maximize the cell voltage. The cell capacity, on the other hand, is determined by the atomic or molecular weight of the elements or compounds used as electrodes and the degree of reaction (number of electrons involved) per mole of the electrode material [Eq. (6)]. Lightweight elements such as hydrogen, lithium, or oxygen and low molecular weight compounds are preferred as electrodes to maximize cell capacity.

In addition to high cell voltage and capacity, several other criteria are important in designing a battery to achieve high efficiency and minimal energy loss. The electrolyte should have good ionic conductivity, but should be an electronic insulator to avoid internal short-circuiting. High ionic conductivity in the electrolyte is essential to minimize the IR drop or ohmic polarization. Using a given electrolyte, the IR drop due to electrolyte resistance can be reduced, and the rate capability can be improved by a higher electrode interfacial area and thin separators. The electrode should have a high electronic conductivity and diffusion rate for the ions to minimize the IR drop. The electronic conductivity of the electrodes can be improved by adding electrically conducting additives such as carbon. The electrode reaction rates at the cathode and anode should be high enough to minimize activation polarization. This is commonly achieved by using a porous electrode design, which can reduce the local current density by providing high surface area. Adequate flow or passage of electrolytes is essential to facilitate mass transfer and minimize concentration polarization. Electrode porosity and pore size, optimum separator thickness and structure, and concentration of the reactants in the electrolytes are important factors in minimizing concentration polarization. In addition to these points, the electrolyte should have

good chemical stability and should not undergo any direct reaction with the electrodes. In rechargeable batteries, chemical reversibility on the electrodes is crucial to maintaining good capacity retention. Raw materials and fabrication costs, cell safety, and environmental factors are additional considerations.

Types of Batteries

Batteries can be classified into two types: primary (non-rechargeable) and secondary (rechargeable) batteries. Electrode materials undergo irreversible chemical reactions in primary batteries, but they exhibit reversible chemical reactions in secondary batteries. Some major primary and secondary battery systems are given in Tables 1 and 2 (2). The tables give the cell reactions, voltage, and capacity for each system. Most of the primary and secondary systems are based on aqueous electrolytes; the lithium-based primary systems in Table 1 and the lithium-ion system in Table 2 are based on nonaqueous electrolytes. The aqueous systems are limited in cell voltage (≤ 2.1 V) due to a smaller separation E_g between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) of water (Fig. 4) and the consequent vulnerability of water to reduction/oxidation reactions at higher cell voltages. The use of nonaqueous electrolytes that have a larger E_g , on the other hand, permits higher cell voltages in lithium-based systems.

SMART BATTERIES

The discovery of smart materials and the development of new processes have revolutionized the electronics industry over the years. The continued reduction in the sizes and weights of popular portable electronic devices such as cellular phones and laptop computers has driven the parallel, development of smart batteries to power them. In this regard, lithium-ion batteries have become appealing because they offer higher energy density (volumetric and gravimetric) compared to other rechargeable systems (Fig. 5) such as lead-acid, nickel–cadmium, and nickel–metal hydride batteries (7). Lithium-ion batteries are smaller and lighter compared to other systems. Lithium-ion batteries have become a commercial reality since Sony Corporation introduced them in 1990 as a result of the discovery of new materials over the years. The history, principles, current status, and future challenges of lithium-ion technology are briefly discussed in the following sections.

For more detailed information, the readers are referred to several references in the literature (1–3, 8–13).

Lithium-Ion Batteries

Maximizing the energy density of a battery requires using electrode materials that offer both high capacity and high cell voltage E_{oc} . High cell voltage can be achieved by using an anode material that has a smaller work function ϕ_a and a cathode material that has a larger work function ϕ_c , as shown in [Eq. (23)]. Lithium metal—the lightest solid in the periodic table—has a high specific capacity and a high standard oxidation potential (small ϕ_a) and is an attractive anode for achieving high energy density. Because of this objective, batteries that consist of metallic lithium as an anode and a lithium insertion compound $Li_xM_yX_z$ (M = transition metal and X = nonmetal) as a cathode became appealing during the 1970s; a lithium insertion compound is a host matrix into/from which the guest species Li^+ can be reversibly inserted/extracted. This concept of a secondary lithium battery was initially demonstrated using a layered metal sulfide TiS_2 as the cathode and a nonaqueous electrolyte consisting of a lithium salt such as $LiClO_4$ dissolved in an organic solvent such as propylene carbonate. In this cell, the Li^+ ions produced at the anode by oxidation of the metallic lithium during discharge migrate through the electrolyte and are inserted into the van der Waals gap between the sulfide layers of TiS_2 , and the electrons flow through the external circuit from the anode to the cathode to give Li_xTiS_2 . During the charging process, the Li^+ ions are extracted from Li_xTiS_2 and the electrons

Figure 5. Comparison of the gravimetric and volumetric energy densities of various rechargeable battery systems.

Figure 6. Schematic of the charging/discharging process in a lithium-ion cell.

flow from the cathode to the anode through the external circuit.

In this cell, however, the chemical reactivity of metallic lithium with the nonaqueous electrolyte results in forming a passivating film on the anode. Although the passivating film prevents further corrosion, it leads to nonuniform plating of lithium during charging, which results in total cell failure due to dendritic short-circuiting and also in serious safety problems due to local overheating. These difficulties of the metallic lithium anode forced the use of lithium insertion compounds as both anodes and cathodes. These cells are called lithium-ion cells or rocking-chair cells because the lithium ion shuttles or rocks between the cathode and anode hosts during the charging/discharging process (Fig. 6). This strategy, however, requires careful selection of cathode and anode pairs to maintain high cell voltage (>3 V) and to minimize the added weight of the insertion compound anode.

Although the concept of secondary lithium batteries was initially demonstrated by using a sulfide cathode, it was recognized during the 1980s that it is difficult to achieve high cell voltage using sulfide cathodes because an overlap of the higher valent M^{n+} :d energies and the top of the S:3p energy and the formation of S_2^{2-} ions lead to an inaccessibility of higher oxidation states for M^{n+} in a sulfide $Li_xM_yS_z$; the stabilization of the higher oxidation state is essential to maximize the work function ϕ_c and thereby the cell voltage E_{oc} [Eq. (23)]. On the other hand, the location of O:2p energy much below the S:3p energy and a larger increase of the M^{n+} :d energies in an oxide compared to those in a sulfide, due to a larger Madelung energy, make the higher valent states accessible in oxides. Accordingly, transition-metal oxide hosts were pursued as cathodes during the 1980s (14–16).

Figure 7 compares the electrochemical potential ranges of some lithium insertion compounds versus metallic

Figure 7. Electrochemical potential ranges of some lithium insertion compounds with reference to metallic lithium.

lithium. Among them, $LiCoO_2$, $LiNiO_2$, and $LiMn_2O_4$ oxides that have a higher electrode potential of 4 V versus metallic lithium have become attractive cathodes for lithium-ion cells. Graphite and coke that have lower electrode potentials <1 V versus metallic lithium and are lightweight have become attractive anodes. In a lithium-ion cell made from, for example, a $LiCoO_2$ cathode and a carbon anode (Fig. 6), the lithium ions migrate from the $LiCoO_2$ cathode to the Li_xC_6 anode through the electrolyte, and the electrons flow through the external circuit from the cathode to the anode during the charging process. Exactly the reverse reaction occurs during the discharging process.

A lithium insertion compound should have several features to be a successful electrode (cathode or anode) in lithium-ion cells:

- The cathode should have a high lithium chemical potential ($\mu_{Li(c)}$), and the anode should have a low lithium chemical potential ($\mu_{Li(a)}$) to maximize the cell voltage:

$$E_{oc} = \frac{\mu_{Li(c)} - \mu_{Li(a)}}{F}. \quad (25)$$

The voltage is determined by the energies involved in both electron transfer and Li^+ transfer. The energy involved in electron transfer is related to the work functions of the cathode (ϕ_c) and anode (ϕ_a) as shown in Eq. (23), whereas that involved in Li^+ transfer is determined by the crystal structure and the coordination geometry of the site into/from which Li^+ ions are inserted/extracted (17). If we consider only electron transfer, then E_{oc} can be given by Eq. (23). This implies that the M^{n+} ion in the insertion compound $Li_xM_yO_z$ should have a high oxidation state to be used as a cathode and a low oxidation state to be used as an anode.

- The insertion compound $\text{Li}_x\text{M}_y\text{O}_z$ should allow insertion/extraction of a large amount of lithium x to maximize the cell capacity. This depends on the number of available lithium sites and the accessibility of multiple valences for M in the insertion host.
- The lithium insertion/extraction process should be reversible and have no or minimal changes in the host structure across the entire range x of lithium insertion/extraction to provide a good cycle life.
- The insertion compound $\text{Li}_x\text{M}_y\text{O}_z$ should have good electronic conductivity σ_e and Li^+ -ion conductivity σ_{Li} to minimize polarization losses during the discharging/charging process and thereby to support a high current and power densities.
- The insertion compound $\text{Li}_x\text{M}_y\text{O}_z$ should be chemically stable and should not react with the electrolyte across the entire range x of lithium insertion/extraction.
- The Fermi energies of the cathode and anode in the entire range x of lithium insertion/extraction should lie within the band gap of the electrolyte, as shown in Fig. 4, to prevent any unwanted oxidation or reduction of the electrolyte.
- The insertion compound $\text{Li}_x\text{M}_y\text{O}_z$ should be inexpensive, environmentally benign, and lightweight.

Figure 8. Crystal structure of layered LiCoO_2 .

Layered Cobalt Oxide Cathodes

LiCoO_2 has a layer structure in which the Li^+ and Co^{3+} ions occupy the alternate (111) planes of a rock salt structure, as shown in Fig. 8, to give a layer sequence of $-\text{O}-\text{Li}-\text{O}-\text{Co}-\text{O}-$ along the c axis. This structure has an oxygen stacking sequence of ABCABC along the c axis, and the Li^+ and Co^{3+} ions occupy the octahedral interstitial sites of the cubic close-packed oxygen array. Accordingly, it is designated as an O3 layer structure. The structure provides reversible extraction/insertion of lithium ions from/into the lithium planes. Two-dimensional motion of the Li^+ ions between the strongly bonded CoO_2 layers provides fast lithium-ion diffusion (high σ_{Li}), and the edge-shared CoO_6 octahedral arrangement that has a direct $\text{Co}-\text{Co}$ interaction provides good electronic conductivity σ_e necessary for a high rate. A large work function ϕ_c for the highly oxidized $\text{Co}^{3+/4+}$ couple provides a high cell voltage of around 4 V, and the discharge voltage does not change significantly as the degree of lithium extraction/insertion x in $\text{Li}_{1-x}\text{CoO}_2$ changes (Fig. 9). These features have made LiCoO_2 an attractive cathode, and most of the commercial lithium-ion cells are currently made from LiCoO_2 .

However, only 50 % of the theoretical capacity of LiCoO_2 that corresponds to a reversible extraction of 0.5 lithium per Co (practical capacity of 140 Ah/kg) can be practically used. The limitation in practical capacity has been attributed in the literature (18) to an ordering of Li^+ ions and consequent structural distortions around $x = 0.5$ in $\text{Li}_{1-x}\text{CoO}_2$. However, it has been shown more recently that the limited capacity could be due to the tendency of $\text{Li}_{1-x}\text{CoO}_2$ to lose oxygen (or react with the electrolyte) at

a deep charge when $(1-x) < 0.5$ (19). Figure 10 shows the variation of the oxidation state of cobalt and the oxygen content as the lithium content $(1-x)$ varies. The data in Figure 10 were obtained by chemically extracting lithium from LiCoO_2 using the oxidizing agent NO_2PF_6 in a non-aqueous (acetonitrile) medium and determining the oxidation state of cobalt by a redox (iodometric) titration. Constancy of the cobalt oxidation state and an oxygen content significantly less than 2 at low lithium contents demonstrate the chemical instability of $\text{Li}_{1-x}\text{CoO}_2$ cathodes at a deep charge when $(1-x) < 0.5$. The tendency of $\text{Li}_{1-x}\text{CoO}_2$ to lose oxygen at a deep charge is consistent with the recent X-ray absorption spectroscopic (20) and electron energy loss spectroscopic (21) data. The spectroscopic data indicate that the holes (removal of electrons) are introduced

Figure 9. Typical discharge curves of layered LiCoO_2 (—), layered $\text{LiNi}_{0.85}\text{Co}_{0.15}\text{O}_2$ (···), and spinel LiMn_2O_4 (---).

Figure 10. Variations of the oxidation state of the transition-metal ions and oxygen content as lithium content varies in $\text{Li}_{1-x}\text{CoO}_{2-\delta}$ and $\text{Li}_{1-x}\text{Ni}_{0.85}\text{Co}_{0.15}\text{O}_{2-\delta}$.

into the O:2p band rather than the Co:3d band during the electrochemical extraction of lithium. Introduction of a significant amount of holes into the O:2p band will lead to evolution of oxygen from the lattice. However, note that neutral oxygen in the presence of electrolytes in lithium-ion cells may not be evolved under conditions of overcharge when $(1-x) < 0.5$. Instead, the cathode may react with the electrolyte due to the highly oxidized nature of the deeply charged $\text{Li}_{1-x}\text{CoO}_2$ cathode.

Figure 11 shows the X-ray diffraction patterns of the $\text{Li}_{1-x}\text{CoO}_2$ samples that were obtained by chemically extracting lithium from $\text{Li}_{1-x}\text{CoO}_2$. The samples maintain the initial O3 layer structure (CdCl₂ structure) for $0.35 \leq (1-x) \leq 1$. For lithium contents $(1-x) < 0.35$, a second phase begins to form as indicated by the appearance of a shoulder on the right-hand side of the (003) reflection centered around $2\theta = 20^\circ$. The intensity of the new reflection increases as the lithium content decreases further, and the end member $\text{CoO}_{2-\delta}$ consists of reflections corresponding only to the new phase. The X-ray diffraction pattern of the new phase could be indexed on the basis of a two-phase mixture consisting of a major P3 phase and a minor O1 (CdI₂ structure) phase. The P3 and O1 phases have oxygen stacking sequences of ABBCCA and ABABAB, respectively. The Li⁺ ions occupy prismatic (trigonal prism) and octahedral sites, respectively, in the P3 and O1 structures. The formation of the P3 and O1 phases from the initial O3 structure is due to sliding of the oxide ions, as shown in Fig. 12. The driving force for the sliding appears to be structural instability caused by the formation of oxygen vacancies at low lithium contents (Fig. 10). The observed transformation of the O3 phase at low lithium content is consistent with that found in electrochemically

prepared samples (22). The tendency to lose oxygen and the associated structural transitions limit the practical capacity of LiCoO_2 cathodes.

Layered Nickel Oxide Cathodes

LiNiO_2 has an O3 layer structure (Fig. 8) like LiCoO_2 , and the $\text{Ni}^{3+/4+}$ couple that has a larger ϕ_c provides a high cell voltage of around 4 V. However, LiNiO_2 suffers from a few drawbacks: (1) difficulty in synthesizing LiNiO_2 as a perfectly ordered phase without mixing Li⁺ and Ni³⁺ ions in the lithium plane (23,24), (2) Jahn–Teller distortion (tetragonal structural distortion) associated with a low spin $\text{Ni}^{3+}:d^7$ ion (25), (3) irreversible phase transitions during the charge/discharge process, and (4) safety concerns in the charged state. As a result, LiNiO_2 is not a promising material for commercial cells. However, some of these difficulties have been overcome by partially substituting cobalt for nickel. For example, the composition $\text{LiNi}_{0.85}\text{Co}_{0.15}\text{O}_2$, has been shown to exhibit attractive electrochemical properties (26). It has a reversible capacity of around 180 Ah/kg (Fig. 9) and excellent cyclability. This capacity is 30% higher than that of LiCoO_2 , and it corresponds to 65% of the theoretical capacity. The substitution of cobalt for nickel has been found to suppress the cation disorder and Jahn–Teller distortion, as indicated by X-ray absorption fine structure studies (25). The higher capacity of $\text{LiNi}_{0.85}\text{Co}_{0.15}\text{O}_2$ has made it an attractive alternate for LiCoO_2 .

However, the reason for the higher capacity of $\text{LiNi}_{0.85}\text{Co}_{0.15}\text{O}_2$ compared to the analogous LiCoO_2 cathodes was not clear in the literature. The structural stability of the $\text{LiNi}_{0.85}\text{Co}_{0.15}\text{O}_2$ cathodes during long-term cycling, particularly under mild heat, also remained to be assessed. Recent experiments on $\text{Li}_{1-x}\text{Ni}_{0.85}\text{Co}_{0.15}\text{O}_2$ samples obtained by chemically extracting lithium from $\text{LiNi}_{0.85}\text{Co}_{0.15}\text{O}_2$ show that the higher capacity of $\text{LiNi}_{0.85}\text{Co}_{0.15}\text{O}_2$ compared to that of LiCoO_2 is due to its resistance to losing oxygen at low lithium contents. Figure 10 compares the variations of the average oxidation state of the transition-metal ions and the oxygen contents as lithium content varies in $\text{Li}_{1-x}\text{Ni}_{0.85}\text{Co}_{0.15}\text{O}_2$ and $\text{Li}_{1-x}\text{CoO}_2$. The data show that the former system exhibits better stability without losing much oxygen at a deep charge. Figure 13 shows the X-ray diffraction patterns of the $\text{Li}_{1-x}\text{Ni}_{0.85}\text{Co}_{0.15}\text{O}_2$ samples that were obtained by chemically extracting lithium from $\text{LiNi}_{0.85}\text{Co}_{0.15}\text{O}_2$. In this case, the initial O3 structure is maintained for a wider lithium content $0.23 \leq (1-x) \leq 1$, and the new phase is formed at a lower lithium content $(1-x) < 0.23$. More importantly, the X-ray diffraction pattern of the end member $\text{NiO}_{2-\delta}$ could also be indexed on the basis of an O3 structure but had smaller lattice parameters compared to the initial O3 phase. The observation of an O3 structure for the chemically prepared $\text{NiO}_{2-\delta}$ agrees with that found for the electrochemically prepared sample (27,28). The absence of a significant amount of oxygen vacancies appears to prevent the sliding of oxide ion layers and the structural transformation. The absence of oxygen loss and the maintenance of the initial O3 structure to a much

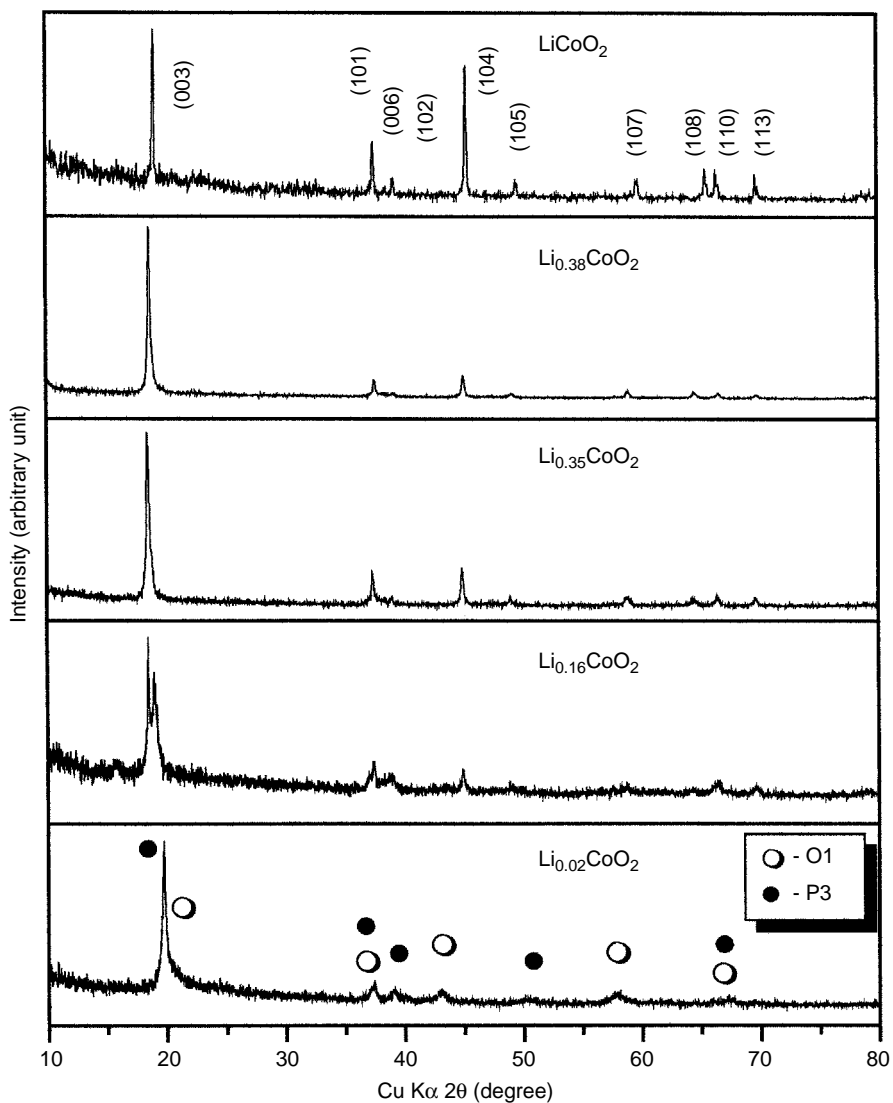

Figure 11. X-ray diffraction patterns of $\text{Li}_{1-x}\text{CoO}_{2-\delta}$ that were synthesized by chemical delithiation.

Figure 12. Schematic of the transformation of $\text{O3} \rightarrow \text{P3} \rightarrow \text{O1}$ structures by sliding of oxide layers.

Figure 13. X-ray diffraction patterns of $\text{Li}_{1-x}\text{Ni}_{0.85}\text{Co}_{0.15}\text{O}_{2-\delta}$ that were synthesized by chemical delithiation.

lower lithium content ($1 - x$) compared to that in $\text{Li}_{1-x}\text{CoO}_2$ permit a higher capacity in the $\text{Li}_{1-x}\text{Ni}_{0.85}\text{Co}_{0.15}\text{O}_2$ system.

The differences in oxygen loss behavior between the $\text{Li}_{1-x}\text{CoO}_2$ and the $\text{Li}_{1-x}\text{Ni}_{0.85}\text{Co}_{0.15}\text{O}_2$ systems can be understood by considering qualitative energy diagrams for $\text{Li}_{1-x}\text{CoO}_2$ and $\text{Li}_{1-x}\text{NiO}_2$ (Fig. 14). In LiCoO_2 that has a $\text{Co}^{3+}:3d^6$ configuration, the t_{2g} band is completely filled, and the e_g band is empty. As lithium is extracted from LiCoO_2 , the Co^{3+} ions are oxidized to Co^{4+} , which is accompanied by removal of electrons from the t_{2g} band. Because the t_{2g} band overlaps the top of the O:2p band, deeper lithium extraction where $(1 - x) < 0.5$ results in a removal of electrons from the O:2p band as well. The removal of a significant amount of electron density from the O:2p band will result in oxidation of the O^{2-} ions and an ultimate loss of oxygen from the lattice. In contrast, the LiNiO_2 system that has a $\text{Ni}^{3+}:3d^7$ configuration involves the removal of electrons only from the e_g band. For

$\text{LiNi}_{0.85}\text{Co}_{0.15}\text{O}_2$, the electrons will be removed from the e_g band for $(1 - x) > 0.15$. Because the e_g band lies well above the O:2p band, this system does not lose oxygen down to a lower lithium content. The band diagrams in Fig. 14 are consistent with the recent spectroscopic evidence for the introduction of holes into the O:2p band rather than into the Co:3d band in LiCoO_2 (20,21) and into the Ni:3d band in $\text{Li}_{1-x}\text{NiO}_2$ and $\text{Li}_{1-x}\text{Ni}_{0.85}\text{Co}_{0.15}\text{O}_2$ (29,30).

To assess the structural stability of $\text{Li}_{1-x}\text{Ni}_{0.85}\text{Co}_{0.15}\text{O}_2$ cathodes during long-term cycling, chemically prepared $\text{Li}_{1-x}\text{Ni}_{0.85}\text{Co}_{0.15}\text{O}_2$ samples were subjected to mild heat and examined by X-ray diffraction (31). The data show a decrease in the c/a ratio of the unit cell parameters of, for example, $\text{Li}_{0.35}\text{Ni}_{0.85}\text{Co}_{0.15}\text{O}_2$ when heated at $T > 50^\circ\text{C}$ due to migration of the Ni^{3+} ions from the nickel plane to the lithium plane. Interestingly, the cobalt oxide $\text{Li}_{0.35}\text{CoO}_2$ that has a similar degree of lithium extraction (charging) shows little or no decrease in the c/a ratio when heated under similar conditions. Thus, the $\text{Li}_{1-x}\text{Ni}_{0.85}\text{Co}_{0.15}\text{O}_2$

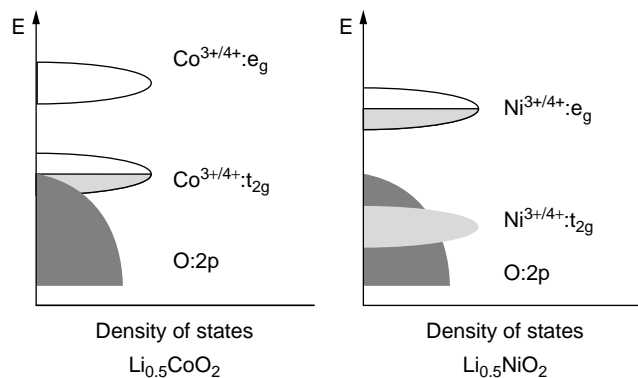

Figure 14. Comparison of the qualitative energy diagrams of $\text{Li}_{1-x}\text{CoO}_2$ and $\text{Li}_{1-x}\text{NiO}_2$.

cathodes experience structural instability under mild heat, whereas the $\text{Li}_{1-x}\text{CoO}_2$ cathodes do not under similar conditions. Although the $\text{LiNi}_{0.85}\text{Co}_{0.15}\text{O}_2$ cathode has higher capacity (180 Ah/kg) than the LiCoO_2 cathode (140 Ah/kg) and is more resistant to losing oxygen from the lattice compared to LiCoO_2 , the structural instability experienced due to cation migration may become an issue under cycling at higher temperatures ($T > 50^\circ\text{C}$). The differences in the structural stability between the two systems can be explained by considering the mechanism of cation migration. The migration of transition-metal ions from octahedral sites in the transition-metal plane to the octahedral sites in the lithium plane needs to occur via the neighboring empty tetrahedral sites, as shown in Fig. 15. While the low spin $\text{Co}^{3+}:3d^6$ ion that has strong octahedral site stabilization energy (32) is unable to migrate to the neighboring tetrahedral site, but the low spin $\text{Ni}^{3+}:3d^7$ ion that has moderate octahedral site stabilization energy is able to move to the tetrahedral site under mild heat.

Figure 15. Schematic representation of the diffusion processes of nickel ions in $\text{Li}_{1-x}\text{Ni}_{0.85}\text{Co}_{0.15}\text{O}_2$. Dotted and solid squares refer to tetrahedral site and lithium-ion vacancy, respectively. T_1 and T_2 refer to tetrahedral sites at $(0, 0, 0.125)$ and $(0, 0, 0.375)$, respectively.

Figure 16. Crystal structure of LiMn_2O_4 spinel.

Spinel Manganese Oxide Cathodes

Although LiCoO_2 and $\text{LiNi}_{0.85}\text{Co}_{0.15}\text{O}_2$ are attractive candidates, both Co and Ni are expensive and relatively toxic. These considerations have created much interest in manganese oxides because Mn is inexpensive and environmentally benign (33–35). In this regard, LiMn_2O_4 that crystallizes in a three-dimensional cubic spinel structure (Fig. 16) has become appealing (16). In the LiMn_2O_4 spinel, the Li^+ and the $\text{Mn}^{3+/4+}$ ions occupy, respectively, the 8a tetrahedral and 16d octahedral sites of the cubic close-packed oxygen array. A strong edge-shared octahedral $[\text{Mn}_2]\text{O}_4$ array permits reversible extraction of the Li^+ ions from the tetrahedral sites without collapsing the three-dimensional spinel framework. An additional lithium-ion can also be inserted into the empty 16c octahedral sites of the spinel framework to give the lithiated spinel $\text{Li}_2[\text{Mn}_2]\text{O}_4$. However, electrostatic repulsion between the Li^+ ions in the 8a tetrahedral and 16c octahedral sites, which share common faces, causes a displacement of the tetrahedral Li^+ ions into the neighboring empty 16c sites to give an ordered rock salt structure that has a cation distribution of $(\text{Li}_2)_{16c}[\text{Mn}_2]_{16d}\text{O}_4$. Thus, theoretically, two lithium ions per LiMn_2O_4 formula unit could be reversibly inserted/extracted. Although the edge-shared MnO_6 octahedral arrangement that has direct Mn–Mn interaction provides good electrical (small polaron) conductivity σ_e , the interconnected interstitial sites in the three-dimensional spinel framework provide good lithium-ion conductivity σ_{Li} .

The lithium extraction/insertion from/into the 8a tetrahedral and 16c octahedral sites of the $\text{Li}[\text{Mn}_2]\text{O}_4$ spinel occurs in two distinct steps (16). The former occurs at around 4 V (Fig. 9) maintaining the cubic spinel symmetry; in contrast, the latter occurs at around 3 V by a two-phase mechanism involving the cubic spinel $\text{Li}[\text{Mn}_2]\text{O}_4$ and the tetragonal lithiated spinel $\text{Li}_2[\text{Mn}_2]\text{O}_4$. Although both involve the $\text{Mn}^{3+/4+}$ couple, the 1 V difference between the two processes reflects the differences in the site energies (17) as differentiated by Eq. (23) and (25). A deep energy well for the 8a tetrahedral Li^+ ions and a high activation energy required for the Li^+ ions to move from one 8a tetrahedral site to another via an energetically unfavorable neighboring 16c site lead to a higher voltage of 4 V (33). The cubic to tetragonal transition from $\text{Li}[\text{Mn}_2]\text{O}_4$ to $\text{Li}_2[\text{Mn}_2]\text{O}_4$ is due

Figure 17. Illustration of the Jahn–Teller distortion in manganese oxides: (a) $\text{Mn}^{4+}:\text{3d}^3$ that has cubic symmetry (no Jahn–Teller distortion) and (b) $\text{Mn}^{3+}:\text{3d}^4$ that has tetragonal symmetry (Jahn–Teller distortion).

to the Jahn–Teller distortion of the single electron in the e_g orbitals of a high spin $\text{Mn}^{3+}:\text{3d}^4$ ion (Fig. 17). A cooperative distortion of the MnO_6 octahedra that have long Mn–O bonds along the c axis and short Mn–O bonds along the a and b axes results in macroscopic tetragonal symmetry for $\text{Li}_2[\text{Mn}_2]\text{O}_4$.

Although, in principle, two lithium ions per LiMn_2O_4 formula unit could be reversibly extracted/inserted from/into the $\text{Li}[\text{Mn}_2]\text{O}_4$ spinel framework, the cubic to tetragonal transition is accompanied by a 16% increase in the c/a ratio of the unit cell parameters and a 6.5% increase in unit cell volume. This change is too severe for the electrodes to maintain structural integrity during the discharge/charge cycle, and so LiMn_2O_4 exhibits drastic capacity fade in the 3 V region. As a result, LiMn_2O_4 has limited practical capacity of around 120 Ah/kg (Fig. 9) that corresponds to an extraction/insertion of 0.4 lithium per Mn in the 4 V region. Furthermore, even though it has limited capacity, LiMn_2O_4 tends to exhibit capacity fade in the 4 V region as well, particularly at elevated temperatures (50°C). The capacity fade in the 4 V region has been attributed to a dissolution of manganese into the electrolyte originating from a disproportionation of Mn^{3+} into Mn^{4+} and Mn^{2+} (36) and the formation of tetragonal $\text{Li}_2[\text{Mn}_2]\text{O}_4$ on the surface of the particles under conditions of nonequilibrium cycling (37).

The difficulties of lattice distortions in the LiMn_2O_4 spinel have motivated strategies to suppress Jahn–Teller distortion. One way to suppress Jahn–Teller distortion is to increase the average oxidation state of manganese because $\text{Mn}^{4+}:\text{3d}^3$ does not undergo Jahn–Teller distortion. The oxidation state of manganese can be increased either by aliovalent cationic substitutions or by increasing the oxygen content in LiMn_2O_4 . Using this strategy, Thackeray et al. (33,38,39) pioneered the Li–Mn–O phase diagram. For example, substituting Li for Mn in $\text{Li}_{1+x}\text{Mn}_2\text{O}_4$ increases the

oxidation state, and the end member $\text{Li}_4\text{Mn}_5\text{O}_{12}$ ($x = 0.33$) has an oxidation state of 4+ for Mn. Similarly, the oxidation state increases as oxygen content increases in $\text{LiMn}_2\text{O}_{4+\delta}$, and the end member $\text{Li}_2\text{Mn}_4\text{O}_9$ ($\delta = 0.5$) will have an oxidation state of 4+ for Mn. However, these defective spinels are difficult to synthesize by conventional high-temperature procedures, and more recently solution-based syntheses have been pursued to obtain them (40,41). It is also difficult to extract lithium from $\text{Li}_4\text{Mn}_5\text{O}_{12}$ and $\text{Li}_2\text{Mn}_4\text{O}_9$ because Mn^{4+} is difficult to oxidize further and therefore they are not suitable for lithium-ion cells that have carbon anodes. Both $\text{Li}_4\text{Mn}_5\text{O}_{12}$ and $\text{Li}_2\text{Mn}_4\text{O}_9$ exhibit most of their capacity in the 3 V region that corresponds to insertion of additional lithium into the 16c sites. Nevertheless, the Jahn–Teller distortion has been shown to be delayed until late in the discharge process in both systems (33,38,39); the cubic symmetry without Jahn–Teller distortion has been shown to be preserved to $x = 2.5$ in $\text{Li}_{4+x}\text{Mn}_5\text{O}_{12}$ and $x = 1.7$ in $\text{Li}_{2+x}\text{Mn}_4\text{O}_9$.

Other Oxide Cathodes

The difficulties of the LiMn_2O_4 spinel also motivated the investigation of several nonspinel manganese oxides, particularly by employing low-temperature synthesis (33–35). LiMnO_2 obtained by conventional synthesis does not crystallize in the $O3$ structure of LiCoO_2 ; it adopts an orthorhombic rock salt structure in which the oxygen array is distorted from the ideal cubic close packing (42). However, LiMnO_2 isostructural with layered LiCoO_2 can be obtained by ion exchange of NaMnO_2 (43) or by partial substitution of Mn by Cr or Al (44). Unfortunately, both the orthorhombic LiMnO_2 and the layered LiMnO_2 ($O3$ structure) that have close-packed oxygen arrays tend to transform to spinel-like phases during electrochemical cycling. In this regard, $\text{Na}_{0.5}\text{MnO}_2$ —designated as $\text{Na}_{0.44}\text{MnO}_2$ in the literature—adopts a non-close-packed structure and has drawn some attention because it does not transform to spinel-like phases (45,46). However, only a small amount of lithium could be extracted from the ion-exchanged sample $\text{Na}_{0.5-x}\text{Li}_x\text{MnO}_2$ although additional lithium could be inserted into $\text{Na}_{0.5-x}\text{Li}_x\text{MnO}_2$. Therefore, it is not attractive for lithium-ion cells that use carbon anodes. Nevertheless, it has been shown that it is a promising candidate for lithium polymer batteries that employ metallic lithium anodes (45). Additionally, it has been shown that amorphous manganese oxides $\text{Li}_x\text{Na}_y\text{MnO}_z\text{I}_7$ synthesized in nonaqueous media exhibit high capacity (300 Ah/kg) and good cyclability (47,48). However, the capacity occurs across the wide voltage range of 4.3 to 1.5 V that has a continuously sloping discharge profile, which is not desirable for commercial cells. Not much lithium could be extracted from the initial material $\text{Li}_x\text{Na}_y\text{MnO}_z\text{I}_7$, and therefore, these amorphous oxides also are not attractive for lithium-ion cells fabricated using carbon anodes.

To improve the cyclability of the LiMn_2O_4 spinel, partial substitution of Mn by several other transition metals $M = \text{Cr}, \text{Co}, \text{Ni}$ and Cu in $\text{LiMn}_{2-y}\text{M}_y\text{O}_4$ has been pursued (49–52). These substitutions, however, result in the development of two plateaus that correspond to the removal of lithium from the 8a tetrahedral sites: one around 4 V that

corresponds to the oxidation of Mn^{3+} to Mn^{4+} and the other around 5 V that corresponds to the oxidation of the other transition-metal ions. The capacity in the 4-V region decreases, whereas that in the 5-V region increases as y in $\text{LiMn}_{2-y}\text{M}_y\text{O}_4$ increases. Although an increase in the cell voltage is attractive from the view point of energy density, the $\text{LiMn}_{2-y}\text{M}_y\text{O}_4$ oxides are prone to suffer from oxygen loss and safety concerns in the 5-V region.

LiVO_2 adopts the *O3* structure of LiCoO_2 . Although lithium can be readily extracted from LiVO_2 , the vanadium ions migrate to the lithium planes for $(1-x) < 0.67$ in $\text{Li}_{1-x}\text{VO}_2$ (53). Similarly, the LiV_2O_4 spinel is plagued by the migration of vanadium ions during the charge/discharge process (54). Interestingly, a number of other vanadium oxides such as $\text{VO}_2(\text{B})$ —a metastable form of VO_2 obtained by solution-based synthesis (55)—and V_6O_{13} (56) exhibit high capacity and good cyclability. However, these oxides that have no lithium are not attractive for lithium-ion cells made using carbon anodes. LiCrO_2 also crystallizes in the *O3* structure of LiCoO_2 , but it is difficult to extract lithium from this material.

Iron oxides offer significant advantages in both cost and toxicity compared to other oxides. Although LiFeO_2 obtained by conventional procedures adopts a different structure, layered LiFeO_2 that has the *O3* structure of LiCoO_2 can be obtained by an ion-exchange reaction of NaFeO_2 . Unfortunately, the layered LiFeO_2 does not exhibit good electrochemical properties because the high spin $\text{Fe}^{3+}:\text{3d}^5$ ion tends to move around between the octahedral and tetrahedral sites. This problem could, however, be overcome by designing complex iron oxides that consist of poly ions such as $(\text{SO}_4)^{2-}$ and $(\text{PO}_4)^{3-}$. For example, it was shown in the 1980s that $\text{Fe}_2(\text{SO}_4)_3$ that has a framework structure that consists of FeO_6 octahedra which share all six corners with $(\text{SO}_4)^{2-}$ tetrahedra has a capacity of around 130 Ah/kg and a flat discharge voltage of 3.6 V (57). However, the poor electronic conductivity of the $\text{Fe}-\text{O}-\text{X}-\text{O}-\text{Fe}$ ($\text{X} = \text{S}$ or P) linkages leads to poor rate capability. Nevertheless, following this initial concept of using poly ions, LiFePO_4 that crystallizes in an olivine structure has recently been shown to be a promising material; it exhibits a flat discharge voltage of around 3.4 V (58). However, LiFePO_4 appears to suffer from limited rate capability due to inferior electronic (σ_e) and lithium-ion (σ_{Li}) conductivity compared to other oxide cathodes such as LiCoO_2 and LiMn_2O_4 .

Carbon Anodes

Carbon has become the material of choice for anodes in lithium-ion cells (59,60) due to its light weight and low electrochemical potential that lies close to that of metallic lithium (Fig. 7). Although the intercalation of alkali metals into graphitic carbon was known for some time, the recognition of a practical carbon anode began in 1989 (61). A subsequent announcement by Sony Corporation in 1990 commercializing lithium-ion cells that have carbon anodes and LiCoO_2 cathodes intensified the interest in carbon. Carbon materials can be broadly classified into two categories: soft carbon (graphitic carbon) and hard carbon (glassy carbon). The former has a better ordering of graphene layers compared to the latter, and they differ significantly in

Figure 18. Typical first discharge/charge curves of graphite. The difference between the discharge and charge curves is irreversible capacity loss.

their physical and chemical properties. The hard carbons are typically obtained by thermal decomposition of, for example, phenolic and epoxy resins and products from petroleum pitch. They have significant amounts of open micropores, which tend to become closed when heated at increasingly higher temperatures. Some hard carbons have been shown to consist of single graphene sheets.

Figure 18 shows a typical first discharge/charge curve of graphite. It has a theoretical capacity of 372 Ah/kg that corresponds to an insertion of one lithium per six carbon atoms ($x = 1$ in Li_xC_6). It shows a significant amount of irreversible capacity during the first discharge/charge cycle due to unwanted, irreversible side reactions with the electrolyte. These side reactions can lead to disintegration of the carbon anode and a decrease in cycle efficiency. More importantly, using electrolytes that consist of propylene carbonate (PC), natural graphite cannot be charged because it leads to an evolution of gas at around 1 V. This is a major drawback of the graphite anode. However, using electrolytes that consist of other solvents such as ethylene carbonate (EC) and diethyl carbonate (DEC), the side reactions are suppressed, and it can be cycled without much difficulty.

The hard carbons generally have higher capacity than graphite. Several models have been proposed to account for the increased capacity: adsorption of lithium on both sides of the single graphene sheets, accommodation of extra lithium into nanometer size cavities, and storage of additional lithium at the edges and surfaces are some of the explanations. Generally, the capacity of carbon materials has been found to increase as the fraction of single layer material increases. However, the hard carbons have a sloping discharge profile between 0 and 1 V, unlike graphite, which has a nearly flat discharge profile between 0 and 0.3 V (Fig. 18). As a result, for lithium-ion cells that use the same cathode, the hard carbons will lead to a slightly lower cell voltage compared to graphite.

Structural modifications to improve the performance of carbon anodes are being pursued by various groups. In

this regard, texture control, surface modification by mild oxidation, and incorporation of other elements such as B, O, Si, and P have been studied. For example, carbon fibers that have different textures and compositions such as $C_{1-y-z}Si_yO_z$ and BC_2N have been investigated.

Other Anodes

The irreversible capacity loss encountered in carbon anodes has motivated the search for other anode hosts. In this regard, a few materials have drawn attention. $Li_4Ti_5O_{12}$ that has a cubic spinel structure accommodates three additional lithium ions per formula unit into the empty 16c sites and has negligible change in volume ($<0.1\%$) at a flat discharge voltage of around 1.5 V (62). However, the higher voltage (1.5 V) and lower capacity (160 Ah/kg) compared to that of carbon make it less attractive. SnO_2 is another candidate that has reversible capacity as high as 600 Ah/kg at 0 to 2 V, but it exhibits high capacity loss during the first cycle (63). More recently, some intermetallic compounds such as Cu_6Sn_5 that have an NiAs-type structure have shown promise (64), and further development of these systems is in progress.

However, all of the preceding candidates and carbon anodes do not contain lithium, and they require that the cathodes be in the lithiated (discharged) form. In this regard, anode hosts based on some lithiated transition-metal nitrides (59) and intermetallic compounds (65) are appealing. For example, $Li_{7-x}MnN_4$ and $Li_{3-x}FeN_2$ exhibit capacities of, respectively, 210 and 150 Ah/kg and a flat discharge voltage of around 1.2 V. $Li_{2.6-x}Co_{0.4}N$ and $Li_{2.6-x}Cu_{0.4}N$ whose structures are similar to that of Li_3N exhibit a much higher capacity of around 470 Ah/kg at 0.2 to 1 V; the formation of an amorphous phase during the initial stages in the latter systems leads to high capacity. Two lithium per formula unit can be reversibly extracted from Li_2CuSn (65). Further development work is necessary to assess the full potential of these lithium-containing anodes. If successful, they have the possibility of being coupled with some of the lithium-free cathodes such as vanadium oxides. However, the resulting lithium-ion cells may have a lower cell voltage compared to the currently available lithium-ion cells fabricated using $LiCoO_2$ cathodes and carbon anodes.

CONCLUDING REMARKS

After providing an introduction to the concepts of electrochemical cells and batteries, lithium-ion batteries that offer much higher energy density compared to other rechargeable systems were discussed. Lithium-ion batteries have become commercial due to the development of smart electrode (cathode and anode) host materials. State-of-the-art lithiumion cells are made by using a transition-metal oxide cathode such as a layered lithium cobalt oxide and a carbon anode. However, only 50 to 65% of the theoretical capacity of the currently available oxide hosts can be practically used. Chemical instability, structural instability, or safety concerns in the charged state limit the usable capacity, depending on the cathode host. The

challenge is to develop smart cathode hosts in which at least one lithium ion per transition-metal ion can be reversibly extracted/inserted and at the same time reduce the material cost; such a cathode can nearly double the energy density. There are also possibilities for increasing the capacity of anode hosts by focusing on amorphous materials. An alternate approach is to develop cells that use lithium-containing anodes and lithium-free cathodes. This strategy will allow using some of the already known high capacity cathodes such as vanadium oxides that have better chemical stability and safety characteristics. From the view points of safety, cycle, and shelf life, cathodes that have a lower voltage (3 to 4 V) but have a significantly increased capacity may be desirable for future applications.

BIOMEDICAL APPLICATIONS

JINHAO QIU
 MAMI TANAKA
 Tohoku University Sendai
 Japan

INTRODUCTION

Biomedical applications of smart materials can be divided into three categories: (1) implants and stents, such as bone plates and marrow needles; (2) surgical and dental instruments, devices, and fixtures, such as orthodontic fixtures and biopsy forceps; and (3) devices and instruments for medical checkups, such as ultrasonic devices. The applications of the first category require strict biocompatibility of a material because it is implanted in the body for long periods. Among many traditional materials, including metals, alloys, and ceramics, that are available commercially, only a limited number are currently used as prostheses or biomaterials in medicine and dentistry. The applications in the second category require excellent mechanical

characteristics as well as biocompatibility. The third category is used mainly for transducers.

Among smart materials, the Ti–Ni shape-memory alloy (SMA) has attracted the most attention for biomedical applications in the first and second categories due to its excellent biocompatibility and mechanical characteristics. Research on biomedical applications of the SMA started in the 1970s with animal experiments initially, followed by clinical tests. The first example of a successful biomedical application of the SMA was a bone plate, which was used to repair broken bones. Now, many medical and dental applications of SMAs are available, and many new applications are being developed. On the other hand, piezoelectric materials have been widely used as transducers for medical ultrasonic devices due to their sensor function that uses piezoelectricity and the actuator function that uses inverse piezoelectricity.

In this article, the properties of SMAs for biomedical applications are discussed next, followed by some clinical examples. Recent examples of biomedical applications of SMAs are summarized there after, and finally the recent examples of biomedical applications of piezoelectric materials are summarized.

PROPERTIES OF SMAS FOR BIOMEDICAL APPLICATIONS

The properties of SMAs that are important and have led to its wide acceptance in biomedical applications are discussed in this section. Of these properties, biocompatibility, which simply means the ability of a material to be accepted by the body, is the most important, especially for implants. The other important properties include superelasticity, the shape-memory effect, hysteresis, and fatigue resistance. The properties of SMAs for biomedical applications are discussed in detail in (1).

Biocompatibility

The biocompatibility of a material is its most important property if it is used as prostheses or biomaterials in medicine and dentistry. Biocompatibility means that the material is nontoxic during the implanted period. Because all materials generate a “foreign body reaction” when implanted in the body, the degree of biocompatibility is related to the extent of this reaction. Due to the rigorous demands on material properties for biocompatibility, only these three metallic materials were qualified for use as implant materials: Fe–Cr–Ni, Co–Cr and Ti–Al–V before SMA. Investigations were carried out by many researchers on the biocompatibility of Ti–Ni (2), and an extensive review can be found in (1). The results of these studies show that Ti–Ni has superior corrosion resistance due to the formation of a passive titanium oxide layer (TiO_2) similar to that found on Ti alloys. This oxide layer increases the stability of the surface layers by protecting the bulk material from corrosion and creates a physical and chemical barrier to Ni oxidation.

In *in vitro* dissolution studies, Bishara et al. (3) found that Ti–Ni appliances release an average of $13.05 \mu\text{g/day}$ Ni in saliva, which is significantly lower than the estimated

average dietary intake of $200\text{--}300 \mu\text{g/day}$. In addition, the measured nickel blood levels of orthodontic patients who have Ni–Ti appliances show no significant increase during a 5-month period.

Shape-Memory Effect

Predeformed SMAs can remember their original shapes before deformation and can recover the shape when heated if the plastic deformation takes place in the martensitic phase (4,5). Shape recovery is the result of transformation from the low-temperature martensitic phase to the high-temperature austenitic phase when it is heated. The shape-memory effect makes it easy to deploy an SMA appliance in the body and makes it possible to create a prestress after deployment, when necessary. SMA appliances are first in a compact state during deployment and then restored to their expanded shape by heating. If the phase transformation temperature of an SMA is below body temperature, shape recovery can easily be induced by the heat of the body. When the phase transformation temperature is higher than the body temperature, SMA appliances are usually heated by warm salt water or a high frequency magnetic field.

In recent studies, the shape-memory effect has also been used for actuator functions in medical applications such as a urethral valve and artificial sphincter which are discussed later.

Superelasticity

SMAs exhibit superelasticity when they are in the austenitic phase (1,5). Figure 1 shows the typical superelastic stress–strain curve (solid line) compared with the stress–strain curve of stainless steel (dashed line). As shown in the figure, an important feature of superelastic materials is that they exhibit constant loading and unloading stresses across a wide range of strain. As shown in Fig. 1, the

Figure 1. Typical stress–strain curve of superelastic materials and stainless steel. The superelastic materials exhibit constant unloading stress over a wide range of strain.

effective strain range $\varepsilon_{\text{eff}}(\text{TN})$ of Ti–Ni that corresponds to an optimal force zone is much larger than the $\varepsilon_{\text{eff}}(\text{SS})$ of stainless steel. Hence, a superelastic device can provide constant pressure even if the pressed part recedes by a limited amount during the installed period. On the other hand, the pressure exerted by an appliance made from stainless steel will drop drastically if the pressed part deforms, so that performance deteriorates. The orthodontic arch wire that is presented as an example of an application in the next section was the first product to use this property. Another example of applying this property is superelastic eyeglass frames (6). These eyeglass frames have become very popular in the United States, Europe, and Japan and are available in almost every optician's store. These frames can be twisted a full 180° , but more importantly the frames press against the head with a constant and comfortable stress. Not only is "fit" less important, but small bends and twists that may develop do not cause discomfort to the wearer.

The superelasticity of SMAs also makes it easy to deploy SMA stents. Stents made from stainless steel are expanded against the vessel wall by plastic deformation caused by inflating a balloon placed inside the stent. Ti–Ni stents, on the other hand, are self-expanding. More details can be found later.

Hysteresis of SMA

As shown in Fig. 1, superelastic SMA exhibits a hysteretic stress–strain relationship; the stress from A to B in the loading phase and the stress from C to D in the unloading are different. Hysteresis is usually regarded as a drawback in traditional engineering applications, but it is useful in biomedical applications. If the SMA is set at some stress–strain state, E, for example, upon unloading during deployment, it should provide a light, constant force against the organ wall, even under a certain amount of further strain release (e.g., from E to D). On the other hand, it would generate a large resistive force to crushing if it is compressed in the opposite direction because it takes the loading path from E to F. Hence, the SMA material exhibits a biased stiffness at point E, which is very important in designing a SMA stent. Because the stress at the loading phase from A to B and the stress in the unloading phase from C to D depend on the material composition of the SMA, the desirable stress–strain curve can be obtained by optimizing the material composition.

Anti-Kinking Properties

As shown in Fig. 1, the stress of stainless steel remains nearly constant in the plastic region. This means that a small increase in stress in the plastic region could lead to a drastic increase in strain or failure of a medical appliance made from stainless steel (1). On the other hand, the stiffness of superelastic Ti–Ni increases drastically after point B at the end of the loading plateau. The increase in stiffness would prevent the local strain in the high strain areas from further increasing and partition the strain in the areas of lower strain. Hence, strain localization is prevented by creating a more uniform strain than could be realized by using a conventional material.

EXAMPLES OF BIOMEDICAL APPLICATIONS

Orthopedic

Marrow Needles. Figures 2 and 3 show two types of marrow needles that are used in the repair of a broken thigh bone (4,6–8). When a stainless steel Kunster marrow needle is used, blood flow inside the bone can be blocked, and recovery can be delayed. It also has the drawback of low torsional strength. On the other hand, a Kunster marrow needle of SMA can be inserted into the bone in its initial straight shape and transformed to a curved shape by heating, as shown in Fig. 2. Hence, the SMA Kunster marrow

Figure 2. Kunster marrow needle (6).

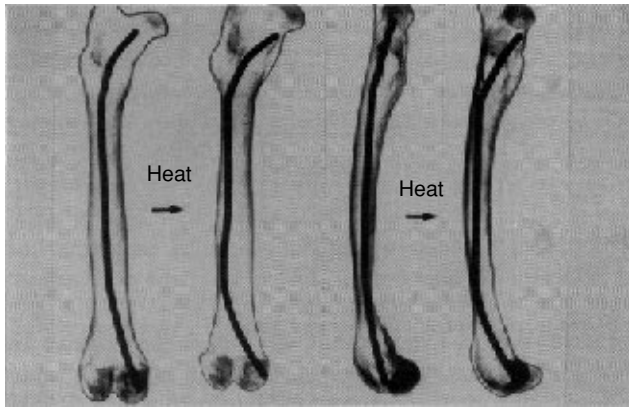

Figure 3. Marrow needles before and after heating (5,8).

needle can avoid the disadvantages of the stainless steel needle. The SMA Kunster marrow needle can also provide a compressive force on the fracture surfaces.

The marrow needle shown in Fig. 3 has a complicated shape for purposes of reinforcement, which makes it difficult to insert in the broken bone. Using the shape-memory effect, insertion can be greatly improved, as shown in the figure, without losing the reinforcing function, because the needles can be inserted in a simpler shape and the necessary size and shape are recovered by heating the needle in the marrow.

Currently available joint prostheses are made of bone cement to be fixed in the bone. Stress acting on the joint prosthesis is quite intense and severe: three to six times the body weight of the patient under nominal action, and the stress is cycled up to 10^6 times. Conventional bone cement causes several inconveniences: gradual loosening after implantation, resultant infection, and other complications. A prosthetic joint made of Ti-Ni SMA was developed to avoid such problems. High wear resistance is also another advantage of the Ti-Ni prosthetic joint.

Bone Staple and Bone Plate. The bone staple shown in Fig. 4 and the bone plate in Fig. 5 are used to fix broken bones (4-6). As shown in Fig. 4, a bone staple made of SMA can be inserted at low temperature in the holes opened in the bone, and then heated by the body temperature, it recovers its original shape to provide a compressive force on the surfaces of the broken bone. Bone plates are attached by screws for fixing broken bones. Bone plates made of Ti-Ni SMA are more effective in connecting broken bones than bone plates made of conventional material because SMA

Figure 5. Bone plate used to fix broken bones (4-6).

bone plates provide compressive force on the fracture surface of the broken bones as well as repair, as shown in Fig. 5. Healing proceeds faster under uniform compressive force.

Dental Applications

Orthodontic Fixtures. Due to its superelasticity, Ti-Ni is used in many applications in dentistry. It is obvious that superelasticity gives the orthodontists better mechanical characteristics compared to conventional elastic materials such as stainless steel. Figure 6a,b shows a clinical example of orthodontic treatment using a superelastic Ti-Ni arch wire (5,9). When fixtures made of conventional elastic material such as stainless steel are used, the reforming force drops, and the fixture loosens due to movement of the teeth. Hence, the fixture must be replaced several times before the treatment is finished. An SMA fixture maintains a constant reforming force in a wide range of teeth movement due to its superelasticity, so that no replacement is required after the initial installation. Clinical results also showed faster movement of the teeth and a shorter chair time compared with stainless steel wire.

Tooth-root Prosthesis. Among several methods that restore the masticatory function of patients missing more than one tooth, a tooth-root prosthesis is considered the method that creates the most natural masticatory function. Blade-type implants made of Ti-Ni SMA, as shown in Fig. 7, have been used in Japan (5,6). The open angle of the blade is used to ensure tight initial fixation and to avoid accidental sinking during mastication. But to make the insertion operation easy, the tooth-root prosthesis is

Figure 4. Bone staple used to fix broken bones (4,6).

Misaligned teeth before treatment

Normally aligned teeth after the first stage of treatment

Figure 6. Orthodontic treatment using a superelastic arch wire: (a) misaligned teeth before treatment; (b) normally aligned teeth after the first stage of treatment (5,9).

implanted in the jawbone as a flat shape and then the opened shape is changed by heating. Fig. 8 shows an X-ray photograph of the implanted tooth-root prosthesis. More than 5,000 clinical examples of SMA tooth-root prostheses have been reported.

Partial Denture. The key to a partial denture is the development of an attachment for connecting the partial

Figure 7. Tooth-root prosthesis (5,6).

Figure 8. X-ray photo of implanted tooth-root prosthesis (6).

denture to the retained teeth. Clasps have been conventionally used for about a century as the attachment for a partial denture. One of the drawbacks of clasps made of conventional elastic materials is loosening during use; this can be improved by replacing the elastic materials by a superelastic Ti-Ni alloy (5,10). Another drawback of clasps is aesthetics because they are visible in the teeth alignment. To solve the problem, the size of the attachment must be smaller than the width of the teeth so that it can be embedded completely in the teeth. A precision attachment using a small screw has recently become available, but it has to be designed and fabricated very precisely so that it lacks flexibility to follow the change in the setting condition during long-term use due to the shape change of the jawbone. Because of its flexibility, this problem can be solved by using an attachment made of SMA.

The SMA attachment consists of two parts: a fixed part that is made of a conventional dental porcelain-fusible cast alloy and is attached to the full cast crown on the anchor teeth and a movable part that is made of Ti-Ni SMA and is fixed on the side of the partial denture. Examples of movable and fixed parts are shown in Fig. 9.

Surgical Instruments

Since superelastic tubing became available in the early to mid-1990s, a variety of catheter products and other endovascular devices using Ti-Ni has appeared on the market. Early applications of Ti-Ni were retrieval baskets that have Ti-Ni kink-resistant shafts, as well as a superelastic basket to retrieve stones from kidneys, bladders, and bile ducts. An interesting example is the intraortic balloon pump (IABP) used in cardiac assist procedures (Fig. 10). The use of Ni-Ti allowed a reduction in the size of the device compared with the polymer tube designs and increased the flexibility and kink resistance compared with stainless steel tube designs (1).

Biopsy forceps made from stainless steel are very delicate instruments that can be destroyed by even very slight mishandling. Ti-Ni instruments, on the other hand, can handle serious bending without buckling, kinking, or permanent deformation. Figure 11 shows a 1.5-mm biopsy forceps that consists of thin wall Ti-Ni tubing and a Ti-Ni actuator wire inside. Together they can be bent around a

Movable part

Fixed part

Figure 9. Shape-memory alloy attachment for partial denture; (a) movable part; (b) fixed part (4,5).

radius of less than 3 cm without kinking, and still allow for the opening and closing of the distal grasper jaws without increased resistance. The instrument continues to operate smoothly even while bent around tortuous paths.

Figure 10. The Arrow interaortic balloon pump uses a Nitinol™ tube to pressurize the balloon (1).

Figure 11. Nitinol™ tubing that has an internal actuating wire allows this 0.8-mm diameter grasper to operate while tied in a knot (1).

Stent

The term stent is used for devices that are used to scaffold or brace the inside circumference of tubular passages or lumens, such as the esophagus biliary duct, and most importantly, a host of blood vessels, including coronary, carotid, iliac, aorta, and femoral arteries (Fig. 12) (1). Stenting in the cardiovascular system is most often used as a follow-up to balloon angioplasty, a procedure in which a balloon is placed in the diseased vessel and expanded to reopen a clogged lumen. Ballooning provides immediate improvement in blood flow, but 30% of the patients have restenosed within a year and need further treatment. The placement of a stent immediately after angioplasty, it has been shown, significantly decreases the propensity for restenosis. Stents are also used to support grafts, for example, in treating aneurysms (Fig. 13).

Most stents today are stainless steel and are expanded against a vessel wall by plastic deformation caused by inflating a balloon placed inside the stent. Ti–Ni stents, on the other hand, are self-expanding—they are shape-set to the open configuration, compressed into a catheter, then

Figure 12. A stent that maintains vessel patency and blood flow to the brain is portrayed in a cutaway view of the internal carotid artery (1).

Figure 13. Stentgrafts used to exclude aneurysms, to provide an artificial replacement for injured vessels, or prevent restenosis after angioplasty (1).

pushed out of the catheter and allowed to expand against a vessel wall. Typically, the manufactured stent's outer diameter is about 10% greater than the vessel's diameter to ensure that the stent anchors firmly in place. The flexibility of Ti-Ni is about 10–20 times greater than stainless steel, and it can bear a reversible strain as high as 10%. Ni-Ti stents are made from knitted or welded wire, laser-cut or photoetched sheet, and laser-cut tubing. The preferred devices are laser-cut tubing, thus avoiding overlaps and welds (Fig. 14).

CURRENT BIOMEDICAL APPLICATIONS OF SMA

Artificial Urethral Valve

Urinary incontinence is the involuntary discharge of urine caused by weakness of the urinary canal sphincter muscles due to aging and expansion of the prostate gland. However, the difference in ages, the sex of patients, and the various causes of the disorder make it difficult to treat the disease simply by drugs or surgery. In this section, an artificial urethral valve system driven by an SMA actuator is introduced (11).

Figure 14. Stents made from laser-cut tubing (1).

Figure 15. Artificial urethral valve.

Urethral Valve. The artificial urethral valve should be compact and should have no protrusions when it is implanted in the lower abdominal region. In addition, it should be attachable onto various sizes of urethrae. A compact urethral cylindrical valve is presented in Figs. 15 and 16. The valve is 15 mm across and 20 mm long. It is composed of two semicircular stainless steel shells 0.2 mm thick and a 0.2-mm circular-arc Nitinol™ plate. The shells and the Nitinol™ plate are fixed together by stainless steel clamps. Further, a cylindrical sponge rubber filling is placed inside the valve to effect uniform contact between the valve and the urinary canal. In the normal state, the valve presses on the canal, so that it is choked. To free the canal, the valve is opened by actuating the SMA element. The SMA plate, which is cylindrical at body temperature, flattens as heat is increased, and the valve, which is closed by the force of the bias spring in the normal state, is opened to release the choked urethra and allow urinary flow. To heat the SMA, a Nichrome™ wire, insulated by a polyimide membrane, was placed on the surface of the nitinol plate.

Transcutaneous Energy Transformer System. The energy to drive an in-dwelled valve should be supplied from outside the body. A transcutaneous energy transformer system will be effective for this purpose (12,13). The system consists of two induction coils that transmit electrical energy wirelessly from the primary to the secondary coil. In this study, the primary coil was 70 mm in diameter and had 12 turns, and the secondary coil was 60 mm across and had eight turns. The coils are spirals formed of twisted wires that consist of 20 lengths of copper wire 0.2 mm in diameter.

Experimental Setup. Figure 17 is the schematic of an animal experiment that used the urethrae of male dogs of average weight 12 kg, whose thickness is similar to that of human male urethrae. The urinary canal uncovered by the cut was equipped with the SMA valve and then loaded with water at a hydrostatic pressure of 75 cmH₂O, which is comparable to human abdominal muscle pressure. The temperature of the valve and the flow rate of the water passing through the canal were measured. First, the valve

Figure 16. Geometry of urethral valve: (a) externals; (b) body; (c) heating.

Figure 17. Schema of animal experiment.

Figure 18. Time variations of applied direct current, valve temperature, and flow rate of water passing through the valve.

was heated by direct current from the transcutaneous energy transformer system and then it was left to cool naturally by cutting the electric power to the heating wire. In the energy transformer system, the secondary coil was placed under the abdominal wall, and the primary coil on the skin face-to-face with the secondary coil. The capacity of the condenser to enhance the resonant effect of the circuit was set at $C_2 = 1.0 \mu\text{H}$. The frequency of the input current, which should coincide with the resonant frequency of the circuit, was 90 kHz. Further, the peak-to-peak amplitude of the current was set at 25 V.

Results and Discussion. Figure 18 shows the opening/closing functions of the valve when it was driven by the direct current heating of the SMA. The input current to the heating wire on the SMA, the temperature of the valve, and the flow rate of water passing out through the urethra are plotted as functions of time. The valve started to open, and the water began to flow 20 seconds after electric current was supplied. The current was cut off when the temperature of the valve reached 45°C . It is seen that the valve completely intercepted the water flow 30 seconds after the electric current was cut off. Thus, the valve possesses the necessary function of an artificial urethral valve.

Figure 19 illustrates the motor functions of the valve when it was driven by the transcutaneous energy transformer system.

Figure 19. Opening/closing functions of valve driven by transcutaneous energy transformer system.

Figure 20. Schematic of the artificial sphincter using SMA.

transformer system. The distance between the primary and secondary coils was 3–4 mm, and the induced current to the heating wire was 7.6 V in the peak-to-peak amplitude. The figure shows that the valve started to open and released the choked canal 6 seconds after the electric current was supplied. The current was cut off when the temperature of the valve reached 45°C, which was 35 seconds after the current supply was started. It is shown that the water flow was intercepted 25 seconds after the current was cut off. These motor functions of the valve showed that the induction coil system worked well as a transcutaneous energy transformer for heating the artificial urethral valve.

Artificial Sphincter

Similar to the urethral valve, the development of an artificial sphincter is also required for the medical treatment of patients who have fecal incontinence due to a colostomy, a congenitally anorectal malformation, or surgical operations for anorectal diseases. The lack of an anal sphincter is the main reason for the problem. In this section, an artificial sphincter using a SMA actuator was one of the solutions of these problems, as introduced in (14).

Mechanism of Artificial Sphincter. A schematic drawing of the proposed artificial sphincter is shown in Fig. 20. The actuator consists of two SMA plates joined by two hinges and the heating coils attached to the SMA plates. The SMA plates are 70 mm long. The width and the thickness are 18 and 0.7 mm, respectively. The material used for the SMA plates, Ti51at%Ni, is known to exhibit an all-round shape-memory effect (ARSME); it reverses shape to the “memorized” shape in its martensitic phase. Because the highest temperature for the complete reverse transformation might reach 55°C, thermally insulated materials such as cork sheets and sponge rubber sheets cover the outer and inner sides of the SMA plates, respectively. When electric power is applied to the coils for heating, the reverse transformation occurs in the SMA plates, accompanied by shape changes from a flat shape to an arc, the restrained shape during annealing. The shape change results in a gap between the two SMA plates to open the intestines. After switching off the electric power, the shape of the SMA plates recovers by natural cooling, and the intestines are closed again.

Animal Experiments. Animal experiments have been conducted to examine the fundamental functions and the biocompatibility of the actuator. The experiments were carried out on a pig that had the same dimensions of intestines as those of the human body.

Preliminary tests of the fundamental functions of the actuator were conducted. As illustrated in Fig. 21, an artificial anus was made in the pigs abdomen using a rectum after the resection of its colons. Then the artificial sphincter was installed around the rectum located between the abdominal wall and the peritoneum (see Fig. 22). The inside pressure of the rectum generated by the artificial sphincter was measured first. A pressure sensor was inserted from the artificial anus into the intestine and then moved out. The pressure exhibited a rise of 50 mmHg in the region clipped by the actuator, corresponding to the width of the SMA plates: 18 mm (see Fig. 23). The pressure tests were also carried out when the inner part of the rectum was

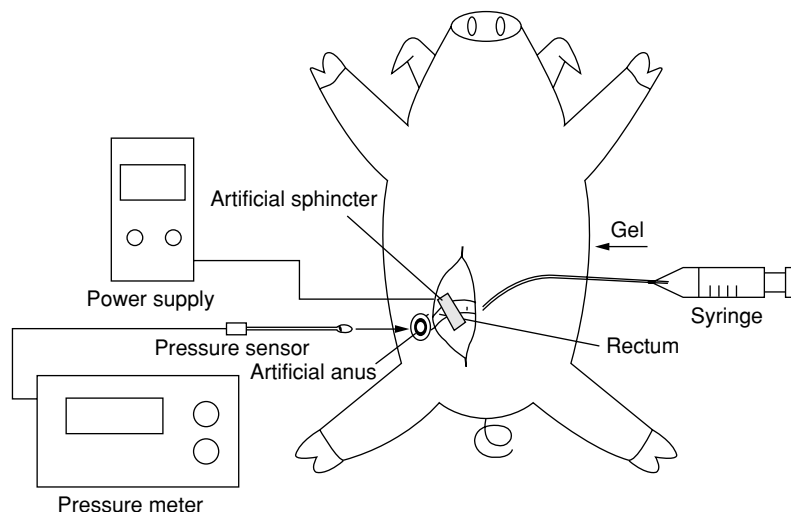

Figure 21. Schema of animal experiment.

Figure 22. A photograph of the artificial sphincter installed in the rectum of a pig.

subjected to pressure. The inner pressure of the rectum was generated by pouring gel into the intestines. Figure 24 shows the pressure change measured during the test. As seen in Fig. 24, the pressure was increased to 75 mmHg without any leak of the gel, and then decreased by opening the artificial sphincter using electric power. Discharge of the gel from the artificial anus was observed.

A clinical test on a living pig has also been carried out. The artificial sphincter enables a controlled bowel movement of the pig. From the dissecting examination after six days of experiments, neither infections nor burn scars were observed in the body around the artificial sphincter. Furthermore, the artificial anus was in good condition; this suggested that the pressure due to the artificial sphincter was tolerable. Additionally, in these experiments,

Figure 23. Pressure distribution in an intestine clipped by the artificial sphincter.

Figure 24. Pressure change in the rectum: (a) start pouring gel into the rectum; (b) switch on the input power; (c) discharge of gel was observed.

electric power was supplied through a pair of current lead wires that penetrated the body. The use of an inductive power transmission for the power supplement of the actuator could lead to a complete implantation-type artificial sphincter based on further research.

CURRENT BIOMEDICAL APPLICATIONS OF PIEZOELECTRIC MATERIALS

Due to its piezoelectricity, a piezoelectric material has a sensor function that can convert a mechanical signal to an electric signal. Electrical voltage generated by mechanical stress in piezoelectric materials decays very fast due to charge dissipation. The voltage signal takes the form of a very brief potential wave at the onset of the applied force and a similar brief wave at termination. It increases as force is applied but drops to zero when the force remains constant. There is no response during the stationary plateau of the applied stimulus. Voltage drops to a negative peak as the pressure is removed and subsequently decays to zero (15). The response is quite similar to the response of the Pacinian corpuscle in the human skin (16), one of the sensory receptors in the dermis. PVDF (polyvinylidene fluoride) piezofilm is suitable for uses in the biomedical field, because it is very flexible and sensitive to the fast variation of stress or strain. In this section, several recent studies of medical applications of PVDF film are introduced.

Active Palpation Sensor for Detecting Prostatic Cancer and Hypertrophy

Prostatic carcinoma and hypertrophy are examined in general by rectal palpation where the doctor's index finger is used as a probe together, in most cases, with ultrasonic tomography. The two lesions found in this study are diagnosed by noticing their morphological features. Prostatic hypertrophy is a symmetrical enlargement of the prostate glands; the stiffness varies from soft to hard. Prostatic cancer, on the other hand, is a hard asymmetrical uneven tumor. Palpation depends on the tactile perception of the forefinger, which is said to be ambiguous, subjective, and much affected by the physician's experiences. Hence, the development of a palpation sensor for detecting prostatic cancer and hypertrophy is important.

Palpation Sensor and Measurement System. The geometry of an active palpation sensor and tip probe are presented

Figure 25. Active palpation sensor that has a recessed sensor head.

in Figs. 25 and 26. The tip probe is mounted on a linear z-translation aluminum bar. It fits into a cylindrical outer aluminum shell 15 mm in diameter and is driven by a dc micromotor and crank mechanism. The drive mechanism is essentially the same as that of an electric toothbrush. The probe is positioned so that its face is to the prostate gland, and, it is oscillated at about 50 Hz at a constant peak-to-peak amplitude of 2 mm. The probe is an assembly of layered media.

The base is a thin aluminum circular plate 10 mm in diameter, on which a cylindrical rubber sponge 8 mm in diameter and 4 mm thick, a PVDF piezopolymer film 6 mm across and 28 μm thick as the sensory receptor, and a thin acetate film as a protect cover for the piezopolymer film are stacked in sequence. Furthermore, a convex layer of vulcanized rubber 3 mm across was placed on the surface of the acetate film to enhance the sensitivity of the sensor (17).

In the experiment, the sensor head is pressed sinusoidally against the object, and the output signal from the piezopolymer film is collected for 100 ms, sent to a digital storage oscilloscope for every sampling time of 0.2 ms, and further forwarded to a personal computer via a GP-IB interface as 500 eight-bit data for processing.

Signal Processing. The output voltage from the piezopolymer film is proportional to the rate of the strain induced in the film, which means that the maximum amplitude of the signal from the sensor is rather superposed by noises from the measuring system. Bearing this fact in mind, the following data analysis can be done by using the absolute output signal of the sensor integrated across the period of data collection:

$$I = \sum_{n=1}^N |V(n)|, \quad (1)$$

Table 1. Average μ , Minimum I_{\min} , Maximum I_{\max} , and Standard Deviation σ of Output

	μ	I_{\min}	I_{\max}	σ
Elastic soft or elastic firm	0.93	0.8	1.0	0.11
Elastic firm	1.72	1.0	3.4	0.75
Hard	16.0	11.5	18.8	2.40

Figure 26. Geometry of a sensory receptor.

where I is the integrated output signal and $N (= 500)$ is the total number of data collected in a period of 100 ms.

Clinical Test. Rectal palpation was done by using the sensor to verify the discrimination function of the sensor. First, the doctor examined the stiffness of the prostate gland of a person by using his own index finger. Next, the sensor protected by a medical rubber glove was inserted into the subject's rectum. The relative position of the sensor to the prostate gland was monitored by the ultrasonic diagnostic, and the sensor was placed face to face to the prostate gland and driven to generate sensor output. The examinees in this time were eight in total. One 74-year-old person was suffering from a carcinoma. Four persons of average age 77 were patients who had prostatic hypertrophy, and two persons (average age 52) suffered from prostatitis. The last person diagnosed had no definite lesions on his prostate gland. The stiffness of the prostate glands diagnosed this time was "elastic soft or elastic firm," "definitely elastic firm," and "hard." The results obtained are presented in Table 1, which shows the average, the minimum and maximum output, and the standard deviation of the output. It is seen clearly that the output from the prostate gland of the diagnosis "hard" is greater than the output of the gland of "elastic firm."

Haptic Sensor for Monitoring Skin Conditions

Assessing the pharmaceutical action of liniments on skin disease is a matter of importance to dermatologists. This has drawn much attention to the development of objective techniques for measuring the morphological features of skin (18). Evaluating the substantiation of the cosmetic efficacy of toiletries is another of the objective measuring techniques. The features that affect the health appraisal

Figure 27. Tribosensor.

and/or the physical beauty of skin are the morphology such as rashes, chaps, or wrinkles. This noninvasive technology has made great advances in the studies of dermatology during the last decade, and several methods have been developed to measure the mechanical properties of the dermis such as measuring transepidermal water loss using an evaporimeter (19) and image processing of a negative replica of the dermis (20). These methods, however, fall in the category of indirect measuring techniques for the dermis. In this section, the development of haptic tribosensors for monitoring skin conditions and distinguishing atopic and normal healthy skins directly is introduced.

Tribosensor. A tactile sensor for measuring skin surface conditions is presented in Figs. 27 and 28. The sensor is a layered medium, whose construction is analogous to that of the human finger. It is composed of an aluminum shell as the phalanx, sponge rubber 3 mm thick as the digital pulp, a PVDF piezopolymer film 28 μm thick and 12 mm across as the sensory receptor, an acetate film as a protective cover for the piezofilm, and gauze on the surface as the fingerprint that enhances the tactile sensitivity of the sensor. The sensor was attached to the tip of an acrylic elastic beam, and a strain gauge was mounted on the surface of the beam to monitor the force applied to the skin by the sensor.

Figure 28. Schematic of PVDF piezofilm sensor.

Figure 29. Setup of measuring instruments.

Measuring Apparatus. A measurement system using the tribosensor is presented in Figure 29. The sensor was moved by hand over the sample skin to maintain a constant speed and force. The voltage signal from the PVDF sensory film was sent to a digital storage oscilloscope as eight-bit quantized digital signals of 4096 points and then transmitted to a personal computer via a GPIB board for signal processing. The sampling frequency was held constant at 40 kHz. In the process of measurement, it was necessary to reduce the potential difference between the surface of the skin and the sensor to minimize the overlap of noises on the sensor signal. To this end, the subject and the sensor were grounded by fitting a grounding conductor around the wrist. Still, some noises from the power sources, which were due to outside sources, were observed around 50 Hz and 100 MHz, respectively. Thus, a band-pass filter that had cutoff frequencies of 70 Hz and 20kHz was inserted after the sensor to remove the noise effect.

Signal Processing and Identification of Skins. Dermatitis is a factor that affects the skin condition. The neck skin of subject A, who was suffering from mossybacked atopic dermatitis, was compared with the healthy skins of subjects B–E. The sensor was moved by hand over a prescribed region of skin to maintain a constant speed and force. Hence, a method of identifying sample skins employing signal processing and neural network-based training was introduced. First, the variance was calculated as an index to extract the features of the collected data:

$$V = \frac{1}{N} \sum_{j=1}^N (x(j) - \bar{x})^2, \quad (2)$$

Table 2. Segmented Frequency Range for Power Spectrum Integration

Level	1	2	3	4
Frequency range (Hz)	29–88	98–586	596–1191	1201–19990

Table 3. Rate of Correct Answer for Discrimination of Atopic and Normal Skins

Input Parameter	P_i		P_i, V	
Cycle of Training	10^3	10^4	10^3	10^4
A	0%	0%	100%	100%
B	100%	100%	100%	100%
C	100%	100%	100%	100%
D	100%	100%	100%	100%
E	100%	87%	100%	100%

where, $x(j)$ is the j th quantitized digital signal, \bar{x} is the average of $x(j)$, and N is the total number of digital signals.

Next, FFT analysis was introduced to extract the features of the collected data. Careful reading of the spectra obtained led to an understanding that there were some differences in the distribution profiles of spectra among the subjects. In the light of this, the power spectrum was segmented into several frequency ranges, and the ratio of the power in an individual frequency range to the power of the whole frequency range was calculated and used as the second index that described the characters of the sample skin:

$$(R_s)_i = (S)_i/S, \quad (S)_i = \int_i P(f)df, \quad S = \sum_i (S)_i, \quad (3)$$

where $P(f)$ is the power spectrum density, S is the total power distributed across the frequency range considered, and $(S)_i$ is the power at frequency level i . Here, the level $i(=1-4)$ stands for the range of frequencies given in Table 2.

Discrimination of Skin that has Atopic Dermatitis. The neural network was trained to recognize atopic and normal healthy skins. The neural network employed was a hierarchical network; the training method used was instructor-assisted training, in which the correct answers were provided as an aid to the training; the training algorithm employed was back-propagation. Two networks were examined. One was the network that used the four power ratios $(R_s)_i$, $i = 1-4$, as the cell input, and the other used the variance V in addition to $(R_s)_i$. Five sets of data were obtained for each skin. The neural network had an input sensory layer of four or five cells, an intermediate association layer that had the same number of cells as the input layer, and an output response layer that had a single cell. The correct output value was set to one for the atopic skin, and zero was set for the healthy skin. Training was repeated by using the gradient descent method until the error function became sufficiently small, up to 10^3 and 10^4 cycles. The networks were constructed separately three times for three sets of randomly selected initial values of synaptic weights. After completing the training of 12 individual networks, the recognition experiments were performed on the atopic skin and the healthy skin using the newly obtained five sets of data for each subject. The results obtained are

shown in Table 3. Here, the percentage denotes the rate of the correct answer averaged across the three networks of randomly selected initial synaptic weights. Atopic dermatitis cannot be identified without the input of the variance, and the recognition was perfect when the variance was introduced as the input.

BIOMEDICAL SENSING

CHRISTOPHER S. BRAZEL
University of Alabama
Tuscaloosa, Alabama

INTRODUCTION

In recent years, biomedical diagnostics research has led to the development of simple, less invasive, and more accurate evaluative techniques. Much of this is due to biosensor technology, which has played an important role in material improvements used to sense, carry signals, and respond to signals. Biosensor devices can measure micromolar or even smaller quantities of biological substances, including chlorides, glucose, lactose, and urea. Pietro (1) defines biosensors as “any discrete sensing device that relies on a biologically derived component as an integral part of its detection mechanism,” although sensors that are used to monitor biological conditions are usually also included. Medical applications abound, ranging from diagnostic tests for home testing to *in vivo* monitoring of vital conditions and using feedback to control drug delivery or send amplified signals of a change in patient health. Smart materials are frequently combined with biological components to create systems that respond to environmental conditions, such as temperature, pH, concentration of particular analytes, or even light. These smart materials are typically polymeric, and most have the common characteristic that changing environmental condition cause a thermodynamic change between hydrophilic and hydrophobic states, as detailed later. pH paper strips may be one of the simplest sensing devices; they relay a physiological condition through a colorimetric response, and because they are a form of dry chemistry, they simplify detection and diagnostics, which is especially important for home diagnostic kits.

This article presents the use of intelligent polymers in sensing systems, that range from traditional biosensors to advanced self-responsive systems. This review of biomedical diagnostics using smart polymers examines some of the medical applications for intelligent polymers used in electrode-based systems and in bioconjugate systems.

Sensing devices are categorized by the mechanisms of signal detection and response, and examples of systems that monitor analytes, such as glucose, are addressed. Additional modes of response beyond the traditional electronic signal as well as synthesis techniques and examples of medical diagnostics using smart polymers, will be discussed.

Smart materials sense their environment, judge the magnitude of changes, and respond to obtain the most thermodynamically favorable state. This response can cause changes such as surface modification (from hydrophobic to hydrophilic or vice versa), swelling or shrinking of gels, enzyme solubility (if covalently attached to a phase-separating polymer), and binding of polymer and proteins (especially in reversible ionic interactions) (2). These reversible phenomena are useful for biosensors in protecting biological materials, collecting and concentrating analytes, and responding to stimuli to transduce a signal or deliver a drug (3). Smart materials act as on/off switches and can be barriers for an enzyme to protect it from the body's immune system and from harmful solutes or pH conditions. The ability of polymers to phase separate can also aid in separating and preserving enzymes or antibodies to be reused in future diagnostic tests.

The use of intelligent polymer systems in sensors provides the possibilities of combining sensing, transduction of signals, and response in the same independent device and the possibility of controlling biological events based on the signal by delivery of drugs or other means. These three behaviors (sensing, transduction, and response) are characteristic of biosensors, although the traditional response is often electronic (Fig. 1).

Sensing and response processes in smart materials are reversible, and after the hydrogen ions diffuse from the polymer, it returns to its normal unswollen state, and drug release stops. This creates a positive feedback mechanism whereby the device senses abnormal biological or biomedical events and treats the diseased state only when the triggering molecule is present. An example of the structure of a feedback drug delivery biosensor is shown in Fig. 2, where a silicon chip is used as a platform for the biosensor (4). This is similar to the current research of the National Science Foundation's “Lab on a Chip” technology program, where chemical moieties are analyzed on a molecular scale. In the scheme shown, drug reservoirs are kept

Figure 1. Steps involved in biomedical sensing using intelligent polymers. First, the substrate (S) diffuses to an enzyme immobilized in the polymeric device and reacts; the signal that a particular substrate is present is then transmitted to the surrounding polymer by diffusion of the products (P, H⁺) of the enzymatic reaction, such as hydrogen ions. The hydrogen ions, in turn, elicit a swelling response from a smart material, such as pH-sensitive poly(acrylic acid), which can then deliver an embedded drug by diffusion.

Figure 2. Model scheme for the structure of a sensor device [reprinted with permission from (4); copyright 1996 The Controlled Release Society, Inc.].

behind molecular gates made of pH-sensitive poly(acrylic acid) to yield a sensor that provides a drug delivery feedback response to changing pH.

Traditional biosensors include electrochemical sensors that have been under development since the early 1970s and in which enzymes, antibodies, chemoreceptors, and cellular tissue are used as catalysts for reactions that create electrical signals (5). An example of an electrochemical sensor is shown in Fig. 3, where an enzyme is deposited directly onto a metal conducting electrode and a polymer or protein is used to immobilize the enzyme. This

Figure 3. SEM photograph (200x) of a portion of the working electrode that had glucose oxidase and albumin electrodeposited and cross-linked onto the exposed surface. The visible metal layer surrounding the layer of glucose oxidase and albumin is the conductor underlying the insulating layer [reprinted with permission from (6); copyright 1994 American Chemical Society].

particular device was designed for subcutaneous implantation to monitor glucose concentrations in diabetic patients (6). The magnitude of the sensor response is proportional to the analyte concentrations, but the response also depends on the diffusion of the analyte to the enzyme or receptor, the kinetics of the enzyme reaction, and the diffusion of reaction products (such as O_2 or H_2O_2) to an electrode. Biosensor technologies include biochemical sensors, enzymatic sensors, cellular sensors, sensors for redox reactions, antigen/antibody interactions, and other materials that provide recognition surfaces (7). They typically include a specific reaction site (sensor), a mode of transporting the signal (transducer), and a signal measurement or feedback mechanism (responder). These sensing materials can involve antibody/antigen (8) or enzyme/substrate interactions, where the interaction is highly specific and a singular target analyte can be recognized (9). Organelles, whole cells, or tissue can also be used as the sensor (10). Spichiger-Keller (11) divides the types of sensors by the recognition processes used (Table 1). Biosensor devices are one class of intelligent materials, but they can also be combined with smart polymers (such as those sensitive to environmental pH or temperature) to aid in signal collection through specific interactions with the analyte, signal transduction, or the response mechanism (as depicted in Fig. 1).

Because of the complex nature of biosensors, it is important to understand the requirements of sensing in general, and then apply those guidelines to the additional requirements needed to use the sensor in a biological environment. Complications can arise when multiple functional materials are combined into the sensor device. Several important characteristics of biosensors ensure accurate, reproducible, and specific results. Diamond (12) summarized some of the important considerations in Table 2. Many of the characteristics, such as reproducibility of results, robustness, and proportional signal output, are common to process control theory. In addition to the requirements of Table 2, materials (especially the surfaces exposed to biological environments) must be biocompatible, the device should be as noninvasive as possible for medical applications,

Table 1. Classification According to the Type of Recognition Process^a

Sensor Type	Reacting Pairs	Chemical Reaction Recognition Process
Chemical sensors in the strict sense	Host–guest; ligand–analyte; carrier–ion; ion, neutral species, and gas sensors	Complexation association, addition, typical equilibrium reactions
Oxide semiconductor sensors	Inorganic metal oxide; layer–reactive gases	Absorption, reduction, oxidation
Enzymatic sensors	Active site–substrate–cosubstrate mediated sensing reactions; active site–mediator–electrode	Metabolic turnover, typical steady state, Kinetic reactions
Immunochemical sensors	Antibody (catalytic antibody)–antigen; antibody–antigenic protein–hapten	Affinity, association, Equilibrium reactions
Receptrodes, living organs, bilayers hybridised as abzymes, etc.	Receptor–substrate	Association, affinity, metabolic turnover

Table 2. Ideal Characteristics of a Sensor^a

Characteristic	Comments
Signal output should be proportional or bear a simple mathematical relationship to the amount of the species in the sample	This is becoming less important because of on-device electronics and integration of complex signal processing options to produce so-called smart sensors.
No hysteresis	The sensor signal should return to baseline after responding to the analyte.
Fast response times	Slow response times arising from multiple sensing membranes or sluggish exchange kinetics can seriously limit the range of possible application and prevent use in real-time monitoring situations.
Good signal-to-noise(S/N) characteristics	The S/N ratio determines the limit of detection; can be improved by using the sensor in flow analysis rather than for steady-state measurements; S/N ratio can also be improved by filter or impedance conversion circuitry built into the device(“smart” sensor).
Selective	Without adequate selectivity, the user can not confidently relate the signal obtained to the target species concentration.
Sensitive	<i>Sensitivity</i> is defined as the change in signal per unit change in concentration (i.e., the slope of the calibration curve); this determines the ability of the device to discriminate accurately and precisely between small differences in analyte concentration.

and biosensors must have adequate lifetimes, especially if implanted. Immobilization is often necessary in enzymatic or immunosensors, so that the active material can be kept near the electrode or other transduction and feedback device.

The ideal biosensor characteristics listed in Table 2 provide some of the driving forces for research in this field. Hysteresis limits the effective lifetime of a sensing device; because of repetitive cycling, the sensor's response becomes less reproducible. Poshossian et al. (13) report a penicillin biosensor based on a pH-sensitive gel that has a hysteresis of less than 4 mV (less than 0.4% of the signal) and a usable lifetime of at least one year; perhaps more importantly, they demonstrated that by using an absorptive technique to immobilize penicillinase, the sensor could be regenerated by desorption and resorption of fresh enzyme. To achieve faster responses in immobilized enzyme-based systems, macroporous gels have been employed to reduce any potential hindrances due to diffusion (14). The limits of sensitivity are also important in creating sensing devices. The minimum detection level has dropped as low as the nanomolar level (15), but the range of analyte concentration across which the biosensor is useful must also match the system being monitored.

Although the functioning of a biosensor must be accurate and robust, the largest barrier to successful implementation of a biomedical sensing device is ensuring that it is readily usable and simple for patient compliance. The development of assays that extract metabolites across the skin (16–18) or those that sample biological fluids that are more readily collected, such as urine, sweat, or saliva (19), are examples.

Compared to all sensor markets, the medical and biological fields have become leading drivers for new research in recent years and have great potential for improving pharmaceutical processing, medical diagnostics, and patient treatment (12). The driving forces for future development of biomedical sensing devices include improving and diversifying recognition mechanisms, developing new materials for immobilization that meet the stringent requirements of biocompatibility, developing materials that do not use enzymes or biological components (using techniques such as enzyme mimics and molecular imprinting), improving the flexibility of design (especially through dry chemistry and removing the requirement for electrolytic fluids in the sensor), discovery and development of new sensor molecules that are highly specific to diseased states, and improving signal processing and reproducibility (12). Many biosensors have a linear response to concentrations across only a narrow window, so one continuing focus will be to develop sensors that are more robust and have proportional responses across a wider range of analyte concentrations.

A variety of biological components have been used in sensing mechanisms for biosensors; the majority is based on enzymes because enzymatic reactions are highly specific, occur at low analyte concentrations, and can differentiate between enantiomers and compounds of similar structures. Particular enzymes can also be selected to catalyze any of a range of medically significant biochemical reactions. Because obtaining highly purified enzymes or

proteins is often expensive, McCormack et al. (9) suggest using whole cells in the substrate recognition step. Cell-based sensors would be more adaptable and resilient compared to proteins or enzymes and may lead to biosensor products that have longer lifetimes; cells can carry out more complex reactions by using multiple enzymes and metabolic pathways to produce a product that signals a response from the biosensor. On the negative side, cell-based biosensors are much more complex, and the direct cause-effect (reactant–product) relationship of enzymatic reactions becomes more difficult to define. One example where a cell-based sensor would be preferred is in monitoring the products of cell metabolism to determine the availability of nutrient supply. If carbon or nitrogen sources are in short supply, secondary metabolites may be formed, which could be monitored; alternatively, if the oxygen supply is short, partial metabolites, such as lactates, may build up in the tissue near the biosensor. This would be potentially useful in monitoring cells used for tissue engineering or implanted organs to verify that the region is becoming vascularized and not rejected by the host. It is also possible to use multiple cells or even plant or mammalian tissue in combination with sensors to monitor the production of highly specific metabolites.

MEDICAL, THERAPEUTIC, AND DIAGNOSTIC APPLICATIONS OF BIOSENSORS

Biosensors have made it possible to reduce human health care costs by using available at-home test kits so that patients can monitor their own glucose levels, pregnancy hormones, and cholesterol (20). Most of these kits can monitor easily collected biological specimens, such as saliva or urine, or require training the patient to collect blood samples (for glucose monitoring). Several *ex vivo* diagnostic tests, including glucose and cholesterol screenings, have been made possible through biosensors that incorporate enzyme assays into dry chemistry electrodes (21). In many of these tests, polymers are included with the biological sensing component along with a simple readout, such as an indicating dye. Biosensors are used in many biological systems, including control of reactions in biological reactors for producing pharmaceutical agents (22), measuring analytes in biological samples, such as blood or urine (23), and monitoring health information *in vivo* (16).

As an example of biosensors used with smart materials, Mizutani et al. (24) developed enzyme electrodes based on oxidoreductase enzymes for monitoring lactates and ethanol. Their device consisted of a stimuli-responsive “smart” polymer system of poly(L-lysine)/poly(4-styrenesulfonate) to which enzymes are bound by ionic interactions with the polymers. The ionic polymer is involved in both enzyme immobilization and in screening solutes such as L-ascorbic acid and uric acid, which interfere with signal transduction if they are near the electrode. Lactate levels in sour milk and human serum were tested using the biosensor and were compared to conventional test kit methods (Table 3). Results must compare favorably in accuracy and reproducibility to consider biosensor devices feasible.

Table 3. Comparison of Results Obtained for L-Lactic Acid in Human Sera and Sour Milk by Different Methods^a

Sample	L-Lactate Concentration Proposed Method	(mM) F-kit method
Serum 1	2.03	2.02
Serum 2	1.44	1.36
Serum 3	2.80	2.86
Serum 4	1.75	1.67
Sour milk 1	63.8	61.4
Sour milk 2	74.6	73.0
Sour milk 3	53.3	53.6
Sour milk 4	87.7	86.1
Sour milk 5	72.4	74.4

Medical applications of biosensors cover a wide range of analytes (Table 4) and medical conditions (Table 5). Diabetes monitoring and treatment is the primary thrust of research and product development in current medical sensing technology, but as the understanding of molecular biochemistry advances, there are possibilities of developing economically feasible sensors based any of these conditions and more.

Some of the enzymes of potential use in biomedical sensors are listed in Table 6. Much of biosensor development has focused on oxidoreductases because changes in oxidized states of chemicals cause electron flow that can be detected by using electrodes.

Biomaterials that respond to environmental changes and fractures to self-repair are considered smart materials that sense biological events and give feedback by releasing healing chemicals. In these systems, the "sensing" is not as sophisticated as in traditional biosensors, but the use of self-repairing structures in biomaterials makes them able to sense stresses and cracks and respond *in vivo* without surgical procedures to replace or reset the implant. Dry (30) described techniques to improve biomaterial performance by using smart materials that self-heal upon mechanical erosion. This is particularly important in developing load-bearing biomechanical materials for replacing bones and joints. Hastings (33) also cites the use of smart materials that self-repair upon shear and fracture or release drugs or hormones in conjunction with biomaterial implants to reduce inflammatory response. These devices typically use encapsulation to hold the active ingredient, and shear or pressure are used to break the capsule wall and trigger release.

Another area where biosensing is done nontraditionally is targeted drug delivery. Some of the same interactions, especially using chemoreceptors, can be used to design drug

carrier surfaces so that a drug is delivered to a specific area. Yang and Robinson (34) used glycoproteins to bind drug delivery vehicles to a selected site. These surface derivatives may be used to anchor controlled release devices or biosensors to a particular type of cell in the body. Smart polymers used in biosensors for drug delivery are detailed later in this article.

Monitoring lactate and pyruvate levels by using a biosensor can indicate when secondary and partial oxidation products are formed *in vivo* and indicate when the supply of nutrients or oxygen to tissue is insufficient (35). These enzymatic electrochemical sensors are used in extracorporeal evaluation of blood in patients who have an artificial pancreases; and the lifetime of the sensor is 30 days/300 assays. The results from the biosensor correlated well with spectrophotometric analysis of blood serum.

Many biomedical sensing devices have been proposed and constructed for monitoring blood glucose levels, and some of these approaches are detailed later in this article. The reader is referred to Campanella and Tomassetti (36) for a review of biosensors for clinical and pharmaceutical analysis.

POLYMERS AS ELECTRODE COATINGS AND BIOSENSOR MEDIATORS

To date, most research on biosensors has focused on devices that consist of a metal layer to conduct electrons as the signal, an enzyme or antibody to sense the presence of a particular analyte, and a membrane to immobilize the enzyme and also possibly aid in transducing the signal to the electrode. A common approach used to design glucose sensors, as demonstrated by Johnson et al. (6), is based on glucose oxidase, which is immobilized between an outer membrane permeable to glucose and oxygen and a platinum electrode to reduce the formed hydrogen peroxide and transmit electronic signals (Fig. 4). The design of the membrane is crucial to operation because the pore size must allow rapid diffusion of glucose and oxygen and yet retain the enzyme.

Polymer gel coatings on electrodes serve multiple purposes. Polymer gels form semipermeable membranes to

Table 6. Enzymes Used in Biosensors

Enzyme	Medical Use
Lactate dehydrogenase	Test for metabolic acidosis
Alcohol dehydrogenase, alcohol oxidase	Test for blood alcohol content
Monoamine oxidase	Drug testing—amphetamines or cocaine
Glucose-6-phosphate dehydrogenase	Test for diabetes
Glucose oxidase	Test for high/low glucose concentration in blood
Isocitrate dehydrogenase	Test for normal metabolism (citric acid cycle)
Lactate oxidase, pyruvate oxidase	Detect partial oxidation metabolism—sports medicine
Catalase	Used in conjunction with glucose oxidase to drive reaction toward gluconic acid product by consuming hydrogen peroxide
Ascorbate oxidase	Monitoring of vitamin levels
Urease	Detoxification of blood
Cholesterol oxidase	Detect cholesterol levels

control substrate diffusion and immobilize an enzyme near an electrode. Because hydrophilic polymers, such as poly(vinyl alcohol), poly(lactic acid-co-glycolic acid), and poly(ethylene glycol) have densities and compositions similar to those of natural tissue and interact minimally with the immune system, they are used to make biosensor surfaces more biocompatible. The definition of biocompatibility has been redefined in recent years from totally inert when exposed to living tissue to actively interacting with the biological components (37). Some of the important characteristics of biocompatible materials include thromboresistance, infection resistance, and minimal effects on blood flow and nutrient supply (38), but the physical aspects of biocompatibility may change for the intended application, so as to obtain the desired host-material interaction (39). The surface characteristics of implanted biomaterials are often modified to create interfaces that have low platelet adhesion by derivatizing polymers with heparin or poly(ethylene glycol) (40,41). Interfacial properties are important for biocompatibility, but the polymer matrix can also act as a signal mediator to transmit electrons from the reaction site to the electrode, especially if the polymer is doped with conducting materials (42,43). Electron transfer in many polymer systems is hindered by the insulating nature of polymers, so several materials have been used to dope or modify the electrical properties of polymers used in immobilization. The use of naturally occurring redox chemicals, such as FAD/FADH₂ and NAD/NADH, has improved signal transduction and response time for some biosensors

(5). Good mediators should have reversible kinetics so that they are ready to transmit multiple signals; they should be independent of environmental factors such as temperature or pH, be stable, and be retained easily near the surface of the electrode. Some small molecules, such as quinone, methylene blue, thionine, and ferrocene, have been used because they diffuse easily through porous polymers (5). These mediators have been successfully applied to such commercial products as home glucose meters. Usmani (44) and Chen et al. (45) used osmium-containing poly(4-vinyl pyridine), ferrocene-modified polysiloxanes, quinones, and other organic salts to aid in signaling and charge transport.

Polymers selected for use in biosensors must meet many requirements: they must not interfere with the chemistry of the reaction in the sensor and must also be neutral and stabilizing for biological components used in the sensor, such as enzymes (21). Many smart polymers are ionic to accommodate pH-sensitive transitions, but ionic interactions between the polymer and biological substances may cause interference with or fouling of the sensor device (46,47). The method used for synthesis may also leave residual monomer, cross-linking agent, or solvent trapped within the polymer gel, which can be detrimental in sensitive measurements. So care must be taken to purify polymers used in biosensors or to select techniques that do not use any potentially harmful or interfering chemicals. Particle size and porosity must also be considered because the diffusion path and surface area exposed to a solution being monitored may greatly affect the amplitude of the response.

IMMOBILIZATION TECHNIQUES AND MATERIALS

Enzymes are often used in biomedical sensing devices to catalyze reactions that are specific for certain substrates. The products formed by enzymes embedded in smart polymer networks in turn elicit a response, such as swelling to release drugs for treatment, markers for detection, or phase separation to change the hydrophilic/hydrophobic balance of the local environment. Oxidation-reduction enzymes lend themselves well to combination with pH-sensitive polymers because hydrogen ions can be used

or released as a result of enzymatic reactions. Hoffman (48) presents three possible methods of immobilizing an enzyme in a hydrogel: equilibrium partitioning, cross-linking in the presence of active agent, or derivatizing the enzyme with a reactive double bond to form covalent linkages the polymer gels (Fig. 5).

Enzymes are typically large protein molecules that have molecular weights in the tens to hundreds of thousands and can be combined with polymer gels and networks by a number of methods. The methods described before by Hoffman (48) can be used, as can other methods developed recently (49–52). Platé, Valuev, and co-workers used a macromonomer reaction for incorporating enzymes into polymer networks. These systems are formed by first forming a reactive derivative of the target enzyme by attaching a polymerizable double bond, such as an acrylate, to the enzyme by reacting it with acryloyl chloride (Fig. 6).

Figure 6. Macromonomer procedure for preparing derivatized enzymes that have an active double bond for polymerization.

Acryloyl chloride is particularly reactive to basic groups, such as amino organic groups found commonly in enzymes on the side groups of amino acids, such as lysine, histidine, and arginine. The reaction forms an acrylate linkage through one of these enzyme subgroups, which is reactive to free radical polymerizations to form cross-linked gels. As long as the solutions used to form the macromonomers and polymer gels do not destroy the folded structure of the enzyme and the double bond reaction does not take place in the enzyme active site, the result is a polymer that has an active enzyme covalently attached and immobilized. The activity of the enzyme is typically reduced somewhat during the derivatization procedure, depending on the environmental pH and temperature, as well as the effect of the polymerization chemicals on the protein configuration. Because the active site of an enzyme is only a small portion of the protein's molecular structure, attachment of the acrylate double bond within the active site occurs in only a small fraction of enzyme molecules, although inhibition of enzyme kinetics may occur due to linkages anywhere on the enzyme. The resulting systems synthesized by the macromonomer technique include a biological chemical, such as an enzyme or protein, dispersed throughout a polymer network but chemically immobilized within the membrane.

In addition to the methods mentioned before, enzymes and antibodies (8) can be entrapped by physical or chemical methods (Table 7). Immobilization normally uses polymers to restrict diffusion or to serve as matrices for adsorbing or binding enzymes. A variety of polymers, both synthetic and naturally occurring, have been used for chemical linkages to enzymes or in gelled forms to control diffusion (Table 8). Some standard microencapsulation techniques that can be used for immobilization include spray drying, rotary atomization, coextrusion, fluid bed coating, solvent evaporation, and emulsion and suspension polymerization (53).

Immobilization provides several advantages to biosensors. Immobilization can improve enzyme stability and preserve its biological providing activity by a nondenaturing environment (55) and preventing the loss of enzyme to the surrounding fluid; this allows using the device to multiple times. The polymer matrices used can be designed to control the diffusion of the substrate to the enzyme, and conducting polymers can transduce redox charges from enzyme active sites to electrode surfaces (19). Immobilization is also used to protect enzymes from denaturing proteins and helps avoid extreme pH and chemical microenvironments for the biomolecule (56). Enzyme stability is crucial for commercial viability because destabilization can result in false biosensor readings.

The sterility of medical devices is also of utmost importance in developing biosensors. This issue can lead to selecting particular methods of immobilization even though the activity of the enzyme and the structure of the membrane may not be ideal. Some alternatives to chemical cross-linking of polymers include radiative cross-linking (57), thermal gelation, or the use of ionic polymers, such as alginates, that do not require monomer or organic solvents. Preservation of the biological activity is paramount in ensuring the robustness of the biosensing device; organic solvents, extreme pH or temperature, and radiation can affect the structure and thus the activity of proteins and enzymes.

Pazur et al. (58) and Gibson and Woodward (55) studied the activity of alcohol oxidase stabilized by saccharides and stored in dry form. The activity was monitored as a function of time, and certain sugars, especially cellobiose, inositol, and trehalose, maintained the enzyme at high activity levels, and the resulting mixtures also demonstrated higher activity in methanol oxidation (Fig. 7). Enzyme activity can be altered in many ways. The geometric structure of the polypeptides that make up enzymes must be kept intact, so that the active site of the enzyme retains its configuration. Enzymatic structure can be altered by pH, temperature, organic solvents, and shear stresses as well as the presence of other chemicals in solution. These chemicals can act as inhibitors or activators to alter the rates of substrate/enzyme reaction. The reaction mechanisms are shown in Scheme 1.

Figure 7. Alcohol oxidase stabilization by disaccharides. Sugars were added to the enzyme at concentrations of 1–10% immediately before drying. The solutions were dried in shallow dishes at 30°C under a vacuum and then harvested, ground to a powder, and stored in vials at 37°C. Enzymatic activity was assayed with methanol as a substrate using an oxygen electrode and a colorimetric assay [reprinted with permission from (55); copyright 1992 American Chemical Society].

Scheme 1. Enzyme (E) reaction mechanisms for substrate (S) conversion involve the formation of an enzyme–substrate complex at the active site, which catalyzes the conversion of substrate(s) to product(s) (P). The presence of an inhibitor (I) chemical can reduce reaction velocities because fewer enzymes are available for complexation with the substrate. Alternatively, enzyme activators (A) help to stabilize the enzyme conformation and may make the active site more accessible to forming the substrate–enzyme complex (EAS, when the enzyme is complexed with both the activator and substrate).

Enzyme activity can also be reduced due to diffusional limitations imposed by the polymer network on interactions between the enzyme and its substrate. The Damköhler number, Da , as defined following, provides a measure of the importance of diffusional resistance to normal enzyme kinetic behavior:

$$Da = \frac{v_{\max}}{\left(\frac{D_{es}}{\delta^2}\right) s_0} \quad (1)$$

In Eq. (1), v_{\max} is the maximum reaction velocity for the enzyme–substrate reaction, D_{es} is the effective diffusion coefficient for diffusion of the substrate through the polymer membrane, taking tortuosity and porosity into account; δ is the distance required for the solute to diffuse through the membrane; and s_0 is the substrate concentration in the bulk solution (59). For Da values greater than 1, the enzyme–substrate reaction proceeds as usual, but for Da much less than 1, the matrix is a significant hindrance to substrate diffusion and lowers the observed reaction rates.

SMART POLYMERS FOR IMMOBILIZATION AND BIOCONJUGATE MATERIALS

The recent research in smart polymers has led to intriguing materials for applications ranging from separations and surface modifications to drug delivery and self-contained biomedical sensing devices. In addition to the materials listed in Table 7, many researchers have used smart polymers to immobilize enzymes. The devices formed by this combination afford possibilities of protecting the enzyme from temperature or pH swings or acting as part of a biosensor response mechanism. Chen et al. (60) immobilized α -amylase by esterifying the side chains of temperature-sensitive poly(*N*-isopropylacrylamide) and poly(*N*-acryloxysuccinimide) gels to improve the thermal stability of the enzymes by preventing structural changes and exposure to solvent as the immobilized enzyme is exposed to high temperatures. There was no significant loss in enzymatic activity after immobilization when exposed to high temperatures because the temperature-sensitive phase separation of the polymer network shielded the amylase from solutions above the polymer lower critical solution temperature (LCST). Above this temperature (in aqueous solutions, at approximately 30°C for polymers based on *N*-isopropylacrylamide), the gel collapses, reducing the amount of water surrounding the enzyme, and the polymer collapses providing stabilization to the enzyme structure.

In addition to protecting enzymes from thermal denaturation, thermally reversible gels can also be used to control rates of reaction. For example, the temperature-dependence of α -chymotrypsin activity was affected by the polymer behavior when immobilized by physical entrapment in poly(*N*-isopropylacrylamide-*co*-hydroxyethyl methacrylate) gels (61). Figure 8 shows the effect of temperature on free enzymatic activity versus enzyme bound in the temperature-sensitive gel. The maximum reaction rate for the immobilized enzyme was observed below the gel's LCST, at 30°C, and decreasing activity observed at higher temperatures was attributed to the polymer which

caused a change in enzyme conformation and diffusion limitations on the substrate, which must pass through the collapsed porous structure.

Smart polymers have also been used to influence binding and interactions between polymers and solutes, which can be controlled thermodynamically using pH, electrical current, temperature, or solution ionic strength as modulators for reversible processes in separations (62). These materials can be used to improve or modulate the sensitivity of biosensors by concentrating very low levels of analytes near the electrode or sensing device to amplify the signal (63). Schild (64) and Ogata (65) used phase-separating polymers to collect a particular analyte (Figure 9), such as immunoglobulin G (IgG). This method can aid in concentrating the analyte for detection, such as in antigen capture fluorescence immunoassays (48), where IgG concentrations can be correlated with fluorescent intensity. This method would be ideal for use in combination with optical detectors. As shown in Fig. 9, antibodies bound or otherwise immobilized to temperature-sensitive polymers can be designed to select and attract antigens.

BIOSENSOR OPERATION

In Table 1, biosensors are categorized by recognition processes. They can also be classified by the response mechanism used. Biosensor responses can be categorized as chemical such as production of dissolved oxygen or hydrogen ions, electrical, optical (using fluorescent or colored molecules), or mechanical (7). Colorimetric dyes, pH indicators, and bioluminescent molecules create optical responses that can be quantified spectrophotometrically; electrodes are used to deliver electronic signals that can be interpreted by computerized or simplified controllers; and smart polymers can change shape to give an optical response, swell, or shrink to control diffusion of a drug for release (Table 9). Bioluminescent molecules, such as luciferin, can be used in sensors, where light is emitted through metabolic production of adenosine triphosphate (ATP), so they are often used to detect bacteria in food and pharmaceutical production (20,66). Bioluminescence can also be used to monitor uptake of ATP due to the presence of glucose in sufficient quantity to begin the glycolytic metabolic pathway at the first reaction to convert glucose to glucose-6-phosphate; this results in reduced luminescent intensity (20).

Intelligent materials are used in biosensors in three main areas: signal detection, transmission of signal to a measuring electrode or the response element, and controlling the feedback response to the signal. Intelligent materials are those that respond to changes in the neighboring environment, and the response can be of different types. Polymer swelling can lead to physical work, such as shutting off a valve or making contact between the sensor and a secondary component. Swelling is also used in controlled drug delivery, whereby diffusion of embedded drugs controlled by the porosity of the cross-linked polymer carrier can be triggered by environmental changes that indicate the need for therapeutic agents. The material may provide a pathway for electron transport by using semiconducting

polymers, such as polypyrrole (67), polyaniline, or poly(vinyl pyridine) (68). Schuhmann (69) showed ways to improve electron transfer mediation in immobilized enzyme systems by using polypyrrole or polyazulen to facilitate electron hopping, similar to semiconductor materials, so that the signal could be transferred from the enzyme to the electrode (Fig. 10). Many intelligent polymers behave according to two-component thermodynamics and phases separate from a homogeneous solution as the polymer turns from a primarily hydrophilic to a hydrophobic entity.

The signal can be transduced by using amperometric or potentiometric methods, field effect transistors, piezoelectric crystals, thermistors or optoelectronic systems (10), or by using closed-loop systems within the device where feedback is sent by using a smart polymer. Amplification

of the signal is important, especially when the target molecule is in very small concentrations. Skaife and Abbott (70) used liquid crystals to measure the binding of IgG, where the concentration ranged from 1–100 nM.

GLUCOSE SENSORS

Much of the recent literature on biomedical sensing has focused on methodologies for detecting glucose levels in diabetic patients to sense the need for insulin release without requiring self-diagnosis through needle sticks. Diabetes is a highly prevalent disease in the United States, and many researchers have been searching for methods of mimicking a naturally functioning pancreas through tissue engineering, encapsulating pancreatic islets of Langerhans cells, creating insulin pumps that use electronic glucose sensors, or developing responsive polymers to detect high glucose levels and deliver insulin. As of 1996, the blood glucose monitoring market in the United States amounted to approximately \$750 million per year and was growing at a rate of 10% per year (21). There is great potential and motivation to study more convenient, reproducible, and cheaper methods of determining blood glucose, and because of the recent intensity of research in this area, many novel glucose monitors, such as the Glucoprocessur(R)

marketed by Solea-Tacussel in France as early as 1988 (10), Bayer's Glucometer[®] DEX[®] Diabetes Care System, and Roche Diagnostics' Accu-Chek[™] line, have reached consumers.

Glucose sensors include a range of devices. Amperometric biosensors use immobilized glucose oxidase, an enzyme that converts glucose to gluconic acid and hydrogen peroxide. Hydrogen peroxide is measured by electrodes and can be correlated with the glucose levels, even at micromolar concentrations (6, 71–73). Subcutaneous insulin pumps are either user-controlled or contain a glucose-sensing system that creates a closed-loop feedback insulin delivery system to provide a simplified method for monitoring and treating hyperglycemia (21). Diabetic glucose is typically monitored by sampling a small quantity of blood and using a chemical test kit; biosensors have been developed to analyze samples extracted across the skin by electroporation or iontophoresis (16). Several methods using smart materials for insulin delivery incorporate glucose-sensitive enzymes or chemical linkages that are disrupted by glucose (74,75).

Martin et al. (76) studied ultrathin film composite glucose sensors based on a glucose-permeable membrane to immobilize a solution of glucose oxidase, ferrocene as a mediator, and amperometric electrodes. Transduction of signals from the reaction is rapid because all diffusion is in the aqueous phase. They found a linear relationship between glucose concentration and current in the range of 2–22 mM glucose (Fig. 11).

Schuhmann et al. (69) demonstrated that adding electron transport functional groups to polymers (such as the material shown in Fig. 10) using conducting polymers (β -amino(polypyrrole), poly(4-aminophenyl)azulen, or poly(*N*-(4-aminophenyl)-2,2'-dithienyl) pyrrole), the amperometric response to glucose could be modified (Fig. 12). The poly(*N*-(4-aminophenyl)-2,2'-dithienyl) pyrrole conduction mediator showed the greatest proportional amperage response to glucose, but the linear relationship ended around 5 mM glucose concentration. The other two mediator-conducting polymers provided nearly linear current–concentration curves across the range from 1–14 mM glucose. Fortier et al. (77) verified the same

Figure 11. Calibration curve for the prototype ultrathin film composite glucose sensor. The regression coefficient for the linear region (up to 22 mM) is 0.995 [reprinted with permission from (76); copyright 1994 American Chemical Society].

general behavior of glucose oxidase electrodes, using a catalytic current from 0–200 microamps generated from 0–20 mM glucose solutions. Sung et al. (78) also used polypyrrole composites with polyanionic-GOx conjugates to improve electrical conduction within the hydrogel to achieve a correlation between glucose concentration and current. These results may provide a rationale for selecting particular components based on the glucose concentration range of interest.

These devices are designed for subcutaneous implantation, but biomedical diagnostic sensors can also be valuable for use *ex vivo* or on the surface of the skin to monitor glucose levels. A unique use of biosensors in detecting glucose is a method developed by Berner et al. (16), where glucose can be monitored without sampling blood. Glucose is iontophoretically extracted across the skin, a noninvasive method that may be much more convenient for diabetic patients. A smart material is used to sense glucose, using glucose oxidase to create hydrogen peroxide, which is determined electrochemically by a platinum electrode. Tierney et al. (15) developed a hydrogel coating for an electrode that incorporates glucose oxidase to make it possible to sense glucose levels electro-osmotically extracted from the skin as a diagnostic indicator for diabetic patients. Micromolar concentrations of H_2O_2 can be correlated with electrical signals of the order of several hundred nanoamps. The glucose sensors were also tested for response time to a small (2 nM) increase in glucose concentration (Fig. 13). The biosensor's response was an increase in current of $1.5 \mu A$ in about 30 seconds. Tamada et al. (79) also used the transdermal extraction technique to monitor glucose concentrations in blood.

Intelligent polymers have been used in a number of insulin delivery systems. Podual et al. (75) offer a different method for detecting glucose. Their method is based on glucose oxidase, as those mentioned before, to cause the reaction to produce gluconic acid, but the response is due to the localized increased concentration of acid (decreased pH) within the polymer membrane which causes pH-sensitive polybasic hydrogels to swell and release embedded insulin. Catalase, a second enzyme in the gels developed by Podual et al., was used to help drive the reaction toward

the formation of more gluconic acid by removing the hydrogen peroxide produced. Hassan et al. (80) used gels based on this technique to demonstrate that pH-sensitive hydrogels that contain glucose oxidase incorporated by Valuev's macromonomer technique are responsive to glucose concentrations, swell rapidly as glucose is converted to gluconic acid, and return to normal swelling states as the hydrogen ions dissipate from the localized area within the gel (Fig. 14).

Another method for glucose-sensitive insulin release was proposed by Kim et al. (74) and Okano and Yoshida (81), where glycosylated insulin is attached to concavalin A and encapsulated in a semipermeable membrane that allows glucose to diffuse in. Concavalin A prefers to bind to glucose, and insulin is released in proportion to the glucose that enters the capsule.

Okano (82) also demonstrated a concept using smart polymers to sense the presence of glucose. Insulin is encapsulated inside a composite polymer membrane that is cross-linked with boric acid (Fig. 15). Glucose disrupts the borate cross-links and opens small pores in the membrane, which allow the encapsulated insulin to diffuse through the network until the glucose level returns to normal. This method may require some improvements to function *in vivo* because the pH and the buffering effect of physiological fluids may disrupt the release mechanism.

Yuk et al. (83) showed that the pH- and temperature-responsive copolymers P(DMAEMA-co-EAAM) could be pressed into tablets that include glucose oxidase and insulin; an observed pulsatile release of insulin occurs, and release is turned on at glucose concentrations of 5.0 g/L and off when it dropped to 0.5 g/L (Fig. 16). This method makes it possible to combine sterilizable polymers and known amounts of insulin and glucose oxidase without the complications of forming hydrogel systems, which generally require a solvent. This method also may prevent degradation or inactivation of biological components, including both the enzyme and insulin, during the immobilization step.

OTHER ANALYTES FOR BIOLOGICAL SENSING

There is tremendous potential for biosensors based on analytes besides glucose. In addition to the chemicals listed in Table 4, biosensors have been developed that respond to or measure pH, chloride levels, magnesium (18), bilirubin, blood gases (84), triglycerides (21), creatinine, and various saccharides (23,85). For example, Karube and Sode (85) used microbial detectors to determine fish freshness by immobilizing CO_2 -using bacteria to measure metabolic rates in fish. They also developed microbial immobilization methods for determining creatinine levels in kidney dialysis and enzymatic immobilization methods to determine hypoxanthine concentrations. Maeda et al. (86) formed block copolymers of poly(styrene-co-acrylonitrile) with poly(L-glutamate) which respond to Ca^{2+} and urea and produce smart materials that give a linear current response to urea concentration (Fig. 17), because the poly(L-glutamate) changes conformation in response to high urea concentrations.

Sirkar and Pishko (87) showed that hydrogel biosensors can detect galactose and lactose by incorporating their respective oxidases into polymer networks. Galactose sensing is useful in monitoring liver response to sepsis (88), and lactose monitoring can be used in sports medicine, myocardial infarction, and pulmonary edema to determine lack of oxygen supply to tissue (89). Sirkar and Pishko's biosensors produce a nanoamp range current proportional to galactose concentrations, but also noted that oxygen in the air surrounding the device reduces the response, due to enzyme inhibition by O_2 .

MODES OF RESPONSE IN SMART POLYMERS

As shown in Fig. 1, the use of smart materials in conjunction with sensing devices makes it possible to have a closed-loop device that responds by pH-stimulated drug

Figure 18. An “on-off” release profile of acetaminophen from NiPAAm/AAC gel in response to a temperature change between 35 and 40°C [reprinted from (93); copyright 1997, with permission from Elsevier Science].

delivery. Kaetsu et al. (4) immobilized acetylcholine esterase and glucose oxidase in poly(acrylic acid) to achieve a biosensor that has a pH-sensitive drug delivery feedback mechanism, and they showed that the device can deliver drugs in response to elevated substrate concentrations.

Ichikawa and Fukumori (90) developed temperature-sensitive networks that have small temperature-responsive beads made of poly(*N*-isopropylacrylamide) dispersed in ethylcellulose that allow the pores to open as temperature increased for drug delivery. Drug delivery based on pH- and temperature-responsive materials has been extensively researched (64,91–95), and is reviewed elsewhere within this article. Using materials that act similarly to amperometric biosensors, Guiseppi-Elie et al. (96) showed that electroconductive gels synthesized from polyaniline/polypyrrole could respond to an electric charge for direct delivery of peptides. These drug delivery systems do not respond directly to an increase in a particular molecular concentration (except for $[H^+]$ in pH-responsive systems), but they do sense changes in biological conditions that may occur naturally, such as pH-gradients in the gastrointestinal tract, pH changes due to the coagulation cascade, or temperature changes in tissue which is necrosed or nutrient-starved. Gutowska et al. (93) showed an on-off acetaminophen delivery system as a function of

Figure 19. (a) A long bi-gel strip that has one PAAM side modulated by NIPA gel. At room temperature, the bi-gel is straight. (b) When the sample temperature is raised to 39°C, the gel becomes a spiral [From (Vol); copyright 1997; reprinted by permission of John Wiley & Sons, Inc.].

temperature for a gel made from *N*-isopropylacrylamide and acrylic acid (Fig. 18).

Targeted drug delivery devices also fit in the category of materials for biomedical sensing because they are designed to detect cellular or other biological surfaces or chemicals in the body to trigger release. Enteric delivery systems (97) are a well-used version of targeted systems. Other targeted systems rely on surface modification, so that the carrier recognizes the target tissue or biomolecules (98).

A unique response for diagnostic tests using biosensors and smart polymers is the change of device shape observed when asymmetrical gels are exposed to variations in temperature or pH. Zhang et al. (99) and Hu et al. (100) showed that PNIPAAm asymmetrical gels bend due to differential swelling capacities to change shape as temperature changes (Fig. 19). These gels have potential applications based on visual observation of analyte level changes and also on the possibility of controlling electrical conduction

Figure 20. Method of forming molecularly imprinted surfaces on polymers. (a) Target molecules (such as proteins or antibodies) are placed at the surface of a prepolymer solution. This solution is then polymerized or cross-linked in the presence of the target molecule at the surface (b), creating a geometry on the surface of the polymer which is complementary to the target molecule and can fit together like a jigsaw puzzle after surface extraction (c).

Figure 21. Mechanism of selective interaction between a molecularly imprinted polymer surface and biological molecules. The surface is designed to match the three-dimensional geometry of proteins or other biomolecules and prevent interactions with nontarget molecules. If the imprinted polymer is an environmentally sensitive material, a change in pH, temperature, or other conditions will provide a transition mechanism to attract and release the target molecule.

by alternately completing and disconnecting molecular switches if the asymmetric gels are formed from semiconducting polymers.

MOLECULAR IMPRINTING

Molecular imprinting is a relatively new research area that may have applications in biomedical sensing. Polymer templates are formed, as shown in Fig. 20, where an imprint of the target molecule is placed on the surface of the polymer or gel to enhance interactions and binding between the surfaces and mimic the complementary geometries of enzymes and substrates. These materials can easily be mass-produced and would be much cheaper than their biosensor counterparts, which use enzymes or cells for detection. The combination of smart materials and molecularly imprinted surfaces may make binding interactions reversible because the geometrically complementary site will match only under specific physiological conditions (Fig. 21).

A recent example of the development of molecularly imprinted polymers is reported by Sreenivasan (102), who created cholesterol-recognition sites in radiation-polymerized poly(2-hydroxyethyl methacrylate) which increased the affinity for molecular interactions between the polymer and cholesterol, so that it was easier to detect very small quantities of “imprinted” analytes. Arnold et al. (103) reported the use of molecularly imprinted polymers in combination with fiber-optic luminescence to create highly sensitive chemical sensors. Several other researchers have reported methods of synthesizing imprinted devices (104) and advantages of this technique (105). This field shows much promise for making synthetic biosensors that do not rely on often expensive enzymes or microbes for detection.

POSSIBILITIES FOR FUTURE DEVELOPMENT

Based on rapid advances in thin film chemistry, design of microchips, and tissue and cellular engineering, it is quite foreseeable that biological sensors can be made more reproducibly to detect analytes and disease states using complex enzyme or cellular reactions. Intelligent polymers will be used in these devices in the feedback loop—either in conducting a signal or in responding to treat the abnormality

directly—through combination with drug reservoirs, for example. Some of the challenges still lying ahead for the developing materials for biomedical sensing include improvements in biocompatibility, lifetime of the sensor, minimizing signal drift, maximizing sensitivity, developing the capability to recalibrate sensors *in vivo*, and using materials that are sterile or sterilizable.

BIOMIMETIC ELECTROMAGNETIC DEVICES

MORLEY O. STONE
 RAJESH R. NAIK
 Wright-Patterson Air Force Base
 Dayton, Ohio

INTRODUCTION

Literally, the term *biomimetics* means to imitate life. Practically, biomimetics is an interdisciplinary effort aimed at understanding biological principles and then applying those principles to improve existing technology. This approach can mean changing a design to match a biological pattern, or it can mean actually using biological materials, for example, proteins, to improve performance (1). Biomimetics had its earliest and strongest footholds in materials science, and it is rapidly spreading to areas such as electromagnetic sensors and computer science.

The area of biomimetics covered in this article applies to sensing electromagnetic (EM) radiation. Volumes have been written regarding how higher organisms perceive visible light, and thus, this will be largely ignored here. Mostly, coverage is limited to biological sensing of EM radiation on either side of the visible, the ultraviolet, and the infrared. From a biological sensing perspective, spectral regions are defined as follows: near-ultraviolet wavelengths (λ) from 200–400 nm and infrared wavelengths from 0.75–15 μm (Fig. 1). Operationally, both the ultraviolet and infrared extend over larger wavelength intervals. This article outlines some of the electromagnetic detection/sensitive systems in biology.

BIOLOGICAL ULTRAVIOLET AND VISIBLE SYSTEMS

The electromagnetic spectrum extends from gamma and X rays of wavelengths less than 0.1 nm through ultraviolet, visible, infrared, radio, and electric waves. The solar spectrum of radiation that reaches the earth's surface ranges from 300–900 nm; radiation in the ultraviolet (200–300 nm) is mostly absorbed by the ozone layer in the upper atmosphere. Light that passes through the atmosphere reaches the earth's surface and also enters large water bodies. As penetration increases, the extremes of the visible spectrum are absorbed, allowing a narrow radiation of

Figure 1. Chart of EM radiation definitions used in this article.

blue-green light (500 nm) to penetrate at depths greater than 100 meters. Radiation in the near ultraviolet, from 300–500 nm, is important in photobiological responses that include phototropism, phototaxis, and vision. For example, the spectral sensitivity of many insects and some birds is from 360–380 nm, and for invertebrates, it is from 500–600 nm. Radiation from 600–700 nm is important in photosynthesis, and radiation from 660 nm into the near-infrared is important for plant and animal growth, flowering of plants, and sexual cycles in animals. Nucleic acids and proteins absorb ultraviolet radiation at 260 nm and 280 nm, respectively. Absorption at these wavelengths produces damaging effects including mutations and cell death. Fortunately, organisms can repair the damaging effects of ultraviolet light on their genetic material by activating UV repair mechanisms.

Insect Vision

The discovery of visual sensitivity in insects dates back to the 1800s, but substantial proof of the visual sensitivity of insects was provided in the last 20 years or so. The spectral range visible to insects extends from the ultraviolet through the red. Studies of the behavioral response of insects suggest that insects have wavelength-dependent behaviors. The ability of an organism to discriminate differences in wavelength distribution and use this information to direct its behavioral response within a given environmental setting enables it to select its food source, avoid detection by prey, and identify potential mates (2).

The compound eyes of insects are made of eye facets, or ommatidia. The number of ommatidia varies from one species to another: about 10,000 in the eyes of dragonflies, 5500 in worker honeybees, 800 in *Drosophila*, and one in ants. Each ommatidium is a complete eye that consists of an optical system and the photoreceptor, which converts light energy to electric energy. The optical system consists of the corneal lens and the crystalline cone that transmits the image to the photoreceptors. The compound eye of the common fruit fly *Drosophila melanogaster* is composed of about 800 ommatidia (Fig. 2); each ommatidium is approximately 10 μm in diameter and 100 μm long. The ommatidium consists of a corneal lens, a crystalline cone, retinula cells, and a sheath of pigment cells that extend across the entire length of the rhabdom (2). The rhabdom consists of eight individual rhabdomeres (R1 to R8), but as seen in Fig. 2D, only R1–R7 are visible; R8 is not visible because it lies underneath R7 (1). The ommatidia of honeybees consist of nine rhabdomeres (3). The rhabdomeres contain unique photopigments (opsins) that have characteristic spectral properties.

Image formation depends on the optical properties of the corneal lens and crystalline cone that aids in maximizing the amount and quality of light and focuses that light onto the rhabdomeres. The chromoproteins (rhodopsins) within the rhabdomeres interact with visible photons and in turn convert light energy to electrical energy (4). The rhabdom acts as a light guide or waveguide, mainly because of its long narrow cylindrical geometry. The length of the rhabdom increases the probability that an entering photon of visible light will interact with the visual pigment.

Figure 2. (A) Scanning electron micrograph of the adult eye; (B) longitudinal section through the eye showing the corneal lens, crystalline cone, rhabdom and the pigment sheath; (C) cross section through the ommatidium; and (D) cross section through the rhabdom to show the orientation of the photoreceptors (courtesy of John Archie Pollock).

Light that enters the rhabdom at a certain angle to its long axis is totally reflected and contained within the rhabdom, whereas light that enters at oblique angles is lost.

Rhabdomeres whose diameters ($0.5 \mu\text{m}$) are similar to the wavelength of light in the visible spectrum function as waveguides. The rhabdomere can transmit or guide this electromagnetic energy within its small cross-sectional area. The small cross-sectional area of rhabdomeres prevents light from being uniformly distributed which causes interference. This, in turn, causes the light to

propagate in patterns known as modes (dielectric waveguide). The effect of confining the photopigment within a rhabdomere of small cross section, it is believed, causes a shift from its visible absorptive peak to lower wavelengths and increases the UV peak absorption (5). In other words, the physical properties (size and shape) of rhabdomeres affect their spectral, polarization, angular, and absolute sensitivity. For example, in *Drosophila*, photoreceptor R7 that has a smaller diameter filters out a high proportion of the ultraviolet and blue light, whereas R8 (beneath R7)

Figure 3. A scanning electron micrograph of a transparent insect wing (courtesy H. Ghiradella).

receives longer wavelengths. In bees, the rhabdomeres that are short and have a larger cross-sectional area mediate polarized vision (3). The sky appears bright blue because sunlight is scattered by molecules in the atmosphere (Rayleigh scattering), and as a result the light becomes polarized. The polarization pattern of skylight offers insects a reference for orientation. The ommatidia in the dorsal rim of compound eyes in insects are used as a polarized light detector (3). Rhabdomeres generally fall into three classes that are maximally sensitive to light: 350 nm (ultraviolet), 440 nm (blue), and 540 nm (green) (6).

Optical engineers have attempted to develop imaging systems that function like the eyes of animals. Although replicating the visual system of an eye is probably a very arduous task, imaging systems have been developed that combine light sensors, photocells, microchips, and cameras. Nature has developed optical systems in animals through millions of years of evolution, so much can be learned by studying animal or insect eye architecture. The compound eyes of insects have been quite informative in designing imaging devices. A multiaperture lens that has an array of glass rods arranged in a hemisphere was developed by Zinter in 1987. The multiaperture lens consists of hundreds of rod elements that have a graded index of refraction, and each rod or optic element acts as a single lens. Each lens transmits a small portion of the image, and at the focal point, each rod produces an overlapping image. The images are then transmitted via optic-fiber bundles, and the superimposition of the image creates an intensified image. This type of device has advantages such as detecting objects in low light and a wide field of view.

Antireflective Coatings

The surfaces of compound eyes of numerous insects appear smooth, but in certain insects, the front surface of the corneas are completely covered by protuberances known

as “corneal nipples” (7). These corneal nipples are an antireflective device in the broadband wavelengths from the near-UV to red (8). It is believed that these structures function to match the impedance of air to that of the lens cuticle; thereby they increase the transmission of light and decrease the reflection from the corneal surface across a broad wavelength range. The nipple array gives the insect two important advantages: greater camouflage and increased visibility.

Apart from insect eyes, insect wings also, it is known, function as antireflective devices. The transparent wing of a hawkmoth *Cephonodes hylas* functions as an antireflective device (9). It was shown that the wing reduces light reflectance by about 29–48% across a broad wavelength range (200–800 nm). An examination of the wing surface reveals the presence of nanosized protuberances similar to the corneal nipples in insect eyes (Fig. 3). The wing protuberances, like the corneal nipple, also function to match the impedance between the cuticle and air. The individual protuberances are not detectable under visible light because their small size limits visible light diffraction. Each single protuberance functions as an antireflective device. By packing the protuberances closely in two-dimensional space, nature has optimized the most efficient way for the wing to function as an antireflective device. The transparent wing is difficult to distinguish from the background and provides good camouflage to the insect. Interestingly, wings coated by a thin layer of nanosized gold particles (8 nm) reduced the metallic reflection of the gold particles presumably by changing the surface metal from a reflective to a dark absorptive one (9). The optical properties of the nanostructures on insect wings can be used as a model for designing new optical devices that consist of nanosized structures (Fig. 4).

Butterfly Wings

The wings of butterflies are adorned by beautiful patterns and colors. Some wings are uniformly colored, whereas others reflect yellow, orange, red, green, blue, violet, or black. The colors of butterfly wings as well as insect eyes are generated by interference, diffraction, and scattering. The nature of the wing surface structure leads to the absorption of certain wavelengths and the reflection of other wavelengths of light; in addition, some wavelengths may even be transmitted. The rainbow-like display of colors on butterfly wings is caused by iridescence, due to the reflection from multiple thin-film interference filters on the wing scales (10). For example, the metallic iridescence of *Morpho* butterflies is an interference color attributable to the structural features of its wings. Interference colors result from the reflection of light from a series of superimposed structures separated by distances equal to the wavelengths of light. The wing scale of the butterflies consists of a flat basal plate that carries a large number of vanes (or ridges) that run parallel to the length of the scale (Fig. 5). Each vane consists of a series of obliquely horizontal and vertical lamellae oriented lengthwise on the scale and their spacing is comparable to the bands of reflection. In *Morpho* wing scales, the horizontal lamellae are approximately 185 nm apart and are stacked in an alternate fashion to each other. *Morpho* butterfly wings produce a metallic blue

Figure 4. The fine nipples function as an antireflective coating. (a) Microlens array that functions to focus light onto the active area of a sensor; (b) subwavelength structure that functions as an antireflective surface (courtesy SY Technology, Inc.).

Figure 5. Butterfly wing scale structure.

interference color. *Morpho* butterflies can be seen from low-flying aircraft due to the iridescent colors of their wings and are visible from a quarter of a mile (11).

The male *Eurema* wing scales reflects light whose peak wavelength is 350 nm. The lamellae in the *Eurema* wing scales are stacked opposite each other and separated by an equal spacing of 83 nm. Ghiradella et al. (1972) demonstrated ultraviolet reflection from wing surfaces when the wing was tilted by 20° with respect to the incident light. The flapping of butterfly wings caused a change in hue proportional to the angle of the wing. A change in reflectance, abrupt intensity change, and a strong ultraviolet component that contrasts with the background may serve as long-range communication signals between insects. As mentioned earlier, insect compound eyes are maximally sensitive to UV, and hence, UV patterns caused by this reflection may serve as a potential source of communicative signals. Furthermore, vegetation generally absorbs UV wavelengths in this region, and this may serve to maximize color contrast with respect to insect vision. Most vertebrates do not see UV, so this spectral region may serve as a private channel of communication among insects.

BIOLOGICAL INFRARED DETECTION

The ability of biological organisms to sense infrared radiation has been studied in snakes, beetles, moths, bacteria, numerous other organisms, and even subcellular organelles. In much of this study, there is overlap and confusion between differentiating a process as infrared photon detection versus thermal detection. This is evidenced by the fact that literature comprising the infrared sensing area is quite limited; however, literature in the thermoreception area is voluminous. This section treats infrared and thermal reception as indistinguishable processes from a biological standpoint, and the terms are used interchangeably. Additionally, this treatment extends to three experimental infrared/thermal systems: snake, beetle, and bacteria.

Before delving into the specifics of biological infrared detection, a brief tutorial on blackbody radiation and thermal sources of IR is needed. Warm objects, such as mammals, emit energy in the infrared part of the electromagnetic spectrum. Table 1 lists three different temperatures: 300 K is listed as a background temperature, 310 K is listed to represent 37°C prey, and the 1000 K listing is representative of a forest fire. The 310 K listing and the 1000 K listing pertain to the snake model and beetle model of infrared

Table 1. List of Blackbody Infrared Emission Values For Objects at Various Temperatures

Temperature (K)	λ_{\max} (μm)	Total Flux (W/cm^2)	Bandpass Flux (W/cm^2)	
			3–5 Microns	8–12 Microns
300	9.66	4.59e-02	5.84e-04	1.21e-02
310	9.35	5.23e-02	8.31e-04	1.42e-02
1000	2.90	5.67	2.04	5.04e-01

reception, respectively, because each system tries to detect objects at these temperatures.

At first glance, the main difference between snake-based and beetle-based infrared detection is the wavelength region of peak intensity (λ_{\max}). Cooler objects, for example, mammals at 37°C, emit maximally in the far-IR, in the 8–12 μm atmospheric transmission window. As an object becomes hotter, for example, a forest fire at $\sim 750^\circ\text{C}$, the λ_{\max} shifts to shorter wavelengths that place it in the 3–5 μm atmospheric transmission window. Roughly two orders of magnitude more total flux come from a 1000 K object compared to that from a 310 K object. An object at 310 K emits 27% of its total flux in the 8–12 μm bandpass and 1.6% in the 3–5 μm bandpass. Alternatively, an object at 1000 K emits 8.9% of its total flux in the 8–12 μm bandpass and 36% in the 3–5 μm bandpass. This discussion of infrared emitting objects and which is the better emitter is important to keep in mind as we discuss biological infrared detectors.

Bacterial Thermoreception

Cellular processes are influenced by temperature, and therefore, cells must possess temperature-sensing devices that allow for the cell's survival in response to thermal changes. Virtually all organisms show some kind of response to an increase or decrease in temperature, but sensing mechanisms are not well understood. When bacterial cells are shifted to higher temperatures, a set of proteins known as "heat-shock" proteins are induced. These proteins include molecular chaperones that assist in re-folding proteins that aggregate at higher temperatures as well as proteases that degrade grossly misfolded proteins (12,13). Changes in temperatures can also be sensed by a set of coiled-coil proteins called methyl-accepting proteins (MCPs), that regulate the swimming behavior of the bacterium *Escherichia coli* (14). Coiled-coil proteins are formed when a bundle of two or more alpha-helices are wound into a superhelix (Fig. 6) (15). The MCPs can be reversibly methylated at four or five glutamate residues (16). Methylation and demethylation, it is presumed, is the trigger that dictates the response during temperature

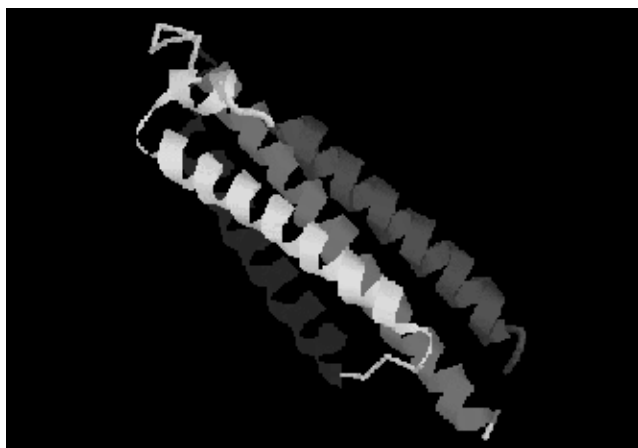

Figure 6. A cartoon showing the coiled-coil structure of MCP-II from *Escherichia coli*.

changes. The mechanism through which MCPs sense temperature is still not fully understood. In *Salmonella*, a coiled-coil protein known as TlpA has been identified as a thermosensing protein (17). TlpA regulates the transcription of genes by binding to sequence-specific regions on the DNA molecule. At low temperatures ($<37^\circ\text{C}$), TlpA interacts with another molecule of TlpA to form a functional (dimeric) molecule. As the temperature increases, TlpA dissociates from itself and becomes nonfunctional. However, the unwinding of TlpA helices is highly reversible, and a downshift in temperature leads once again to the formation of functional dimers. Because TlpA is not irreversibly denatured, it serves as an active thermosensing device. The fact that the denaturation and renaturation process is rapid allows cells to adapt quickly to changes in temperature. As shown in Fig. 7, the change in the structure of TlpA was measured by circular dichroic spectroscopy as a function of temperature. We observed that the thermal unfolding–folding is reversible and the protein displayed 100% recovery. To date, of all the proteins tested by us, TlpA exhibits the highest degree of reversibility with respect to this thermal unfolding transition. It is likely that TlpA, as well as MCPs, represent an adaptation of the coiled-coil motif as a temperature sensor by coupling its folding and unfolding to temperature cues. In addition, the ability of short synthetic coiled-coil peptides to undergo rapid thermal denaturation and renaturation (Naik and Stone, unpublished observations), suggests that the coiled-coil motif would be a model for designing new peptide-based thermosensing devices.

Snake Infrared Reception

The longest and best studied system of biological infrared sensing is the snake system. Snakes from two families, Crotalidae (pit vipers) and Boidae (boas and pythons), can sense infrared radiation by using specialized organs. In the crotalines, two infrared pit organs are positioned on either side of the head between the eyes and upper jaw. In boids, an array of infrared pit organs line the upper and lower jaw, and the number of pit organs is species specific. The ability of these organs to detect thermal energy was first

Figure 7. Reversibility of the thermal unfolding of TlpA.

Figure 8. SEM micrograph of IR pit organ surface.

described by Noble and Schmidt in the 1930s (18). Bullock and co-workers at UCLA further defined this area by their electrophysiological studies in the 1950s. His publications from this period continue as the referenced sources for the stated sensitivity of 0.003°C for crotaline infrared pit organs (19,20). Hartline continued to further the study of thermoreception in snakes throughout the 1970s, and he wrote a wonderful review article for the layperson in 1982 (21). For more than three decades, the center of snake infrared research has been in Japan based on the work of Terashima and Goris. Recently, this group published a book that compiles their research papers from this past decade (22).

Much of this previous body of work has been electrophysiological and descriptive using electron microscopy techniques. We recently published a detailed examination of the morphology of Boidae infrared pits using both atomic force microscopy (AFM) and scanning electron microscopy (SEM) (23). Our results were consistent with the earlier results of Amemiya et al. (24). In both publications, the function of the unique surface morphology that covers the infrared pit organs was speculated about (see Fig. 8). This speculation centered on the hypothesis that unwanted wavelengths of light, that is, visible, were being scattered and desired wavelengths of light, that is, infrared, were being preferentially transmitted.

To prove the speculation about visible light, we conducted a series of spectroscopy experiments to test the spectral properties of infrared pit scales compared to other parts of the snake (Fig. 9). This data suggested that the IR pit organ surface microstructure indirectly aids infrared detection by scattering unwanted visible wavelengths of light. Using various samples and repeated measurements, there was consistently more than a fourfold reduction in the amount of transmitted visible light. This loss of

Figure 9. Fiber-optic spectrophotometry, visible wavelengths.

transmission was attributed to scatter due to measurements using a helium–neon laser at 632 nm and a silicon detector. Shed IR pit skin transmission dropped faster as a function of detector distance compared to eye scale transmission; this indicated an increased scattering angle and limited sample absorption. The increased visible light scatter can be accounted for by using a simple Rayleigh model of scatter and incorporating the micropit dimensions of different snakes (23).

This difference in skin surface morphology as a function of location on the snake is a wonderful example of evolved tissue engineering. These unique dimensions are confined to a few square millimeters within the IR pit organ. From the standpoint of chemical composition, there is no difference, as indicated by FT-IR analysis (Fig. 10). The FT-IR spectra from shed IR pit skin and shed spectacle (eye) skin are identical to the amide bands of keratin that dominate the absorbance profile. Interestingly, note that regions of high skin transmission correspond to regions of high atmospheric transmission (3–5 and 8–12 microns).

As mentioned previously, the sensitivity of crotaline (pit viper) infrared detection, widely stated as 0.003°C , refers to the seminal work by Bullock and co-workers (20). However, this value was never measured directly but rather extrapolated from calculated assumptions. Furthermore, the measured values were determined as water was running over the pits—a conductive mode rather than a radiant mechanism of heat transfer. The function of prey detection has been studied extensively for these sensors (25). Bearing this function in mind, we attempted to examine the phenomenon of snake infrared reception in the context of the thermal radiative transfer among the sensor, prey, and background.

The actual molecular mechanism for infrared pit organ function is an active area of research in our group and others. Several models were proposed by de Cock Buning, and based on his work, we sought to construct a radiative transfer model that would measure the radiant flux of a biological object as a function of distance (26–28). De Cock Buning (27) presented thresholds and corresponding

Figure 10. FT-IR analysis of shed crocotaline skin.

detection ranges, but this analysis did not take into account the form factor relationships between emitter and detector and ignored the effect of the thermal background from the soil and atmosphere. The output from our model is the change in radiant flux (ΔQ) at the infrared pit organ as a 37°C object is moved. When this value becomes negative, the object (prey) no longer has a thermal signature greater than the background—essentially, it becomes invisible from an infrared, or thermal perspective. What was surprising in this analysis was how quickly the ΔQ value became negative, indicating extremely short detection distances of the order of <4 cm. The specifics of this model have been published elsewhere (29).

This modeling result raises very probing questions about the function of the infrared pit organs and suggests limited function in long-range prey detection. Instead, we agree with the speculation of Theodoratus et al. that IR sensing may be playing a role in strike orientation (25). Interestingly, when we apply this same type of modeling analysis to the beetle infrared system, we agree with the sensing distance quoted by Schmitz that a 10-hectare fire can be sensed at a distance of 12 km (see later) (30). This limited detection distance also raises questions as to how this research can contribute to IR sensor technology. Approaches that we are taking to increase the efficiency of biological thermal detection are covered in Biomimetic Applications.

Beetle (*Melanophila acuminata*) Infrared Sensing

The Buprestid family of beetles encompasses the genus *Melanophila*; for almost sixty years, research has shown that it is attracted to fires and smoke (31). Evans published the first scientific analysis of *Melanophila acuminata*'s response to specific infrared wavelengths (32). This early work documented *Melanophila*'s ability to detect forest fires at extreme distances. A current estimate is that it can detect a 10-hectare fire at a distance of 12 km, but distances as long as 50 km were proposed in the early literature

(30,31). The obvious question is why these particular beetles are attracted to forest fires. The answer is that many insects are drawn to forest fires because the burnt trees lack a natural defense against insect larvae and *M. acuminata* is the best characterized insect in this regard.

Estimated forest fire temperature is between 500 and 1000°C . We have chosen 1000 K as an approximate median, and as mentioned in the introduction to this section, an object at this temperature would emit radiation maximally around $3\ \mu\text{m}$. Therefore, this family of beetles responds to a fundamentally different part of the infrared spectrum, the $3\text{--}5\ \mu\text{m}$ atmospheric transmission window, compared to snake infrared reception at longer infrared wavelengths. Another distinction between the two systems is that snake IR reception is definitely thermal and may or may not involve mechanoreception; however, it is most likely that *Melanophila* IR reception is based on mechanoreception. In a recent report, Gronenberg and Schmitz analyzed the neurons from *M. acuminata* IR sensilla and postulated that they evolved from mechanosensory ancestors (33).

The IR pit organ of *M. acuminata* is a small structure that measures approximately $450 \times 200\ \mu\text{m}$. *Melanophila* possess two such organs under the second set of mesothoracic legs. Each organ is comprised of $70\text{--}100$ spherical sensilla that are approximately $15\ \mu\text{m}$ in diameter each (Fig. 11). The only other components of the IR organ are

Figure 11. Optical microscope image of *Melanophila acuminata* IR organ.

numerous wax glands that, it is hypothesized, keep the organ free of dust and dirt (34). The chemical composition of insect cuticle (chitin) and the secreted wax contain numerous C–H, N–H, and O–H chemical bonds that respond via stretch and vibrational resonances in this 3–5 μm wavelength range. Upon absorption of 3- μm radiation from a sufficiently hot thermal source, for example, a forest fire, the sensillum are thought to expand approximately 1 nm. This minute expansion is sufficient to trigger the firing of a mechanoreceptor at the base of each sensillum.

From an application standpoint, the IR pit organs of *M. acuminata* are a much more attractive target for biomimetic EM sensing. The known mechanical nature of the organ and the unique morphology of the sensilla make attractive targets for replication in a biosensor. In fact, we have begun to view this organ as nature's equivalent to the Golay detector developed in the 1950s. The following is a definition from Hudson's book on infrared detectors (35): "(An absorber) is heated by the incident radiation, which in turn heats the gas in the chamber. The resulting increase in pressure is observed optically by the deflection of a small flexible mirror." If one were to replace the small flexible mirror by a mechanosensitive neuron, this definition of a Golay cell's operation becomes very similar to the way *Melanophila's* sensilla detect IR radiation. Particulars regarding this type of biosensor development are covered in the next section.

ELECTROMAGNETIC APPLICATIONS OF BIOMIMETIC RESEARCH

When examining the landscape of biomimetics, the application is obvious in many areas, and many of these applications are defense-related. The study of fish swimming has obvious tie-ins to underwater locomotion and naval interests (36). Much of the work in structural biomimetics has Army interest due to the potential of producing next-generation, lightweight armor based on naturally occurring, biological composites (37,38). From a commercial standpoint, few biomimetic results have been as exciting as the recent successes in the biocatalyzed formation of silica and silica polymerization (39,40). A major portion of our economy, especially the technology sector, is based on manipulating silicon. It is easy to see why the ability to manipulate this element under benign, ambient conditions by using enzymes has many people excited.

Sensing electromagnetic radiation is of particular interest in aviation because of the increasing distances over which sensors operate. The ability to detect EM in the infrared without cryogenics has been an important technology driver because of increased sensor reliability and reduced payloads. The latter are becoming more important as space migration dominates defense and commercial interests. Against this backdrop, it is easy to see why biomimetics, and in particular biomimetic EM sensing, has been a growing part of research in many funding agencies.

We already discussed in the first section (Biological Ultraviolet and Visible Systems) how nature evolved incredibly intricate coatings and patterns to reflect, absorb, and transmit light. The complexity of these natural

coatings has made replicating them a challenge. Many of the curved surfaces involved in biological coatings, for example, the hawkmoth's corneal nipples and *Melanophila's* domed IR sensilla, would require gray-scale lithography, which at present is not a "standard" technique in micro- and nano fabrication. However, the 15- μm domed structure of each IR sensillum is giant compared to the feature sizes currently being produced by the microprocessor industry. Commercial companies are currently engaged in applying advanced lithographic procedures to replicate biological surfaces, and many of these lithographic techniques are being applied to nonstandard, that is, nonsilicon, materials like germanium (41).

The ability of insect structures like hairs or microscopic spines to gather electromagnetic radiation was postulated by Callahan (42). In that publication, insect antennae are considered dielectric waveguides that work in the infrared. Similarity is drawn between this biological structure and a drawing of an electromagnetic wave energy converter (EWEC) that was patented through NASA (US Pat. No. 3,760,257) for converting microwave EM energy into electrical energy (42).

In our own research, replicating the surface structure of boid and crotaline infrared pit organs has been a top priority. We feel that the replicating this surface structure would be an important advancement in optical coatings for infrared optics. The micropits of the IR pit organ are approximately 300 nm in diameter and the scale ridges are spaced at 3.5 μm . This latter dimension has implications in the infrared, and the former dimension has visible light consequences, as mentioned earlier. In recent publications, we have reported successful holographic duplication of snake scale structure in a photopolymer matrix (43,44). In using a holographic approach, light is used to record the fine details of a biological surface. By combining this "reading" beam and a reference beam, the resulting interference pattern can record a multitude of biological information.

Before proceeding from coatings to the application of biomimetics to infrared sensors, we will briefly review the state of artificial or man-made sensors. For further reference, *Infrared System Engineering* by Richard Hudson is an excellent source of information (35). Broadly, infrared sensors fall into two categories: thermal and photon (quantum) detectors. On the thermal side are thermocouples, thermopiles, bolometers, and pneumatic (Golay) detectors. The microbolometer format currently dominates this class of noncooled IR detectors in state-of-the-art detectors. On the photon detector side are photoconductive, photovoltaic (p-n junction), and electromagnetic detectors. In general, this class of detectors is cryogenically cooled and made from semiconductor materials. In comparing these two classes of detectors, speed has always been a big differentiator; thermal detectors respond relatively slowly times (ms) versus photon detectors (μs).

From a biological perspective, it is clear that biological infrared sensing is thermal. This conclusion arises from the fact that the pit organs are not made of semiconductors and that IR photons in the mid- to far-IR region of the EM spectrum simply lack sufficient energy to catalyze or trigger a conventional biochemical reaction. This is graphically represented in Fig. 12; the energy required to move an

Figure 12. Graph of energy (quanta) as a function of wavelength for various detector materials.

electron into the conduction band is plotted on the y axis and the wavelength on the x axis. In a photon detector, arriving quantized energy displaces electrons from the valence band to the conduction band. In semiconductors like InSb (indium antimonide), the forbidden energy gap is small, so that the energy contained in a mid- to long-IR photon is still sufficient to move an electron across this barrier. A material such as silicon has a larger forbidden energy gap, so that a photon past $\sim 1 \mu\text{m}$ in wavelength no longer possesses enough energy to move an electron into the conduction band (Fig. 12). If one extends this treatment to a generalized protein, the main intrinsic absorption at 220 nm (via the amide bond) correlates with an energy gap that can be bridged only by high-energy photons outside of the infrared region of the EM spectrum. Even highly conjugated biological chromophores, for example, chlorophylls, cannot use light that is beyond the very near-infrared.

After reaching this conclusion that biological infrared sensing is thermal, how then does one apply this knowledge to new detector strategies? To compete with an artificial inorganic detector that directly converts a photon to an electron, one needs to make the biological thermal process more efficient. In a biological system, infrared photons are absorbed in the form of bond vibrational and stretch resonant frequencies inherent in the chemical structure of the tissue. This molecular motion is eventually dissipated as thermal energy on a very minute scale. We believe that this is enough of a thermal change to alter the dynamic ionic concentration gradient maintained in the terminal nerve masses of the IR pit organ that eventually leads to a change in the neuronal firing rate. This change in neuronal firing rate is interpreted by the brain as either “hot” (increased rate) or “cold” (decreased rate). A successful biomimetic approach would simplify this process by engineering the “trigger” in this process, the original IR absorbing biological macromolecule.

A model for this engineering process is the aforementioned bacterial thermoproteins. The ability to manipulate bacterial genes easily and produce the desired recombinant proteins via fermentation make this a model system. To increase the efficiency of this biological system, we are exploring ways of optically sensing thermally induced

Figure 13. Schematic drawing of a thermal sensor based on a thermoprotein.

changes in protein structure. The use of circularly polarized light in circular dichroic (CD) spectroscopy is a common laboratory technique that optically records changes in protein secondary structure. A recent publication examined temperature-induced changes in polymer hydrogel swelling behavior using synthetic coiled-coil domains and CD spectroscopy (45). We are examining similar sensing concepts, as shown in Fig. 13. A critical step in the maturation of biomimetics for EM sensing will be meshing traditional synthetic polymer synthesis and processing with biochemistry and molecular biology.

There is a growing awareness of the contribution biomimetics can make to numerous well-established research areas, of which electromagnetic sensing is a small part. The highly interdisciplinary nature of biomimetic work makes it difficult for a single research group to be successful unless it truly spans several departments. The work is not only interdisciplinary, but additionally, few areas span basic, fundamental science to applied research as completely as biomimetics. Bearing this grand challenge in mind, there are still undreamed advances that can be made by imitating nature’s optimization that has occurred across millions of years.

INTRODUCTION

Biosensors consist of a biologically active layer that responding to an analyte in solution and a powerful transducer that transforms and amplifies the reaction into a measurable signal. Biosensors can constantly measure the presence, absence, or concentration of specific organic or inorganic substances in short response time and ultimately at low cost. They are used commercially in health care, biotechnological process control, agriculture, veterinary medicine, defense, and environmental pollution monitoring. A common requirement of all of these applications is on-site chemical information—preferably in real time—on some dynamic or rapidly evolving process. Most biosensors are based on molecular events as they take place at the cellular membrane or inside the cell involving enzyme cascades. Their perceived advantages over existing technologies include the ability to monitor broad or narrow spectra of analytes continuously in real time, and their weakness is the instability of the biological molecules outside their natural environment, which results in a restricted lifetime for the device. The challenge is to find a matrix for biomolecules that provides high compatibility of the material with biological substances, low-cost fabrication, and special optical and electrical properties to generate a signal that measures the interaction between analytes in solution and the receptive biological layer. It is also desirable that it be compatible with conventional microfabrication techniques to miniaturize the device or to build individually addressable arrays.

The high surface area in conjunction with its unique optical and electrical properties and its compatibility with silicon microelectronics fabrication techniques has led to the proposal that porous silicon may be a suitable material for building sensor devices. Several different transducer

schemes have evolved based on thin film interference, capacitance changes, and the photoluminescent properties of porous silicon.

HISTORICAL OVERVIEW

Porous silicon is not a newly discovered material. Ulhir reported 45 years ago that porous silicon (PSi) is generated during the electropolishing of silicon under anodic polarization in a hydrofluoric acid containing electrolyte if the current density falls short of a critical value (1). Since its first discovery, the material has been studied extensively because it was considered suitable for electronic applications (local insulation, gettering of impurities, sacrificial layers, etc.). However, the impact of PSi increased far more than expected in 1990 when Canham unexpectedly discovered a red bright photoluminescence from PSi at room temperature (2). The emission of visible light from PSi produced a sensation because the energy gap of silicon (1.1 eV) corresponds to the infrared region and does not explain the occurrence of photoluminescence in the visible regime. Within months after this observation, several labs reportedly detected visible light emission from PSi by passing an electric current through it (electroluminescence) (3). This was a vital discovery because any optoelectronic device that might use PSi will probably operate by conventional electroluminescence. Inspired by this unique property of PSi, the efforts of the scientific community during the last 10 years led to much useful information about aspects of PSi formation and its physical and chemical properties. Despite these efforts, several aspects of PSi formation and even some of the physical and chemical properties are still a matter of discussion.

POROUS SILICON FORMATION

PSi layers can be prepared chemically or electrochemically (4). The electrochemical route starting from boron (p-type) or phosphorus (n-type) doped silicon is mostly employed. For most electrochemical preparations of PSi (2–6), single-crystal silicon [(100)- or (111)-oriented wafers] is anodized in an aqueous or ethanolic HF solution under constant current conditions. The exact dissolution chemistry of silicon is still in question, although it is generally accepted that holes are required in the initial oxidation steps. This means that for n-type material, significant dissolution occurs only under illumination, high electric fields, or other hole-generating mechanisms. A couple of facts have been gathered about the course of pore formation: (1) hydrogen gas evolves in a 2:1 atomic ratio to silicon; (2) current efficiencies have been measured at approximately two electrons per dissolved silicon atom and (3) the final, stable end product for silicon in HF is H_2SiF_6 (4,5). Though the reaction mechanism is still unclear and several different mechanistic variants for the anodization of silicon surfaces have been proposed, a simplified sum equation can be written for the dissolution process:

One mechanistic model presented by Lehmann and Gösele comprises an entirely surface-bound oxidation scheme of hole capture and subsequent electron injection to produce the divalent silicon oxidation state (7). The silicon surface continuously vacillates between hydride and fluoride coverage at each pair of electron/hole exchanges. It appears that, despite the thermodynamic stability of the Si–F bond, it does not remain on the silicon surface in any stable, readily measured form. The present consensus is that hydrogen exists on the silicon surface in at least two different forms, Si–H and Si–H₂ and possibly a third form, Si–H₃. For both n- and p-type silicon, low current densities are essential in PSi formation (Fig. 1).

Low current densities ensure a sufficient amount of HF molecules (or F[−] ions) at the silicon–electrolyte interface. Because holes from the bulk silicon phase reach the bottoms of the pores first, silicon at the pore bottoms is preferentially dissolved. This is, however, a very simple explanation. Several other aspects of pore propagation are discussed in the literature, such as image force effects, hole diffusion, crystallography, charge transfer, quantum confinement, and surface tension (5). Higher current densities result in an excess of holes at the silicon–electrolyte interface, and the corrosion reaction becomes limited by diffusion of HF molecules (or F[−] ions). This leads to a preferential reaction of the upper parts of the silicon surface that results in smooth electropolishing (Fig. 1). Because electropolishing does not occur in organic solutions, it appears to depend on the formation of an oxide layer atop the silicon surface.

The formation of pores results from the complex interplay of chemical kinetics, charge distribution, and differing crystal face reactivities, so it is obvious that the issue of PSi films comprises rather different porous structures ranging from those holding micron-sized pores to sponge-like layers that contain nanometer-sized pores. Pore structures and dimensions are determined by a large number of preparative conditions: doping level and type, crystal orientation, composition of electrolyte, construction of the electrolytic cell, anodization regime, sample preconditioning, and postanodization processing (5). In fact, samples produced by different research groups are hardly comparable, even if the preparative conditions are apparently the same. No wonder great controversy exists over the mechanism of PSi formation.

CHARACTERIZATION OF POROUS SILICON

The body of knowledge about PSi formation has been obtained from current–voltage characteristics, as described earlier (5). Besides electrochemistry, several other methods have been employed to study the morphology of PSi. Among them, transmission electron microscopy (TEM) has contributed a large amount of information about structural details on individual pore propagation and silicon microcrystals because it is the only method to visualize microporous silicon directly (4). Scanning electron microscopy (SEM) is used mainly for macroporous silicon obtained from n-type or heavily doped p-type silicon etched at high current densities. Scanning probe techniques such as atomic force microscopy (AFM) are especially useful for

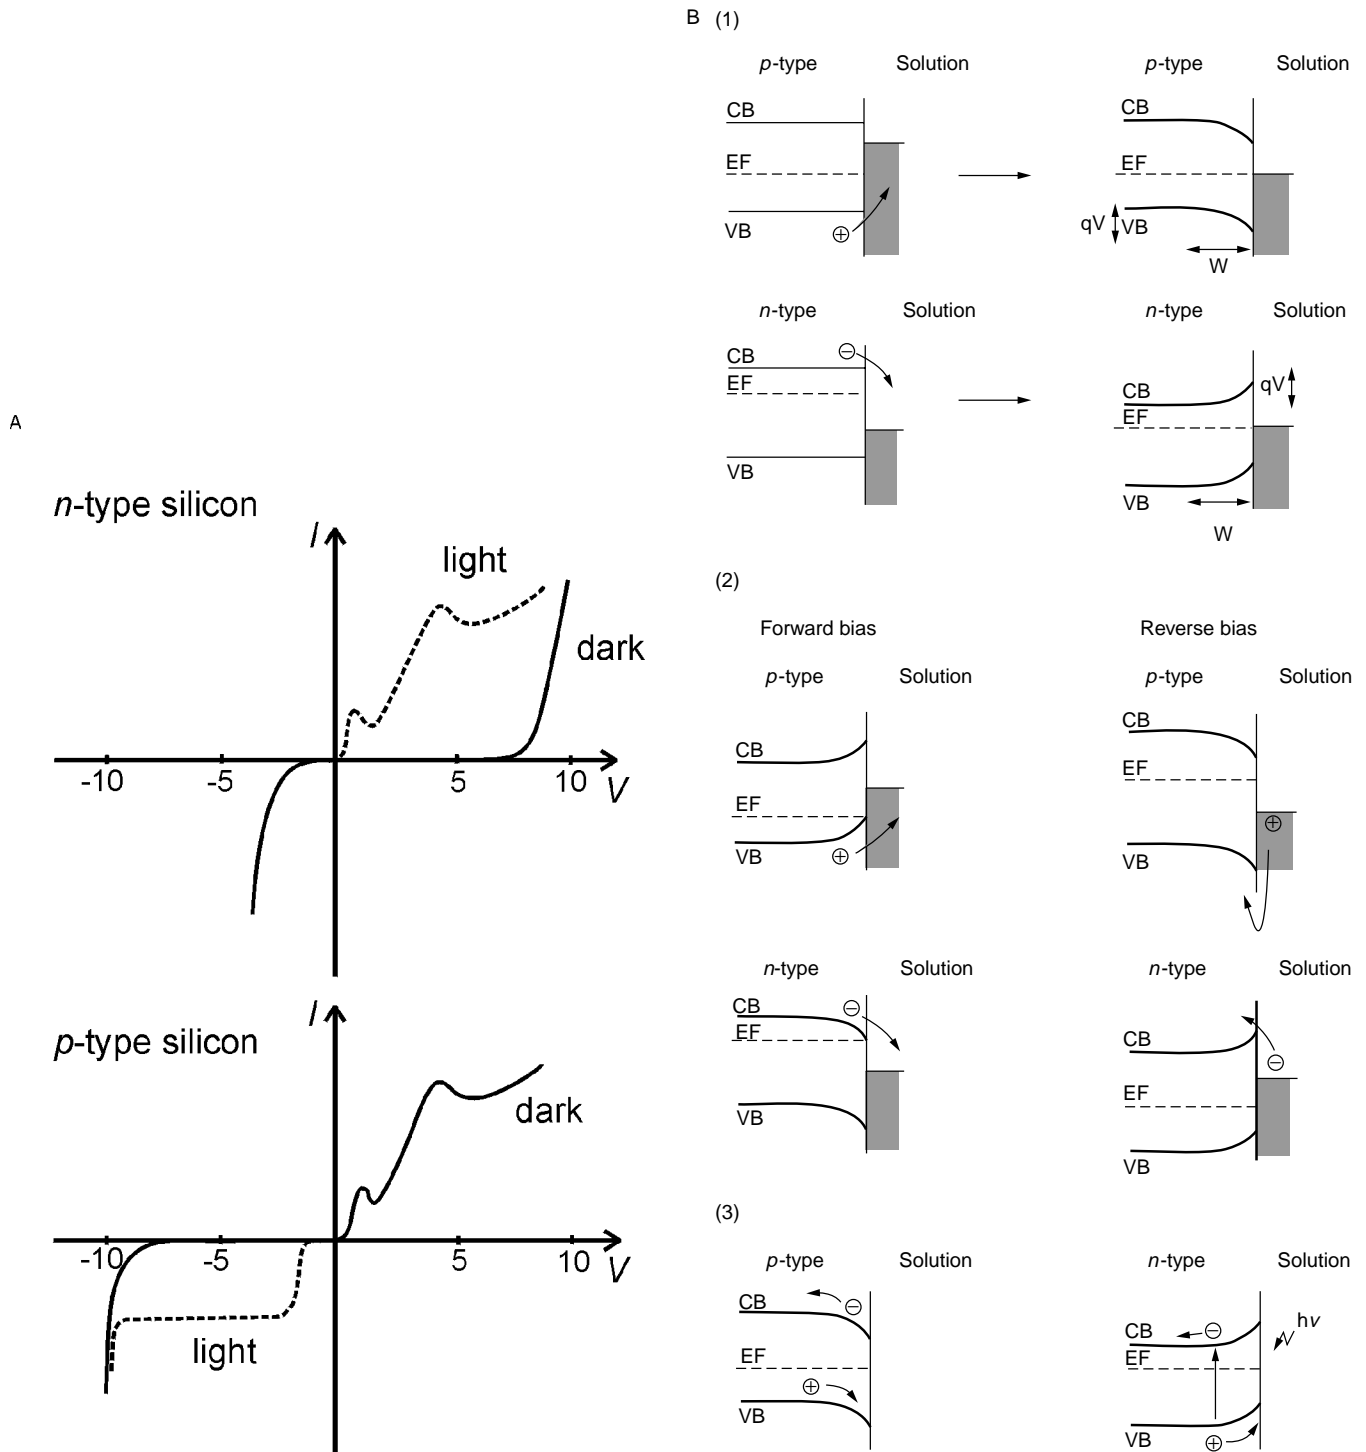

Figure 1. (a) Typical current–voltage relationships for n - and p -type silicon. The solid line is the dark response, and the dashed line indicates the response under illumination. The first (lower) current peak corresponds to a surface anodic oxide formed during and required for electropolishing. The second (higher) current peak marks the beginning of stable current oscillations and the possible formation of a second type of anodic oxide (5). (b) (1) The semiconductor–electrolyte interface before (left) and in thermal equilibrium (right), (2) at forward and reverse bias, and (3) during anodic etching. n -type PSi has to be illuminated to provide holes for the etching process. CB: conduction band, EF: Fermi energy, VB: valence band, W : width of the depletion layer.

detecting topographical features in conjunction with material properties such as friction, elasticity, conductance, and energy dissipation. Quantitative data about porosity and poreradii distribution may be inferred from low-temperature adsorption and desorption of gases. The most prominent technique, the BET (Brunauer–Emmett–Teller) method, is based on measuring the gas volume adsorbed by a material as a function of pressure; the BJH (Barret–Joyner–Halendra) method uses the Kelvin equation to infer the pore radius from gas condensation inside the pores (8). Simple gravimetric analysis and profilometer measurements of pore nucleation and propagation have provided valuable information about the anodization of silicon (9). Optical properties and morphological details are studied by spectroscopic techniques such as UV-vis, Raman and IR spectroscopy, as well as spectroscopic ellipsometry (10). Ellipsometry reveals information about porosity and the dielectric function of the material and is particularly useful for determining changes in the refractive index and thickness of the material. Details of pore morphology can also be obtained from X-ray crystallography measurements, as demonstrated by grazing angle experiments using X rays and synchrotron radiation.

Key parameters that describe the overall properties of porous material are porosity and pore radius, which depend mainly on the composition and temperature of the electrolyte, the dopant concentration, and the current density (5). Pore sizes can vary over a wide range from macropores (pores >50 nm wide) and mesopores (2–50 nm) to micropores (<2 nm). Generally, an increase in pore radius accompanies an increase in the anodization potential or current density for both n- and p-type silicon. At low current densities, the pores are randomly oriented and filamentlike. In contrast, the pores “pipe” at high current densities close to the electropolishing regime. The effect of dopant concentration on pore morphology is well explored. The pore diameters and interpore spacings of lightly doped p-type silicon are between 1 and 5 nm and exhibit a networklike appearance. Increasing the dopant concentration results in forming clear channels that have larger pore diameters and directed pore growth. Although the n-type silicon is more complex, increased dopant concentration is characterized by decreasing pore diameter and interpore spacing. The pore diameters in n-type PSi are considerably larger than those of the p-type silicon at low dopant concentration (3,5). Electrochemical etching of lightly doped n-type silicon wafers in the dark results in forming low porosity materials that exhibit macropores whose radii are in the micrometer range. Under illumination, much larger porosities can be obtained and micro- to macropores are found. Using p-type silicon of low resistivity, the porous texture is always thin, and the pore size distribution is in the 1 to 5-nm regime.

The results of a systematic study of porous layers formed in heavily doped substrates has been published by Herino (11). Generally, the porosity increases as HF concentration decreases in p-type silicon, whereas the influence of the HF concentration on the pore size of the n-type is not very pronounced. The specific surface area is in the range of 180–230 m²/cm² in p-type silicon and 90–230 m²/cm² in n-type silicon and is not very sensitive to the forming parameters.

Figure 2. Photoluminescent spectra of lightly doped p-type PSi layers of various porosities. The layer is about 1 μm thick, and the specific resistivity of the silicon 0.2 $\Omega\text{ cm}$ in all cases [reprinted with permission from (10)].

OPTICAL PROPERTIES OF POROUS SILICON

The demand for visible light-emitting devices made entirely from silicon is enormous because silicon is the dominant material for electronic and optical devices such as waveguides, detectors, and modulators. However, silicon is an indirect semiconductor, and thus light emission is inefficient. A direct photon transition at the energy of the minimum band gap does not meet the requirement of conservation of momentum in silicon. Therefore, electrons at the minimum of the conduction band need a significant amount of time to receive the necessary momentum transfer to recombine with holes in the valence band. Consequently, nonradiative recombination reduces the quantum efficiency considerably and results in emission of weak infrared wavelength light due to its small indirect band gap of 1.1 eV (12). In 1990, Canham announced the discovery of photoluminescence from PSi electrochemically etched at room temperature (2). Figure 2 shows typical photoluminescent spectra of p-type PSi that depend on porosity.

Tunable photoluminescence from anodically etched silicon is expected to have great impact on the development of optoelectronics, filters, chemical and biological sensors, and optical data storage, to name just a few applications. The mechanism of luminescence, however, is still a matter of controversial discussions. Available models can be grouped into four classes: those based on quantum confinement alone, nanocrystal surface states, specific defects or molecules, and structural disordered phases (13). Experimental data, however, are most consistent with the so-called smart quantum confinement model that comprises the quantum confinement model, including contributions from surface states (14). The general features of light emission from PSi may be explained in terms of reduced nonradiative recombination, as deduced from time development of photoluminescent intensity after short laser pulse excitation. The rather slow decay provides evidence that reduction of nonradiative recombination, rather than an increased amount of radiative

transitions, is the reason for the enhanced quantum efficiency, compared to bulk silicon. Significant light emission is observed only for microporous silicon, and the band gap widens (1.4–2.2 eV) as crystal size decreases, essentially identical to the particle in the box phenomenon in quantum mechanics. The increased path length of electrons in larger crystals renders recombination with surface defects or other mechanisms very likely. Consequently, light emission from larger structures is poor, whereas bright luminescence occurs in microporous material and is accompanied by a shift to higher photon energies from the near IR to the visible region. There is a correlation between porosity as an indirect measure of particle size and emissive energy. The smallest particle size is obtained from lightly doped p-type PSi etched at low current densities. Moreover, evidence for nanocrystallinity of the porous material from ESR analysis, TEM measurements, and phonon-assisted luminescence strongly support the quantum confinement model (13). All three primary colors were obtained, and the consequences are important for future display applications (13,15). Many chemical sensors based on PSi use luminescent reduction and thus provide a transducing mechanism for quantifying adsorption of analytes on the surface. Examples of chemical sensors employing photoluminescent reduction are given later.

Because recent biosensor developments are based on the dielectric function of PSi films, it is instructive to review briefly the reflectance and transmission of PSi layers and emphasize interference patterns and suitable effective medium approximations. The dielectric function $\varepsilon(\omega)$ connects the dielectric displacement D to the electric field vector E (12). The polarization P represents the part of D that arises due to polarization of the dielectric material induced by an external electrical field. The total polarizability of matter is usually separated into three parts: the electronic, ionic, and dipolar. The dielectric constant at optical wavelengths (UV-vis) arises almost entirely from electronic polarizability, and the dipolar and ionic contributions are small at high frequencies (Fig. 3).

The dielectric function is not a constant but depends strongly on the frequency of the external electrical field. The frequency dependence of the dielectric function arises from relaxation processes, vibrations of the electronic system and atomic cores, that are accompanied by macroscopic polarization. At certain wavelengths, however, it is reasonable to assume a constant value. The dielectric function of a solid can be inferred from measuring the reflectivity, refractive index, and absorbance, all functions that are accessible by optical spectroscopy. The real and imaginary function of the dielectric function can be accessed from reflectivity measurements. The refractive index $n(\omega)$ and the extinction coefficient $K(\omega)$ are related to the reflectivity $r(\omega)$ at normal incidence in vacuum by (16)

$$r(\omega) = \frac{n + iK - 1}{n + iK + 1}. \quad (1)$$

By definition, n and K are related to the dielectric function by

$$\sqrt{\varepsilon(\omega)} = n + iK. \quad (2)$$

The measured quantity is the reflectance $R(\omega)$, which is related to the reflectivity $r(\omega)$ by its complex product:

$$R(\omega) = \frac{E_{\text{ref}}^* E_{\text{ref}}}{E_{\text{inc}}^* E_{\text{inc}}} = r^* r, \quad (3)$$

where E_{ref} is the electric field vector of the reflected light and E_{inc} that of the incoming light. The following description of thin film interference provides the necessary foundation to understand the functioning of most popular biosensors based on the shift of interference fringes that arise from reflections at thin transparent PSi layers. Because PSi can be described as a film of a particular dielectric function different from that of bulk silicon, it is instructive to look at wave propagation in thin films on solid supports. Assumption of transparency due to the high porosity of PSi simplifies the treatment. At the interface between two media that have different refractive indices (n_1 and n_2), an incident wave is partially transmitted in the medium and reflected (Fig. 4).

This follows from the boundary conditions for electric and magnetic fields. Reflectivity and transmission coefficients can be obtained from the Fresnel equations which can be simplified for normal incidence and ideal transparent media by taking $K = 0$.

In the visible range, the dielectric function of PSi may be described by an effective medium approximation (EMA). Porous silicon consists of two media, the pore filling and the pore walls. The geometry of the pores determines the way the dielectric functions of these two media can be combined to give an effective dielectric function between that of silicon and the pore filling medium. The following section briefly summarizes the most prominent effective

Figure 3. Frequency dependence of the different contributions to polarizability (12).

Figure 4. Concept of thin film interference. The incoming light is reflected at the PSi surface whose thickness is l and combines with the light beam reflected from bulk silicon to form an interference pattern. The path difference between the two rays is $\delta = \overline{abc} = 2n_2l\cos(\alpha)$. n_1 : refractive index of the upper medium; n_m : refractive index of the pore filling medium; n_3 : refractive index of bulk silicon; and n_2 : refractive index of the porous layer that has a pore filling.

medium theories (10), that are applicable to PSi films. The Maxwell-Garnett approach for two media is given by

$$\frac{\varepsilon_{\text{eff}} - \varepsilon_m}{\varepsilon_{\text{eff}} + 2\varepsilon_m} = (1 - p) \frac{\varepsilon_3 - \varepsilon_m}{\varepsilon_3 + 2\varepsilon_m}, \quad (4)$$

where p is the porosity of the material, ε_{eff} the effective dielectric function, ε_3 the dielectric function of bulk silicon, generally the host material, and ε_m denotes the dielectric function of the medium inside the pores—air or liquid in most sensors. The simple Maxwell-Garnett model is a good approximation for highly porous, spherical particles at a large distance from each other. It is seldom applied to PSi. The Bruggeman approximation is most frequently used to describe the effective dielectric function of two or more different media:

$$p \frac{\varepsilon_m - \varepsilon_{\text{eff}}}{\varepsilon_m + 2\varepsilon_{\text{eff}}} + (1 - p) \frac{\varepsilon_3 - \varepsilon_{\text{eff}}}{\varepsilon_3 + 2\varepsilon_m} = 0. \quad (5)$$

A concept for highly porous solids is provided by the Looyenga model that also involves one parameter, the porosity, to describe the microtopology of the material:

$$\varepsilon_{\text{eff}}^{1/3} = (1 - p)\varepsilon_3^{1/3} + p\varepsilon_m^{1/3}. \quad (6)$$

Theiss and co-workers developed a more realistic approximation taking into account the strength of percolation and a broadening parameter of resonances (10). This three-parameter approach is a good compromise between the general model from Bergmann that has a normalized distribution function $g(n, p)$ of so-called geometrical resonances and the simple one-parameter approaches. Porous silicon multilayers or superlattices may serve as a material for interferometric devices that lead to a number

of different applications in the design of Fabry–Perot interferential filters, distributed Bragg reflectors, and interferometric biosensors. Illumination of the porous matrix by white light leads to a characteristic interference pattern in the reflectance spectrum. Assuming smooth surfaces and a negligible absorption coefficient, one may infer the effective optical thickness n_2l , where l is the thickness of the layer and n_2 the refractive index of the effective medium from the reflectance spectrum that displays interference fringes due to alternating constructive and destructive interference of the light reflected from the top and bottom of the porous layer. Assuming an incident angle of 0° , the reflectance R of a thin PSi layer is given by

$$R = \frac{r_1^2 + 2r_1r_2\cos\left(\frac{4\pi}{\lambda}n_2l\right) + r_2^2}{1 + 2r_1r_2\cos\left(\frac{4\pi}{\lambda}n_2l\right) + r_1^2r_2^2}, \quad (7)$$

where r_1 is the reflectivity at the interface between the medium on top of the film (n_1) and the porous layer (n_2) and r_2 is the reflectivity at the interface PSi (n_2) and bulk silicon (n_3):

$$\begin{aligned} r_1 &= \frac{n_1 - n_2}{n_1 + n_2}, \\ r_2 &= \frac{n_2 - n_3}{n_2 + n_3}. \end{aligned} \quad (8)$$

Constructive interference occurs if the path difference fulfills $\delta = 2n_2l$ and is a multiple of the wavelength $m\lambda = 2n_2l$ ($m = 1, 2, 3, \dots$) that marks the distance between the interference maxima. It is instructive to consider the minimum and maximum reflectance at normal incidence. Evaluation of R_{min} and R_{max} permits one to obtain the effective refractive index of the PSi layer from interference measurements without knowing the thickness of the layer ($n_3 > n_2 > n_1$):

$$\begin{aligned} R_{\text{max}} &= \frac{(n_3 - n_1)^2}{(n_3 + n_1)^2}, \\ R_{\text{min}} &= \frac{(n_2^2 - n_1n_3)^2}{(n_2^2 + n_1n_3)^2}. \end{aligned} \quad (9)$$

For $n_2 > n_3 > n_1$, the expressions for R_{min} and R_{max} are vice versa, but this does not apply for PSi. Because the refractive index of the porous matrix is smaller than that of bulk silicon, one has to take into account that the reflectivity of the whole system is smaller than that of bulk silicon. Lower n_2 , however, results in steeper fringes, as shown in Fig. 5. Correction terms for finite roughness at both interfaces of the PSi layer were introduced by Lérondel et al. (17). Theiss and co-workers established a theory accounting for thickness variations (10).

The preceding treatment considers merely two-beam interference. However, multiple internal reflections occur in transparent films that give rise to sharper maxima than sinusoidal curves. An exiting wave, either in reflection or transmission, will combine the waves that have corresponding phase increments at each stage. It can be shown that the intensity of the transmitted light (a geometric series) gives a Lorentzian function. Multiple PSi layers

Figure 5. Simulated reflectance spectra of PSi exposed to air. The layer was $3.5 \mu\text{m}$ thick, the refractive index of bulk silicon 3.7, and the effective refractive index of the porous layer was chosen as 1.25 (dotted), 1.5 (solid), and 2 (dashed line). The maximum of the spectrum is limited by the differences between the refractive index of the outer medium and that of bulk silicon, and the fringe visibility increases as the refractive index of the PSi rises.

require more cumbersome mathematics but are of great commercial interest in designing Bragg reflectors characterized by an alternating sequence of layers of low (L) and high (H) porosity [air–HLHL ($\times n$) HLHL–PSi] so called random PSi multilayers (10,18).

For successful comparison between experimental and simulated spectra, it is important to find reasonable referencing. For instance, a simple measurement gives the intensity $I(\omega) = R(\omega)I_0(\omega)$, in which $I_0(\omega)$ contains all spectral features of the incident light source. Therefore, the reflectance $R(\omega)$ can be obtained only if $I_0(\omega)$ is measured as accurately as possible by using highly reflective reference samples such as metal-coated smooth surfaces of known reflectivity. Reflectance spectra of bulk silicon can be described very well by a constant and real dielectric function where $\epsilon_\infty = 11.7$ and a Drude contribution from the absorption of free carriers that depends on the doping level (10). In transmission spectra of thick silicon wafers, typical absorption bands that arise from carbon (610 cm^{-1}) and oxygen (1105 cm^{-1}) impurities occur, as well as multiphonon excitations. The dielectric function of freshly prepared PSi is governed by Si–H vibrations, which can be modeled by harmonic analysis, assuming a Gaussian distribution of resonant frequencies. Stretching, scissors, and wagging modes are found. A comparison with spectra obtained from Si–H-terminated amorphous PSi samples shows significant difference in resonant frequencies and bandwidths. Although silicon (lightly doped) is sufficiently transparent in the IR region, accurate conversion from transmission to absorbance is not possible because the reflectivity of bare silicon as the reference and PSi differ significantly from each other. This is due to the lower effective refractive index of PSi compared to bulk silicon and multiple beam interference within the porous

layer. Interference patterns in the infrared show up as a baseline. Therefore, reflectance rather than transmission techniques are recommended to cope with this problem for routine measurements.

Optical reflection spectroscopy in the UV-vis has been employed to investigate the electronic band structure because direct transitions occur that contribute significantly to the dielectric function of PSi. Transmission is usually too weak near the interband transitions, and the penetration depth of UV light is small. Within the reflectance spectrum, there is a clear distinction between the low-frequency region of transparent PSi that gives rise to the formation of interference fringes and the high-frequency part (UV) where no radiation is reflected from the interface between PSi and bulk silicon. In the UV region, a broad peak is detected due to the vast number of dipole-allowed transitions that arise from the complex microstructure of PSi (Fig. 6). The peak broadens as porosity increases and thus gives rise to the assumption that quantum size effects play a key role.

Effective modeling of the dielectric function remains to be elucidated, although introducing a sufficient number of extended oscillatory terms provides good agreement with experimental data. Once a model for the dielectric function of the pore walls has been found, EMA theories need to be employed to ensure the “right averaging” between the dielectric function of the pore-filling and the silicon pillars.

FUNCTIONALIZATION OF POROUS SILICON SURFACES

Any chemical or biochemical sensor is based on a highly specific receptive layer. These layers are best prepared by chemical reactions of the PSi surface. A large number of mild chemical reactions have recently been developed (Scheme 1) to modify PSi surfaces for optical and sensor applications (19). The formation of PSi by anodic dissolution of crystalline silicon in a HF-based electrolyte leads to a hydride-terminated silicon surface that is the starting point for a variety of modifying procedures.

Si–H-terminated Surfaces

A PSi surface obtained by an anodic or chemical etch of crystalline silicon using HF comprises Si–H_x ($x = 1, 2, 3$) bonds that can be readily oxidized and hydrolyzed, single-bonded Si–Si groups, and Si atoms that have free valences (dangling bonds). In the last few years, new reaction schemes have been developed based on hydride-terminated PSi layers.

Formation of Si–O–C-Bonds

Chemical reactions at the surface of electronic materials can be very different from the corresponding solution-phase transformations. In particular, the electronic structure of the semiconductor provides a source of electrons and holes that can be used to induce surface reactions. For example, for a nucleophilic attack on n-type PSi, the surface is brought under positive potential control. This is called the reverse-bias condition, where the applied potential adds to the band bending potential, thereby increasing the

barrier height. As a result, in n-type silicon, an excess of positive charges in the semiconductor renders the silicon surface susceptible to nucleophilic attack. Nucleophiles such as H_2O and CH_3OH react with this surface of reverse-biased PSi (20). Less active nucleophiles such as trifluoroacetic, acetic, and formic acids, however, react only with the silicon surface and produce a silyl-ester-modified surface upon irradiation (20–22). Because this kind of reaction takes place only under illumination, porous silicon can be photopatterned by illuminating the surface through a mask during the derivatization procedure. Esterification changes the chemical and physical properties of

silicon surfaces. The ester-modified surface is hydrophilic as opposed to the hydrophobic, native, hydride-terminated surface. Reaction of an ester-modified surface with organomethoxysilanes results in replacing the ester by organosilanes, and they do not react with hydride-terminated surfaces. Reactions that are not based on photo- or electrochemical methods were carried out by Laibinis and co-workers using alcohols under modest heat that resulted in the forming Si–O–C bonds (23,24). The major disadvantage of a surface modification based on Si–O–C bonds is their limited stability in aqueous solution. The Si–O bond in this case is readily hydrolyzed and limits the applicability of these functionalized surfaces to sensor devices.

Formation of Si–C Bonds

Since Canham and co-workers discovered the photoluminescence of PSi in 1990, modification and characterization of photoluminescent PSi surfaces has become an area of intense interest. However, hydride-terminated silicon oxidizes slowly in air, often resulting in the loss of photo- and electroluminescent properties. Many studies addressed the chemical properties of H-terminated silicon surfaces to protect PSi from losing its luminescent properties and to prepare PSi that is chemically stable. The attachment of species to silicon surfaces by forming Si–C bonds (25) provides greater stability to oxidation. Methyl groups were grafted on PSi surfaces by an anodic electrochemical stimulus using CH_3MgBr or CH_3Li (26,27). Without photo- or electrochemical methods that often proceed by oxidizing the substrate, it is possible to derivatize PSi surfaces by using a variety of Grignard (23,24,28) or aryllithium and alkylolithium reagents (29,30) at room temperature. Si–Li species on the surface are readily hydrolyzed by water resulting in considerable surface oxidation and thus, loss of photoluminescence. However, surface-bound lithium can also be replaced by H- or acyl species that reduce the rate of air oxidation. Greater stability to hydrolysis and oxidation can be obtained by using hydrosilylation reactions applicable to a wide range of different PSi samples, independent of doping and pore morphology. Hydrosilylation of native hydride-terminated PSi can be induced by Lewis acids (31–35). Insertion of alkenes and alkynes into surface Si–H groups yields alkyl or alkenyl termination, respectively. Robins et al. (36) reported on electrochemical grafting of terminal alkynes. Cathodic electrografting attaches alkynes directly to the surface, whereas anodic electrografting yields an alkyl surface. Hydrophobic surfaces capped by a monolayer of long alkyl chains are dramatically stabilized under chemically demanding conditions, such as basic solutions, compared to nonfunctionalized PSi. High surface coverage and short reaction time were achieved by an electrochemical method based on the reductive electrolysis of alkyl iodide, alkyl bromide, and benzyl bromide (37).

Silicon OH-Terminated Surfaces

Besides direct use of Si–H-terminated surfaces as obtained from a HF etch, the PSi surface can first be oxidized, resulting in an OH-terminated surface that has a layer of SiO_2 underneath. Several methods have been employed

that partly transform silicon into silica (19). The extent of oxidation depends on the procedure. Porous silicon that has very stable photoluminescent properties can be generated by rapid thermal oxidation in O_2 at high temperature (38). Then, the surface is then coated by a thick silicon oxide layer and is stable in air indefinitely. However, only a few OH groups are exposed. Other techniques have been evolved, including chemical oxidation using reagents such as hydrogen peroxide, nitric oxide, and ozone, leading to an OH-terminated PSi surface.

Silane Chemistry

Traditionally, almost all of the chemistry of silicon at moderate temperatures and pressures is based on OH-terminated surfaces. Common examples are the use of substituted chloro- and alkoxy silanes to form self-assembled monolayers of organosilanes (39,40). Trichloro- and trialkoxy silanes react with OH groups on the PSi surface but also cross-react with themselves to form an organosilane network, depending on the conditions. A sole reaction of organosilanes with OH groups on the surface can be accomplished by using monofunctional instead of trifunctional silanes. However, the surface coverage in this case depends strongly on the number of available OH groups, which in turn is determined by the oxidation procedure.

Si-Halide-Terminated Surfaces

A variation of traditional silane chemistry starting with Si–OH species is the formation of reactive Si halides on the PSi surface. Exposing a Si–H-terminated surface to halogen vapor breaks Si–Si bonds and creates Si halide species (41,42). The Si halide surface is then exposed to a silanol or an alcohol to generate Si–OR surfaces. The halogenation route avoids the need to generate a silicon oxide surface before derivatization. Exposure to air leads to oxidation of only the outer layer of Si atoms and leaves a large number of OH groups behind. However, in contrast to other oxidation procedures, Si–H groups are still present on the surface and make PSi susceptible to hydrolysis and further oxidation. A different strategy was followed by Lewis and co-workers (43), who functionalized silicon with an alkyl layer by first chlorinating the H-terminated silicon surface with PCl_5 . The Si–Cl surface is then treated with an alkyl Grignard or alkylolithium reagent to generate the surface-bound alkyl species.

POROUS SILICON CHEMOSENSORS

Most chemical sensors based on PSi use the material's unique property to emit light efficiently at room temperature. Reversible reduction of photoluminescence due to the specific or nonspecific adsorption of analytes from vapor to the porous matrix renders PSi a fast responding sensor for many vapors and, if suitably functionalized, for adsorbents in liquids. A typical photoluminescent spectrum of PSi usually has a bandwidth of 200 nm and the wavelength of maximum emission varies from 500–900 nm. Time-resolved spectroscopy revealed half-lives of the order of several tens of microseconds at the high wavelength

limit of the spectrum and 5 μs at the blue end. The decay is indicative of a distributed number of emission lifetimes rather than a single one. This is readily explained by an ensemble of different quantum structures of varying sizes that give rise to a broad emission spectrum that has a distribution of lifetimes. It is well known that surface contamination leads to reduced quantum efficiency, thus resulting in decreased emission intensity. Any covalently bound compound may act as a surface defect, if its orbital energies are within the band gap, that results in nonradiative recombination. Fortunately, the energies of the Si–H and Si–O bonds, which are among the most stable bonds of silicon, do not lie within the band gap. Most likely, chemical binding of a species to PSi adds a nonradiative trap but does not change the spectral features of the photoluminescent spectrum. If shifts are observed, they may arise from differences in the photoluminescent lifetimes that range from nanoseconds in the blue to microseconds in the red. Thus, the red part of the spectrum may be more strongly reduced than the blue part, leading to a slight blue shift of the overall spectrum.

Sailor and co-workers reported on PSi chemical sensors that detect vapors by partially reversible photoluminescent reduction. They found that the visible photoluminescence of n-type PSi is quenched by nitric oxide to detection limits of 2 ppm and that of nitrogen oxide to 70 ppb (44). At a partial pressure in the millitorr range, photoluminescent reduction is partly reversible. Recovery from nitrogen oxide occurs on a timescale of minutes. Reversible quenching for both nitric oxide and nitrogen dioxide fits a Stern–Vollmer kinetic model in the low concentration regime, and it deviates at higher partial pressures; a permanent loss of photoluminescence due to oxidation occurs. Interestingly, no significant quenching was observable for nitrous oxide and carbon dioxide and only minor quenching for carbon monoxide and oxygen. A PSi-based NO_x sensor, which is used for monitoring NO concentrations in industrial processes and pollution control, can be used to detect both small and large amounts of NO_x that can overload conventional sensors based on SnO_2 .

Using a similar approach, Content et al. (45) detected explosives such as 2,4-dinitrotoluene (DNT), 2,4,6-trinitrotoluene (TNT), and nitrobenzene in an air stream by the quenching PSi photoluminescence. Detection limits of 500 ppb, 2 ppb, and 1 ppb were observed for nitrobenzene, DNT, and TNT, respectively. Combined with a second transduction mode—Fabry–Perot optical interference—Letant et al. (46) developed an electronic artificial nose based on PSi surfaces that discriminated among solvent vapors, ethyl esters, and perfumes. Discrimination index obtained by PSi sensors have been as good as those obtained from metal oxide sensors.

Zhang et al. (47) reported on the successful functionalization of p-type PSi using calixarene carboxylic derivatives. They described a method for depositing a uniform film of calixarene derivatives varying in ring size that is stable in aqueous and heptane solutions. The authors showed that photoluminescent reduction due to the addition of copper(II) in aqueous solution depends on the ring size and enables one to determine the binding constant from a Stern–Vollmer plot. A concentration of 1504 M^{-1} for calix[8]-COOH-coated PSi versus 128 M^{-1} for

calix[4]-COOH-coated PSi was found for copper(II) ions dissolved in water.

Besides the reduction of photoluminescence, other transducing properties of PSi have been used to design chemical sensors. Recently, Letant and Sailor (48) described the design of a chemical HF vapor sensor based on detecting the effective refractive index. The authors report on the dissolution of SiO_x species upon exposure to wet HF vapor that was detected by a decreased effective optical thickness.

Tobias and co-workers (49) reported a 440% increase in capacitance in response to a humidity change from 0 to 100% using an aluminum contact to p-type PSi (Schottky-barrier sensor). This sandwich structure, in which PSi is located between the Al film and the bulk silicon, serves as the dielectric sensor matrix that responds to the condensation of vapor inside the pores. The capillary condensation is readily described by the Kelvin equation for closed-end capillaries:

$$\ln \frac{p}{p_0} = \frac{-2\gamma M \cos \theta}{\rho r RT}, \quad (10)$$

where p is the effective vapor pressure, p_0 the standard vapor pressure, γ the surface tension, M the molecular weight, θ the contact angle, ρ the density of the liquid, r the pore radius, R the gas constant, and T the temperature.

BIOSENSOR APPLICATIONS OF POROUS SILICON

Although silicon technology has a lot to offer in miniaturized intelligent devices, the range of applications has been limited to those where the electronic chip is almost isolated from a biological environment primarily because aqueous media rapidly destroy silicon—it has not been considered biocompatible. However, it was demonstrated that PSi could be designed to be more compatible than bulk silicon with biological environments due to recent developments in surface derivatization (50). This implies that this particular material might be well suited for developing biosensor devices based on silicon technology. Several physical properties of PSi have been employed to detect analytes (signal readout) in solution.

Photoluminescent Transduction

When enhanced photo- and electroluminescence were discovered, PSi also excited great interest among scientists working with biological sensors for detecting a biological analyte fast and at very low concentrations. Starodub and co-workers (51–53) exploited photoluminescence to monitor binding of human myoglobin to mouse monoclonal antibodies. They used PSi samples whose pore size was 10 to 100 nm obtained by laser-beam-treating and chemically etching monocrystalline p-type silicon (specific resistance: $10 \Omega \text{ cm}$). The PSi was functionalized by physisorption of mouse monoclonal antihuman antibodies on the passivated PSi surface that can binds human myoglobin. The physisorption itself induced only little change in the photoluminescent intensity. The influence of nonspecific adsorption on photoluminescent intensity was verified by using bovine serum albumin, rabbit IgG, and sheep

Figure 7. Changes of the photoluminescent intensity (I) upon immersion of the PSi sample antibodies in a myoglobin solution. The silicon surface was functionalized by using monoclonal anti-human antibodies by physisorption. Different myoglobin concentrations were added, and the photoluminescence was monitored [reprinted with permission from (53)].

antirabbit IgG. No change was detected within 2–2.5 h. Adding human myoglobin, however, resulted in a large decrease in photoluminescent intensity (Fig. 7). The origin of the photoluminescent decrease is discussed in terms of dehydrogenation of the PSi surface after formation of a specific immune complex. Hydrogen is released from Si–H bonds and subsequently captured by the immune complex. The sensitivity of the sensor is about 10 ng/mL myoglobin, and the overall detectable concentration regime ranges from 10 ng/mL to 10 µg/mL in buffer solution.

To demonstrate the effectiveness of their biosensor, the concentration of myoglobin in human serum of patients suffering from heart failure determined by the PSi sensor was compared to results from a standard ELISA (enzyme-linked immunosorbent assay) test: in all three cases, the two techniques gave almost the same results; the difference was less than 5%. The overall time, however, taken by the ELISA test (at least 3 h) is significantly greater than for the PSi sensor (15–30 min). Unfortunately, the PSi biosensor cannot be reused. It was found that after the first cycle—including binding and release of myoglobin, which was done by lowering the pH resulting in destruction of the antigen–antibody complex—the photoluminescent intensity is decreased by 50% of the initial value. The authors discuss such a decrease in photoluminescent intensity in terms of a possible destruction of the PSi surface or incomplete removal of the immune complex from the surface. Despite this drawback, the approach offers a simple and cheap technique of preparation and operation combined with high specificity and sensitivity.

Electrochemical Transduction

The use of the electrical characteristics of PSi is a different approach. One advantage of an electrochemical sensor

Figure 8. Schematic drawing of typical behavior of C – V curves for different H^+ concentrations. As the pH of the solution increases, the C – V curves are shifted to larger values along the x axis (54).

based on PSi compared to well-established silicon microelectronics such as ion sensitive field-effect transistors (ISFETs) is the high surface area, which allows for higher sensitivity but uses a smaller active area. Lüth and co-workers investigated PSi as a substrate material for potentiometric biosensors operating in aqueous solution. The principle of this device is a shift of the capacitance (C)–voltage (V) curve upon pH shifts (Fig. 8).

The shape of the C – V curve for p-type silicon can be explained as follows: at negative voltage, an accumulation of holes occurs at the interface, and as a result, the measured differential capacitance is close to that of the SiO_2 layer. As the negative voltage is reduced, a depletion region that acts as a dielectric in series with the SiO_2 layer is formed near the silicon surface, leading to a decrease in overall capacitance. The parallel shift of the C – V curve is caused by the flat-band voltage shift toward positive values as pH decreases. It can be explained by the presence of Si–OH groups at the surface of hydrated SiO_2 , described in site-binding theory. The ionization state of the silanol groups changes by varying the pH, and the resulting surface charge affects the depletion layer at the Si/ SiO_2 interface. Thus, the performance of the sensor is strongly affected by the response of the oxide-covered PSi to pH change. Any reaction that changes the pH close to the silica surface can be measured by monitoring corresponding C – V curves. Lüth and co-workers developed a biosensor that detects penicillin by the following enzyme-catalyzed reaction (54–56):

The enzyme that catalyzes this reaction is penicillinase, also termed β -lactamase from *Bacillus cereus*. Porous silicon samples were prepared from p- or n-type by anodic etching followed by thermal annealing in an oxygen atmosphere to generate a SiO_2 layer, which protects the PSi surface from corrosion in aqueous solution. The bioactive compound, penicillinase, is immobilized via physisorption on the PSi surface. This mild immobilization method requires no additional reagents and does not affect the activity of the enzyme. Due to the holes within the porous

material, fast leaching out of the sensor compound was prevented. A penicillin G (benzylpenicillin) concentration in the range of 0.1–100 mmol/L can be monitored by a linear potentiometric response from 0.5 to 20 mM and a sensitivity of about 40 mV. Experiments performed using n-type PSi indicated even higher sensitivities of about 50 mV. To enhance pH sensitivity of the biosensor to penicillin, Lüth and co-workers deposited Si_3N_4 by plasma-enhanced chemical vapor deposition. Calibration curves indicate a pH sensitivity of 54 mV per decade that is close to the theoretical Nernstian slope of 59.1 mV/pH (57). An example of a constant capacitance measurement of a penicillinase-covered PSi surface is given in Fig. 9. The penicillin concentration is varied between 0.01 and 1 mM, and the voltage change is monitored on-line (Fig. 9a). The calibration curve (sensor signal vs. penicillin concentration) is almost linear in the concentration range of 0.01 to 0.75 mM penicillin G (Fig. 9b). The mean sensitivity is 138 ± 10 mV/mM in a concentration range of 0.025 to 0.25 mM penicillin for the first 20 days of operation.

Using a different approach, Al_2O_3 was deposited as a pH-sensitive material, which was characterized by long-term stability, stability to corrosion, and very little drift compared to the Si_3N_4 layer. The pH sensitivity was 55 mV/pH (58). To improve the biosensor further, it might be desirable to immobilize the enzyme molecules covalently to the surface via cross-linkers. Penicillinase was bound by *N*-5-azido-2-nitrobenzoyloxysuccinimide to a planar Si_3N_4 surface of the sensor. This sensor was stable for 250 days (58). The sensor needs to be miniaturized to realize capacitive microsenors. For this purpose, a multisensor array was established by coating the silicon wafer with polyimide as a passivation material that forms a microelectrode array (57).

Optical Transduction—Interferometry

Sensitive label-free biosensors are highly desirable for applications in high-throughput screening and diagnostics.

Optical transduction mechanisms such as interferometric and surface-plasmon-related methods offer several advantages, most notably label-free analyte sensing, which simplifies sample preparation. Ghadiri, Sailor, and co-workers established several biosensor surfaces based on detecting changes in the interference patterns of thin PSi layers (59–63). In a comprehensive study, Ghadiri and co-workers developed a sensor surface that detects streptavidin binding to biotin by interferometry. Several requirements had to be considered to design a proper sensor surface. The prerequisite for using PSi as an optical interferometric biosensor is to adjust the size and the geometric shape of the pores by choosing appropriate etching parameters. The pore size has to be large enough to allow proteins to enter the pores freely but small enough to retain optical reflectivity of the PSi surface. Moreover, it is necessary for the material to be mechanically stable in aqueous solutions to provide reproducible and predictable binding signals. Janshoff et al. (59) extensively studied various parameters in the fabrication of PSi. p-type silicon that has resistivities of 0.1–10 Ω cm etched in aqueous or ethanolic HF solutions generally displays a network of micropores, rather than the desired well-defined cylindrical meso- or macropores. However, the pore size of p-type PSi can be increased by increasing the concentration of the dopant and decreasing the aqueous HF concentration. On the other hand, low current densities result in random orientation of highly interconnected filament-like micropores. Large, cylindrically shaped pores can be obtained when higher current densities are applied near the electropolishing region. By anodizing heavily doped (10^{-3} Ω cm) p-type silicon (100) in ethanolic HF solution at ambient temperatures, Janshoff et al. (59) predictively fabricated PSi layers that had cylindrically shaped structures and tunable pore diameters in the range of 5 to 1200 nm, as deduced from scanning force microscopy images (Fig. 10).

Using low current densities (150 mA/cm²), pores are scarcely visible, and the relatively flat surface is dominated by a distinct hillock structure. As the current densities

Figure 9. (a) Typical constant capacitance measurement. The enzyme penicillinase is immobilized by physisorption onto a Si_3N_4 -covered PSi surface. Different concentrations of penicillin G sodium salt were added, and the change in voltage was monitored on-line. (b) Corresponding calibration curve that exhibits a wide linear range from 0.01 to 0.75 mM penicillin [reprinted with permission from (55)].

Figure 10. SFM images (tapping mode) of porous p-silicon layers freshly etched at different current densities. (a) $1.5 \times 1.5 \mu\text{m}^2$ image etched at 150 mA/cm^2 ; all following images are $5 \times 5 \mu\text{m}^2$ (b) etched at 295 mA/cm^2 ; (c) 370 mA/cm^2 ; (d) 440 mA/cm^2 ; (e) 515 mA/cm^2 ; and (f) at 600 mA/cm^2 . The dopant concentration ($1 \text{ m}\Omega \text{ cm}$) and anodizing solution (37% ethanolic HF) were the same for all samples. All samples were etched at a constant charge of 4.5 C/cm^2 [reprinted with permission from (59)].

are increased, larger pore sizes can be obtained. The pore radius depends approximately exponentially on the current density. The surface porosity of silicon layers, calculated from SFM images by integrating the number of pixels, increases slightly from 27% (330 mA/cm^2) to 30% (410 mA/cm^2) and finally up to 40% by applying

densities $>440 \text{ mA/cm}^2$. The interference or fringe patterns obtained from these PSi layers anodized at different current densities are presented in Fig. 11.

Fabry–Perot fringes using visible light illumination were observed on samples prepared at current densities between 150 and 600 mA/cm^2 . Anodization of p-type

Figure 11. Interference fringe patterns of p-type PSi etched at different current densities. All samples were etched at a constant charge of 4.5 C/cm^2 . The spectra were taken in the center of the chip. (a) 150 mA/cm^2 ; (b) 295 mA/cm^2 ; (c) 370 mA/cm^2 ; (d) 440 mA/cm^2 ; (e) 515 mA/cm^2 ; (f) 600 mA/cm^2 [reprinted with permission from (59)].

silicon at a current density of 600 mA/cm^2 resulted in an obvious matte surface that had a barely discernible fringe pattern due to insufficient reflectivity of the upper PSi layer. Electropolishing occurs at a current density higher than 700 mA/cm^2 . The number of fringes in the observed wavelength range depends on the porosity and the thickness of the porous layer. Samples approximately 3000 nm

thick typically display 9 to 12 fringes in the wavelength region of $500\text{--}1000 \text{ nm}$, depending on the effective refractive index. The higher the current density, the fewer fringes are observed, consistent with the observation that higher current densities lead to greater porosities. To determine the porosity p and thickness l of the porous layers, the pores were filled with organic solvents of different refractive

index n , and the effective optical thickness was determined from interferometric reflectance spectra. Different EMAs were applied to the data to obtain the porosity and thickness of the porous layer simultaneously. The parameters p and l for each sample were determined from the fit to a plot of $n_{\text{eff}}l$ versus n . Independent of the EMA used, the estimated porosity of PSi increases with increasing current density in close agreement with experimental observation. According to the theory of Looyenga, the porosities of the samples etched at different current densities were in the range of 64–90% in good agreement with gravimetric measurements which yielded a porosity of $80 \pm 5\%$ for PSi samples etched at 150 mA/cm^2 and $90 \pm 5\%$ for samples etched at 400 mA/cm^2 .

Because freshly etched, hydride-terminated PSi readily suffers oxidative and hydrolytic corrosion, the surface needs to be oxidized and functionalized to stabilize it. Stability was proven by measuring the effective optical thickness (EOT) as a function of time (Fig. 12).

The observed decrease in EOT is caused by oxidation and dissolution of the PSi. The conversion of silicon to silica results in a decrease in the effective refractive index of the PSi layer, leading to the observed blue shift of the interference fringes. Furthermore, dissolution of the porous layer can lead to a decrease in thickness of the layer, which would also result in a decrease in the effective optical thickness, and therefore to a shift of the spectrum to shorter wavelengths. Ghadiri and co-workers found that ozonolysis followed by capping using a long-chain alkoxy silane linker (Scheme 2a) stabilized the surface sufficiently for sensing in aqueous media. Ozonolysis was the preferred oxidation route because a larger number of Si–OH groups are generated compared to thermal oxidation through which binding of the alkoxy silane linker occurred. A monoalkoxy instead of a trialkoxy silane was used to prevent the formation of cross-linking reactions, which might result in clogging the pores by silane polymers. By tethering a biotin molecule to the end of the linker, streptavidin can bind to the chemically modified PSi surface. To eliminate nonspecific binding further and to space the binding sites apart to reduce crowding on the surface, Sailor and co-workers (60) synthesized a linker molecule containing bovine serum albumin (BSA) (Scheme 2b).

Figure 12. Stability of various surface-derivatized PSi samples in 10% (v/v) EtOH in PBS buffer, pH 7.4, presented as the normalized relative effective optical thickness change (normalized EOT) as a function of time. The slopes of $n_{\text{eff}}l/t$ are given in brackets (□). Hydride-terminated PSi sample (6 nm/min); (■) ozone oxidized sample (2 nm/min); (○) thermally oxidized (400°C, 1h), (1 nm/min); (●) ozone oxidized PSi wafer functionalized by using (2-pyridyldithiopropionamido) butyldimethylmethoxysilane (0.05 nm/min) [reprinted with permission from (59)].

The accessibility of the porous matrix to biological molecules was probed by exposure of a concentrated BSA solution in PBS buffer to an ozone-oxidized PSi sample functionalized by 2-pyridyldithio(propionamido) dimethylmonomethoxysilane and pretreated by using with BSA to inhibit nonspecific adsorption to the silicon surface. The expected shift in EOT of about 10–30 nm, considering the volume of the pores and the refractive index of the aqueous BSA solution, was reached within 2–3 min and confirmed that proteins can enter and fill the porous matrix within a reasonable timescale. Although the observed shift is mainly due to the bulk effect of the protein solution, the slower rate of recovery after rinsing the sample with buffer suggests that some proteins were physisorbed on

Scheme 2

Figure 13. Time course of the EOT (n_{eff}) of a p-type PSi chip etched at 440 mA/cm^2 , oxidized by ozone for 20 min, and functionalized as shown in Scheme 2 a. The arrow labeled **A** identifies the addition of $10 \mu\text{M}$ streptavidin preincubated in 1 mM biotin dissolved in PBS buffer, pH 7.4 (control); **B** addition of $10 \mu\text{M}$ streptavidin without biotin (washing cycles in between); **C** washing cycles with buffer; **D** addition of dithiothreitol, which was used to reduce the disulfide bridge and therefore release the bound protein-linker complex. The sample was mounted in a flow cell using a constant flow rate of 0.5 mL/min [reprinted with permission from (59)].

the silicon walls. Using an ethanol-water mixture instead of the protein solution results in a rectangular signal response upon adding the mixture and rinsing with water.

Specific binding of streptavidin to the biotin-functionalized PSi matrix was measured by monitoring the changes in EOT time-resolved in a PBS buffer containing 0.1% TritonTM to minimize nonspecific adsorption (Fig.13).

As expected, specific binding of streptavidin to the biotin-derivatized porous layer resulted in an increase in the measured effective optical thickness. The change in the EOT is due to binding of proteins that have a higher refractive index ($n_{\text{protein}} = 1.42$) than the water ($n_{\text{water}} = 1.33$) in the pores and is in direct quantitative agreement with what was expected from effective medium approximations. The overall change in the EOT (Δn_{eff}) after 80 min was 23 nm. In a control experiment, in which all streptavidin binding sites were deactivated by saturating them with biotin in solution, a change in EOT was not observed, suggesting that there is little or no nonspecific protein adsorption to the PSi matrix. Rinsing the surface with buffer after the protein has bound does not alter the EOT significantly. However, because the biotin recognition element is linked to the surface via a disulfide bond, the protein-ligand complex could be released from the surface by adding dithiothreitol to the bulk phase. The initial red shift of 23 nm upon binding streptavidin to the biotinylated PSi can be completely reversed and provides further support for the interpretation that the observed red shift is due to specific binding of the protein to the functionalized surface. Moreover, the reversible linkage of the proteins via disulfide bridges to the surface offers the possibility of reusing the functionalized PSi chips for further binding experiments. Sailor and co-workers bound protein A to the PSi surface through the BSA-containing linker (60,61). Streptavidin binds to the biotin-terminated linker and adds three accessible free biotin-binding sites to the surface (Fig. 14).

Adding a solution of biotinylated protein A results in attaching it to the surface. This prefunctionalized surface can be used for binding studies of aqueous human IgG. The observed change in EOT for binding IgG required several minutes to reach a steady-state value, presumably due to slow diffusion of this large molecule into the pores of the PSi film. The proteinA/IgG complex was partly dissociated by rinsing with buffer and completely dissociated by a pH switch to a low pH. Protonation of the binding sites on

Figure 14. Binding curve (change in EOT) on a PSi surface functionalized as shown in Scheme 2b. Sequential addition of streptavidin (1 mg/mL), biotinylated protein A (2.5 mg/mL), and human IgG (2.5 mg/mL). Reversible binding of IgG was demonstrated by binding of IgG followed by a pH-induced release and a second binding of IgG to the immobilized protein A layer [reprinted with permission from (60)].

protein A by decreasing the pH of the solution releases IgG from protein A. A second binding of IgG after its release can be demonstrated that shows the reproducibility of the method. The incorporation of BSA in the linker offered two advantages. Due to the increased hydrophilicity of the chemically modified PSi, surface nonspecific adsorption was not observed, and the addition of detergent in the buffer was no longer necessary. A second reason for incorporating BSA in the linker was to separate binding sites in the PSi films. Sailor and co-workers (61) found that without BSA the sensor did not scale with the mass of analyte, as was expected, assuming the same refractive index for all proteins investigated. Larger analytes were consistently underestimated, indicating crowding of binding sites at the surface. The insertion of BSA in the linker avoided crowding and thus, the sensor scaled with the analyte mass above 20 kDa (60).

Optical Transduction—Ellipsometry

Optical biosensing is usually based on the interaction of light with biomolecules. Techniques such as surface plasmon resonance and ellipsometry have focused mostly on interactions on a macromolecular scale, for example, antigen–antibody and nucleic acid interactions. The optical detection of small molecules (0.2–2 kDa) that have biological receptors is much more difficult due to their small change in EOT. Mandenius and co-workers (64) demonstrated the advantage of using oxidized PSi as a surface enlargement for binding small receptor molecules such as biotin or small peptides. They used p-type silicon that had (111) orientation and a resistivity of 0.01–0.02 Ω cm. The samples were thermally oxidized to stabilize the porous structure. The PSi surface was functionalized by using streptavidin, either physisorbed on the silica surface or cross-linked via glutardialdehyde. Streptavidin adsorption monitored by ellipsometry showed a 10-fold larger response compared to a planar surface. However, the rate of adsorption was one order of magnitude lower, probably due to the long diffusion time of the protein within the pores. Theoretically, the refractive index and the thickness of a thin layer can be calculated from the measured parameters ψ (the ratio of the amplitude change of light polarized parallel and perpendicular to the plane of incidence) and Δ (the phase shift). For PSi, however, the microstructure of the porous layer is very complicated, and a simple optical model that allowing quantifying film thickness and surface concentration is not straightforward to define. Therefore, Madenius and co-workers used changes in ψ and Δ as a direct measure of analyte binding without quantification. Using this setup, they detected binding of biotin and an oligopeptide in a concentration range of 2–40 μ M and a response time of 30 s for the oligopeptide at a concentration of 40 μ M.

CONCLUSIONS

Porous silicon based biosensors may add a new dimension to conventional technologies due to their unique optical and electronic properties. Tunable properties such as pore size,

porosity, dielectric function, and thickness render porous silicon a versatile matrix for biological compounds that act as the receptive layer for molecular recognition of analytes in solution. Interferometry has been successfully employed to detect changes in the effective optical thickness upon adsorption of molecules on the pore walls. The large surface area of porous silicon that displays a spongelike appearance or exhibits ordered cylindrical pores provides a quasi three-dimensional space that increases the signal-to-noise ratio of many transducing principles.

CERAMICS, PIEZOELECTRIC AND ELECTROSTRICTIVE

INTRODUCTION

In a rapidly developing world, the use of smart materials becomes increasingly important when executing sophisticated functions within a designed device. In a common definition (1), smart materials differ from ordinary materials because they can perform two or several functions, sometimes with a useful correlation or feedback mechanism between them. For piezoelectric or electrostrictive materials, this means that the same component may be used for both sensor and actuator functions. Piezoelectric/electrostrictive sensors convert a mechanical variable (displacement or force) into a measurable electrical quantity by the piezoelectric/electrostrictive effect. Alternately, the actuator converts an electrical signal into a useful displacement or force. Typically, the term transducer is used to describe a component that serves actuator (transmitting) and sensor (receiving) functions. Because piezoelectrics and electrostrictors inherently possess both direct (sensor) and converse (actuator) effects, they can be considered smart materials. The degree of smartness can vary in piezoelectric/electrostrictive materials. A merely smart material (only sensor and actuator functions) can often be engineered into a “very smart” tunable device or further, into an “intelligent structure” whose sensor and actuator functions are intercorrelated with an integrated processing chip.

Recent growth in the transducer market has been rapid and, it is predicted will continue on its current pace through the turn of the century. The sensor market alone rose to \$5 billion in 1990, and projections are \$13 billion worldwide by the year 2000 and an 8% annual growth rate during the following decade (2). Piezoelectric/electrostrictive sensors and actuators comprise a significant portion of the transducer market. There is a growing trend due especially to automobile production, active vibration damping, and medical imaging. In this article, the principles of piezoelectric/electrostrictive sensors and actuators are considered along with the properties of the most useful materials and examples of successful devices.

PIEZOELECTRIC AND ELECTROSTRICTIVE EFFECTS IN CERAMIC MATERIALS

Piezoelectricity, first discovered in Rochelle salt by Jacques and Pierre Curie, is the term used to describe the ability of certain crystals to develop an electric charge that is directly

proportional to an applied mechanical stress (Fig. 1a) (3). Piezoelectric crystals also show the converse effect: they deform (strain) proportionally to an applied electric field (Fig. 1b). To exhibit piezoelectricity, a crystal should belong to one of the twenty nonsymmorphic crystallographic classes. An important subgroup of piezoelectric crystals is ferroelectrics, which possess a mean dipole moment per unit cell (spontaneous polarization) that can be reversed by an external electric field. Above a certain temperature (Curie point), most ferroelectrics lose their ferroelectric and piezoelectric properties and become paraelectrics, that is, crystals that have centrosymmetric crystallographic structures do not spontaneously polarize. Electrostriction is a second-order effect that refers to the ability of all materials to deform under an applied electrical field. The phenomenological master equation (in tensor notation) that describes the deformations of an insulating crystal subjected to both an elastic stress and an electrical field is

$$x_{ij} = s_{ijkl} X_{kl} + d_{mij} E_m + M_{mni} E_m E_n, \quad (1)$$

$$i, j, k, l, m, n = 1, 2, 3,$$

where x_{ij} are the components of the elastic strain, s_{ijkl} is the elastic compliance tensor, X_{kl} are the stress components, d_{mij} are the piezoelectric tensor components, M_{mni} are the electrostrictive moduli, and E_m and E_n are the components of the external electrical field. Here, the Einstein summation rule is used for repeating indexes. Typically, the electrostriction term ($\propto E_m E_n$) is more than an order of magnitude smaller than the piezoelectric term in Eq. (1), that is, the electrostrictive deformations are much smaller than the piezoelectric strains. In this case, under zero stress, Eq. (1) simply transforms to

$$x_{ij} \approx d_{mij} E_m, \quad i, j, m = 1, 2, 3. \quad (2a)$$

Eliminating symmetrical components simplifies the relationship in matrix notation (4) expressed as

$$x_i \approx d_{mi} E_m, \quad m = 1, 2, 3, \quad (2b)$$

$$i = 1, 2, 3, 4, 5, 6,$$

where $i = 4, 5,$ and 6 describe the shear strains perpendicular to the crystal axis resulting from application of the electrical field. Equations (2a) and (2b) describe the converse piezoelectric effect where the electrical field induces a change in the dimensions of the sample (Fig. 1b). The piezoelectric effect is absent in centrosymmetric materials, and the elastic strain is due only to electrostriction. In ferroelectric crystals that have a centrosymmetric paraelectric phase, the piezoelectric and electrostriction coefficients can be described in terms of their polarization and relative permittivity. For example, when the electrical field and deformation are along the orthogonal axis in a tetragonal crystal system, longitudinal piezoelectric d_{33} and longitudinal electrostrictive M_{11} coefficients can be

Figure 1. Schematic representations of the direct and converse piezoelectric effect: (a) an electric field applied to the material changes its shape; (b) a stress on the material yields an electric field across it.

described in matrix notation as follows (5):

$$d_{33} = 2Q_{11}\epsilon_0\epsilon_{33}P_3, \quad (3a)$$

$$M_{11} = Q_{11}(\epsilon_0\epsilon_{33})^2, \quad (3b)$$

where ϵ_{33} and P_3 are the relative permittivity and polarization in the polar direction, $\epsilon_0 = 8.854 \times 10^{-12}$ F/m is the permittivity of vacuum, and Q_{11} is the polarization electrostriction coefficient, which couples longitudinal strain and polarization (in matrix notation), as described by the general electrostriction equation,

$$S_3 = Q_{11}P_3^2. \quad (4)$$

In matrix notation, the mathematical definition of the direct piezoelectric effect, where applied elastic stress causes a charge to build on the major surfaces of the piezoelectric crystal, is given by

$$P_i = d_{ij}X_j, \quad i = 1, 2, 3, \quad (5)$$

$$j = 1, 2, 3, 4, 5, 6,$$

where P_i is the component of electrical polarization. In electrostriction (centrosymmetric crystals), no charge appears on the surface of the crystal upon stressing. Therefore, the converse electrostriction effect is simply a change of the inverse relative permittivity under mechanical stress:

$$\Delta \left[\frac{1}{\epsilon_0\epsilon_{33}} \right] = 2Q_{11}X_3. \quad (6)$$

The piezoelectric and electrostrictive effects were described for single crystals in which spontaneous polarization is homogeneous. A technologically important class of materials is piezoelectric and electrostrictive ceramics, that consist of randomly oriented grains, separated by grain boundaries. Ceramics are much less expensive to process than single crystals and typically offer comparable piezoelectric and electrostrictive properties. The piezoelectric effect of individual grains in nonferroelectric

Figure 2. Schematic of the longitudinal (a), transverse (a) and shear deformations (b) of the piezoelectric ceramic material under an applied electric field.

ceramics is canceled by averaging across the entire sample, and the whole structure has a macroscopic center of symmetry that has negligible piezoelectric properties. Only electrostriction can be observed in such ceramics. Sintered ferroelectric ceramics consist of regions that have different orientations of spontaneous polarization—so-called ferroelectric domains. Domains appear when a material is cooled through the Curie point to minimize the electrostatic and elastic energy of the system. Domain boundaries or domain walls are movable in an applied electric field, so the ferroelectric can be poled. For example, domains become oriented in a crystallographic direction closest to the direction of the applied electric field. Typically, poling is performed under high electric field at an elevated temperature to facilitate domain alignment. As a result, an initially centrosymmetric ceramic sample loses its inversion center and becomes piezoelectric (symmetry ∞m). There are three independent piezoelectric coefficients: d_{33} , d_{31} , and d_{15} , which relate longitudinal, transverse, and shear deformations, respectively, to the applied electric field (Fig. 2).

Other material coefficients that are frequently used to characterize the piezoelectric properties of ceramics are the piezoelectric voltage coefficients g_{ij} , which are defined in matrix notation as

$$E_i = g_{ij}X_j, \quad (7)$$

where E_i are components of the electric field that arise from external stresses X_j . The piezoelectric charge d_{ij} and voltage g_{ij} coefficients are related by the following equation:

$$g_{ij} = d_{ij}/(\epsilon_0\epsilon_{ii}). \quad (8)$$

An important property of piezoelectric and electrostrictive transducers is their electromechanical coupling coefficient k defined as

$$k^2 = \text{output mechanical energy/input electrical energy,}$$

or

$$k^2 = \text{output electrical energy/input mechanical energy.} \quad (9)$$

The coupling coefficient represents the efficiency of the piezoelectric material in converting electrical energy into mechanical energy and vice versa. Energy conversion is never complete, so the coupling coefficient is always less than unity.

MEASUREMENTS OF PIEZOELECTRIC AND ELECTROSTRICTIVE EFFECTS

Different means have been developed to characterize the piezoelectric and electrostrictive properties of ceramic materials. The resonance technique involves measuring characteristic resonance frequencies when a suitably shaped specimen is driven by a sinusoidal electric field. To a first approximation, the behavior of a poled ceramic sample close to its fundamental resonance frequency can be represented by an equivalent circuit, as shown in Fig. 3a. The schematic behavior of the reactance of the sample as a function of frequency is shown in Fig. 3b. The equations used to calculate the electromechanical properties are described in the IEEE Standard on piezoelectricity (6). The simplest example of a piezoelectric measurement by the resonance technique can be shown by using a ceramic rod (typically 6 mm in diameter and 15 mm long) poled along its length. The longitudinal coupling coefficient (k_{33}) for this configuration is expressed as a function of the fundamental series and parallel resonance frequencies f_s and f_p ,

Figure 3. (a) Equivalent circuit of the piezoelectric sample near its fundamental electromechanical resonance (top branch represents the mechanical part and bottom branch represents the electrical part of the circuit); (b) electrical reactance of the sample as a function of frequency.

respectively:

$$k_{33} = (\pi/2)(f_s/f_p) \tan[(\pi/2)(f_p - f_s)/2]. \quad (10)$$

Then, the longitudinal piezoelectric coefficient d_{33} is calculated using k_{33} , the elastic compliance s_{33} , and the low-frequency relative permittivity ϵ_{33} :

$$d_{33} = k_{33}(\epsilon_{33}s_{33})^{1/2}. \quad (11)$$

Similarly, other coupling coefficients and piezoelectric moduli can be derived using different vibration modes of the same ceramic sample. The disadvantage of the resonance technique is that measurements are limited to specific frequencies determined by the electromechanical resonance. Resonance measurements are difficult for electrostrictive samples due to the required application of a strong dc bias field to induce a piezoelectric effect in relaxor ferroelectrics (see next section of the article).

Subresonance techniques are often used to evaluate the piezoelectric properties of ceramic materials at frequencies much lower than their fundamental resonance frequencies. These include the measurement of piezoelectric charge upon the application of a mechanical force (direct piezoelectric effect) and the measurement of electric-field-induced displacement (converse piezoelectric effect) when an electric field is introduced. It has been shown that piezoelectric coefficients obtained by direct and converse piezoelectric effects are thermodynamically equivalent.

The electrostrictive properties of ceramics are easily determined by measuring displacement as a function of the electric field or polarization. Thus the M and Q electrostrictive coefficients can be evaluated according to Eqs. (1) and (4), respectively. As an alternative, Eqs. (3b) and (6) can also be used for electrostriction measurements.

A direct technique is widely used to evaluate the sensor capabilities of piezoelectric and electrostrictive materials at sufficiently low frequencies. Mechanical deformations can be applied in different directions to obtain different components of the piezoelectric and electrostrictive tensors. In the simplest case, metal electrodes are placed on the major surfaces of a piezoelectric sample normal to its poling direction (Fig. 1b). Thus, the charge produced on the electrodes with respect to the mechanical load is proportional to the longitudinal piezoelectric coefficient d_{33} and the force F exerted on the ceramic sample: $Q = d_{33}F$. The charge can be measured by a charge amplifier using an etalon capacitor in the feedback loop. Details of direct piezoelectric measurements can be found in a number of textbooks (7).

Electric-field-induced displacements can be measured by a number of techniques, including strain gauges, linear variable differential transformers (LVDT), the capacitance method, fiber-optic sensors, and laser interferometry. Metal wire strain gauges are the most popular sensors used to measure strain at a resolution of about 10^{-6} m. To perform the measurement, the strain gauge is glued to the ceramic sample, and the resistance of the gauge changes according to its deformation. The resistance variation is measured by a precise potentiometer up to a frequency of several MHz. However, several gauges need to be used to obtain a complete set of piezoelectric and electrostrictive coefficients of the sample.

Figure 4. Principle of the linear variable differential transformer (LVDT) used for measuring electric-field-induced deformations in a piezoelectric sample.

Figure 4 illustrates the design of an LVDT. The moving surface of the sample is attached to the magnetic core inserted into the center of the primary and secondary electromagnetic coils. The change of the core position varies the mutual inductance of the coils. An ac current supplies the primary coil, and the signal in the secondary coils is proportional to the displacement of the core. The response speed depends on the frequency of the ac signal and the mechanical resonance of the coil, which typically does not exceed 100 Hz. Generally the resolution is sufficiently high and approaches $\sim 10^{-2}$ – 10^{-1} μm , depending on the number of turns.

The capacitive technique for strain measurements is based on the change of capacitance in a parallel-plate capacitor that has an air gap between two opposite plates. One of the plates is rigidly connected to the moving surface of the sample, and another plate is fixed by the holder. The capacitance change due to the vibration of sample can be measured precisely by a zero-point potentiometer and a lock-in amplifier. Therefore, high resolution (in the \AA range) can be achieved by this technique. The measurement frequency must be much lower than the frequency of the ac input signal, which typically does not exceed 100 Hz.

All of the aforementioned techniques require mechanical contact between the sample and the measurement unit. This, however, limits the resolution and the maximum operating frequency, which prevents accurate measurement of piezoelectric loss (the phase angle between the driving voltage and the displacement). The force exerted on the moving surface of the sample (especially on a thin ceramic film) may damage the sample. Therefore, noncontact measurements are often preferred to determine the electric-field-induced displacement of piezoelectric and electrostrictive materials accurately. Figure 5 shows the operating principle of a Photonic fiber-optic sensor, which can be used to examine the displacement of a flat reflecting

Figure 5. Schematic of the fiber-optic photonic sensor used for nondestructive evaluation of electric-field-induced strains.

surface (8). The sensor head consists of a group of transmitting and receiving optical fibers located in the immediate vicinity of the vibrating surface of sample. The intensity of the reflected light depends on the distance between the moving object and the probe tip. This dependence allows exact determination of displacement in both dc and ac modes. Using a lock-in amplifier to magnify the output signal, which is proportional to the light intensity, a resolution of the order of 1 \AA can be achieved (8). The frequency response is determined by the frequency band of the photodiode and the amplifier (typically of the order of several hundreds of kHz).

Optical interferometry is another technique that allows noncontact accurate measurement of the electric-field-induced displacements. Interferometric methods of measuring small displacements include the homodyne (9), heterodyne (10), and Fabri–Perot (11) techniques. The most common technique is the homodyne interferometer that uses active stabilization of the working point to prevent drift from thermal expansion. When two laser beams of the same wavelength (λ) interfere, the light intensity varies periodically ($\lambda/2$ period) corresponding to the change of optical path length between the two beams. If one of the beams is reflected from the surface of a moving object, the intensity of the output light changes, which can later be translated to the amount of displacement. Using a simple Michelson interferometer (12), a very high resolution of $\sim 10^{-5}$ \AA is achievable. However, the measurements are limited to a narrow frequency range because the sample is attached to a rigid substrate and only the displacement of the front surface of the sample is monitored (12). As a result of this configuration, the errors arising from the bending effect of the sample can be very high, especially in ferroelectric thin films. In response to that, a double beam (Mach–Zehnder) interferometer is used to take into account the difference of the displacements of both major surfaces of the sample (13). The modified version of the double-beam

interferometer, specially adapted to measure thin films, offers resolution as high as 10^{-4} Å in the frequency range of 10 – 10^5 Hz and long-term stability ($<1\%$) (14).

COMMON PIEZOELECTRIC AND ELECTROSTRICTIVE MATERIALS

Single Crystals

A number of single crystals (ferroelectric and nonferroelectric) have demonstrated piezoelectricity. However, nonferroelectric piezoelectric crystals exhibit piezoelectric coefficients much lower than those of ferroelectric crystals. The former are still extensively used in some applications in which either high temperature stability or low loss is required. The most important nonferroelectric piezoelectric crystal is quartz (SiO_2) which has small but very stable piezoelectric properties [e.g., $d_{11} = 2.3$ pC/N, x-cut (15)]. Ferroelectric LiNbO_3 and LiTaO_3 crystals that have high Curie temperatures (1210 and 660°C , respectively) are used mostly in surface acoustic wave (SAW) devices. Recent investigations (15) have shown that rhombohedral single crystals in the $\text{Pb}(\text{Zn}_{1/3}\text{Nb}_{2/3})\text{O}_3$ – PbTiO_3 system have exceptionally large longitudinal piezoelectric ($d_{33} = 2500$ pm/V) and coupling ($k_{33} = 0.94$) coefficients. In addition, ultrahigh strain of 1.7% has been observed in these materials under high electric field. These single crystals are now being intensively investigated and show significant promise for future generations of smart materials.

Piezoelectric and Electrostrictive Ceramics

As indicated earlier, the randomness of the grains in as-prepared polycrystalline ferroelectric ceramics yields nonpiezoelectric centrosymmetric material. Thus “poling” the ceramic (Fig. 6) is required to induce piezoelectricity. Due to symmetry limitations, all of the domains in a ceramic can never be fully aligned along the poling axis. However, the end result is a ceramic whose net polarization along the poling axis has sufficiently high piezoelectric properties.

The largest class of piezoelectric ceramics is made up of mixed oxides that contain corner-sharing octahedra of O^{2-} ions. The most technologically important materials in this class are perovskites that have the general formula ABO_3 , where $\text{A} = \text{Na}, \text{K}, \text{Rb}, \text{Ca}, \text{Sr}, \text{Ba},$ or Pb , and $\text{B} = \text{Ti}, \text{Sn}, \text{Zr}, \text{Nb}, \text{Ta},$ or W . Some piezoelectric ceramics that have this structure are barium titanate (BaTiO_3), lead titanate (PbTiO_3), lead zirconate titanate

Figure 6. Schematic of the poling process in piezoelectric ceramics: (a) in the absence of an electric field, the domains have random orientation of polarization; (b) the polarization within the domains are aligned in the direction of the electric field.

Figure 7. The crystal structure of BaTiO_3 : (a) above the Curie point, the cell is cubic; (b) below the Curie point, the cell is tetragonal, and Ba^{2+} and Ti^{4+} ions are displaced relative to O^{2-} ions.

($\text{PbZr}_x\text{Ti}_{1-x}\text{O}_3$, or PZT), lead lanthanum zirconate titanate ($\text{Pb}_{1-x}\text{La}_x(\text{Zr}_y\text{Ti}_{1-y})_{1-x/4}\text{O}_3$, or PLZT), and lead magnesium niobate ($\text{PbMg}_{1/3}\text{Nb}_{2/3}\text{O}_3$, or PMN).

The piezoelectric effect in BaTiO_3 was first discovered in the 1940s (3), and it became the first recognizable piezoelectric ceramic. The Curie point of BaTiO_3 is about 120 – 130°C . Above 130°C , a nonpiezoelectric cubic phase is stable, and the center of positive charges (Ba^{2+} and Ti^{4+}) coincides with the center of the negative charge (O^{2-}) (Fig. 7a). When cooled below the Curie point, a tetragonal structure (Fig. 7b) develops where the center of positive charges is displaced relative to the O^{2-} ions. This induces an electric dipole. The piezoelectric coefficients of BaTiO_3 are relatively high: $d_{15} = 270$ and $d_{33} = 190$ pC/N (3), and the coupling coefficient of BaTiO_3 is approximately 0.5 . Due to its high dielectric constant, BaTiO_3 is widely used as a capacitor.

Lead titanate (PbTiO_3) first reported to be ferroelectric in 1950 (3), has a structure similar to BaTiO_3 but has a significantly higher Curie point ($T_c = 490^\circ\text{C}$). When cooled through the Curie temperature, the grains go through a cubic to tetragonal phase change that leads to a large strain which causes the ceramic to fracture. Thus, it is difficult to fabricate pure lead titanate in bulk form. This spontaneous strain has been decreased by adding dopants such as $\text{Ca}, \text{Sr}, \text{Ba}, \text{Sn},$ and W . Calcium-doped PbTiO_3 (16) has a relative permittivity of ~ 200 and a longitudinal piezoelectric coefficient (d_{33}) of 65 pC/N. Because of its high piezoelectric coefficient and low relative permittivity, the voltage piezoelectric coefficient of lead titanate ceramic is exceptionally high. Therefore, lead titanate is used in hydrophones and sonobuoys (17).

Lead zirconate titanate (PZT) is a binary solid solution of PbZrO_3 and PbTiO_3 (3). It is an ABO_3 perovskite structure in which Zr^{4+} and Ti^{4+} ions randomly occupy B sites. PZT has a temperature-independent morphotropic phase boundary (MPB) between tetragonal and rhombohedral phases, when the $\text{Zr}:\text{Ti}$ ratio is $52:48$. (Fig. 8). This composition of PZT has efficient poling and excellent piezoelectric properties because of its large number of polarization orientations. At the MPB composition, PZT is usually doped by a variety of ions to form what are known as “hard” and “soft” PZTs (3). Doping PZT with acceptor ions, such as K^+ or Na^+ at the A site, or Fe^{3+} , Al^{3+} , or Mn^{3+} at the B site, creates hard PZT. This doping reduces the piezoelectric properties and makes the PZT

Figure 8. Phase diagram of lead zirconate titanate piezoelectric ceramics (PZT) as a function of mole% PbTiO_3 .

more resistant to poling and depoling. Introducing donor ions such as La^{3+} into the A site, or Nb^{5+} or Sb^{5+} into the B site, makes soft PZT. This doping increases the piezoelectric properties and makes the PZT easier to pole and depole. Table 1 compares the piezoelectric properties of several major piezoelectric ceramics.

Lead magnesium niobate, $\text{PbMg}_{1/3}\text{Nb}_{2/3}\text{O}_3$ (PMN), is a perovskite ceramic known as a relaxor ferroelectric. Unlike normal ferroelectrics, which have well-defined Curie points in their weak-field relative permittivity, relaxor ferroelectrics exhibit a broad transition peak between ferroelectric and paraelectric phases (18). This kind of transition is often referred to as a diffuse phase transition. The distinctive features of relaxor ferroelectrics are their strong frequency dispersion of relative permittivity and a shift of their maximum relative permittivity with frequency. Local inhomogeneity of B site ions (e.g., Mg^{2+} and Nb^{5+}) in the perovskite lattice are the proposed cause of relaxor properties. Relaxors do not possess piezoelectricity without a dc bias field to break the paraelectric cubic phase into the rhombohedral ferroelectric piezoelectric phase. Relaxors have been used as actuators because of their negligible hysteresis and large induced polarization (electrostrictive strain of the order of 10^{-3}). Figure 9 compares the electric-field-induced strains of typical piezoelectric (PZT) and electrostrictive (PMN) ceramics.

Processing of Piezoelectric Ceramics

The electromechanical properties of piezoelectric ceramics are largely influenced by their processing conditions.

Figure 9. Comparison of the electric-field-induced strain in a typical piezoelectric (PZT) and relaxor (0.9PMN–0.1PT).

Each step of the process must be carefully controlled to yield the best product. Figure 10 is a flowchart of a typical oxide manufacturing process for piezoelectric ceramics. First, high purity raw materials are accurately weighed according to their desired ratio and then are mechanically or chemically mixed. During the calcination step, the solid phases react to form the piezoelectric phase. After calcination, the solid mixture is milled to fine particles. Shaping is accomplished by a variety of ceramic processing techniques, including powder compaction, tape casting, slip casting, and extrusion. During the shaping operation, organic materials are typically added to the ceramic powder to improve its flow and binding characteristics. The organic is then removed in a low-temperature (500–600°C) burnout step. After organic removal, the ceramic structure is fired to an optimum density at an elevated temperature. Lead-containing ceramics (PbTiO_3 , PZT, PMN) are fired in sealed crucibles in an optimized PbO atmosphere to prevent lead loss above 800°C.

PIEZOELECTRIC COMPOSITES

Single-phase piezoelectric/electrostrictive materials are not ideally suited for hydrostatic and ultrasonic applications where ceramic elements radiate and receive acoustic waves. Although d_{33} and d_{31} piezoelectric coefficients are exceptionally high in PZT ceramics, their hydrostatic voltage response is relatively low due to the high dielectric constant and low hydrostatic charge coefficient $d_h = d_{33} + 2d_{31}$. Because $d_{31} \approx -0.4d_{33}$ in PZT ceramics (3), their hydrostatic sensor capabilities are rather low. In

Table 1. Piezoelectric Properties of Major Piezoelectric Ceramics

	Quartz	BaTiO_3	PZT-4	PZT-5	$\text{PbTiO}_3\text{:Sm}$
d_{33} (pC/N)	2.3(x-cut)	190	289	593	65

T_c (°C)		130	328	193	355

Figure 10. Flowchart for processing piezoelectric ceramics.

addition, the high density of ceramics results in a high acoustic impedance mismatch between the transducer and the medium in which the acoustic waves are propagating. On the other hand, piezoelectric polymers have low density (low impedance), dielectric constant, and piezoelectric coefficients.

In the past three decades, researchers have focused on methods for combining the best characteristics of ceramics and polymers to overcome the aforementioned deficiencies. Integration of a piezoelectric ceramic with a polymer allows tailoring the piezoelectric properties of composites. The mechanical and electrical properties of a composite depend strongly on the characteristics of each phase and the manner in which they are connected. In a diphasic composite, the materials can be oriented in ten different ways in a three-dimensional space (19). The possible connectivity patterns are 0-0, 1-0, 2-0, 3-0, 1-1, 2-1, 3-1, 2-2, 3-2, and 3-3. As a matter of convention, the first and second numbers in the connectivity denote the continuity of the piezoelectric and polymer phases, respectively. Figure 11 shows some of the composites made in the past 30 years (20). The most important connectivity patterns are 0-3, 1-3, 3-3, and 2-2. The 0-3 composites are made of a homogeneous distribution of piezoelectric ceramic particles within a polymer matrix. The primary advantage of these composites is that they can be formed into shapes and still retain their piezoelectricity. However, they cannot be sufficiently poled because the ceramic phase is not self-connected in the poling direction. On the other hand, 3-0

composites that are simply the ceramic matrix containing a low concentration of polymer inclusions or voids can be effectively poled and exhibit hydrostatic properties superior to those of single-phase PZT (20).

In composites of 3-3 connectivity, the piezoceramic and polymer phases are continuous in three dimensions and form two interlocking skeletons. The first composite of 3-3 connectivity was formed by the replamine process using a coral skeleton (21). Another effective method of making 3-3 composites is called BURPS (acronym for burned out plastic spheres) (22) which provides properties similar to the replamine composites. In this process, a mixture of PZT powder and burnable plastic spheres is used to fabricate the PZT/polymer composites. Other techniques, such as relic processing (23) and distorted reticulated ceramics (24) have been developed to fabricate 3-3 composites. Recently, fused deposition modeling (FDM) and fused deposition of ceramics (FDC) have been used to make ladder and 3-D honeycomb composites (25). In the FDM technique, a 3-D plastic mold is prepared and filled with PZT slurry. The FDC process deposits a mixture of PZT and polymer directly in the form of a three-dimensional ladder structure. Either structure is heat treated to burn the organic, sintered, and embedded in epoxy polymer.

The composites most extensively studied and used in transducer applications are those that have 1-3 connectivities. They consist of individual PZT rods or fibers aligned in the direction parallel to poling and embedded in a polymer matrix. The rod diameter, spacing between them,

Figure 11. Schematic of various piezoelectric composites of different connectivities.

composite thickness, volume% of PZT, and polymer compliance influence the composite's performance. The most common methods of forming 1–3 composites are the dice and fill technique (26) and injection molding (27). In the former method, the composite is fabricated by dicing deep grooves in perpendicular directions into a solid sintered block of poled PZT. The grooves are backfilled with polymer, and the base is removed via grinding or cutting. In the latter method, a thermoplastic mixture of ceramic powder and organic binder is injected into a cooled mold. The process can be used to form composites that have a variety of rod sizes, shapes, and spacings. This technique has recently been employed by Materials Systems, Inc. to mass produce SmartPanels™ (28).

APPLICATIONS OF PIEZOELECTRIC/ELECTROSTRICTIVE CERAMICS

By directly coupling mechanical and electrical quantities, piezoelectrics and electrostrictives have been extensively used in a variety of electromechanical devices for both sensor and actuator applications. The direct piezoelectric effect is currently being used to generate charge (voltage) in applications such as gas igniters, acoustic pressure sensors, vibration sensors, accelerometers, and hydrophones (29). The best known examples of actuators, which take advantage of the converse effect, are piezoelectric motors, piezoelectrically driven relays, ink-jet heads for printers, noise cancellation systems, VCR head trackers, precise positioners, and deformable mirrors for correcting of optical images (30). Acoustic and ultrasonic vibrations can be generated by piezoelectrics using an ac field at resonance conditions and/or detected by a piezoelectric receiver. Very often, an acoustic sender and receiver are combined in the same piezoelectric devices. Transducers have a variety of applications, including imaging, nondestructive testing, and fish finders (31). At high frequencies, piezoelectric transducers also function as frequency control devices, bulk and surface acoustic wave (SAW) resonators, filters, and delay lines.

Ultrasonic transducers operate in a so-called pulse-echo mode, where a transducer sends an acoustic wave that is reflected from the interfaces and is received by the very same transducer. These echoes vary in intensity according to the type of interface, which may include tissue and bone. Therefore, the ultrasonic image that is created clearly represents the mechanical properties of human tissue. Thus, anatomic structures of different organs can be recognized in real time. A sensitive ultrasonic transducer that generates low-intensity acoustic waves can be one of the safest diagnostic devices for medical imaging. These transducers are usually composed of matching and backing layers and the piezoelectric material itself. The matching layers are added to the transducer to reduce the acoustic impedance mismatch between the imaged object and the transducer, and the backing layers dampen the acoustic backwaves. Composite materials instead of single phase materials are frequently used to increase the performance of transducers (20).

Figure 12. Typical actuator designs: simple structures [(a)–(d)] and structures with strain amplification [(e)–(g)].

When a transducer function is to displace an object, it is called an actuator. It is desirable for an actuator to generate a significant displacement and/or generative force under a moderate electric field. In addition, actuators must have reproducible displacements when precise positioning is important. Thus, electrostrictive materials such as PMN or its solid solution with PT are preferred over PZT materials due to their small hysteresis. Figure 12 shows several possible designs of piezoelectric/electrostrictive actuators. In simple structures, like those shown in Fig. 12a–d, the actuator displacements are solely due to d_{33} , d_{31} , or d_{15} effects of the ceramic rod, plate, or tube. Because strain is limited to 10^{-3} , the typical displacement of a 1-cm long actuator is $\sim 10 \mu\text{m}$. Multilayer actuators (Fig. 12b) use a parallel connection of ceramic plates cemented together. In this case, the displacements of many individual sheets of a piezoelectric ceramic are summed. The advantage of multilayer actuators is their small operating voltage, fast speed, and large generative force. A useful design is the piezoelectric tube (Fig. 12c) which is poled and driven by the voltage applied in a radial direction (through the wall width). The axial response is due to the d_{31} coefficient of the material and is proportional to the length/width ratio. The radial response can be tuned to almost zero by manipulating the geometry of the tube (32). This configuration is beneficial in suppressing unwanted lateral displacements. Another important design is a shear actuator (Fig. 12d) which directly transforms the voltage applied normal to the polarization vector into a pure rotation due to the d_{15} coefficient (33).

As previously indicated, all of the simple structures are based on pure d_{31} , d_{33} , or d_{15} actions, so that displacements are limited to tens of microns. The amplification of strain at the expense of generative force can be achieved by using monomorph and bimorph structures (Fig. 12e–f). These types of actuators produce large displacements (up to several mm) but have low generative force and slow response. Another type of strain amplification can be achieved by flexensional transducers. One of the designs,

Figure 13. Example of the smart system using a PZT sensor incorporated in the MOONE actuator (36).

called MOONE, is shown in Fig. 12g (34). This type of actuator uses the bending effect of the moon-shaped metallic cap attached to both sides of a multilayer actuator. The d_{31} motion of the actuator is amplified by bending the metallic cap. Other examples of flextensional actuators are RAINBOWs and CYMBALs (not shown in the figure) (35, 36). Flextensional actuators have characteristics intermediate between multilayers and bimorphs and are now extensively used in various actuator applications. An example of a smart structure using flextensional actuator (MOONE) is shown in Fig. 13. The actuator portion of the device consists of the standard MOONE and a small piezoelectric ceramic embedded in the upper cap that serves as a sensor. The sensor detects vibrations normal to the actuator surface and, via a feedback loop, sends a signal of appropriate amplitude and phase to the actuator, so that it effectively cancels the external vibration. Potential applications of the smart structure shown in Fig. 13 include active optical systems, rotor suspension systems, and other noise cancellation devices.

Recent trends toward miniaturization have resulted in extensive use of piezoelectric/electrostrictive materials in microelectromechanical systems (MEMS). Because miniaturization of bulk ceramics is limited, these materials are used in a thin/thick film form. Thin film actuators based on the piezoelectric effect in PZT materials have been demonstrated. They include micromotors (37), acoustic imaging devices (38), components for atomic force microscopes (AFM) (39), and micropumps (40). Figure 14 shows the design of an atomic force microscope using PZT film for both sensing and actuating functions. The excitation ac voltage signal superimposed on the actuation dc voltage is applied to the PZT film deposited on the Si cantilever. The vibrational amplitude, which is sensitive to the atomic force between the tip and investigated surface, is detected by measuring the difference between the cantilever current and the reference current. The feedback system maintains a constant current while scanning in the x, y plane. This system does not require optical registration of the vibration that makes PZT-based AFM compact and it allows the multiprobe systems to be achieved. Because PZT film is very sensitive to vibrations, the vertical resolution of such an AFM approaches that of conventional systems. This electromechanically driven AFM is an excellent example of using piezoelectric ceramic thin films as smart materials.

Figure 14. Schematic of the AFM cantilever sensor and actuator based on a PZT thin film.

FUTURE TRENDS

Most piezoelectric/electrostrictive ceramics currently rely on lead oxide based materials due to their excellent properties as sensors and actuators. However, due to increased public awareness of health problems associated with lead and environmental protection policies, future research will be focused on finding lead-free compounds that have piezoelectric properties similar to those of PZT. Relaxor single-crystal materials that have a giant piezoelectric effect will probably find a wide range of applications from composite transducers for medical imaging to microelectromechanical systems. The current trend of miniaturization will continue to give rise to complex sensors and actuators integrated directly on a silicon chip. Further, batch processing will effectively reduce the cost of such devices. In addition, the research will continue toward the development of more resilient piezoelectric/electrostrictive materials used for operation under severe external conditions (temperature, pressure, harsh chemical environments). This will further improve their potential application in space and deep ocean exploration, as well as in noise cancellation in airplanes and helicopters.

INTRODUCTION

Smart Material

Let us start with the “smartness” of a material. Table 1 lists the various effects that relate the input—electric field, magnetic field, stress, heat and light—to the output—charge/current, magnetization, strain, temperature, and light. Conducting and elastic materials that generate current and strain outputs, respectively, from input voltage, or stress (well-known phenomena!) are sometimes called “trivial” materials. Conversely, pyroelectric and piezoelectric materials that generate an electric field from the input of heat or stress (unexpected phenomena!) are called “smart” materials. These off-diagonal couplings have a corresponding converse effect such as electrocaloric and converse piezoelectric effects, and both “sensing” and “actuating” functions can be realized in the same materials. “Intelligent” materials should possess a “drive/control” or “processing” function which is adaptive to the change in environmental conditions, in addition to the actuation and sensing functions. Note that ferroelectric materials exhibit most of these effects, except magnetic-related phenomena. Thus, the ferroelectrics are said to be very “smart” materials.

The “actuator” in a narrow meaning stands for materials or devices that generate mechanical strain (or stress) output. As indicated by the thick columnar border in Table 1, solid state actuators use converse piezoelectric, magnetostriction, elasticity, thermal expansion, or photostriction phenomena. A shape-memory alloy is a kind of thermally expanding material. On the other hand, a “sensor” requires charge/current output in most cases. Thus, conducting/semiconducting, magnetoelectric, piezoelectric, pyroelectric, and photovoltaic materials are used for detecting electric fields, magnetic fields, stress, heat, and light, respectively (see the thin columnar border in Table 1).

In this sense, piezoelectric materials are most popularly used in smart structures and systems because the same material is applicable to both sensors and actuators, in principle. We treat mainly piezoelectric transducers, sensors, and actuators in this article. Even though transducers, in general, are devices that convert input energy to a different energy type of output, the piezoelectric

“transducer” is often used to denote a device that possesses both sensing and actuating functions, exemplified by underwater sonar.

Piezoelectric Effect

Certain materials produce electric charges on their surfaces as a consequence of applying mechanical stress. When the induced charge is proportional to the mechanical stress, it is called a direct piezoelectric effect and was discovered by J. and P. Curie in 1880. Materials that show this phenomenon also conversely have a geometric strain generated that is proportional to an applied electric field. This is the converse piezoelectric effect. The root of the word “piezo” is the Greek word for “pressure”; hence the original meaning of the word piezoelectricity implied “pressure electricity” (1,2).

Piezoelectric materials couple electrical and mechanical parameters. The material used earliest for its piezoelectric properties was single-crystal quartz. Quartz crystal resonators for frequency control appear today at the heart of clocks and are also used in TVs and computers. Ferroelectric polycrystalline ceramics, such as barium titanate and lead zirconate titanate, exhibit piezoelectricity when electrically poled. Because these ceramics possess significant and stable piezoelectric effects, that is, high electromechanical coupling, they can produce large strains/forces and hence are extensively used as transducers. Piezoelectric polymers, notably polyvinylidene difluoride and its copolymers with trifluoroethylene and piezoelectric composites that combine a piezoelectric ceramic and a passive polymer have been developed and offer high potential. Recently, thin films of piezoelectric materials are being researched due to their potential use in microdevices (sensors and microelectromechanical systems). Piezoelectricity is being extensively used in fabricating various devices such as transducers, sensors, actuators, surface acoustic wave devices, and frequency controls.

We describe the fundamentals of piezoelectric effect first, then present a brief history of piezoelectricity, followed by present day piezoelectric materials that are used, and finally various potential applications of piezoelectric materials are presented.

PIEZOELECTRICITY

Relationship Between Crystal Symmetry and Properties

All crystals can be classified into 32 point groups according to their crystallographic symmetry. These point groups are divided into two classes; one has a center of symmetry, and the other lacks it. There are 21 noncentrosymmetric point groups. Crystals that belong to 20 of these point groups exhibit piezoelectricity. Although cubic class 432 lacks a center of symmetry, it does not permit piezoelectricity. Of these 20 point groups, 10 polar crystal classes contain a unique axis, along which an electric dipole moment is oriented in the unstrained condition.

The pyroelectric effect appears in any material that possesses a polar symmetry axis. The material in this category develops an electric charge on the surface owing to the change in dipole moment as temperature changes. The pyroelectric crystals whose spontaneous polarization are reorientable by applying an electric field of sufficient magnitude (not exceeding the breakdown limit of the crystal) are called ferroelectrics (3,4). Table 2 shows the crystallographic classification of the point groups.

Piezoelectric Coefficients

Materials are deformed by stresses, and the resulting deformations are represented by strains ($\Delta L/L$). When the stress X (force per unit area) causes a proportional strain x ,

$$x = sX, \tag{1}$$

where all quantities are tensors, x and X are second rank, and s is fourth rank. Piezoelectricity creates additional

Table 2. Crystallographic Classification According to Crystal Centrosymmetry and Polarity^a

Polarity	Symmetry	Crystal system										
		Cubic		Hexagonal		Tetragonal		Rhombohedral		Orthorhombic	Monoclinic	Triclinic
Non-polar (22)	Centro (11)	<i>m3m</i>	<i>m3</i>	<i>6/mmm</i>	<i>6/m</i>	<i>4/mmm</i>	<i>4/m</i>	<i>3m</i>	<i>3</i>	<i>mmm</i>	<i>2/m</i>	
	Non-centro (21)	432	23	622	6	422	4	32		222

^a Piezoelectrics are inside the boldline.

strains by an applied electric field E . The piezoelectric equation is given by

$$x_{ij} = s_{ijkl}X_{kl} + d_{ijk}E_k, \quad (2)$$

where E is the electric field and d is the piezoelectric constant which is a third-rank tensor. This equation can be also expressed in a matrix form such as for a poled ceramic:

$$\begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \\ x_5 \\ x_6 \end{pmatrix} = \begin{pmatrix} 0 & 0 & d_{31} \\ 0 & 0 & d_{31} \\ 0 & 0 & d_{33} \\ 0 & d_{15} & 0 \\ d_{15} & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} E_1 \\ E_2 \\ E_3 \end{pmatrix} \quad (3)$$

Another frequently used piezoelectric constant is g which gives the electric field produced when a stress is applied ($E = gX$). The g constant is related to the d constant through the relative permittivity ε :

$$g = d/\varepsilon\varepsilon_0, \quad (4)$$

where ε_0 is the permittivity of free space. A measure of the effectiveness of the electromechanical energy conversion is the electromechanical coupling factor k , which measures the fraction of electrical energy converted to mechanical energy when an electric field is applied or vice versa when a material is stressed (5):

$$k^2 = (\text{stored mechanical energy}/\text{input electrical energy}), \quad (5)$$

or

$$= (\text{stored electrical energy}/\text{input mechanical energy}). \quad (6)$$

Let us calculate k^2 in Eq.(5), when an electric field E is applied to a piezoelectric material. Because the input electrical energy is $(1/2)\varepsilon_0\varepsilon E^2$ per unit volume and the stored mechanical energy per unit volume under zero external stress is given by $(1/2)x^2/s = (1/2)(dE)^2/s$, k^2 can be calculated as

$$\begin{aligned} k^2 &= [(1/2)(dE)^2/s]/[(1/2)\varepsilon_0\varepsilon E^2] \\ &= d^2/\varepsilon_0\varepsilon s. \end{aligned} \quad (7)$$

Note that k is always less than one. Typical values of k are 0.10 for quartz, 0.4 for BaTiO₃ ceramic, 0.5–0.7 for PZT ceramic and 0.1–0.3 for PVDF polymer. Another important material parameter is the mechanical quality factor Q_m that determines frequency characteristics. Q_m is given by an inverse value of mechanical loss:

$$Q_m = 1/\tan \delta. \quad (8)$$

A low Q_m is preferred for sensor applications in general to cover a wide frequency range. Conversely, a high Q_m is most desired for ultrasonic actuators (e.g., ultrasonic motors) to suppress heat generation through the loss.

History of Piezoelectricity

As already stated, Pierre and Jacques Curie discovered piezoelectricity in quartz in 1880. The discovery of ferroelectricity accelerated the creation of useful piezoelectric materials. Rochelle salt was the first ferroelectric discovered in 1921. Until 1940 only two types of ferroelectrics were known, Rochelle salt and potassium dihydrogen phosphate and its isomorph. In 1940 to 1943, unusual dielectric properties such as an abnormally high dielectric constant were found in barium titanate BaTiO₃ independently by Wainer and Salmon, Ogawa, and Wul and Golman. After the discovery, compositional modifications of BaTiO₃ led to improvement in temperature stability and high-voltage output. Piezoelectric transducers based on BaTiO₃ ceramics became well established in a number of devices.

In the 1950s, Jaffe and co-workers established that the lead zirconate–lead titanate system (called the PZT system) induces strong piezoelectric effects. The maximum piezoelectric response was found for PZT compositions near the morphotropic phase boundary between the rhombohedral and tetragonal phases. Since then, the PZT system containing various additives has become the dominant piezoelectric ceramic for a variety of applications. The development of PZT-based ternary solid solutions was a major success of the piezoelectric industry for these applications.

In 1969, Kawai et al. discovered that certain polymers, notably polyvinylidene difluoride (PVDF), are piezoelectric when stretched during fabrication. Such piezoelectric polymers are also useful for some transducer applications.

Table 3. Material Parameters of Representative Piezoelectric Materials

Parameter	Quartz	BaTiO ₃	PZT4	PZT 5H	(Pb,Sm)/TiO ₃	PVDF-TrFE
d_{33} (pC/N)	2.3	190	289	593	65	33
g_{33} (10 ⁻³ Vm/N)	57.8	12.6	26.1	19.7	42	380
k_t	0.09	0.38	0.51	0.50	0.50	0.30
k_p		0.33	0.58	0.65	0.03	
$\varepsilon_3 T/\varepsilon_0$	5	1700	1300	3400	175	6
Q_m	>10 ⁵		500	65	900	3-10
T_C (°C)		120	328	193	355	

In 1978, Newnham et al. improved composite piezoelectric materials by combining a piezoelectric ceramic and a passive polymer whose properties can be tailored to the requirements of various piezoelectric devices.

Another class of ceramic material has recently become important: relaxor-type electrostrictors such as lead magnesium niobate (PMN), typically doped with 10% lead titanate (PT), which have potential applications in the piezoelectric actuator field. A recent breakthrough in the growth of high-quality, large, single-crystal relaxor piezoelectric compositions has created interest in these materials for applications ranging from high strain actuators to high-frequency transducers for medical ultrasound devices due to their superior electromechanical characteristics. More recently, thin films of piezoelectric materials such as zinc oxide (ZnO) and PZT have been extensively investigated and developed for use in microelectromechanical (MEMS) devices.

PIEZOELECTRIC MATERIALS

This section summarizes the current status of piezoelectric materials: single-crystal materials, piezoceramics, piezopolymers, piezocomposites, and piezofilms. Table 3 shows the material parameters of some representative piezoelectric materials described here (6,7).

Single Crystals

Piezoelectric ceramics are widely used at present for a large number of applications. However, single-crystal materials retain their utility; they are essential for applications such as frequency stabilized oscillators and surface acoustic devices. The most popular single-crystal piezoelectric materials are quartz, lithium niobate (LiNbO₃), and lithium tantalate (LiTaO₃). The single crystals are anisotropic in general, and have different properties depending on the cut of the materials and the direction of the bulk or surface wave propagation.

Quartz is a well-known piezoelectric material. α -Quartz belongs to the triclinic crystal system with point group 32 and has a phase transition at 537°C to the β -type that is not piezoelectric. Quartz has a cut with a zero temperature coefficient at the resonant frequency change. For instance, quartz oscillators using the thickness shear mode of the AT-cut are extensively used as clock sources in computers and as frequency stabilized oscillators in TVs, and VCRs. On the other hand, an ST-cut quartz substrate that has X propagation has a zero temperature coefficient for surface

acoustic waves and so is used for SAW devices that have highly stabilized frequencies. Another distinguishing characteristic of quartz is its extremely high mechanical quality factor $Q_m > 10^5$.

Lithium niobate and lithium tantalate belong to an isomorphous crystal system and are composed of oxygen octahedran. The Curie temperatures of LiNbO₃ and LiTaO₃ are 1210 and 660°C, respectively. The crystal symmetry of the ferroelectric phase of these single crystals is 3m, and the polarization direction is along the c axis. These materials have high electromechanical coupling coefficients for surface acoustic waves. In addition, large single crystals can easily be obtained from their melts by using the conventional Czochralski technique. Thus, both materials are very important in SAW device applications.

Perovskite Ceramics

Most of the piezoelectric ceramics have the perovskite structure ABO₃, shown Fig. 1. This ideal structure consists of a simple cubic unit cell that has a large cation A at the corner, a smaller cation B in the body center, and oxygens O in the centers of the faces. The structure is a network of corner-linked oxygen octahedra surrounding B cations. The piezoelectric properties of perovskite-structured materials can be easily tailored for applications by incorporating various cations in the perovskite structure.

Barium Titanate. Barium titanate (BaTiO₃) is one of the most thoroughly studied and most widely used piezoelectric materials. Figure 2 shows the temperature dependence

Figure 1. Perovskite structure ABO₃.

Figure 2. Dielectric constants of BaTiO_3 as a function of temperature.

of dielectric constants in BaTiO_3 , that demonstrate the phase transitions in BaTiO_3 single crystals. Three anomalies can be observed. The discontinuity at the Curie point (130°C) is due to a transition from a ferroelectric to a paraelectric phase. The other two discontinuities are accompanied by transitions from one ferroelectric phase to another. Above the Curie point, the crystal structure is cubic and has no spontaneous dipole moments. At the Curie point, the crystal becomes polar, and the structure changes from a cubic to a tetragonal phase. The dipole moment and the spontaneous polarization are parallel to the tetragonal axis. Just below the Curie temperature, the vector of the spontaneous polarization points in the $[001]$ direction (tetragonal phase), below 5°C it reorients in the $[011]$ (orthorhombic phase), and below -90°C in the $[111]$ (rhombohedral phase). The dielectric and piezoelectric properties of ferroelectric ceramic BaTiO_3 can be affected by its own stoichiometry, microstructure, and by dopants entering into the A or B site solid solution. Modified ceramic BaTiO_3 that contains dopants such as Pb or Ca ions have been used as commercial piezoelectric materials.

Lead Zirconate–Lead Titanate. Piezoelectric $\text{Pb}(\text{Ti}, \text{Zr})\text{O}_3$ solid-solution (PZT) ceramics are widely used because of their superior piezoelectric properties. The phase diagram of the PZT system ($\text{Pb}(\text{Zr}_x\text{Ti}_{1-x})\text{O}_3$) is shown in Fig. 3. The crystalline symmetry of this solid solution is determined by the Zr content. Lead titanate also has a tetragonal ferroelectric phase of the perovskite structure. As the Zr content x increases, the tetragonal distortion decreases, and when $x > 0.52$, the structure changes from the tetragonal $4mm$ phase to another ferroelectric phase of rhombohedral $3m$ symmetry. Figure 4 shows the dependence of several d constants on the composition near the morphotropic phase boundary between the tetragonal and rhombohedral phases. The d constants have their highest values near the morphotropic phase boundary. This enhancement in the piezoelectric effect is attributed to the increased ease of reorientation of the polarization in an electric field. Doping the PZT material with donors or acceptors changes the properties dramatically. Donor doping with ions such as Nb^{5+} or Ta^{5+} provides soft PZTs like PZT-5, because of the facility of domain motion due to the charge compensation

Figure 3. Phase diagram of the PZT system.

of the Pb vacancy which is generated during sintering. On the other hand, acceptor doping with Fe^{3+} or Sc^{3+} leads to hard PZTs such as PZT-8 because oxygen vacancies pin the domain wall motion.

Lead Titanate. PbTiO_3 has a tetragonal structure at room temperature and has large tetragonality $c/a = 1.063$.

Figure 4. Piezoelectric d strain coefficients versus composition for the PZT system.

The Curie temperature is 490°C. Densely sintered PbTiO_3 ceramics cannot be obtained easily because they break up into powders when cooled through the Curie temperature. This is partly due to the large spontaneous strain that occurs at the transition. Lead titanate ceramics modified by small amounts of additives exhibit high piezoelectric anisotropy. Either $(\text{Pb}, \text{Sm})\text{TiO}_3$ (8) or $(\text{Pb}, \text{Ca})\text{TiO}_3$ (9) has extremely low planar coupling, that is, a large k_t/k_p ratio. Here, k_t and k_p are thickness-extensional and planar electromechanical coupling factors, respectively. $(\text{Pb}, \text{Nd})(\text{Ti}, \text{Mn}, \text{In})\text{O}_3$ ceramics that have a zero temperature coefficient of surface acoustic wave delay have been developed as superior substrate materials for SAW devices (10).

Relaxor Ferroelectrics. Relaxor ferroelectrics differ from normal ferroelectrics; they have broad phase transitions from the paraelectric to the ferroelectric state, strong frequency dependence of the dielectric constant (i.e., dielectric relaxation), and weak remanent polarization at temperatures close to the dielectric maximum. Lead-based relaxor materials have complex disordered perovskite structures of the general formula $\text{Pb}(\text{B}_1, \text{B}_2)\text{O}_3$ ($\text{B}_1 = \text{Mg}^{2+}, \text{Zn}^{2+}, \text{Sc}^{3+}$; $\text{B}_2 = \text{Nb}^{5+}, \text{Ta}^{5+}, \text{W}^{6+}$). The B-site cations are distributed randomly in the crystal. The characteristic of a relaxor is a broad and frequency dispersive dielectric maximum. In addition, relaxor-type materials such as the lead magnesium niobate $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$ –lead titanate PbTiO_3 solid solution (PMN–PT) exhibit electrostrictive phenomena that are suitable for actuator applications. Figure 5 shows an electric-field-induced strain curve that was observed for 0.9 PMN–0.1 PT and reported by Cross et al. in 1980 (11). Note that a strain of 0.1% can be induced by an electric field as small as 1 kV/mm and that hysteresis is negligibly small for this electrostriction.

Because electrostriction is the secondary electromechanical coupling observed in cubic structures, in principle,

Figure 5. Field-induced electrostrictive strain in 0.9PMN–0.1PT.

the charge is not induced under applied stress. The converse electrostrictive effect, which can be used for sensor applications, means that the permittivity (the first derivative of polarization with respect to an electric field) is changed by stress.

In relaxor ferroelectrics, the piezoelectric effect can be induced under a bias field, that is, the electromechanical coupling factor k_t varies as the applied dc bias field changes. As the dc bias field increases, the coupling increases and saturates. These materials can be used for ultrasonic transducers that are tunable by a bias field (12).

The recent development of single-crystal piezoelectrics started in 1981, when Kuwata et al. first reported an enormously large electromechanical coupling factor $k_{33} = 92$ –95% and a piezoelectric constant $d_{33} = 1500$ pC/N in solid-solution single crystals between relaxor and normal ferroelectrics, $\text{Pb}(\text{Zn}_{1/3}\text{Nb}_{2/3})\text{O}_3$ – PbTiO_3 (13). After about 10 years, Yamashita et al. (Toshiba) and Shrout et al. (Penn State) independently reconfirmed that these values are true, and much more improved data were obtained in these few years, aimed at medical acoustic applications (14,15). Important data have been accumulated for $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$ (PMN), $\text{Pb}(\text{Zn}_{1/3}\text{Nb}_{2/3})\text{O}_3$ (PZN), and binary systems of these materials combined with PbTiO_3 (PMN–PT and PZN–PT) for actuator applications. Strains as large as 1.7% can be induced practically for a morphotropic phase boundary composition of PZN–PT solid-solution single crystals. Figure 6 shows the field-induced strain curve for [001] oriented 0.92PZN–0.08PT (15). It is notable that the highest values are observed for a rhombohedral composition only when the single crystal is poled along the perovskite [001] axis, not along the [111] spontaneous polarization axis.

Polymers

Polyvinylidene difluoride, (PVDF or PVF_2) is a piezoelectric when stretched during fabrication. Thin sheets of the cast polymer are drawn and stretched in the plane of the

Figure 6. Field induced strain curve for [001] oriented 0.92PZN–0.08PT.

sheet in at least one direction and frequently also in the perpendicular direction to convert the material into its microscopically polar phase. Crystallization from a melt forms the nonpolar α phase, which can be converted into another polar β phase by uniaxial or biaxial drawing; these dipoles are then reoriented by electric poling. Large sheets can be manufactured and thermally formed into complex shapes. Copolymerization of vinylidene difluoride with trifluoroethylene (TrFE) results in a random copolymer (PVDF-TrFE) that has a stable, polar β phase. This polymer does not need to be stretched; it can be poled directly as formed. A thickness-mode coupling coefficient of 0.30 has been reported. Such piezoelectric polymers are used for directional microphones and ultrasonic hydrophones.

Composites

Piezocomposites comprised of piezoelectric ceramics and polymers are promising materials because of excellent tailored properties. The geometry of two-phase composites can be classified according to the connectivity of each phase (0, 1, 2, or 3 dimensionality) into 10 structures; 0-0, 0-1, 0-2, 0-3, 1-1, 1-2, 1-3, 2-2, 2-3, and 3-3 (15). A 1-3 piezocomposite, or PZT-rod/polymer-matrix composite is a most promising candidate. The advantages of this composite are high coupling factors, low acoustic impedance (square root of the product of its density and elastic stiffness), a good match to water and human tissue, mechanical flexibility, a broad bandwidth in combination with a low mechanical quality factor, and the possibility of making undiced arrays by structuring only the electrodes. The thickness-mode electromechanical coupling of the composite can exceed the k_t (0.40–0.50) of the constituent ceramic and almost approaches the value of the rod-mode electromechanical coupling k_{33} (0.70–0.80) of that ceramic (16). The acoustic match to tissue or water (1.5 Mrayls) of typical piezoceramics (20–30 Mrayls) is significantly improved by forming a composite structure, that is, by replacing a heavy, stiff ceramic by a light, soft polymer. Piezoelectric composite materials are especially useful for underwater sonar and medical diagnostic ultrasonic transducers.

Thin Films

Both zinc oxide (ZnO) and aluminum nitride (AlN) are simple binary compounds that have Wurtzite type structures, which can be sputter-deposited in a c -axis oriented thin film on a variety of substrates. ZnO has reasonable piezoelectric coupling, and its thin films are widely used in bulk acoustic and surface acoustic wave devices. The fabrication of highly c -axis oriented ZnO films has been extensively studied and developed. The performance of ZnO devices is, however, limited due to their small piezoelectric coupling (20–30%). PZT thin films are expected to exhibit higher piezoelectric properties. At present, the growth of PZT thin film is being carried out for use in microtransducers and microactuators. A series of theoretical calculations on perovskite type ferroelectric crystals suggests that large d and k values of magnitudes similar to those of PZN-PT can also be expected in PZT. Crystal orientation dependence of piezoelectric properties was phenomenologically

Figure 7. The principle of enhancement in electromechanical couplings in a perovskite piezoelectric.

calculated for compositions around the morphotropic phase boundary of PZT (17). The maximum longitudinal piezoelectric constant d_{33} (4–5 times the enhancement) and the electromechanical coupling factor k_{33} (more than 90%) in the rhombohedral composition were found at angles of 57 and 51° respectively, canted from the spontaneous polarization direction [111], which correspond roughly to the perovskite [100] axis.

Figure 7 shows the principle of the enhancement in electromechanical couplings. Because the shear coupling d_{15} is the highest in perovskite piezoelectric crystals, the applied field should be canted from the spontaneous polarization direction to obtain the maximum strain. Epitaxially grown, [001] oriented thin/thick films using a rhombohedral PZT composition reportedly enhance the effective piezoelectric constant by four to five times.

APPLICATIONS OF PIEZOELECTRICITY

Piezoelectric materials can provide coupling between electrical and mechanical energy and thus have been extensively used in a variety of electromechanical devices. The direct piezoelectric effect is most obviously used to generate charge or high voltage in applications such as the spark ignition of gas in space heaters, cooking stoves, and cigarette lighters. Using the converse effect, small mechanical displacements and vibrations can be produced in actuators by applying an electric field. Acoustic and ultrasonic vibrations can be generated by an alternating field tuned at the mechanical resonant frequency of a piezoelectric device and can be detected by amplifying the field generated by vibration incident on the material, which is usually used for ultrasonic transducers. Another important application of piezoelectricity is frequency control. The application of piezoelectric materials ranges over many fields, including ultrasonic transducers, actuators, and ultrasonic motors; electronic components such as resonators, wave filters, delay lines; SAW devices and transformers and high-voltage applications; and gas igniters, and ultrasonic cleaning and machining. Piezoelectric-based sensors, for instance, accelerometers, automobile knock sensors, vibration sensors, strain gages, and flow meters have been developed because pressure and vibration can be directly sensed as electric

Figure 8. Cylindrical gyroscope commercialized by Tokin (Japan).

signals through the piezoelectric effect. Examples of these applications are given in the following sections.

Pressure Sensor/Accelerometer/Gyroscope

The gas igniter is one of the basic applications of piezoelectric ceramics. Very high voltage generated in a piezoelectric ceramic under applied mechanical stress can cause sparking and ignite a gas.

Piezoelectric ceramics can be employed as stress sensors and acceleration sensors, because of their “direct piezoelectric effect.” Kistler (Switzerland) is manufacturing a 3-D stress sensor. By combining an appropriate number of quartz crystal plates (extensional and shear types), the multilayer device can detect three-dimensional stresses (18).

Figure 8 shows a cylindrical gyroscope commercialized by Tokin (Japan) (19). The cylinder has six divided electrodes; one pair is used to excite the fundamental bending vibration mode, and the other two pairs are used to detect acceleration. When rotational acceleration is applied around the axis of this gyro, the voltage generated on the electrodes is modulated by the Coriolis force. By subtracting the signals between the two sensor electrode pairs, a voltage directly proportional to the acceleration can be obtained. This type of gyroscope has been widely installed in handheld video cameras to monitor the inevitable hand vibration during operation and to compensate for it electronically on a display by using the sensed signal.

Ultrasonic Transducer

One of the most important applications of piezoelectric materials is based on the ultrasonic echo field (20,21). Ultrasonic transducers convert electrical energy into a mechanical form when generating an acoustic pulse and convert mechanical energy into an electrical signal when detecting its echo. Nowadays, piezoelectric transducers are

being used in medical ultrasound for clinical applications that range from diagnosis to therapy and surgery. They are also used for underwater detection, such as sonars and fish finders, and nondestructive testing.

Ultrasonic transducers often operate in a pulse-echo mode. The transducer converts electrical input into an acoustic wave output. The transmitted waves propagate into a body, and echoes are generated that travel back to be received by the same transducer. These echoes vary in intensity according to the type of tissue or body structure, and thereby create images. An ultrasonic image represents the mechanical properties of the tissue, such as density and elasticity. We can recognize anatomical structures in an ultrasonic image because the organ boundaries and fluid-to-tissue interfaces are easily discerned. Ultrasonic imaging can also be done in real time. This means that we can follow rapidly moving structures such as the heart without motional distortion. In addition, ultrasound is one of the safest diagnostic imaging techniques. It does not use ionizing radiation like X rays and thus is routinely used for fetal and obstetrical imaging. Useful areas for ultrasonic imaging include cardiac structures, the vascular system, the fetus, and abdominal organs such as the liver and kidney. In brief, it is possible to see inside the human body by using a beam of ultrasound without breaking the skin.

There are various types of transducers used in ultrasonic imaging. Mechanical sector transducers consist of single, relatively large resonators that provide images by mechanical scanning such as wobbling. Multiple element array transducers permit the imaging systems to access discrete elements individually and enable electronic focusing in the scanning plane at various adjustable penetration depths by using phase delays. The two basic types of array transducers are linear and phased (or sector). Linear array transducers are used for radiological and obstetrical examinations, and phased array transducers are useful for cardiological applications where positioning between the ribs is necessary.

Figure 9 shows the geometry of the basic ultrasonic transducer. The transducer is composed mainly of

Figure 9. Geometry of the fundamental transducer for acoustic imaging.

matching, piezoelectric material, and backing layers (22). One or more matching layers are used to increase sound transmissions into tissues. The backing is attached to the transducer rear to damp the acoustic returnwave and to reduce the pulse duration. Piezoelectric materials are used to generate and detect ultrasound. In general, broadband transducers should be used for medical ultrasonic imaging. The broad bandwidth response corresponds to a short pulse length that results in better axial resolution. Three factors are important in designing broad bandwidth transducers. The first is acoustic impedance matching, that is, effectively coupling the acoustic energy to the body. The second is high electromechanical coupling coefficient of the transducer. The third is electrical impedance matching, that is, effectively coupling electrical energy from the driving electronics to the transducer across the frequency range of interest. The operator of pulse-echo transducers is based on the thickness mode resonance of the piezoelectric thin plate. The thickness mode coupling coefficient k_t is related to the efficiency of converting electric energy into acoustics and vice versa. Further, a low planar mode coupling coefficient k_p is beneficial for limiting energies from being expended in a nonproductive lateral mode. A large dielectric constant is necessary to enable a good electrical impedance match to the system, especially in tiny piezoelectric sizes.

Table 4 compares the properties of ultrasonic transducer materials (7,23). Ferroelectric ceramics, such as lead zirconate titanate and modified lead titanate, are almost universally used as ultrasonic transducers. The success of ceramics is due to their very high electromechanical coupling coefficients. In particular, soft PZT ceramics such as PZT-5A and 5H type compositions are most widely used because of their exceedingly high coupling properties and because they can be relatively easily tailored, for instance, in the wide dielectric constant range. On the other hand, modified lead titanates such as samarium-doped materials have high piezoelectric anisotropy: the planar coupling factor k_p is much less than the thickness coupling factor k_t . Because the absence of lateral coupling leads to reduced interference from spurious lateral resonances in longitudinal oscillators, this is very useful in high-frequency array transducer applications. One disadvantage of PZT and other lead-based ceramics is their large acoustic impedance (approximately $30 \text{ kgm}^{-2}\text{s}^{-1}$ (Mrayls) compared to body tissue (1.5 Mrayls). Single or multiple matching layers of intermediate impedances need to be used in PZT to improve acoustic matching.

On the other hand, piezoelectric polymers, such as polyvinylidene difluoride-trifluoroethylene, have much lower

acoustic impedance (4–5 Mrayls) than ceramics and thus match soft tissues better. However, piezopolymers are less sensitive than ceramics, and they have relatively low dielectric constants that require large drive voltage and give poor noise performance due to mismatching of electrical impedance.

Piezoelectric ceramic/polymer composites are alternatives to ceramics and polymers. Piezocomposites that have 2–2 or 1–3 connectivity are commonly used in ultrasonic medical applications. They combine the low acoustic impedance advantage of polymers and the high sensitivity and low electrical impedance advantages of ceramics.

The design frequency of a transducer depends on the penetration depth required by the application. Resolution is improved as frequency increases. Although a high-frequency transducer can produce a high-resolution image, higher frequency acoustic energy is more readily attenuated by the body. A lower frequency transducer is used as a compromise when imaging deeper structures. Most medical ultrasound imaging systems operate in the frequency range from 2–10 MHz and can resolve objects approximately 0.2–1 mm in size. At 3.5 MHz, imaging to a depth of 10–20 cm is possible, and at 50 MHz, increased losses limit the depth to less than 1 cm. Higher frequency transducers (10–50 MHz) are used for endoscopic imaging and for catheter-based intravascular imaging. Ultrasound microscopy is being done at frequencies higher than 100 MHz. The operating frequency of the transducer is directly related to the thickness and velocity of sound in the piezoelectric materials employed. As the frequency increases, resonator thickness decreases. For a 3.5 MHz transducer, the PZT ceramic must be roughly 0.4 mm thick. Conventional ceramic transducers, such as PZT, are limited to frequencies below 80 MHz because of the difficulty of fabricating thinner devices (24). Piezoelectric thin-film transducers such as ZnO have to be used for microscopic applications (at frequencies higher than 100 MHz, corresponding to a thickness of less than $20 \mu\text{m}$) (25).

Resonator and Filter

When a piezoelectric body vibrates at its resonant frequency, it absorbs considerably more energy than at other frequencies, resulting in a fall of the impedance. This phenomenon enables using piezoelectric materials as wave filters. A filter is required to pass a certain selected frequency band or to stop a given band. The bandwidth of a filter fabricated from a piezoelectric material is determined by the square of the coupling coefficient k . Quartz crystals that have very low k values of about 0.1 can pass very narrow

Table 4. Comparison of the Properties of Ultrasonic Transducer Materials

	PZT Ceramic	PVDF Polymer	PZT-Polymer Composite	ZnO Film
k_t	0.45–0.55	0.20–0.30	0.60–0.75	0.20–0.30
Z (Mrayls)	20–30	1.5–4	4–20	35
$\epsilon_{33} T / \epsilon_0$	200–5000	10	50–2500	10
$\tan \delta$ (%)	<1	1.5–5	<1	<1
Q_m	10–1000	5–10	2–50	10
ρ (g/cm ³)	5.5–8	1–2	2–5	3–6

frequency bands of approximately 1% of the center resonance frequency. On the other hand, PZT ceramics whose planar coupling coefficient is about 0.5 can easily pass a band of 10% of the center resonance frequency. The sharpness of the passband depends on the mechanical quality factor Q_m of the material. Quartz also has a very high Q_m of about 10^6 which results in a sharp cutoff of the passband and well-defined frequency of the oscillator.

A simple resonator is a thin disk electrode on its plane faces and vibrating radially for applications in filters whose center frequency ranges from 200 kHz to 1 MHz and whose bandwidth is several percent of the center frequency. The disk diameter must be about 5.6 mm for a frequency of 455 kHz. However, if the required frequency is higher than 10 MHz, other modes of vibration such as the thickness extensional mode are exploited, because of its smaller size disk. Trapped-energy type filters made from PZT ceramics have been widely used in the intermediate frequency range, for example, 10.7 MHz for FM radio receivers and transmitters. By employing the trapped-energy phenomenon, the overtone frequencies are suppressed. The plate is partly covered by electrodes of a specific area and thickness. The fundamental frequency of the thickness mode beneath the electrode is less than that of the unelectroded portion because of the extra inertia of the electrode mass. The longer wave characteristic of the electrode region cannot propagate in the unelectroded region. Higher frequency overtones can propagate into the unelectroded region. This is called the trapped-energy principle. Figure 10 shows a schematic drawing of a trapped-energy filter. In this structure, the top electrode is split so that coupling between the two parts is efficient only at resonance. More stable filters suitable for telecommunication systems have been made from single crystals such as quartz or LiTaO_3 .

Piezoelectric Transformer

The transfer of vibrational energy from one set of electrodes to another on a piezoelectric ceramic body can be used to transform voltage. The device is called a piezoelectric transformer. Recently, office automation equipment that has a liquid crystal display such as notebook type personal computers and car navigation systems has been successfully commercialized. This equipment that uses liquid crystal display requires a very thin transformer without electromagnetic noise to start the glow of

Figure 10. Trapped-energy filter.

Figure 11. Piezoelectric transformer.

a fluorescent back-lamp. This application has recently accelerated the development of piezoelectric transformers. Figure 11 shows the basic structure, where two differently poled parts coexist in one piezoelectric plate. The plate has electrodes on half of its major faces and on an edge. The plate is then poled in its thickness direction at one end and parallel to the long axis over most of its length. A low-voltage ac supply is applied to the large-area electrodes at a frequency that excites a length extensional mode resonance. Then, a high-voltage output can be taken from the small electrode and from one of the larger electrodes. Following the proposal by Rosen mentioned before, piezoelectric transformers of several different structures have been reported (26). Multilayer type transformers are proposed to increase the voltage step-up ratio (27). The input part has a multilayer structure and has internal electrodes, and the output electrodes are formed at the side surface of the half of the rectangular plate. This transformer uses the piezoelectric transverse mode for the input and output parts.

SAW Device

A surface acoustic wave (SAW), also called a Rayleigh wave, is composed of a coupling between longitudinal and shear waves in which the SAW energy is confined near the surface. An associated electrostatic wave exists for a SAW on a piezoelectric substrate that allows electroacoustic coupling via a transducer. The advantages of SAW technology are that a wave can be electroacoustically accessed and trapped at the substrate surface and its velocity is approximately 10^4 times slower than an electromagnetic wave. The SAW wavelength is of the same order of magnitude as line dimensions that can be photolithographically produced, and the lengths for both short and long delays are achievable on reasonably size substrates (28,29).

There is a very broad range of commercial applications, including front-end and IF (intermediate frequency) filters, CATV (community antenna television) and VCR (video cassette recorder) components, synthesizers, analyzers, and navigators. In SAW transducers, finger electrodes provide the ability to sample or tap the wave, and the electrode gap gives the relative delay. A SAW filter is composed of a minimum of two transducers. A schematic of a simple SAW bidirectional filter is shown in Fig. 12. A bidirectional transducer radiates energy equally from each side of the transducer. Energy not received is absorbed to eliminate spurious reflection.

Various materials are currently being used for SAW devices. The most popular single-crystal SAW materials are lithium niobate and lithium tantalate. The materials have different properties depending on their cuts and the direction of propagation. The fundamental parameters are the

Figure 12. Typical SAW bidirectional filter that consists of two interdigital transducers.

SAW velocity, the temperature coefficient of delay (TCD), the electromechanical coupling factor, and the propagative loss. Surface acoustic waves can be generated and detected by spatially periodic, interdigital electrodes on the plane surface of a piezoelectric plate. A periodic electric field is produced when an RF source is connected to the electrode, thus permitting piezoelectric coupling to a traveling surface wave. If an RF source of a frequency f is applied to an electrode whose periodicity is p , energy conversion from an electrical to mechanical form will be maximum when

$$f = f_0 = V_s/p, \quad (9)$$

where V_s is the SAW velocity and f_0 is the center frequency of the device. SAW velocity is an important parameter that determines the center frequency. Another important parameter for many applications is the temperature sensitivity. For example, the temperature stability of the center frequency of a SAW bandpass filter is a direct function of the temperature coefficient for the velocity and delay time of the material used. The first-order temperature coefficient of delay time is given by

$$(1/t)(dt/dT) = (1/L)(dL/dT) - (1/V_s)(dV_s/dT), \quad (10)$$

where $t = L/V_s$ is the delay time and L is the SAW propagative length. The surface wave coupling factor k_s^2 is defined in terms of the change in SAW velocity that occurs when the wave passes across a surface coated by a thin massless conductor, so that the piezoelectric field associated with the wave is effectively shorted-circuited. The coupling factor

k_s^2 is expressed by

$$k_s^2 = 2(V_f - V_m)/V_f, \quad (11)$$

where V_f is the free surface wave velocity and V_m is the velocity on the metallized surface. In SAW applications, the value of k_s^2 relates to the maximum bandwidth obtainable and the amount of signal loss between input and output that determines the fractional bandwidth versus minimum insertion loss for a given material and a filter. Propagative loss, one of the major factors that determines the insertion loss of a device, is caused by wave scattering by crystalline defects and surface irregularities. Materials that have high electromechanical coupling factors combined with small temperature coefficients of delay time are likely to be required. The free surface velocity V_0 of the material is a function of the cut angle and the propagative direction. The TCD is an indication of the frequency shift expected from a transducer due to a temperature change and is also a function of the cut angle and the propagative direction. The substrate is chosen on the basis of the device's design specifications for operating temperature, fractional bandwidth, and insertion loss.

Table 5 shows some important material parameters of representative SAW materials. Piezoelectric single crystals such as 128°Y-X (128° -rotated Y cut and X propagation) LiNbO_3 and $\text{X-}112^\circ\text{Y}$ (X cut and 112° -rotated Y propagation) LiTaO_3 have been extensively employed as SAW substrates for VIF filters. ZnO thin films c-axis oriented and deposited on a fused quartz, glass, or sapphire substrate have also been commercialized for SAW devices.

Actuators

Currently, another important application of piezoelectric materials exists in the actuator field (30). Using the converse piezoelectric effect, a small displacement can be produced by applying an electric field to a piezoelectric material. Vibrations can be generated by applying an alternating electric field. There is a demand in advanced precision engineering for a variety of types of actuators that can adjust position precisely (micropositioning devices), suppress noise vibrations (dampers), and drive objects dynamically (ultrasonic motors). These devices are used in areas, including optics, astronomy, fluid control, and precision machinery. Piezoelectric strain and electrostriction induced by an electric field are used for actuator applications.

Table 5. Material Parameters for Representative SAW Materials

	Material	Cut-Propagation Direction	k^2 (%)	TCD		
				(ppm/C)	V_0 (m/s)	ϵ_r
Single crystal	Quartz	ST-X	0.16	0	3158	4.5
	LiNbO_3	128°Y-X	5.5	-74	3960	35
	LiTaO_3	$\text{X}112^\circ\text{-Y}$	0.75	-18	3290	42
	$\text{Li}_2\text{B}_4\text{O}_7$	(110)<001>	0.8	0	3467	9.5
Ceramic	$\text{PZT-In}(\text{Li}_{3/5}\text{W}_{2/5})\text{O}_3$		1.0	10	2270	690
	$(\text{Pb,Nd})(\text{Ti,Mn,In})\text{O}_3$		2.6	<1	2554	225
Thin film	ZnO/glass		0.64	-15	3150	8.5
	ZnO/sapphire		1.0	-30	5000	8.5

Figure 13. Structures of ceramic actuators.

Figure 13 shows the design classification of ceramic actuators. Simple devices composed of a disk or a multilayer type use the strain induced in a ceramic by the applied electric field directly. Complex devices do not use the induced strain directly but use the amplified displacement through a special magnification mechanism such as a unimorph, bimorph or moonie. The most popularly used multilayer and bimorph types have the following characteristics: The multilayer type does not have a large displacement ($10\ \mu\text{m}$) but has advantages in generation force (1 kN), response speed ($10\ \mu\text{s}$), lifetime (10^{11} cycles), and electromechanical coupling factor k_{33} (0.70). The bimorph type has a large displacement ($300\ \mu\text{m}$) but has disadvantages in generation force (1 N), response speed (1 ms), lifetime (10^8 cycles), and electromechanical coupling factor k_{eff} (0.10). For instance, in a 0.65 PMN–0.35 PT multilayer actuator made of 99 layers of $100\text{-}\mu\text{m}$ thick sheets ($2 \times 3 \times 10\ \text{mm}^3$), an $8.7\text{-}\mu\text{m}$ displacement is generated by a 100 V voltage, accompanied by a slight hysteresis. The transmitted response of the induced displacement after the application of a rectangular voltage is as quick as $10\ \mu\text{s}$. The multilayer has a field-induced strain of 0.1% along the length.

Unimorph and bimorph devices are defined by the number of piezoelectric ceramic plates: only one ceramic plate is bonded onto an elastic shim, or two ceramic plates are bonded together. The bimorph causes bending deformation because each piezoelectric plate bonded together produces extension or contraction in an electric field. In general, there are two types of piezoelectric bimorphs: the antiparallel polarization type and the parallel polarization type,

Figure 14. Two types of piezoelectric bimorphs: (a) antiparallel polarization type and (b) parallel polarization type.

as shown in Fig. 14. Two poled piezoelectric plates $t/2$ thick and L long are bonded so that their polarization directions are opposite or parallel to each other. In the cantilever bimorph configuration where one end is clamped, the tip displacement δ_z under an applied voltage V is

$$\delta_z = (3/2)d_{31}(L^2/t^2)V, \quad (\text{antiparallel type}) \quad (12)$$

$$\delta_z = 3d_{31}(L^2/t^2)V. \quad (\text{parallel type}) \quad (13)$$

The resonance frequency f_r for both types is given by

$$f_r = 0.16 t/L^2(\rho s_{11}^E)^{-1/2}, \quad (14)$$

where ρ is the density and s_{11}^E is the elastic compliance. A metallic sheet (called a shim) is occasionally sandwiched between the two piezoelectric plates to increase reliability; the structure can be maintained even if the ceramics fracture. Using the bimorph structure, a large magnification of displacement is easily obtainable. However, the disadvantages include low response speed (1 kHz) and low generative force.

A composite actuator structure called a “moonie” has been developed to amplify the small displacements induced in piezoelectric ceramics. The moonie consists of a thin multilayer element and two metal plates that have narrow moon-shaped cavities bonded together. This device has characteristics intermediate between the conventional multilayer and bimorph actuators; it has an order of magnitude larger displacement ($100\ \mu\text{m}$) than the multilayer, much larger generative force (100 N), and quicker response ($100\ \mu\text{s}$) than the bimorph.

Some examples of applications of piezoelectric and electrostrictive actuators are described here. The piezoelectric impact dot-matrix printer is the first mass-produced device that uses multilayer ceramic actuators (Fig. 15). The advantages of a piezoelectric printer head compared to conventional magnetic type are low energy consumption, low heat generation, and fast printing speed. Longitudinal multilayer actuators do not have a large displacement, and thus a suitable displacement magnification mechanism is necessary. The displacement induced in a multilayer actuator pushes up the force point, and its displacement magnification is carried out through hinge levers to generate a large wire stroke. When the displacement in

Figure 15. Impact dot-matrix printer head.

the piezoactuator is $8 \mu\text{m}$, a wire stroke of $240 \mu\text{m}$ can be obtained; the magnification rate is 30 times.

Bimorph structures are commonly used for VCR head-tracking actuators because of their large displacements. An autotracking scan system uses a piezoelectric actuator so that the head follows the recording track, even driven in both still and quick modes. As can be anticipated, the bimorph drive is inevitably accompanied by torsional motion. A special mechanism has to be employed to obtain perfectly parallel motion. Piezoelectric pumps for gas or liquid that use the alternating bending motion of the bimorph have been developed for intravenous drip injection in hospitals and for medication dispensing for chemotherapy, chronic pain, and diabetes. Piezoelectric fans for cooling electronic circuits are made from a pair of bimorphs that are driven out of phase so as to blow effectively. Furthermore, piezo-bimorph type camera shutters have been widely commercialized by Minolta.

Lenses and mirrors in optical control systems require micropositioning, and even the shapes of mirrors are adjusted to correct image distortions. For instance, a space-qualified active mirror, called an articulating fold mirror, uses six PMN electrostrictive multilayer actuators to position and tilt a mirror tip precisely to correct the focusing aberration of the Hubble Space Telescope.

Piezoelectric actuators are also useful for vibrational suppression systems in an automobile. An electronic controlled shock absorber was developed by Toyota.

Figure 16. Bearingless rotor flexbeam and attached piezoelectric strips.

Piezoelectric sensors that detecting road roughness are composed of five layers of 0.5-mm thick PZT disks. The actuator is made of 88 layers of 0.5 mm thick disks. Under 500 V , it generates about $50 \mu\text{m}$ displacement, which is magnified 40 times by a piston and plunger pin combination. This stroke pushes the change valve of the damping force down and then opens the bypass oil route, leading to a decrease in flow resistance. This electronically controlled shock absorber has both controllability and provides comfort simultaneously.

The U.S. Army is interested in developing a rotor control system for helicopters because a slight change in the blade angle dramatically enhances controllability. Figure 16 shows a bearingless rotor flexbeam that has piezoelectric strips attached. Various types of PZT-sandwiched beam structures have been investigated for such a flexbeam application and for active vibrational control.

Ultrasonic Motors

An ultrasonic motor (USM) is an example of a piezoelectric actuator that uses resonant vibration. Linear motion in ultrasonic motors is obtained by frictional force from elliptical vibration. The motor consists of a high-frequency power supply, a vibrator, and a slider. The vibrator is composed of a piezoelectric driving component and an elastic vibratory part, and the slider is composed of an elastic moving part and a friction coat. The characteristics of ultrasonic motors are low speed and high torque compared to the high speed and low torque of conventional electromagnetic motors (30,31).

Ultrasonic motors are classified into two types: the standing-wave type and the propagating-wave type. The displacement of a standing wave is expressed by

$$x_s(x, t) = A \cos(kx) \cos(\omega t); \quad (15)$$

for a propagative wave displacement is given by

$$\begin{aligned} x_p(x, t) &= A \cos(kx - \omega t) \\ &= A \cos(kx) \cos(\omega t) + A \cos(kx - \pi/2) \cos(\omega t - \pi/2). \end{aligned} \quad (16)$$

Figure 17. Vibratory-coupler type ultrasonic motor.

A propagating wave can be generated by superimposing two standing waves whose phases differ from each other by 90° in both time and in space. The standing-wave type is sometimes called a vibratory coupler or a "woodpecker" type; a vibratory piece is connected to a piezoelectric driver, and the tip portion generates a flat elliptical movement (Fig. 17). The vibratory piece is attached to a rotor or a slider at a slight cant angle. The standing-wave type has high efficiency, up to 98% of theoretical. However, a problem of this type is lack of control in both clockwise and counterclockwise directions. The principle of the propagative type is shown in Fig. 18. In the propagating-wave type, also called the "surfing-type," a surface particle of the elastic body draws an elliptical locus due to coupling of the longitudinal and transverse waves. This type generally requires two vibrational sources to generate one propagating wave; this leads to low efficiency (not more than 50%), but it is controllable in both rotational directions. An ultrasonic rotary motor is successfully used in an autofocusing camera to produce precise rotational displacements. The advantages of this motor over the conventional electromagnetic motor are silent drive (inaudible), thin motor design, and energy savings.

Tiny conventional electromagnetic motors, smaller than 1cm that have sufficient energy efficiency are rather difficult to produce. Therefore, the ultrasonic motor is gaining widespread attention. Ultrasonic motors whose efficiency is independent of size are superior in the minimotor area. A compact ultrasonic rotary motor as tiny as 3 mm in diameter was developed by Uchino et al. (32). The stator consists of a piezoelectric ring and two concave/convex metal end caps that have windmill-shaped slots bonded together, so as to generate a coupled vibration of the up-down and

Figure 18. Principle of the propagating-wave type ultrasonic motor.

torsional type. Because the number of components and the fabrication process are minimized, the cost of fabrication will decrease remarkably, and it can be disposable; this is very suitable for medical catheter and endoscopic applications. When driven at 160 kHz, a maximum speed of 600 rpm and maximum torque 1 mN m were obtained.

The following key problems should be systematically studied in developing reliable ultrasonic motors: (1) development of low loss and high vibrational velocity piezoelectric materials; (2) piezoactuator designs that account for heat generation and degradation mechanisms; (3) USM designs, including displacement amplification mechanisms and frictional contact parts.

CHARACTERIZATION OF PIEZOELECTRIC CERAMIC MATERIALS

T.L. JORDAN
 Z. OUNAIES
 NASA Langley Research Center
 Hampton, VA

INTRODUCTION

This article explores piezoelectric ceramics analysis and characterization. The focus is on polycrystalline ceramics; therefore, single crystals, polymeric materials, and organic/inorganic composites are outside the scope of this review. To grasp the behavior of a piezoelectric polycrystalline ceramic thoroughly, a basic understanding of the ceramic itself should not be overlooked. To this end, we have presented a brief introduction of the history of piezoelectricity and a discussion on processing of the ceramic and the development of the constitutive relationships that define the behavior of a piezoelectric material. We have attempted to cover the most common measurement methods and to introduce parameters of interest. Excellent sources for more in-depth coverage of specific topics can be found in the bibliography. In most cases, we refer to lead zirconate titanate (PZT) to illustrate some of the concepts because it is the most widely used and studied piezoelectric ceramic to date.

PIEZOELECTRIC MATERIALS: HISTORY AND PROCESSING

Smart materials are materials that undergo transformations through physical interactions. An alternate definition is that a smart material is a material that senses a change in its environment and adapts to correct or eliminate such a change by using a feedback system. Piezoelectric materials, shape-memory alloys, electrostrictive materials, magnetostrictive materials, and electrorheological fluids are some examples of currently available smart materials.

Piezoelectricity stems from the Greek word *piezo* for pressure. It follows that a piezoelectric material develops a

potential across its boundaries when subjected to a mechanical stress (or pressure), and vice versa, when an electric field is applied to the material, a mechanical deformation ensues. Therefore, piezoelectric materials fall in the class of smart materials. Ferroelectricity is a subgroup of piezoelectricity, where a spontaneous polarization exists that can be reoriented by applying an ac electric field.

Definition and History

Piezoelectricity is a linear effect that is related to the microscopic structure of a solid. Some ceramic materials become electrically polarized when they are strained; this linear and reversible phenomenon is referred to as *the direct piezoelectric effect*. The direct piezoelectric effect is always accompanied by *the converse piezoelectric effect* where a solid becomes strained when placed in an electric field. The microscopic origin of the piezoelectric effect is the displacement of ionic charges within a crystal structure. In the absence of external strain, the charge distribution within the crystal is symmetrical, and the net electric dipole moment is zero. However when an external stress is applied, the charges are displaced, and the charge distribution is no longer symmetrical. A net polarization develops and results in an internal electric field. A material can be piezoelectric only if the unit cell has no center of inversion.

Piezoelectricity is a property of a group of materials that was discovered in 1880 by Pierre and Jacques Curie during their study of the effects of pressure on the generation of electrical charge by crystals such as quartz, tourmaline, and Rochelle salt. In 1881, the term "piezoelectricity" was first suggested by W. Hankel, and the converse effect was deduced by Lipmann from thermodynamics principles. In the next three decades, collaborations within the European scientific community established the field of piezoelectricity, and by 1910, Voigt's *Lerbuch der Kristallphysic* was published and became a standard reference work detailing the complex electromechanical relationships in piezoelectric crystals (1). However, the complexity of the science of piezoelectricity made it difficult for it to mature to an application until a few years later. Langevin et al. (2) developed a piezoelectric ultrasonic transducer during World War I. Its success opened up opportunities for piezoelectric materials in underwater applications and a host of other applications such as ultrasonic transducers, microphones, and accelerometers. In 1935, Busch and Scherrer discovered piezoelectricity in potassium dihydrogen phosphate (KDP). The KDP family was the first major family of piezoelectrics and ferroelectrics discovered.

During World War II, research in piezoelectric materials expanded to the United State, the Soviet Union, and Japan. Until then, limited performance by these materials inhibited commercialization, but that changed when a major breakthrough came with the discovery of barium titanate and lead zirconate titanate (PZT) in the 1940s and 1950s, respectively. These families of materials exhibited very high dielectric and piezoelectric properties. Furthermore, they offered the possibility of tailoring their behavior to specific responses and applications by using dopants. To date, PZT is one of the most widely used piezoelectric materials. Most commercially available ceramics (such

Figure 1. Perovskite structure.

as barium titanate and PZT) are based on the perovskite structure (Fig. 1). The perovskite structure (ABO_3) is the simplest arrangement where the corner-sharing oxygen octahedra are linked together in a regular cubic array; smaller cations (Ti, Zr, Sn, Nb, etc.) occupy the central octahedral B site, and larger cations (Pb, Ba, Sr, Ca, Na, etc.) fill the interstices between octahedra in the larger A site. Compounds such as $BaTiO_3$, $PbTiO_3$, $PbZrO_3$, $NaNbO_3$, and $KNbO_3$ have been studied at length and their high-temperature ferroelectric and antiferroelectric phases have been extensively exploited. This structure also allows multiple substitutions at the A site and B site that result in a number of useful though more complex compounds such as $(Ba,Sr)TiO_3$, $(Pb,Sr)(Zr,Ti)O_3$, $Pb(Fe,Ta)O_3$, and $(KBi)TiO_3$.

Starting around 1965, several Japanese companies focused on developing new processes and applications and opening new commercial markets for piezoelectric devices. The success of the Japanese effort attracted other nations, and today the needs and uses extend from medical applications to the communications field to military applications and the automotive field.

A review of the early history of piezoelectricity is found in the work of Cady (3), and in 1971, Jaffe et al. published the book *Piezoelectric Ceramics* (4) that is still one of the most referenced works on piezoelectricity.

Piezoelectric Ceramic Processing

The fabrication of most bulk piezoelectric ceramics starts with powder preparation. The powder is then pressed to the required shapes and sizes, and the green shapes are in turn processed into mechanically strong and dense ceramics. The more important processes that influence the product characteristics and properties are powder preparation, powder calcining and sintering. The next steps are machining, electroding, and poling, the application of a dc field to orient the dipoles and induce piezoelectricity.

The most common powder preparation is the mixed-oxide. In this process, powder is prepared from the appropriate stoichiometric mixture of the constituent oxides. Lead oxide, titanium oxide, and zirconium oxide are the main compounds for, lead zirconate titanate (PZT). Depending on the application, various dopants are used to tailor the properties of interest. PZT ceramics are rarely used

Figure 2. Mixed-oxide route for preparing PZT.

without adding of dopants to modify some of their properties. A-site additives tend to lower the dissipation factor, which affects heat generation, but also lower the piezoelectric coefficients; for this reason they are used mostly in ultrasonics and other high-frequency applications. B-site dopants increase the piezoelectric coefficients but also increase the dielectric constant and loss. B-site doped ceramics used are as actuators in vibrational and noise control, benders, and optical positioning applications.

Figure 2 shows a flowchart of the mixed-oxide route for making PZT ceramics. The powders can be mixed by dry ball milling or wet ball milling; both methods have advantages and disadvantages: wet ball milling is faster than dry milling; however, the disadvantage is the added step of liquid removal. The most common method for making PZT ceramics is wet ball milling; ethanol and stabilized zirconia media are added for wet milling. A vibratory mill may be used rather than a conventional ball mill; Herner (5) showed that this process reduces the risk of contamination by the balls and the jar. Zirconia media are used to reduce the contamination risks further. Calcination is a very crucial step in processing PZT ceramics; it is important for crystallization to be complete because the perovskite phase forms during this step. The goals are to remove any organics, water, or other volatiles left after mixing; to react the oxides to form the desired phase composition before the ceramic is processed into useful devices; and to reduce volume shrinkage and allow for better homogeneity during and after sintering.

After calcining, a binder is added to the powder, and then the mixture is shaped usually by dry pressing in a die for simple shapes, or extrusion, or casting for more complicated bodies. Next, the shapes are sintered—placed in an oven for binder burnout and densification.

The major problem in sintering a PZT ceramic is the volatility of PbO at about 800°C. To minimize this problem, the PZT samples are sintered in the presence of a lead source, such as PbZrO₃, and placed in closed crucibles. Saturation of the sintering atmosphere with PbO minimizes lead loss from the PZT bodies. Sintering can now be carried out at temperatures varying between 1200–1300°C. Despite precautions, usually 2–3% of the initial lead content is lost.

After cutting and machining into desired shapes, electrodes are applied, and a strong dc field is used to orient the domains in the polycrystalline ceramic. Dc poling can be done at room temperature or at higher temperatures, depending on the material and the composition. The poling process only partially aligns the dipoles in a polycrystalline ceramic, and the resulting polarization is lower than that of single crystals.

This processing technique presents many uncertainties; the existence of a wide number of other fabrication techniques is an indication that there is a great need for the production of reliable PZT ceramics whose properties and microstructure are optimal. One problem often encountered is deviation from stoichiometry. This problem is often due to impurities in the raw materials as well as the lead loss during sintering, and invariably results in substantial alterations of the PZT properties. As a result, the elastic properties can vary as much as 5%, the piezoelectric properties 10%, and the dielectric properties 20% within the same batch (6). The piezoelectric and dielectric properties generally suffer also if there is any lack of homogeneity from poor mixing. It is important then that the constituent oxides be intimately mixed. In the method described before, however, the constituents are solid solutions and it has been shown that intimate mixing of solid solutions is difficult if not impossible. More information on the preparation of piezoelectric ceramics can be found in Jaffe et al. (4), and Moulson and Herbert (7). Other processing methods, including hydrothermal processing and coprecipitation methods, are described in (8–10). Noted that there has been a great deal of development in powder processing, shaping, and sintering (11–13) that has resulted in further expanding the application of piezoelectric ceramics.

Ferroelectricity

Some piezoelectric materials are also ferroelectric. A ferroelectric material possesses spontaneous polarization whose direction can be reversed by applying a realizable electric field across some temperature range. Most ferroelectric materials have a Curie temperature T_c below which they are polar and above which they are not. The dielectric permittivity often has a peak at T_c and linearly decreases above it according to the Curie–Weiss law (4,7). The very large permittivity values that are characteristic of ferroelectric materials are greatly exploited in many applications, most widely in the multilayer-capacitor industry.

Applying a large alternating electric field reverses the polarization, and this gives rise to the ferroelectric

Figure 3. P - E hysteresis loop of a poled piezoelectric ceramic.

hysteretic loop that relates polarization P to applied electric field E . A typical field-polarization loop is illustrated in Fig. 3. For large signals, both the electric displacement D and the polarization P are nonlinear functions of the field E . They are related to each other through the linear equation

$$D_i = P_i + \varepsilon_0 E_i, \quad (1)$$

where ε_0 is the permittivity of free space ($= 8.85 \times 10^{-12}$ C/Vm). The second term in Eq. (1) is negligible for most ferroelectric ceramics, and a D - E loop and P - E loop become interchangeable. Two key characteristics of the P - E loop are the coercive field E_c and the remanent polarization P_r , both defined by analogy to ferromagnetic materials. E_c is the field at which polarization is zero. P_r is the value of the polarization when the electric field is zero. Once the field is switched off, the material's polarization is equal to P_r . Once the P - E loop is saturated, both P_r and E_c can be determined. A loop is said to be saturated once the values of P_r and E_c no longer vary.

Generally, the existence of the P - E loop is considered evidence toward establishing that a material is ferroelectric. A Sawyer–Tower circuit (14), or a modified version of it, is commonly used to obtain a P - E loop. An ac voltage is applied to the electroded sample; the resulting charge stored on the sample is determined by a large reference capacitor placed in series with the sample. An electrometer can be used to detect the voltage across the capacitor; by multiplying this voltage by the value of the reference capacitor, the charge across the sample results. The capacitance of the reference capacitor should be 100 to 1000 times the value of the capacitance of the sample. Note that ferroelectric hysteretic loops are both frequency- and temperature-dependent.

In addition to the P - E loop, polarization switching leads to strain–electric field hysteresis. A typical strain–field

Figure 4. Butterfly loop indicating switching.

response curve is shown in Fig. 4. The shape resembles that of a butterfly, and it is often referred to as the “butterfly loop.” As the electric field is applied, the converse piezoelectric effect dictates that a strain results. As the field is increased, the strain is no longer linear with the field, as domain walls start switching.

For more sources on ferroelectricity, the reader should consult the bibliography (15–19).

PIEZOELECTRIC CONSTITUTIVE RELATIONSHIPS

An understanding of piezoelectricity begins with the structure of the material. To explain it better, let us consider a single crystallite (a small single crystal less than $100\ \mu\text{m}$ in average diameter) from a polycrystalline ceramic. This crystal is made up of negatively and positively charged atoms that occupy specific positions in a repeating unit or cell. The specific symmetry of the unit cell determines the possibility of piezoelectricity in the crystal. All crystals can be divided into 32 classes or point groups (from seven basic crystal systems: triclinic, monoclinic, orthorhombic, tetragonal, rhombohedral, hexagonal, and cubic). Of the 32 classes, 21 do not possess a center of symmetry, and 20 are piezoelectric (although one class lacks a center of symmetry, it is not piezoelectric because of the combination of other symmetry elements). The lack of a center of symmetry means that a net movement of positive and negative ions with respect to each other as a result of stress produces an electric dipole. Because the ceramic is composed of randomly oriented piezoelectric crystallites, it is inactive, that is, the effects of the individual crystals cancel each other and no discernable piezoelectricity is present. Regions of equally oriented polarization vectors are known as domains. “Poling” is a commonly used method to orient the domains by polarizing the ceramic through the application of a static electric field. Electrodes are applied to

Figure 5. Poling of a piezoelectric, ferroelectric ceramic.

the ceramic, and a sufficiently high electric field is applied such that the domains rotate and switch in the direction of the electric field. Full orientation of all domains never results; however, the polycrystalline ceramic exhibits a large piezoelectric effect. During this process, there is a small expansion of the material along the poling axis and a contraction in both directions perpendicular to it (see Fig. 5). Due to large number of allowable polar directions such as near the morphotropic phase boundary (where the Zr to Ti ratio is 48 to 52), the maximum deviation of the polar axis of a grain from the average polar direction is smaller, and the reduction of polarization is minimized, assuming optimum alignment.

Constitutive Relationships

When writing the constitutive equations for a piezoelectric material, account must be taken of changes of strain and electrical displacement in three orthogonal directions caused by cross-coupling effects due to applied electrical and mechanical stresses. Tensor notation is first adopted, and the reference axes are shown in Fig. 6. The state of strain is described by a second-rank tensor S_{ij} , and the state of stress is also described by a second-rank tensor T_{kl} . The relationships relating the stress tensor to the strain tensor, compliance s_{ijkl} , and stiffness c_{ijkl} , are then fourth-rank tensors. The relationship between the electric field E_j (first-rank tensor) and the electric displacement D_i (also a first-rank tensor) is the permittivity ϵ_{ij} , which is a second-rank tensor. Therefore the piezoelectric

Figure 6. Reference axes.

equations are

$$D_i = \varepsilon_{ij}^T E_j + d_{ijk} T_{jk}, \quad (2)$$

$$S_{ij} = \underline{d}_{ijk} E_k + s_{ijkl}^E T_{kl}, \quad (3)$$

where d_{ijk} , \underline{d}_{ijk} are the piezoelectric constants (third-rank tensor). Superscripts T and E indicate that the dielectric constant ε_{ij} and the elastic constant s_{ijkl} are measured under conditions of constant stress and constant electric field, respectively. In general, a first-rank tensor has three components, a second-rank tensor has nine components, a third-rank tensor has 27 components, and a fourth-rank tensor has 81 components. Not all of the tensor components are independent.

Both of these relationships depend on orientation; they describe a set of equations that relate these properties in different orientations of the material. The crystal symmetry and the choice of reference axes reduce the number of independent components. A convenient way of describing them is by using axis directions, as given by Fig. 6. The convention is to define the poling direction as the 3 axis, the shear planes are indicated by the subscripts 4, 5, and 6 and are perpendicular to directions 1, 2, and 3, respectively. This simplifies the notations introduced before, where a 3-subscript tensor notation ($i, j, k = 1, 2, 3$) is replaced by a 2-subscript matrix notation ($i = 1, 2, 3$ and $j = 1, 2, 3, 4, 5, 6$), and a 2-subscript tensor notation ($i, j = 1, 2, 3$) is replaced by a 1-subscript matrix notation ($i = 1, 2, 3, 4, 5, 6$). A shear strain such as S_4 is a measure of the change of angle between the two initially orthogonal axes in the plane perpendicular to axis 1. The first subscript of the d constant gives the "electrical" direction (field or dielectric displacement), and the second gives the component of mechanical deformation or stress. The planar isotropy of poled ceramics is expressed in their piezoelectric constants by the equalities $d_{32} = d_{31}$ (an electric field parallel to the poling axis 3 interacts in the same way with axial stress along either the 2 axis or the 1 axis) and $d_{24} = d_{15}$ (an electric field parallel to the 2 axis interacts in the same way with a shear in the 2,3 plane as a field along the 1 axis with a shear in the 1,3 plane). Similar relationships hold for the elastic constants because of isotropy in the plane perpendicular to the polar axis.

Property Matrix for a Poled Piezoelectric Ceramic

A piezoelectric ceramic has only one type of piezoelectric matrix, regardless of the symmetry of the constituent crystals. The ceramic is initially isotropic. This isotropy is destroyed in the poling direction. The material is transversely isotropic in the directions perpendicular to the poling direction. The symmetry elements are an axis of rotation of infinite order in the direction of poling and an infinite set of planes parallel to the polar axis as reflection planes. In crystallographic notation, this symmetry is described as ∞mm and is equivalent to the hexagonal polar crystal class, 6 mm.

The elastic, dielectric, and piezoelectric matrices for the cylindrical symmetry of poled PZT are shown in the following equations. Matrices analogous to the piezoelectric also apply to other piezoelectric constants such as g_j (described

in the next section).

$$\begin{array}{cccccc} s_{11} & s_{12} & s_{13} & 0 & 0 & 0 \\ s_{12} & s_{11} & s_{13} & 0 & 0 & 0 \\ s_{13} & s_{13} & s_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & s_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & s_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & 2(s_{11} - s_{12}) \end{array} \quad (4)$$

$$\begin{array}{ccc} \varepsilon_1 & 0 & 0 \\ 0 & \varepsilon_1 & 0 \\ 0 & 0 & \varepsilon_3 \end{array} \quad (5)$$

$$\begin{array}{cccccc} 0 & 0 & 0 & 0 & d_{15} & 0 \\ 0 & 0 & 0 & d_{15} & 0 & 0 \\ d_{31} & d_{31} & d_{33} & 0 & 0 & 0 \end{array} \quad (6)$$

For the symmetry of poled ceramics then, general Equations (1) and (2) are replaced by the these specific equations:

$$D_1 = \varepsilon_1 E_1 + d_{15} T_5, \quad (7)$$

$$D_2 = \varepsilon_2 E_2 + d_{15} T_4, \quad (8)$$

$$D_3 = \varepsilon_3 E_3 + d_{31}(T_1 + T_2) + d_{33} T_3, \quad (9)$$

$$S_1 = s_{11}^E T_1 + s_{12}^E T_2 + s_{13}^E T_3 + d_{31} E_3, \quad (10)$$

$$S_2 = s_{11}^E T_2 + s_{12}^E T_1 + s_{13}^E T_3 + d_{31} E_3, \quad (11)$$

$$S_3 = s_{13}^E (T_1 + T_2) + s_{33}^E T_3 + d_{33} E_3, \quad (12)$$

$$S_4 = s_{44}^E T_4 + d_{15} E_2, \quad (13)$$

$$S_5 = s_{44}^E T_5 + d_{15} E_1, \quad (14)$$

$$S_6 = s_{66}^E T_6. \quad (15)$$

Equations (7)–(9) relate to the direct effect, and Eqs. (10)–(15) relate to the converse effect.

PIEZOELECTRIC PARAMETERS: DEFINITIONS AND CHARACTERIZATION

The parameters that are of interest when considering the electromechanical effects of piezoelectric materials are the piezoelectric charge coefficients (d_{31} and d_{33}), the piezoelectric voltage coefficients (g_{31} and g_{33}), and the piezoelectric coupling factors (k_{31} , k_{33} , k_p , and k_t). The d coefficient is the proportionality constant between electric displacement and stress, or strain and electric field [Eqs. (2) and (3)]. High d coefficients are desirable in materials used as actuators, such as in motional and vibrational applications. The g coefficient is related to the d coefficient by the following expression:

$$d_{mi} = \varepsilon_{nm}^T g_{ni}. \quad (16)$$

where $m, n = 1, 2, 3$ and $i = 1, 2, \dots, 6$. High g coefficients are desirable in materials to be used as sensors to produce voltage in response to mechanical stress.

The piezoelectric coupling factor k is a measurement of the overall strength of the electromechanical effect. It is often defined as the square root of the ratio of electrical

energy output to the total mechanical energy input (in the direct effect) or the mechanical energy available to the total electrical energy (in the converse effect). The value of k is, of course, always less than unity because energy conversion is always incomplete.

Other important properties of PZT are the dielectric properties, namely, the dielectric constant ϵ (F/m) and the dissipation factor or loss tangent $\tan \delta$. The dielectric constant is a measure of the charge stored on an electroded material brought to a given voltage. The dielectric constant of vacuum is $\epsilon_0 = 8.85 \times 10^{-12}$ F/m. The relative dielectric constant K (often referred to as just “the dielectric constant”) is the ratio of ϵ and ϵ_0 and is dimensionless. In an ac field, the dielectric constant has both a real part and an imaginary part; the loss tangent is defined as the ratio of the imaginary part to the real part.

The values of these constants depend on the PZT composition. As an example, the d constants, g constants, and the dielectric constant for compositions near the morphotropic phase boundary show their highest values on the tetragonal side of the transition (4). Then, it is possible to tune the values of these properties for most compositions; one way to achieve this is by adding dopants to the PZT formulation.

Resonant Method and Equivalent Circuit

Resonance Method. Any body has certain characteristic frequencies at which it prefers to resonate. When excited at this resonant frequency f_r , the body will resonate freely at a greater amplitude than at other frequencies. Following this resonant frequency is an antiresonant frequency f_a , where the impedance of the body is at a maximum and the oscillatory amplitude is at a minimum. Piezoelectric ceramics are no different, and measuring these characteristic frequencies provides the means to evaluate the piezoelectric and elastic properties of the ceramic. Different modes of vibration of the ceramic, such as thickness or planar, give insight to the different constants for that mode. A typical resonance plot of impedance versus frequency for a piezoelectric ceramic near a resonance is shown in Fig. 7. Notice the resonant frequency f_r at the point of minimum impedance and the antiresonant frequency f_a at the point of maximum impedance.

At resonance, a piezoelectric element may be modeled by the equivalent circuit shown in Fig. 8. This circuit, commonly referred to as Van Dyke’s model, is recommended by the IEEE Standard on Piezoelectricity (20). An alternate model, proposed by Sherrit et al. (21), eliminates the resistance R_1 and instead represents the remaining components as complex to characterize better the losses of certain piezoelectric elements, especially polymers. All discussion following assumes Van Dyke’s model. Below f_r and above f_a , the ceramic behaves capacitively; however, between these two frequencies, the ceramic behaves inductively. This model is valid only near the resonance. Additionally, the resonance must be sufficiently isolated from other modes to eliminate the effects of any adjacent modes. To ensure that the resonance is isolated, sample geometry must be chosen carefully. Geometries suitable for measuring the different piezoelectric and elastic coefficients are presented in Table 1. Fixturing of the sample

Figure 7. Impedance of a piezoelectric ceramic at resonance.

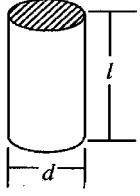

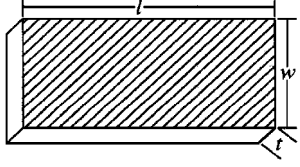

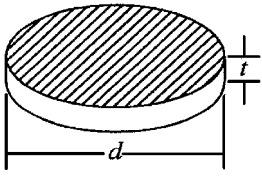

should not impose any constraints on the vibration of the ceramic. This can be accomplished by using a point holder positioned at a node of vibration. All leads should also be shielded up to the contact point, as much as possible, to avoid any stray capacitances that may arise.

Earlier literature has suggested several circuits for measuring f_r and f_a of a piezoelectric ceramic (22–25). These circuits usually consist of an oscillator for exciting the sample, a voltmeter or other device for measuring current through the circuit, and additional discrete components. To find f_r , the frequency of the oscillator is varied until the maximum current is detected through the circuit. Similarly, for f_a , the frequency of minimum current is determined. Note that there are actually six characteristic frequencies that may be identified for a particular resonance; they include f_m and f_n , the frequencies of maximum and minimum impedance; f_r and f_a , the resonant and antiresonant frequencies; and f_p and f_s , the parallel resonant frequency and series resonant frequency. IEEE Standard 177 (23) identifies these six frequencies and establishes that for many cases, including piezoelectric ceramics, one can assume that $f_m = f_s = f_r$ and $f_a = f_p = f_n$. For lossy materials, such as some piezoelectric thin films, this assumption can introduce appreciable errors, so the six frequencies should be considered separately. The magnitude of the minimum impedance Z_m may be determined by substituting an adjustable resistor into the circuit for the ceramic at the previously identified frequency and adjusting the resistance until the voltmeter reading is the same as for the ceramic. Today, fully integrated

impedance analyzers are commercially available to make this type of measurement, allow the researcher to choose an equivalent circuit model, and report the values of the discrete components of the equivalent circuit along with f_r and f_a . Commercial off-the-shelf software is also available now which can be used in conjunction with an analyzer to evaluate the impedance information and calculate the relative material properties of a piezoelectric device (26). These tools can aid the researcher in evaluating material properties, however, a basic understanding of piezoelectric behavior is an important foundation that should not be overlooked.

Measuring Material Properties. Capacitance measurements are usually carried out at 1 kHz and at low excitatory voltages (mV level). Although research has shown that capacitance and loss vary with excitation voltage and frequency (27,28), the 1-kHz, low-voltage measurement is used to determine material properties. The free relative dielectric constant K^T is defined as the ratio of the permittivity of the material to the permittivity of free space. It is calculated from

$$K^T = \frac{tC}{\epsilon_0 A}, \quad (17)$$

where t is the distance between electrodes in meters, C is the capacitance in farads, ϵ_0 is the permittivity of free space (8.85×10^{-12} F/m), and A is the area of an electrode in meters². The loss tangent, $\tan \delta$, is defined as the ratio of resistance to reactance in the parallel equivalent circuit of Fig. 9b. It is a measure of the dielectric losses in the material and therefore, also a measure of the heat generating capacity of the ceramic when operated under dynamic conditions. This is a direct measurement and is usually formed at the same conditions as the capacitance measurement.

The three most common coupling coefficients are k_p , k_{31} , and k_{33} ; where the p is for planar, and the 31 and 33 subscripts are for length extensional and thickness extensional modes. The coefficients k_{33} and k_{31} are calculated from the frequencies of minimum and maximum impedance and are given by the equations

$$k_{33}^2 = \frac{\frac{\pi}{2}}{1 + \frac{(f_a - f_r)}{f_r}} \tan \left[\frac{\frac{\pi(f_a - f_r)}{2f_r}}{1 + \frac{(f_a - f_r)}{f_r}} \right], \quad (18)$$

$$k_{31}^2 = \frac{\psi}{1 + \psi}, \quad (19)$$

Figure 9. Nonresonant (a) series and (b) parallel equivalent circuit.

where

$$\psi = \frac{\pi}{2} \left[1 + \frac{f_a - f_r}{f_r} \right] \tan \left[\frac{\pi(f_a - f_r)}{2f_r} \right]. \quad (20)$$

The planar coupling coefficient k_p is defined for thin disks and can be approximated by

$$k_p \approx \frac{f_a^2 - f_r^2}{f_r^2}. \quad (21)$$

Elastic compliance is the ratio of a material's change in dimensions (strain) relative to an externally applied load (stress). This is the inverse of Young's modulus. For a piezoelectric material, the compliance depends on whether the strain is parallel or perpendicular to the poling axis and the electrical boundary conditions. Elastic constants are calculated from the following equations:

$$s_{33}^D = \frac{1}{4\rho f_a^2 l^2}, \quad (22)$$

$$s_{33}^E = \frac{s_{33}^D}{1 - k_{33}^2}, \quad (23)$$

$$s_{11}^E = \frac{1}{4\rho f_r^2 w^2}, \quad (24)$$

$$s_{11}^D = s_{11}^E (1 - k_{31}^2), \quad (25)$$

where ρ is the density of the material in kg/m^3 , l is the distance between electrodes, and w is the width of the ceramic. The superscripts D and E stand for constant electric displacement (open circuit) and constant electric field (short circuit), respectively.

The d_{ij} piezoelectric constants, which relate the applied electric field to the strain, can be calculated from the coupling, the elastic coefficients, and the dielectric constant:

$$d_{33} = k_{33} \sqrt{\varepsilon_0 K_3^T s_{33}^E}, \quad (26)$$

$$d_{31} = k_{31} \sqrt{\varepsilon_0 K_3^T s_{11}^E}. \quad (27)$$

The g_{ij} piezoelectric constants are related to the d_{ij} coefficients by the following equations:

$$g_{33} = \frac{d_{33}}{\varepsilon_0 K_3^T}, \quad (28)$$

$$g_{31} = \frac{d_{31}}{\varepsilon_0 K_3^T}. \quad (29)$$

Noted that the piezoelectric coefficients calculated are valid only at frequencies well below resonance and do not account for any nonlinear behavior of the ceramic. They do not depend on the dimensions of the material; however, they vary with the degree of polarization of the ceramic. They also do not provide the sign of the coefficient, which must be determined by direct measurements. The mechanical Q_M , the ratio of reactance to resistance in the series equivalent circuit of Fig. 9a is given by

$$Q_M = \frac{1}{2\pi f_r Z_m C_0} \left(\frac{f_a^2}{f_a^2 - f_r^2} \right). \quad (30)$$

Direct Methods

Direct measurements of the piezoelectric constants are possible and have been used to quantify the direct and converse effects in ceramic samples. Direct methods are also used to investigate the behavior of a ceramic in regard to hysteresis, nonlinearity, frequency response, aging, thermal behavior, and other characteristics that are not resolved by previous methods. These methods typically apply a known input to the ceramic, either an electric field or a force, and record the corresponding output, either a deformation or a charge under various conditions. These methods are in contrast to the bulk material characterization using the electrical resonance techniques described before. Many times, direct measurements are carried out on a ceramic that has been configured as a sensor or actuator. Typical processing may include electroding, laminating, applying preload, mounting, and other assembly procedures to adapt the material effectively for use as a sensor or actuator. These measurements aid the researcher in modeling the behavior of the piezoelectric device and allow efficient integration of the devices into real-world applications.

Displacements of piezoelectric actuators are measured to determine the magnitude and sign of the relationship between the applied electric field and the strain developed, that is, the converse effect. For a PZT wafer, this corresponds to the d_{ij} coefficient; however, for bending type actuators, this relationship does not correlate directly with any of the measured properties for out-of-plane bending using the resonance techniques. Based on Eqs. (10)–(15), it can be seen that when the ceramic is free to expand ($T_i = 0$), then the strain is a function only of the product of the applied field E_i and the d_{ij} coefficient

$$S_j = d_{ij} E_i. \quad (31)$$

Careful attention must be paid to the boundary conditions of the ceramic to ensure that this assumption is valid. In a plot of the strain as a function of applied field, the

slope yields an average value of d_{ij} . Typically, these measurements are made by using a noncontacting displacement transducer (29) to reduce the effects of loading on the actuator. Laser-based and other optical or capacitive displacement measurement techniques are most commonly used (30–32). Displacements may range from submicron levels for single PZT wafers to the centimeter level for bending type actuators. For very small displacements, an optical-lever type measurement system or interferometric techniques (33) have been used to resolve the displacement of the ceramic. Direct application of either foil or optical strain gages has also been used for measuring the actuator strain. These measurements may be either static or dynamic, depending on the measurement system and the intended application of the ceramic. If dynamic measurements are made, excitatory frequencies should be at least an order of magnitude less than any resonant frequency of the device to ensure linear behavior and boundary conditions suitable for the intended measurement.

Another direct method used to measure piezoelectric constants is based on the direct piezoelectric effect (22,34). Here, a known load is either applied to or lifted off a ceramic at rest. The resulting charge, which accumulates on the electrodes, is then measured as a voltage across a capacitor in parallel with the ceramic, or the current from the ceramic can be integrated directly. If E_i is 0 (short circuit), then Eq. (2) reduces to

$$D_i = d_{ij} T_j. \quad (32)$$

Knowing the applied stress and measuring the electric displacement, the appropriate d_{ij} coefficient can be found.

If a piezoelectric ceramic is immersed in a liquid and the pressure of the liquid is varied, then the piezoelectric coefficient d_h can be quantified by measuring the voltage on a large capacitor in parallel with the ceramic. This coefficient represents the response of the ceramic to hydrostatic pressure applied equally to all axes. Convention has dictated that electrodes are perpendicular to the 3 direction for the d_h coefficient. The d_h coefficient is related to the other d

coefficients for a ceramic by the equation,

$$d_h = d_{33} + 2d_{31}. \quad (33)$$

The frequency response of the device may be obtained by varying the frequency of the excitatory voltage to the ceramic while measuring the displacement. Typical resonant frequencies of bulk ceramic material are in the kilohertz to megahertz range depending on the mode of vibration, whereas resonant frequencies of bender types (unimorph or bimorph) may be less than 100 Hz. For maximum strain, a piezoelectric actuator can be excited at its natural frequency; however, this nonlinear behavior must be taken into account if the actuator is to be used across a range of frequencies. Careful attention must also be paid to the instrumentation system's dynamic response in both amplitude and phase distortions, when making dynamic measurements. Measurement systems have their own frequency response characteristics which must be separated from the response of the ceramic under test.

Hysteresis is a phenomenon that is present in all piezoelectric materials. Hysteretic behavior is due to the lossy nature of the ceramic where the current trails the applied voltage by an angle α related to the loss tangent of the material. For actuators, this means that the absolute displacement depends on the excitatory voltage and frequency and also on whether the voltage is increasing or decreasing. To characterize the amount of hysteresis in a ceramic, a sinusoidal voltage is applied to the device, and the displacement is recorded. By plotting the displacement versus driving voltage, as shown in Fig. 10, the hysteretic behavior of the ceramic can be observed. The amount of hysteresis (usually expressed in percent) is defined as the largest difference between the maximum and minimum displacement for any voltage divided by the total displacement. Of note in Fig. 10 is the fact that, as the peak voltage is increased, the amount of hysteresis also increases for any given voltage.

Generally, piezoelectric ceramic actuators exhibit a decrease in their displacement for a given excitatory

Figure 10. Strain hysteresis of a piezoelectric ceramic unimorph.

Figure 11. Typical stress/strain relationship for a piezoelectric ceramic.

voltage, as they are loaded. This relationship can be seen in Eq. (3), when $T_k \neq 0$. As the load is increased, the displacement eventually reaches zero, and the actuator provides only a force output. This force is known as the blocked force, and it is the maximum amount of force that the actuator can produce at that voltage. To characterize this relationship, the actuator is loaded with a load less than the blocked force, and the displacement is measured. If the load is varied, then the force/displacement relationship can be determined (Fig. 11). To determine the blocked force, the actuator must be rigidly held so as not to deform, and the force output is measured by using a load cell or other force-measuring device. Because the displacement of some piezoelectric actuators is quite small, this measurement can be difficult. The blocked force F_B can, alternatively be calculated by the equations

$$F_B = \frac{E_3 d_{33} w l}{s_{33}^E}, \quad (34)$$

$$F_B = \frac{E_3 d_{31} w t}{s_{11}^E}, \quad (35)$$

where E is the applied field; and l , w , and t are the length, width, and thickness of the ceramic, respectively. Equation (34) applies to the thickness extensional mode and Eq. (35) applies to the length extensional mode.

Actuators that have greater displacements lend themselves better to blocked force measurement (such as domed prestressed actuators or unimorph/bimorph type actuators). The blocked force may also be determined by extrapolating the force–displacement relationship to zero displacement if a true blocked force measurement is not practical. In most applications, actuators operate somewhere between the free (unloaded) state and the completely constrained state.

It has been previously reported that a constant preload applied to a piezoelectric actuator can actually increase the displacement of the ceramic, compared to an unloaded specimen (34–36). This may result from simply reducing

the compliance or mechanical play in a PZT assembly or may be a real increase in the d coefficient. This effect reaches a maximum and then starts to cause a decrease in the coefficient as the preload is increased up to the blocked force.

Temperature effects on the piezoelectric coefficients of ceramics may also be evaluated. Usually, ceramics must be used well below their Curie temperatures to maintain polarization. The respective Curie temperatures for hard and soft PZTs are of the order of 360°C (680°F) and 330°C (626°F). For operation at lower temperatures, even down to cryogenic levels, the piezoelectric coefficients generally decrease as temperature decreases. This effect can be experimentally quantified through either resonance techniques or direct measurements across the desired temperature range (34).

The power required to drive a piezoelectric ceramic can be calculated from the following equation:

$$P = 2\pi f C \tan \delta V_{\text{rms}}^2, \quad (36)$$

when the ceramic is modeled as in Fig. 9a where f is the driving frequency, C the capacitance, $\tan \delta$ the loss tangent, and V_{rms} the root-mean-square of the excitatory voltage. Typically, it is assumed that both the capacitance and loss tangent of the ceramic are constant when using Eq. (36). Doing so can lead to large errors when estimating the power consumption of a ceramic. To avoid these errors, either the voltage and current supplied to the ceramic should be measured to provide the power consumption directly, or the variation of capacitance and loss of the material as functions of applied field and frequency must be quantified and incorporated into Eq. (36) (28). A number of researchers have investigated the power consumption characteristics of PZT actuators used to excite a host structure (27,37,38) and found a coupling between the mechanical motion of the structure and the electrical characteristics of the piezoelectric actuator. Research by Brennan and McGowan (27) shows that the power consumption of piezoelectric materials used for active vibrational control is independent of the coupling effects of the host structure when the structure is *completely controlled*. From these findings, they conclude that the power requirements of the piezoelectric actuator depend only on its geometry and material properties and the driving voltage and frequency of the control signal. Research (23) has indicated that both capacitance and resistance are nonlinear functions of the peak amplitude and frequency of the excitatory voltage.

In time, piezoelectric effects imparted through poling degrade. Aging of piezoelectric ceramics, like many other materials, is logarithmic with time. In most ceramics, a initial performance levels can be recovered by simply re-poling the sample. Aging levels depend on the composition; the coupling coefficient of a soft PZT composition ages at a rate of -1% per time decade versus -2% for a hard composition. Degradation of piezoelectric behavior also depends on the level of stress to which the ceramic is subjected. High stress levels can lead to switching of the polarization and eventually depoling of the ceramic. High stresses also induce microcracking, which can lead to ceramic breakage and failure.

The methods outlined before can be used either separately or together to investigate the dielectric, piezoelectric, and elastic properties of a ceramic. Resonant techniques, which are the preferred method of measurement in the IEEE standard, are easy to implement, and the associated frequencies can be measured accurately. There is even commercially available hardware and software to assist in these measurements and the evaluation of material properties. However, these methods do not explain any nonlinear behavior that is present in the ceramic. Dependence of material properties on the frequency and amplitude of the applied voltage are among these nonlinear effects. Direct measurements of the piezoelectric constants can quantify the material properties under different operating conditions and provide insight beyond the standard linear behavior predicted by resonance techniques. These methods though, are usually more rigorous in their requirements for material handling and instrumentation.

Modeling of Piezoelectric Ceramics

There are a host of applications for piezoelectric materials, and although they have been studied for more than a century, potential for improvement and innovation still persists. Modeling of piezoelectric ceramics and their properties affords a way to accelerate materials improvement and aid in device design and development. For that reason, we would be remiss not to mention it, albeit briefly. This introduction is in no way meant as a comprehensive review of the vast area of modeling of piezoelectricity; however the references cited provide a good starting place. Care must be taken to differentiate between modeling the piezoelectric material and modeling a "piezoelectric structure;" often, a piezoelectric material is laminated or bonded to a substrate as a unimorph or bimorph.

A number of researchers experimented with commercial packages such as ANSYS[®](39). However, these commercial packages have limitations. Other groups have written their own codes and achieved varying degrees of success (40–43). Finite element schemes that combined piezoelectric and acoustic elements proved useful in characterizing the electromechanical behavior of piezoelectric transducers (44). Most of these schemes are restricted because they assume linearity of the coefficients. Pérez et al. expanded on these models by including nonlinear elements in the equivalent circuit (45). Models of the nonlinear hysteretic behavior of piezoelectric materials are abundant in the literature and can be categorized on the basis of the dimensional scale they probe. Microscopic models stem primarily from energy relationships applied at the atomic or molecular level (46). Macroscopic models (47–49) often use empirical relationships to describe the behavior of the bulk material. Both methods have their advantages and disadvantages; microscopic models require a great number of parameters, often not available, and macroscopic models do not consider the underlying physics. A number of authors proposed a third approach, a mesoscale or semimicroscopic model that combines the advantages of the previous methods, thus allowing a better way to model hysteretic behavior. This is accomplished by starting out from energy principles applied at the microscopic level, then

using a relatively small number of parameters to simulate the behavior of bulk ceramics (50,51).

CONCLUSION

Characterization of the elastic, dielectric and electromechanical properties of piezoelectric ceramics is crucial for several reasons. First, investigations of the material properties provide a link between the manufacturing process and ceramic performance. This enables the developer of the materials to adjust the manufacturing process of the ceramic to produce tailored materials. Second, the engineer can investigate prospective materials for applicability to a specific need. Material parameters obtained through characterization can also be used to develop and validate analytical models of the ceramics. Insights gained through characterization have led to many new devices and uses. For example, investigation of the hydrostatic coefficients of PZT and those of the piezoelectric polymer polyvinylidene fluoride (PVDF) identified the product of d_h and g_h as a figure of merit and led to composite research to combine both materials in a superior device that fits underwater and hydrophone applications better. More than a century after their discovery, piezoelectric ceramics have become commercially viable. Researchers continue diligently to uncover novel ways to characterize the complex electromechanical properties, and as they do so, new processing methods and applications are revealed. Recently, as an example, researchers at MIT successfully grew piezoelectric single crystals (52) that opened opportunities for newer applications. Published articles on composite processing and characterization have also become more abundant. Without question, piezoelectric ceramics have secured a permanent place in the field of material science and engineering.

ACKNOWLEDGMENT

The authors express their sincere appreciation to Dr. Jeffrey A. Hinkley (NASA Langley Research Center) for his review of the manuscript and his helpful comments.

CHEMICAL INDICATING DEVICES

CHRISTOPHER O. ORIAKHI
Hewlett-Packard Company
Corvallis, OR

INTRODUCTION

Most people remember a chemical indicator from their high school chemistry. This kind of indicator is a material that changes color to signify the end point of a titration or to provide a relative indication of the acidity or alkalinity of a chemical substance. The use of indicators extends far beyond this. For example, food, cosmetic, pharmaceutical, and other chemical formulations undergo complex chemical, enzymatic, and microbial interactions when they are exposed to UV light or temperature fluctuations over time. Consequently, product quality may be degraded and may lead to additional safety concerns. The challenges facing the produce industry include successful implementation of Good Manufacturing Practices (GMP), Hazard Analysis and Critical Control Point (HACCP), Total Quality Management (TQM) programs, and other regulations that demand compliance (1).

To address these issues and increase consumer confidence in product quality, safety, and authenticity, many manufacturers incorporate inexpensive monitoring devices into their products during production, packaging, or storage. A large number of consumer-readable indicators are available commercially. Some examples of these types of indicators are tags, labels, seals, and thermometers. Some give a visual color change in response to degradation of product quality, tampering, or to detect a counterfeit. They are used extensively in the chemical, food, and pharmaceutical industries where consumers need assurance of product integrity, quality, and safety during postmanufacture handling.

Generally, chemical indicators may be defined as stimulus responsive materials that can provide useful information about changes in their environment. Organic dyes, hydrogels or “smart polymers,” shape-memory alloys, thermochromic or photochromic inks, and liquid crystals are some examples. They may function by forming structurally altered ionic or molecular complexes with species in their environment through chemical or physical interactions involving proton exchange, chelation, hydrogen bonding, dipole–dipole interactions, or van der Waal forces (1). The resulting characteristic biochemical, chemical, optical, magnetic, thermal, or mechanical changes can be tailored to provide the desired indication response.

This article focuses on inexpensive disposable chemical indicating devices such as pH indicators, temperature indicators, time–temperature indicators (TTI), and tampering and counterfeit indicators. The temperature and TTIs are widely used in the food and pharmaceutical products where date coding on a package may sometimes be inadequate.

CHEMICAL INDICATING DEVICES ARE SMART

Smart materials or devices are defined as materials that produce strong visually perceptible changes in a physical or chemical property in response to small physical or chemical stimuli in the medium. The material properties measured may include pH, concentration, composition, solubility, humidity, pressure, temperature, light intensity, electric and magnetic field, shape, air velocity, heat capacity, thermal conductivity, melting point, or reaction rates (2–6). Chemical indicating devices can respond reversibly or irreversibly to small changes in the physical or chemical properties in their environment in a predictable manner. *They may be regarded as smart materials because of the range of materials properties they encompass.* Typical materials include shape-memory alloys, piezoelectric materials, magnetostrictive substances, electrorheological and magnetorheological fluids, hydrogel polymers, and photo- and thermoresponsive dyes (2–6).

CLASSIFICATION

Indicators can be classified on the basis of the response mechanism, operating principles, or application. Thus there are chemical, biological, biochemical, electrical, magnetic, and mechanical indicators according to the response mechanism. Based on the intended application, indicators can be classified as temperature indicators,

time–temperature indicators, pH indicators, counterfeit indicators, tamper indicators, freeze and thaw indicators, or freshness indicators.

GENERAL OPERATING PRINCIPLES

The response mechanism of most indicators includes one or more of the following: physical, chemical, physicochemical, electrochemical, and biochemical. Physical mechanisms are based on photophysical processes, phase transition, or other critical material properties such as melting, glass transition, crystallization, boiling, swelling, or changes in specific volume. In most cases these transitions are driven by changes in the interactive forces (e.g., hydrophilic–hydrophobic forces) within or around the indicator material. The indicator response mechanism can also be based on chemical, biochemical, and electrochemical reactions. Examples include acid–base, oxidation–reduction, photochemical, polymerization, enzymatic, and microbial reactions. Many of these changes are irreversible, and the onset or termination can be observed visually as a color change, color movement, or mechanical distortion (1–6).

CHOICE OF INDICATORS

Some factors governing the selection of a given indicator device include

- **Cost:** It must be relatively inexpensive. The indicator should not be more expensive than the product it is protecting.
- **Application:** Easy to attach to a variety of containers or packages. Once installed, the device must remain intact and readable during the service life of the package.
- **Response:** The response mechanism must have fast kinetics of the order of seconds to a few hours and must be reproducible. There should be no time delay in response to reactions involving a solid, liquid, or gas. Most applications require the response in the indicator to be irreversible to preserve the needed indication record.
- **Sensitivity:** The indicator must be highly sensitive, accurate, and easily activated. A user-friendly indicator that provides useful information when needed will make both the product manufacturer and the consumer happy.
- **Shelf life:** The indicator must have a shelf life equal to or longer than that of the product it is monitoring.
- **It should be technically difficult to duplicate or counterfeit the indicator’s response.** In this case, the indicator is acting as a “smart” locking mechanism.

pH INDICATORS

The pH indicator is probably the oldest and simplest smart chemical indicating device known. The chemistry of acid–base indicators is well documented (7) and involves proton

Table 1. Selected Indicators for pH Measurement

Common Name	Formula	pK _a ^a	pH Range	Color in Acid	Color in Alkali	λ _{max} [*] (nm)
Bromothymol blue	C ₂₇ H ₂₈ O ₅ Br ₂ S	7.3	6.0–7.6	Yellow	Blue	617
Bromocresol green	C ₂₁ H ₁₄ O ₅ Br ₄ S	4.9	3.8–5.4	Yellow	Blue	618
Bromocresol purple	C ₂₁ H ₁₆ O ₅ Br ₂ S	6.3	5.2–6.8	Yellow	Purple	588
<i>o</i> -C resol red	C ₂₁ H ₁₅ O ₅ S	8.2	0.2–1.8	Red	Yellow	572
Chlorophenol red	C ₁₉ H ₁₂ O ₅ Cl ₂ S	6.25	4.8–6.4	Yellow	Red	572
Methyl red	C ₁₅ H ₁₅ N ₃ O ₂	5.0	4.4–6.3	Red	Yellow	526
Phenol red	C ₁₉ H ₁₄ O ₅ S	8.0	6.4–8.2	Yellow	Red	559
Phenolphthalein	C ₂₀ H ₁₄ O ₄	9.5	8.0–9.8	Colorless	Red–Violet	552

^aMeasurements made in solution at zero ionic strength and for a temperature ranging from 15–30°C.

or electron exchange reactions. It will be mentioned only briefly here. By Brønsted and Ostwald's definition, indicators are weak acids or bases. Upon dissociation, they exhibit a structural and color change that is different from the undissociated form. Indicators commonly used in acid–base and redox titrations are conjugated organic dyes that contain one or more light-absorbing groups called chromophores. The electronic structures of these dyes can be changed by redox or proton exchange reactions. This also changes the absorption energy in the visible region of the electromagnetic spectrum and consequently, the color. Therefore, the color change provides a visual indication of the end point of a titration (1,7).

INDICATOR MATERIALS

An indicator for pH measurement may exist as a solution, emulsion, colloidal gel, paper, or electrode. Methods, for preparing them are described in the literature (1,7,8). Table 1 lists examples of common indicators used in solution form or as indicator papers.

There are also non-dye pH sensitive smart polymers that exhibit critical material changes in response to changes in the concentration of hydrogen or other ions. Typically, these are polymer electrolytes derived from homo- or copolymerization of acidic or basic functionalized monomers. Examples include poly(ethylene oxide); poly(dimethylsiloxane); copolymers of *N,N*-dimethylacrylamide, *N-t*-butylacrylamide, and acrylic acid; mixtures of methacrylic acid and methyl methacrylate; mixtures of diethylaminoethyl methacrylate and butyl methacrylate; polystyrenesulfonate; polyacrylamide; and functionalized cellulose copolymers (8,9). In the presence of specific ions, these polymer gels can swell or shrink across a pH range at room temperature, resulting in a visible color change. Indicators based on them are highly selective, sensitive, and inexpensive (8).

TEMPERATURE AND TIME–TEMPERATURE INDICATORS (TTI)

Recently, interest has grown in using critical temperature indicators and time–temperature indicators in intelligent packaging technology. The production, processing,

distribution, storage, and point of use of temperature-sensitive products poses a great challenge to industries. Temperature plays a leading role in the growth of microorganisms in foods and thus in the incidence of food poisoning. As a result, many perishable food and nonfood products are prone to temperature-induced quality loss and degradation. Pharmaceutical products, medical devices, chemical reagents, industrial formulations such as inks, paints and coatings, photographic materials, and other related items are highly sensitive to temperature abuse. Therefore, it is useful to monitor the temperature history from production to the point of consumption of such products.

There has been greater need to monitor and prevent failure of machine and electronic parts due to overheating. Routine quality control and preventive maintenance of automobile and aircraft engines system against overheating may help avoid catastrophic and costly failures.

To ensure product safety, freshness, minimize losses, and retain customer confidence, dedicated temperature indicators or TTI are attached to many commercial products. They show the temperature or record the thermal history of the product and indicate if abuse has occurred, this allows the consumer to make judgments about product quality or safety. The indicator may incorporate a color changing dye, polymeric substance, enzyme, or time–temperature integrating materials that must be thermally activated to function (10).

Critical Temperature Indicators (CTI)

CTIs visually indicate that a material or product has been exposed to an undesirable temperature below or above a reference critical temperature for a time long enough to alter product quality or cause safety concerns (11). Several temperature indicators have been described in the patent literature, although only a few have been commercialized. Their principle of operation depends on temperature changes resulting from freezing, melting transition, liquid crystal formation, polymerization, enzymatic reactions, or electrochemical corrosion (12). Some formulations are derived from a dye and a chemical blend or a thermoresponsive hydrogel polymer that has a specific freezing or melting transition. Some commercial indicators are described here.

High-Temperature Indicating Crayons. These are used mainly for plant maintenance, quality assurance, engine monitoring, diagnosis, and troubleshooting. For example, a crayon would be useful where knowledge of the exact temperature of engine parts is desirable (13). Such crayons are made of materials whose known melting points are calibrated to have a response time of a few seconds and an accuracy of $\pm 1\%$. Two commercial examples include the Telatemp temperature indicating crayon (made by Telatemp Corporation, Fullerton, CA) and Tempilstik temperature indicators (made by Tempil Division, Air Liquide America, South Plainfield, NJ). They are available for temperature ratings from 125–1200°C. In an application, the indicating crayon is used to mark a desired surface of known operating temperatures such as the exhaust manifold, cylinder head, or fuel injection pump. An instantaneous color change upon marking indicates that the rated temperature has been exceeded. Alternatively, if a color change is observed after one or two seconds, the rated temperature of the indicator has been reached. When the material is operating below the rated temperature, a color change may not be observed, or it may take much longer to occur.

Irreversible Temperature Labels. Temperature labels are designed to respond permanently and irreversibly to and record overheating of surfaces. The indicator labels are made by sealing one or more temperature-sensitive materials in a highly stable self-adhesive polymeric or paper strip (14). Temperature ratings are printed on, below, and above each indicator window in degrees centigrade (°C) and Fahrenheit (°F). Several models in custom sizes/shapes and customer-selected temperature ranges are available from Telatemp Corporation. Indicator labels, are installed on a desired surface. When the calibrated rated temperature is exceeded, the indicator window of the label undergoes a noticeable color change (from silver to black in most Telatemp products). The response time is usually less than one second and has a guaranteed tolerance of $\pm 1\%$. Some uses include monitoring overheating of engine components, electronics, transformers, chemicals, foods, and pharmaceutical items.

Defrost Temperature Indicators. These are color-change indicators that are used mostly to monitor chill and frozen temperatures of chemical and food products during storage or distribution (15). They are *go/no go without delay* or *go/no go with some delay time* devices. The *go/no go* without delay indicators provide information that the temperature has risen above a threshold value during a short period. The *go/no go* with delay indicators show that the indicator has been exposed to a predetermined temperature for a specified length of time. Here are some examples:

1. ColdMark indicators (IntroTech, Inc.) are used to show whether a product has been exposed to critical cold temperature conditions as accurately as $\pm 1^\circ\text{C}$. Several designs have been described in the patent literature (16). They consist of a glass bulb filled with a colorless fluid and a tube partially filled

with a colorless and a violet colored fluid separated by a green barrier fluid. The tube is enveloped in a transparent plastic casing provided with a pressure-sensitive adhesive backing for attachment onto the exterior or interior surface of a package (17). For a freeze-monitoring indicator, the response temperature is $32^\circ\text{F}/0^\circ\text{C}$. Upon exposure to temperatures at or below the response temperature for about 30 minutes, the colorless fluid in the bulb freezes and contracts, causing the colored fluid in the tube to flow downward and color the bulb. When warmed above the response temperature, the bulb remains permanently colored. When not in use, the indicator is stored above the response temperature.

2. The TwinMark indicator (IntroTech, Inc.) is a dual purpose indicator that can respond to cold and hot temperatures. It works like the ColdMark and shows irreversible color change in the bulb when the cold side or hot side of the indicator is exposed to a temperature below or above the predetermined value (17).
3. The ColdSNAP indicator (Telatemp Corporation, Fullerton, CA) is a temperature recorder that contains a bimetallic sensing element (14). When attached to a product, a safety tab is pulled to activate the sensor. A clear window in the indicator means that the product storage temperature is safe. When exposed to a damaging critical temperature, the bimetallic sensor snaps into the indicator window and permanently changes it from clear to red. The accuracy of the indicator is $\pm 2^\circ\text{C}$, and customers can select snapping point temperatures ranging from -20 to $+40^\circ\text{C}$.

Liquid Crystal Display (LCD) Labels. LCDs are miniature reversible thermometers engineered on a label. An indicator window and a self-adhesive backing are provided. A liquid crystalline material or polymer is placed behind the indicator window. When installed, the material changes from opaque to transparent at rated temperatures (12,14). It is possible to select the indicator's color change of interest. LCDs can be designed to monitor surface temperatures continuously across various temperature ranges or to indicate selected temperatures. For example, Telatemp markets LCD reversible temperature decals that cover a range of -30°C to 120°C in $2\text{--}5^\circ\text{C}$ increments, visual tan/green/blue color changes permit readings to 1°C .

Time-Temperature Integrator or Indicators (TTI)

A time-temperature integrator/indicator is a continuous monitoring device or tag that measures both the cumulative exposure time and temperature of perishable products from production, distribution, storage, and even point of use. When a TTI is attached to a product and activated, the time-temperature history to which the product has been exposed is recorded and integrated into a single visual result (such as color change). In theory, TTI can be used as an informational, monitoring, and decision-making protocol at any point in the distribution chain of product quality and safety (11,18).

The response mechanism of a TTI is based on irreversible physical, chemical, or biochemical changes such as oxidation and reduction reactions, protein denaturation, enzymatic browning, sublimation of ice, and recrystallization of ice that occurs from the time of activation. The rate of these changes increases as temperature increases. The application and reliability of time–temperature indicators have been studied extensively by several researchers (19–22). Applications of TTI include food produce, pharmaceutical and blood products, cosmetics, adhesives, paints and coatings, photographic and film products, avionics, plastics, and shipment of live plants and animals.

Chemical Kinetic Basis for TTI Application. Major factors responsible for the deterioration of food and related chemical products include microbial growth, physical changes, and biochemical or chemical reactions within the perishable products. Some examples of spoilage reactions include acid–base catalysis, enzymatic reactions, free radical processes, hydrolytic reactions, lipid oxidation, meat pigment oxidation, nonenzymatic browning reactions, and polymerization or cross-linking processes (23). Like any chemical reaction, the rates of degradation or quality loss of perishables are influenced by environmental factors such as temperature, concentration (e.g., composition of an internal gaseous phases), and water activity. Increasing the temperature, for instance, increases the rates of these reactions.

Both the response of time–temperature indicators and changes in food quality (or other perishables) can be modeled by chemical kinetic equations. It is critical to gather accurate and reliable kinetic data for TTI to be successful and reliable. Several studies are available on the subject (23–25). Briefly, studies of several frozen and refrigerated foods indicated that the response of TTIs correlates with storage-related quality changes (26). In another study, the sensory changes in frozen hamburger reportedly correlate with the response of a commercially available TTI (27).

Several investigators have studied the influence of temperature on the rate of quality loss. It is generally accepted that the rate of quality loss behaves as an exponential function of the reciprocal of the absolute temperature. This is the Arrhenius equation shown here:

$$k = Z \exp(-E_A/RT) \quad (1)$$

where k is the reaction rate constant, Z is the temperature independent preexponential factor, E_A is the activation energy that describes the temperature sensitivity of the quality loss reaction, R is the universal gas constant, and T is the absolute temperature in Kelvin (K).

To measure loss of quality or shelf life in perishables, one or more characteristic measurable quality factors, denoted X are selected. The quality factor X can be a chemical, microbiological, or physical parameter. The rate of change of the quality factor with time under isothermal storage conditions is given by the following equation:

$$d[X]/dt = -k[X]^n \quad (2)$$

Table 2. Activation Energies of Selected Reactions That Result in Food Quality Losses^a

Type of Reaction	Activation Energy Range	
	(kJ/mol)	(kcal/mol)
Diffusion controlled	0–60	0–14.3
Acid–base catalysis	80–120	19.1–28.6
Enzymatic reaction	40–60	9.5–14.3
Hydrolysis	50–60	11.9–14.3
Lipid oxidation	80–100	19.1–23.9
Nutrient losses	20–120	4.8–28.6
Maillard reaction	100–180	23.9–43
Protein denaturation	300–500	71.6–119.3
Spore destruction	250–350	59.7–83.5
Vegetable cell destruction	200–600	47.7–143.2
Microbial growth	60–200	14.3–47.7

^aRefs. 20,28.

where t is the reaction time and n is the reaction order. For most food quality losses, a reaction order of zero or one is typical for a simple rate constant. By considering the kinetics of change in food quality at various temperatures, the activation energy E_A for the quality loss reaction can be obtained (19, 24, 25). Table 2 lists typical values of $E_{A(\text{Food})}$ for quality losses. The activation energy of the indicator ($E_{A(\text{TTI})}$) can be obtained from the TTI kinetics.

Correlation of TTI Response With Food Shelf Life

Taoukis and Labuza developed a correlation scheme for predicting the shelf life of a product based on the TTI response [19,20]. This scheme is based on a series of kinetic equations that describe the quality loss and the TTI response (Fig. 1.)

The effective temperature for a variable time–temperature distribution is determined from TTI response kinetics. This value is used in conjunction with food kinetics to estimate the remaining shelf life or quality loss. The scheme shown in Fig. 1 assumes that the effective temperature and the activation energies of both the TTI device and the food are the same. However, this is not always the case. For practical applications, a difference between $E_{A(\text{food})}$ and $E_{A(\text{TTI})}$ of ± 8.4 kJ/mol (2 kcal/mol) generally gives a good prediction [19,20].

Commercially Available TTIs. Several types of TTI devices have been described in the patent literature, but only three have continued to receive significant attention from the industrial and scientific community during the past 15 years (11,18). These include the 3M Monitormark, Lifeline, and VITSAB TTIs. They are available as labels, tags, pallet sticks, or pallets with sheaths. Each is described here.

3M Monitormark TTI. The principles, characteristics, and operation of the 3M Monitormark TTI (3M Identification and Converter Systems Division, St. Paul, MN) are well documented (29,30). It is designed to respond visually only after a critical threshold temperature has been exceeded. The indicator consists of an assemblage of a porous paper wick, a rectangular paper pad saturated with a blue colored fatty acid ester and phthalate mix that has a specific melting point, a polyester barrier layer that separates

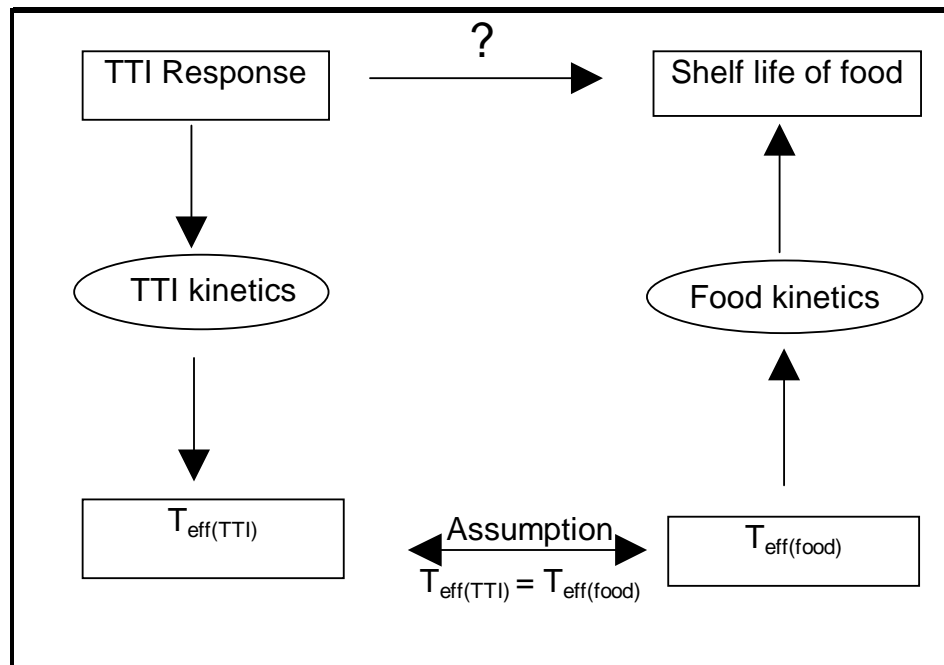

Figure 1. Application of a TTI as a food quality monitor (19).

the wick from the reservoir pad (paper pad), and adhesives. The response temperature is usually the melting point of the specialty chemical. The prepared TTI tag remains inactive until it is activated.

The indicator is activated when a polyester pull-strip is removed and allows contact between the porous paper and the reservoir. When exposed to temperatures higher than the threshold temperature, the chemical in the reservoir melts and migrates into the porous wick. The indicator has five windows that change color progressively as the migrating chemical runs through. Color in the first window implies that the indicator has been exposed to a temperature higher than the preset threshold temperature. The extent of color movement through these windows indicates the cumulative exposure time spent above the threshold temperature. Response cards provided by the manufacturer correlate the time–temperature relationship of each indicator. When all five windows turn blue, the product is considered unacceptable. If stored according to manufacturer's guidelines, the tag shelf life is 2 years from the date of manufacture.

A plot of the square of the run-out distance against time is linear for a Monitormark TTI, and it obeys the Arrhenius equation [20]. The design and operation of this indicator rely on a diffusion mechanism, so that the activation energy of this TTI is limited to 0–60 kJ/mol (0–14.3 kcal/mol). Therefore, it is recommended for use in many enzymatic and diffusion-controlled spoilage reactions.

Lifeline Fresh-Scan and Fresh-Check TTI. Lifeline Technologies (Lifeline Technologies, Morristown, NJ) offers two “full history” time–temperature indicators that monitor the freshness of perishables independent of the temperature threshold. These products are the Fresh-Scan and Fresh-Check indicators that are based on the color change resulting from the solid-state polymerization

of a diacetylenic monomer. The construction, operation, and characteristics of the device are described in detail by Patel and his co-workers (31,32) and by Field and Prusik (33).

The *Fresh-Scan* indicator consists a standard bar code that contains product information and a diacetylenic monomer deposited on a pressure-sensitive band, a portable microcomputer that has a laser scanner to measure changes in the reflectance of the indicator, and a data analysis work station. The indicator band initially shows about 100% reflectance. As the diacetylenic monomer undergoes time–temperature dependent solid-state polymerization during storage, the indicator band darkens and causes a decrease in the measured reflectance. The rate of color change follows Arrhenius behavior, so that higher temperatures enhance the rate of color development. The microcomputer combines this time–temperature characteristic and the product information on the bar code to predict the shelf life of the product.

The *Fresh-Check* indicator is a consumer-readable visual label, which is also based on the color change of an incorporated polymerizable monomer but has a different design and configuration (15). The circular device consists of an inner polymer shell that contains the monomer and an outer nonpolymer shell painted with a reference color. When exposed to some time–temperature storage conditions, the monomer at the center part converts to polymer. This causes progressive color development at a rate that increases as temperature increases. If the polymer center become darker than the outer reference, the consumer is advised to discard the product, regardless of the printed expiration date (15).

These two Lifeline indicators are active as soon as they are manufactured and must be refrigerated at very low temperatures ($< -24^{\circ}\text{C}$) to preserve their high initial reflectance.

Table 3. Activation Energy Values of Some Common Commercial TTIs

Manufacturer	TTI Model	TTI Activation Energy ($E_{A(TTI)}$)		Ref.
		(kJ/mol)	(kcal/mol)	
Visual indicator tag systems, AB-Malmo, Sweden	VITSAB Type 1	57.4	13.7	36
	VITSAB Type 2	94.7	22.6	36

	Fresh-Scan-68	82.5	19.7	19,20

^aVitsab was formerly known as I-Point.

Wells and Singh investigated the use of these indicators as a quality change monitor for perishable and semiperishable products such as tomatoes, lettuce, canned fruitcake, and UHT sterilized milk (22). It was shown that the response kinetics of these indicators correlates with quality loss in the products studied. The indicators studied have activation energies of 84 to 105 kJ/mol (20 to 25 kcal/mol). Major limitations of these indicators are that the polymerization reaction is photosensitive and also that they cannot respond to a short time–temperature history.

VITSAB TTI. Numerous studies have been carried out on the time–temperature-dependent enzymatic reaction on which the Vitsab TTI (former known as I-Point) is based [34,35]. It is a “full history” indicator that records the temperature conditions and temporal history of a product independently of threshold temperature. The device uses two color-coded compartments to store the chemicals. The green part houses a mixture of an enzyme solution and a pH indicating dye. The gray part contains a lipase substrate suspension. The line separating the two chambers is a pressure-sensitive barrier. The device is activated by breaking the barrier between the two chambers. This causes the enzyme solution and the substrate to mix to form the indicating solution. As the reaction progresses, the lipase substrate (triglycerides) hydrolyzes into its component fatty acids and causes the pH to drop. A change in pH causes the dye to change color from an initial green to a final yellow at a rate that is temperature-dependent. A variety of VITSAB indicators can be custom designed for specific temperature-sensitive commodities by judiciously selecting the enzyme concentration and the enzyme–substrate combination.

At present there are four different types of indicators that come in one- and three-dot standard configurations, depending on the level of product safety risk to be communicated. The single-dot indicator changes color from

green to yellow above a predetermined temperature. The three-dot indicator conveys the degree of temperature exposure with high reliability.

The activation energies of the major TTI products are summarized in Table 3. By matching the E_A of these TTIs to the E_A values for some common deterioration reactions in food and pharmaceutical products (Table 2), current TTI technology should provide a range of selections that will meet manufacturers’ needs.

ANTICOUNTERFEITING AND TAMPER INDICATOR DEVICES

Counterfeiting, forgery, tampering, and piracy of valuable documents and products has existed from time immemorial. Counterfeiting has become a multibillion dollar business that is prospering more than many of the victim companies. This highly organized trade results in lost revenue to both companies and governments, as well as loss jobs in private and public sectors. The motivation for professional counterfeiters is the ease of making huge profits and the risk of being caught and penalized is very low. It is impossible to enumerate the products or documents that are counterfeited or to quantify their impact on vulnerable consumers. Activities of counterfeiters have increased in developed countries. The incidence of counterfeiting is even greater in developing countries which have become a dumping ground for counterfeit products. A partial list of goods that are commonly faked include antiquities, currency, letters of credit, credit cards, jewelry, chemicals, processed food, pharmaceutical and cosmetic products, product identification marks, videos, CDs, clothing and apparel accessories, electronics, auto and airplane parts, children’s toys, watches, sporting goods, travel documents such as passports, identity cards and driving permits, and textile materials [37–39].

Advances in technology such as computers, lasers, scanners, charge-coupled devices (CCD), color printers, optical holograms, and analytical tools have enhanced the state of the art in anticounterfeiting security and encryption. Ironically, these advances are also being exploited by adversaries to promote high-tech forgery. To combat these activities, research efforts have continued to develop tamper-resistant security mechanisms that will make counterfeiting too expensive to be lucrative. This subject has been reviewed recently (37,38). A summary of some of the available technologies relevant to this article are presented.

Holographic Technology

An optical hologram is a three-dimensional photo created on a photoresist film or plate by the reflection and refraction pattern of laser light incident on an object. Two of the holograms widely used in security applications are the embossed and the Denisyuk hologram. The embossed hologram can be readily mass-produced as a mechanically tough and durable thin film at a very low cost.

The relatively thicker Denisyuk hologram requires a more stringent manufacturing process. In addition to being more expensive to produce, it is not as mechanically robust as the embossed hologram. This hologram is the more easily counterfeited than an optical hologram.

Holographic Dimensions, Inc. offers the Verigram™ security system that consists of two elements. The display hologram and the machine readable Verigram™ hologram afford a completely secure device. Although the display component may be counterfeited, it is claimed that the Verigram™ element is impossible to forge (40).

One of the leading manufacturers of anticounterfeiting holograms is American Bank Note Holographics, (ABNH) Inc. Their products are used for various commercial and security applications. They include holographic stripes, holomagnetic stripes, holographic threads, transparent holographic laminates, hot stamp foils, hologuards, and frangible vinyl and pressure-sensitive and tamper-evident labels. ABNH can manufacture holograms that have a magnetic stripe, visible and invisible bar code, or micro-printing for added security, product tracking, audits, and authentication. The list of producers and vendors of commercial and security holograms is endless. Only two are mentioned here as examples.

Microtaggant Technology

Taggants are microscopic color-coded particles derived from several layers of a highly cross-linked melamine polymer and are used extensively as markers (41). Layers of magnetic and fluorescent materials are added to the taggant particles during formulation to simplify detection and decoding. The technology (originally developed for explosives) finds applications in antiterrorism, authentication, piracy, counterfeiting, and product identification (41). Taggant particles can be coded with information such as the product manufacturer, production date, and batch number as well as the distributor. Taggants for use in antiterrorism are thoroughly mixed with explosives. When a bomb containing tagged explosive is detonated, remnant taggants

may be collected from debris by using a UV light and a magnet. The coded color sequence information can be retrieved by using an optical microscope. This reliably helps in tracing the origin of the explosive.

Tagged particles can also be added to printing ink for security printing. This provides a way to combat counterfeit, forgery, and product diversion and assist in product/property identification. Microtaggants can be added to many products either directly during formulation or by thermal transfer, films, laminates, and spraying. Some of the companies that market microtaggant identification particles are Microtrace Inc., Minneapolis, MN; MICOT Corporation (St. Paul, MN); SW Blasting (BÜLACH, Switzerland); and Plast Labor (Bulle, Switzerland). Patronage comes from government agencies, law enforcement, and industry.

Smart Ink Technologies

Smart inks or coatings change color predictably in response to alteration of their environment. Color change may or may not be reversible, and they are applied in areas such as security printing, lenses, and other optical devices. The two main classes of smart inks include those derived from photochromic and thermochromic materials.

Photochromic inks are formulated from light-sensitive dyes, pigments, polymers, and other colorless chemical compounds. These inks change color when exposed to ultraviolet light. Examples include extrusion lamination inks, invisible ink security markers, tagged inks, and inks based on copper-free metallics.

Thermochromic inks incorporate temperature-sensitive polymers, dyes, or pigments. When exposed to a predefined temperature, the ink undergoes a color change. Typical color-sensitive components include diacetylenic compounds, hydrogel polymers, and thermochromic liquid crystals.

Security inks incorporate fluorescent dyes, photochromic dyes, thermochromic dyes, or organic pigments in their formulations. These dyes or pigments change color reversibly when exposed to ultraviolet light or heat of predefined intensity or temperature. This forms a basis for their use in security printing, counterfeit or forgery indicators, and tamper-evident and applications. Several companies around the world manufacture and distribute counterfeit detector pens or specialty fluorescent light bulbs for quick authentication of currency bills, gift certificates, and other documents.

Tamper-Indicating Devices

Tamper indicators are security seals or labels designed to detect product or document tampering. Indicator devices available are based on fiber-optic active seal technologies, optical thin films, holograms, and chemical reactions. A major requirement for these materials is that they provide unambiguous evidence of tampering. They must be resistant to environmental conditions such as heat or solvents and must be relatively cheap. Several low-cost tamper indicators are commercially available to meet various customer needs.

Telatemp (Telatemp Corporation, Fullerton, CA) sells TelaSEAL security labels constructed from polyester film, high strength instant-bond adhesive, and other proprietary chemicals (14). For additional security, a repeating geometric pattern is printed onto the TelaSEAL label during construction. The seal can be applied to a variety of surfaces including plastics, metals, wood, and painted surfaces. A disrupted repeating pattern that has a custom message "OPENED" is transferred to the applied surface when the device is peeled from the substrate. This provides permanent and unambiguous evidence of tampering.

Meyercord (Sentinel Division, Carol Stream, IL) supplies several tamper-evident, adhesive-base materials that leave a VOID message on surfaces, thus providing an indication of unauthorized opening of product or tampering. The VOID message can be customized to include the company's name, trademark, logos, or serial number.

3M has developed several authenticating devices based on optical thin film technology for counterfeit detection and tamper indication. A proprietary metallic surface coating is formulated and deposited on a pressure-sensitive material. Specialized imaging technologies are used to generate unique covert graphics and print product information or a serial number on the device. When the device is peeled from the substrate, the covert image is revealed followed by an irreversible color change which provides a sure indication of tampering. These devices are used for asset control, package sealing and identification, parts identification, serial numbering, and consumer information.

Indicating Device Issues And Limitations

Interest in indicating devices continues to grow, and numerous applications have been proposed. Despite significant advances made in chemical indicator technology during the last 25 years, only a few devices have been commercialized compared to the number of patents granted each year. There are several reasons that many manufacturers, governments, and consumers are reluctant to adopt chemical indicating devices. Major considerations on the part of manufacturers include device reliability, cost, and education. Manufacturers fear that consumers will be reluctant to embrace products containing these indicators for reasons of additional cost. The addition of a leak indicator to the headspace of packaged food or pharmaceutical products is likely to be greeted by stiff resistance on the part of the consumer for safety reasons. To gain acceptance, commercial indicators must be relatively inexpensive compared to the products to which they are applied. They must also be technically competent to perform their intended functions.

The response mechanisms of many indicators are poorly understood (42). For example, to produce a reliable time-temperature indicator, the quality index, kinetics, and mechanism of food or chemical product degradation under various environmental conditions must be understood. Some degradation reactions may not always follow simple Arrhenius kinetics. Therefore, predictions based on them may be faulty and thus affect product reliability. Consumer surveys (12,30) on the use of TTIs on food products indicate

that the public reception of these indicators is growing. They also raised awareness of the need to educate consumers about the usefulness, reliability, and application of indicator devices to increase the current level of acceptance.

Even though most of the counterfeit and tamper indicator technologies currently available are reliable, they are quite expensive. This makes many industries reluctant to implement them. Some the indicators are limited in their scope of application and are easily forged or copied, as is the case for many optical holograms (37-40). This has been a major problem for many credit and identification cards. The challenge is to produce indicators that are reliable, technically difficult to copy or fake, and are available at a relatively low price.

Recently, several indicating devices have made inroads into the marketplace by making unsubstantiated claims of what the product can offer. In some cases, instructions for consumers on the application and interpretation of indicator response or color change are inadequate. Consumers can be confused. Information about the safety of the indicator should also be provided. Effort should be made to design indicators that are childproof to avoid ingestion and other accidents. A general specification for the various classes of indicators needs to be established. Such a specification should provide performance criteria that each indicator design must meet for a given application. It should also set standards for acceptable qualification testing. This will ensure that commercial indicating devices meet the needs of industry.

CONCLUSION

The application of chemical indicating devices has come to stay. In many cases, they are living up to expectations in reducing the incidence of counterfeiting, forgery, tampering, or piracy and losses of perishable products. Temperature and time-temperature indicators are now used in routine packaging of some critical food and chemical products. For TTIs, only limited information on the kinetics and response mechanism is available in the literature. New indicators that cover a wide range of activation energies for many spoilage reactions need to be designed. This will allow extending the scope of application of TTIs. More research and development effort could be directed toward the present technical and manufacturing challenges that hinder commercialization of many patented inventions. Public education will accelerate interest and ultimate acceptance of these products. Such acceptance may create sufficient volumes that would lead to lower costs for manufacturing these smart devices.

ACKNOWLEDGMENT

CHITOSAN-BASED GELS

KANG DE YAO

INTRODUCTION

Chitosan is a natural biopolymer obtained by deacetylation of chitin, which is produced from marine shellfish, such as crabs, shrimp, fungal cell walls, and other biological sources. Chemically it is a linear cationic poly(β -(1-4)-2-amino-2-deoxy-D-glucan) derived from chitin, a poly(β -(1-4)-2-acetamido-2-deoxy-D-glucan) by deacetylation. Chitosan is described in terms of the deacetylation degree and average molecular weight. And next to cellulose, it is the second most plentiful biomass and is already known as a biocompatible and biodegradable material. Many researchers have examined tissue response to various chitosan-based implants. Results indicate that these materials evoke minimal foreign body reactions (1).

Gels consist of 3-D polymer networks swollen in swellers, whereas hydrogels swell in water. Smart (intelligent) gels (or hydrogels) can swell or contract in response to stimulus changes, e.g., temperature, pH, ionic strength, chemicals, and fields.

Chitosan has been used for developing smart gels via network or/and complex formation. Due to their various properties that depend on environmental variables such as pH, ionic strength, and electric field, these materials have potential applications such as biomaterials, separation membranes, and field responsive materials.

SUPRAMOLECULAR INTERACTIONS AND GEL FORMATION

As we know, chitosan-based gels are chemically or physically cross-linked networks. To make them smart, special supramolecular interactions are often introduced into the network to provide reversible responsiveness to environmental stimuli. Therefore, different interpolymer complexes are formed within the chitosan-based networks.

These complexes can form or dissociate in response to changes in their environment. They can be divided into these four major categories based on the dominant type of interaction:

1. Hydrogen bonding complexes
2. Polyelectrolyte complexes
3. Coordination complexes
4. Self-assembly

The presence of amino groups in chitosan ($pK_a = 6.5$) results in pH-sensitive behavior. Research efforts have been aimed at tailoring the properties of chitosan through cross-linking, functionalization, copolymerization, and blending to fit smart requirements.

Hydrogen Bond Complexes

The amine groups of glucosamine residue within chitosan chains can serve as cross-linking sites, for example, reacting with glutaraldehyde to form imine cross-links between linear chitosan chains that lead to gel formation (2).

An interpenetrating polymer network (IPN) is defined as a combination of two cross-linked polymers; at least one of them synthesizes or cross-links in the presence of the other. If one of the polymers is linear (not cross-linked), a semi-IPN results. The IPN technique can be used to improve the properties of chitosan-based gels.

Yao et al. (3) examined glutaraldehyde-cross-linked chitosan-poly(propylene glycol) (PPG, MW 3000 daltons) semi-IPN as a pH-sensitive hydrogel. Chitosan-PPG semi-IPN shows pH-dependent swelling; the highest swelling degree is at pH 4.0 and the lowest at pH 7.0 (Fig. 1). The structural features of chitosan-PPG are reversible (e.g. $-\text{NH}_3^+$ to $-\text{NH}_2$) when the gels are transferred from a pH 1.0 to a pH 7.8 buffer (4). Because it is a hydrophobic and water-insoluble polymer, the incorporated PPG is expected to decrease the equilibrium swelling degree in a low pH medium. In addition, linear PPG in the network can enhance the flexibility of semi-IPN.

Polyethylene glycol (PEG) is a water-soluble polymer that has low toxicity and immunogenicity. Hydrophilic PEG can form a diffuse layer containing water molecules

Figure 1. The equilibrium degree of swelling vs. pH for the semi-IPN, synthesized from different amounts of crosslinking agent. Molar ratios of $-\text{CHO} : -\text{NH}_2$ are 2.21(○) and 4.38(□), respectively.

Figure 2. The pH dependence of the degree of swelling of chitosan/silk fibroin semi-IPN. Glutaraldehyde content: 1.5% mol/mol, 30°C. SF10–SF70 denote that the silk fibroin contents in semi-IPN are 10–70% w/w, respectively.

which has protein resistance when PEG is adsorbed on a surface. PEG has been used to improve the biocompatibility of polymers. Glutaraldehyde-cross-linked chitosan-PEG semi-IPN hydrogels were prepared by incorporating PEG (MW 6000) into chitosan. Here, PEG in the network enhances blood compatibility. In addition, because its ether linkage $[-\text{CH}_2\text{CH}_2\text{O}-]_n$ provides rotational freedom, PEG also enhances the flexibility of the network. The swelling degree of semi-IPN drops sharply at high pH (>6). This may be due to the formation of hydrogen bonds between the hydrogens of the amino groups of chitosan and the oxygens of the polyether in alkaline regions, whereas the hydrogen bonds dissociate at acidic pH (5).

Poly(ethylene oxide) (PEO) of average molecular weight ranging from 10,000 to 1 million daltons was used to prepare glyoxal-cross-linked chitosan-PEO semi-IPN; the semi-IPN swells almost ten times more in the low pH environment of gastric fluid (pH 1.2) than in the intestine (pH 7.2) after 6 hours (6).

Silk fibroin, a main component of natural silk, is a fibrous protein whose major amino acids consist of glycine, alanine, and serine residues. Cross-linking chitosan with glutaraldehyde in the presence of silk fibroin creates a chitosan/silk fibroin semi-IPN. The equilibrium swelling degree versus pH of the semi-IPN is shown in Fig. 2. The degree of swelling of silk fibroin is small in the whole pH range, whereas the semi-IPN swells obviously in low pH ($\text{pH} < 5.0$) buffer solutions, and especially at pH 3.3, just like cross-linked chitosan. This may be attributed to the dissociation of hydrogen bonds between chitosan and silk fibroin within the semi-IPN in the strong acidic medium. Moreover, chitosan can bind metal ions, for example, Al^{3+} , resulting in hydrogen bond dissociation. So chitosan/silk fibroin semi-IPN shows ion sensitivity. Figure 3 displays semi-IPN swelling and shrinkage with a change in AlCl_3 concentration. However, relaxation time is longer for ion sensitivity than for pH responsiveness (7).

Gelatin is a denatured form of collagen, composed of glycine, proline, hydroxyproline, arginine, and other amino acids. The amphiphilic protein (isoelectric point = 4.96) can provide amino groups for co-cross-linking with chitosan via

Figure 3. The $[Al^{3+}]$ dependence of the degree of swelling of chitosan/silk fibroin semi-IPN. Glutaraldehyde content: 1.5% mol/mol, 30°C. C_{AlCl_3} denotes the concentration of aqueous $AlCl_3$ solution. SF30 and SF70 denote silk fibroin contents in semi-IPN of 30 and 70% w/w, respectively.

glutaraldehyde to prepare a chitosan/gelatin hybrid polymer network (HPN). The pH-sensitive swelling behavior of the HPN gel is displayed in Fig. 4. The data show that the degree of swelling declines sharply at pH 7.0. This can be explained by the fact that the hydrogen bonds within the chitosan/gelatin HPN dissociate in an acidic medium (8).

Polyelectrolyte Complexes

Polyelectrolyte complexes (PEC) are generally obtained either by the reaction of polycations and polyanions or by polymerizing monomers that have suitable functional groups onto polymeric templates of known structures. PECs have numerous applications such as membranes, medical prosthetic materials, environmental sensors, and chemical detectors. Chitosan, a cationic polysaccharide, has been complexed with anionic polymers.

Figure 4. Swelling behavior of chitosan/gelatin hybrid network specimen with a $-CHO : -NH_2$ molar ratio of 10 in solutions of different pH with ionic strength $I = 0.1$ at 37°C.

Alginate comprises a linear chain of (1,4)-linked β -D-mannuronate and α -L-glucuronate residue arranged blockwise. A gel-like chitosan/alginate PEC was formed with coexisting polyions of opposite charges ($-NH_3^+$ and $-COO^-$). Polysaccharides (chitosan and alginate) have bulky pyranose rings and a highly stereoregular configuration in their rigid linear backbone chains. Their conformation changes with pH and leads to pH dependence of the packing density of PEC membranes. Therefore, the drug release behavior of drug-loaded microcapsules depends on pH as well (9).

Pectin is an acidic polysaccharide that has a repeating unit of α (1,4)-D-galacturonic acid, and its methyl ester is interrupted in places by (1,2)-L-rhamnose units. A polyelectrolyte complex is formed from anionic pectin and cationic chitosan. The PEC swells obviously at $pH < 3$ and $pH > 8$ and does not swell in the range of $3 < pH < 8$. Moreover, its degree of swelling in an acidic medium is by far larger than that in an alkaline medium. The swelling of the PEC correlates with its composition and is also affected by the degree of deacetylation and the methoxy level of pectin (10).

Complex formation via hydrogen bonding occurs between two polymers that contain hydrogen bonding donor groups and acceptor groups, whereas a charged polymer forms polyelectrolyte complexes with other polymers that have inverse charged groups. Bovine atelocollagen and a fully deacetylated high molecular weight chitosan (acetyl content $\approx 2.5\%$) form complexes; whether this is by pure electrostatic interaction or by hydrogen bonding depends on the conditions. In the first case, the interaction takes place between $-NH_3^+$ and $-COO^-$ groups carried by chitosan and collagen, respectively, but the maximum proportion of chitosan in the complex is relatively low ($\approx 10\%$) (11). In the presence of a great excess of chitosan, it is also possible to form a hydrogen bonding complex, in addition to the first complex where chitosan chains seem to induce the destabilization of the triple helix organization and denature collagen (12). Moreover, an increase in the content of chitosan in the complex improves the stability toward collagenase (13).

A chitosan-poly(acrylic acid) polyelectrolyte complex can be obtained by radical polymerization of acrylic acid onto chitosan as a template. The template polymerization provides an ordered structure to the PEC compared to that obtained by reacting chitosan with poly(acrylic acid) (14).

Coordination Complex

Chitosan has one amino group in addition to hydroxyl groups in the repeating unit. So chitosan can strongly coordinate with transition-metal ions to form coordination complexes, which may be used as absorbents for metal ions and separation membranes. The order of the stability constants of these chitosan-transition-metal complexes is $Mn < Fe < C < Ni < Cu < Zn$, which is known as the Irving-Williams order. The difference in the stability of complexes may cause the variance in the degree of swelling of a complex membrane whose metal/glucosamine ratio ranges from 1:8 to 1:64 (15).

Self-Assembly

Block-copolymer micelles and hydrophobic water-soluble polymeric amphipaths can form self-aggregates that

Figure 5. Schematic for aggregation and dissociation behavior of PEG- δ -chitosan in aqueous solution in response to the pH of the solution.

consist of inner cores of hydrophobic segments and outer shells of hydrophilic segments in aqueous media. Chitosan was hydrophobically modified by deoxycholic acid, a main component of bile acid, to yield self-aggregates in aqueous media. The modified chitosan forms self-aggregates in phosphate-buffered saline (PBS pH 7.2) whose mean diameter is less than 180 nm, depending on the degree of substitution of hydrophobic groups. Critical aggregation concentration (*cac*) is the threshold concentration of a self-aggregate formed by intramolecular and/or intermolecular association. In water, the *cac* values ($1.32\text{--}4.47 \times 10^2$ mg/mL) of deoxycholic acid-modified chitosan are lower than the *cac* value (1.0 mg/mL) of deoxycholic acid. Because self-aggregates have positive charges on their outer shells, they can be used as delivery carriers for DNA, a relatively charged polyelectrolyte (16).

PEG is a highly hydrophilic polymer. Grafting PEG onto chitosan results in a water-soluble PEG- δ -chitosan, which is prepared via the coupling reaction of 6-O-triphenylmethylchitosan with MeO-PEG acid, and then deprotecting its triphenylmethyl groups. PEG- δ -chitosan can form intermolecular aggregates in neutral and alkaline conditions and is dissociated in acidic media because of the electrostatic repulsion of protonated amino groups of chitosan moieties (Fig. 5). Therefore, this PEG- δ -chitosan aggregate is expected to be used as a pH dependent material such as a carrier for drug delivery systems (17).

Glycol chitosan (GC, polymerization degree ~ 800) was modified by acylation with palmitic acid *N*-hydroxy-succinimide. The polymer obtained (GCP) can form vesicles by mixing GCP/cholesterol in a 2:1 wt ratio under sonication; the GCP assembles into unilamellar polymeric vesicles in the presence of cholesterol. Anticancer drugs, for example, bleomycin (BLM), can be encapsulated efficiently within the vesicles. The stable GCP-based BLM vesicles were tested *in vivo* (18).

APPLICATIONS

Controlled Release Matrixes

The aim of controlled release of drugs is either to modulate tissue drug levels or to spatially and/or temporarily place a drug in some region of the body to maintain efficacy

and depress side reactions. Therefore, a matrix used for controlled release should offer modulating ability for drug delivery in addition to maintaining drug stability within the matrix. Chitosan has structural characteristics similar to those of glycosaminoglycans; its smart material has been explored for use in controlled release matrixes. The use of chitosan in the development of oral sustained release stemmed from the intragastric "floating tables" of chitosan. Chitosan has gel-forming properties in a low pH range in addition to its antacid, antiulcer characteristics. Thus, it has promising potential for use in oral sustained delivery systems. Gastrointestinal, respiratory, ophthalmologic, cervical, and vaginal mucins are hydrophilic saline gels that are thickened by natural anionic glycoproteins. In searching for drug delivery systems for such substrates, suitable cationic polymers are needed. Chitosan is known to be bioadhesive to mucosal surfaces, such as in the eye, nose, and vagina.

Pluronic[®] (BASF Corp), a well-known biomaterial is a triblock copolymer that contains poly(propylene oxide) (PPO) and poly(ethylene oxide) (PEO) segments in the sequence PEO-PPO-PEO. Here, hydrophobic PPO segments aggregate leading to distinct gelation at body temperature. The PPO aggregation forms micelles that solubilize lipophilic drugs in aqueous media and allow their slow release. Hoffman et al. licensed chitosan grafted with Pluronic[®]. The graft copolymers form clear gels when the temperature is raised from 4 to 37°C at pH 7.4. The copolymer is used as a matrix for receiving proteins via nasal administration. When the proteins are released from the gel *in vitro* through ion exchange and/or diffusion, they are "totally active" (19,20).

The cationic character of the chitosan backbone allows oppositely charged drugs such as insulin, interleukin 1L-2 receptor, IL-4 receptor, and tumor necrosis factor (TNF) receptor to form complexes of Pluronic[®]- δ -chitosan (21).

Proteins and enzymes represent a growing and promising field of therapeutics and are currently administered by injection. As a result of the development of biotechnology, many peptides and proteins have been explored as a new generation of drugs. Maintaining their bioactivity in the drug delivery process is one of the key problems. Oral peptide drug delivery is the easiest method of administration; however, proteins are quickly denatured and degraded in the stomach. Moreover, the intestinal absorption of drugs is generally very poor. Chitosan can enhance the intestinal transport of peptide drugs by increasing the paracellular permeability of the intestinal epithelium. Bioactive peptides, for example, hirudin (a polypeptide whose MW is 10,800 and is a potent antithrombin agent) can be delivered orally by microencapsulation with alginate-PEG/chitosan systems. Actually, oral intake of hirudin via the chitosan alginate matrix can avoid thrombin formation and alter lipid levels of patients beneficially (22).

Chitosan-based materials can be designed as stomach-specific drug delivery systems. Due to the limitations of the gastric emptying time, it is desirable to have a rapid swelling system to release a drug in the stomach. In enzyme-free simulated gastric fluid (pH 1.2), the release rate of metronidazole from freeze-dried chitosan-PEO semi-IPN is significantly higher than that from an air-dried hydrogel. The faster rate is attributed to the higher

Figure 6. Scheme for preparing CS nanoparticles.

porosity of the matrix of the freeze-dried hydrogel compared to that of the air-dried hydrogel (23).

The ionic interaction between the positively charged amino groups of chitosan and negatively charged counterion of tripolyphosphate (TPP, MW 4000) results in polyelectrolyte complex formation and thus allows the formation of beads in very mild conditions. So, chitosan nanoparticles can be prepared by ionic gelation with the counterion TPP (24).

The particle size depends on both the chitosan and TPP concentrations. The minimum size (260 nm) has been obtained. The PEO or PEO-PPO block polymer Synperonic® (1C1 Iberica, Spain) can be incorporated into chitosan nanoparticles by dissolving these copolymers in the chitosan solution either before or after adding the ionic cross-linker TPP (Fig. 6). TEM observation reveals that the chitosan nanoparticles have a solid and consistent structure, whereas chitosan/PEO-PPO nanoparticles have a compact core, which is surrounded by a thin but fluffy coat presumably composed of amphiphilic PEO-PPO copolymer (25). Here, the presence of PEO-PPO within the chitosan nanoparticles can mask the ammonium group of chitosan by a steric effect, thus hindering the attachment of the BSA (isoelectric point $\text{pH} = 4.8$). These hydrophilic chitosan/ethylene oxide-propylene oxide block copolymer nanoparticles are very promising matrices for administering therapeutic proteins and other macromolecules that are susceptible to interaction with chitosan (i.e., genes or oligonucleotides) (26).

Mucoadhesive drug delivery systems can easily be combined with auxiliary agents, such as enzyme inhibitors. Chitosan and EDAC [1-ethyl-3-(3-dimethylamino-propyl) carbodiimide hydrochloride] form chitosan-EDAC conjugates (10 mL of 1% chitosan HCl, 0.1M EDAC, and an amount of EDAC that ranges from 0.454 to 7.26 g) at $\text{pH} 3.0$. The chitosan-EDAC conjugates offers several

advantages as vesicles for peroral administration of peptide and protein drugs: excellent mucoadhesive properties and strong inhibition of the proteolytic activity of zinc proteases, carboxypeptidase A, and aminopeptidase N. The conjugate that has the lowest amount of remaining free amino groups seems to be a useful carrier in overcoming the enzymatic barrier for perorally administered therapeutic peptides (27).

The progress in biotechnology, coupled with an increased understanding of molecular mechanism underlying the pathogenesis of a variety of diseases of the gene level, has effected dramatic changes in therapeutic modalities. Recombinant DNA itself has been used like a “drug” in gene therapy, where genes are applied to produce therapeutic proteins in the patient. Oligonucleotides, relatively small synthetic DNA designed to hybridize specific mRNA sequences, are used to block gene expression. To achieve these goals, the gene drugs must be administered via an appropriate route and be delivered into the intracellular site of the target cells where gene expression occurs.

Gene drugs have substantial problems as polyanionic nucleic acids, including susceptibility to degradation by nucleases and low permeability. So, a suitable carrier system is the key to successful *in vivo* gene therapy. Considering that viral vectors have a number of potential limitations involving safety, cationic lipid polymers developed as DNA carriers can improve *in vivo* transfection efficiency.

Chitosan as a natural amino polysaccharide can form a polyelectrolyte complex with DNA. For site-specific DNA delivery, a quaternary ammonium derivative of trimethylchitosan with antenna galactose was synthesized. It was indicated that the galactose-carrying chitosan derivative as a ligand provides cell-specific delivery of DNA to Hep-G2 cells. The chitosan derivative binds to DNA via electrostatic interaction. The resulting complexes retain their ability to interact specifically with the conjugate receptor on the target cells and lead to receptor-mediated endocytosis of the complex into the cell (28) (Fig. 7).

Separation Membranes

Chemically modified chitosan membranes have been used in various fields, for example, metal-ion separation, gas separation, reverse osmosis, pervaporation separation of alcohol-water mixtures, ultrafiltration of biological macromolecular products, and affinity precipitation of protein isolates.

Pervaporation is a very useful membrane separation technique for separating organic liquid mixtures, such as azeotropic mixtures and mixtures of materials that have close boiling points. In pervaporation, the characteristics of permeation and separation are significantly governed by the solubility and diffusion of the permeates.

The separation mechanism of pervaporation is based on the solution-diffusion theory, the adsorption-diffusion-desorption process of the components in the feed coming across the membrane from one side to the other. Therefore, pervaporation properties can be improved by enhancing the adsorption of one component in the feed to the membrane and/or accelerating the diffusion of one component in the feed through the membrane.

Figure 7. Scheme of gene delivery system via receptor-mediated endocytosis.

Chitosan has been used to form pervaporation membranes for separating water/alcohol mixtures and shows good performance in dehydrating alcohol solutions. To enhance fluxes with more free volume, chitosan membranes cross-linked with hydrophilic sulfosuccinic acid (SSA) were developed where two carboxylic acid groups and one sulfonic acid group offer ionic cross-linking with amine side groups of the chitosan molecules. Because the SSA cross-linked membrane bears more binding sites for the target compound to be separated than the cross-linked chitosan membrane, the former membrane is better than the latter membranes reported earlier (29).

Due to high permeability and good mechanical properties comparable to those of commercial cellulose acetate membranes, the membranes have potential application in pervaporation separation of aqueous organic mixtures (30). The pervaporation properties of isopropanol–water mixture via a chitosan–silk fibroin complex membrane are shown in Fig. 8. The data imply that the flux through the complex membrane expresses ion (Al^{3+}) sensitivity, so the pervaporative flux of the isopropanol–water mixture can be modulated; the high selectivity was maintained by optimizing the AlCl_3 concentrations in the feed (31).

A benzoylchitosan membrane was designed for separating a benzene/cyclohexane mixture, which is very important in the petrochemical industry. The benzene permeation selectivity of the membrane is attributed to the smaller molecular size and higher affinity of the benzene molecules compared to those of cyclohexane (32).

Anionic surfactants for example, sodium lauryl ether sulfate (SLES), can form complexes with the chitosan chain through interaction of their opposite ionic charges. The complexes can survive as a skin layer (ca. 15 μm) on a polyethersulfone ultrafiltration membrane. Here, the ionic property of the surfactant–chitosan complex membrane preferentially promotes the permeation of polar methanol

Figure 8. Separation properties of an isopropanol–water mixture through a chitosan–silk fibroin complex membrane by pervaporation [silk fibroin content in membrane: 30% (w/w), isopropanol in feed: 85% (w/w), C_{AlCl_3} denotes the AlCl_3 concentration in the water part of isopropanol–water mixture].

through the membrane, compared with the less polar and relative bulky methyl-*t*-butylether (MTBE) (33).

A formed-in-place (FIP) membrane is dynamically created by depositing polymers on the surface or at the entrance of the pores of macroporous substrates. Chitosan FIP ultrafiltration membranes can be formed on a macroporous titanium dioxide substrate. The chitosan gel membrane formed on the substrate is cross-linked enough by a supramolecular interaction, for example, hydrogen bonding. The estimated mean pore size for the membrane near neutral conditions (pH 6.0 and 8.2) is about 17 nm, and for the membrane at pH 3.6, it is 55 nm. The contraction and swelling of the chitosan membrane are reversible. Therefore, it is possible to control the pore size of the membrane by simply adjusting the pH of the system according to the separation requirement (34).

Smart polymers are the basis for a new protein isolation technique—affinity precipitation. The precipitation applies a ligand coupled to a water-soluble polymer known as an affinity macroligand, which forms a complex with the target. The phase separation of the complex, triggered by small changes in the environment, for example, pH, temperature, ionic strength, or addition of reagents, makes the polymer backbone insoluble; afterward, the target protein can be recovered via elution or dissolution. Chitosan itself has been successfully used as a macroligand for affinity precipitation of isolated wheat germ agglutinin from its extract and glycosides from cellulose preparation by changes in the pH of the media (35).

A partially sulfonated poly(ether sulfone) microporous hollow fiber membrane was coated with chitosan by electrostatic attraction. After cross-linking by reacting the fiber with ethylene glycol diglycidyl ether (EGDGE), the hydroxyl and amino glucose units of chitosan are then modified to bind recombinant protein A (rPrA) as an affinity ligand at 4.77–6.43 mg rPrA/mL fiber. The immobilized rPrA hollow fiber membrane serves as a support for affinity separation of immunoglobulin (IgG) (36).

Immobilization Supports

Immobilization is an effective measure for using enzymes or microbial cells as recoverable, stable, and specific industrial biocatalysts. Immobilization must be carried out under mild conditions.

An ideal support for enzyme immobilization should be chosen to achieve essential properties such as chemical stability, hydrophilicity, rigidity, mechanical stability, larger surface area, and microbial attack resistance. Several methods are used to modify the supports to improve stability and mechanical strength, and to modify different functional groups that may be superior for enzyme immobilization. One of the ways to improve these properties is grafting of monomers onto the matrix. The graft polymeric support, for example, chitosan-poly(glycidyl methacrylate) (PGMA), is used for glucosidase to immobilize urease (37,38).

Immobilized urease can be used in biomedical applications for the removing urea from blood in artificial kidneys, blood detoxification, or in the dialysate regeneration system of artificial kidneys. In the food industry, it may be used to remove traces of urea from beverages and foods and in analytical applications as a urea sensor.

In addition to urease, other enzymes, for example, glutamate dehydrogenase, penicillin acylase, β -galactosidase, and glucosidase, have been immobilized via chitosan gels. Immobilization improves the stability of the enzymes.

Extracellular Matrixes For Tissue Engineering

Various synthetic and naturally derived hydrogels have recently been used as artificial extracellular matrixes (ECMs) for cell immobilization, cell transplantation, and tissue engineering. Native ECMs are complex chemically and physically cross-linked networks of proteins and glycosaminoglycans (GAGs). Artificial ECMs replace many functions of the native ECM, such as organizing cells into a 3-D architecture, providing mechanical integrity to new tissue, and providing a hydrated space for the diffusion of nutrients and metabolites to and from cells. Chitosan is similar to GAG. Therefore, it is promising for application as a biomaterial in addition to use as a controlled delivery matrix.

Chitosan is a basic polysaccharide, so it is possible to evaluate the percentage of amino functions, which remain charged at the pH of cell cultivation (7.2–7.4). These cationic charges have a definite influence on cell attachment by their possible interaction with negative charges located at the cell surface. Chitosan materials give the best results in cell attachment and cell proliferation for chondrocytes and keratinocytes of young rabbits compared with its polyelectrolyte complex with glycosaminoglycans, such as chondroitin 4 and/or 6 sulfate and hyaluronic acid (39).

Field Responsive Materials

Chitosan-based gels consist of a positive charged network and a fluid (e.g., water) that fills the interstitial space of the network. The gels exhibit a variety of unique field responsive behaviors, such as electromechanical phenomena.

Figure 9. The EMC behaviors of chitosan/PEG crosslinked with different concentrations of ECH.

Electromechanochemical (EMC) behavior deals with contraction of polymers in an electric field. The effects of an electric field on polyelectrolyte hydrogels relate to the protonation of its alkaline amino groups and redistribution of mobile counterions when chitosan/PEG composite fibers is cross-linked with epichlorohydrin (ECH) and glutaraldehyde (GA), respectively. The EMC behavior of fibers in a 0.1% aqueous HCl solution in a 25-V dc electric field is shown in Fig. 9.

The bending direction of the fiber specimen inverts at a critical concentration of the cross-linking agents. When the ECH concentration is more than 9.0×10^3 M or the GA concentration is larger than 5.64×10^4 M, the fiber specimens bend toward the cathode. If the ECH or GA concentration is less than the critical values, they bend toward the anode. The reason may be attributed to variation in the mobile ions within the network (40).

Thin films of chitosan and chitosan doped with rare-earth metal ions can be used as wave-guiding materials. They are transparent across the wavelength range of 300–3000 nm and exhibit low optical loss (less than 0.5 db/cm²) (41,42).

Chitosan/acetic anhydride and acrylate/chitosan hydrogels have an excellent laser-damage threshold (LDT) up to 35 times higher than commercial poly(methyl methacrylate) (PMMA) bulk materials, and their LDT increases as water content increases. As we know, absorbed laser energy can lead to rapid local heating of a laser “hot spot.” A hydrogel can be considered a composite of statistically distributed microchannels and/or fluctuating pores created by the movements of polymer segments within the network in the presence of water. When a hydrogel is irradiated, the energy generated by laser light can be absorbed and dispersed by the water and the polymer frame. These hydrogels have potential applications as new materials for high-power laser-damage usage (43).

INTRODUCTION

Many materials emit light during the application of a mechanical energy. This phenomenon is usually referred to as mechanoluminescence (ML) or triboluminescence (1). The more historical term is “triboluminescence.” It stands for tribo-induced luminescence, and this was the term used for more than a century to refer to light emission induced by any type of mechanical energy (2). The term “mechano-luminescence” was not proposed until 1978 (3). The prefix “mechano” is correlated to the general mechanical way used for exciting luminescence, including concepts such as deformation, piezo, tribo, stress, cutting, grinding, rubbing, and fracto. In recent years mechanoluminescence (ML) has become the preferred nomenclature (4). Although the transfer of mechanical stress into light radiation is very complex, successes in experimental applications suggest possible uses of the ML phenomena in stress sensors, mechanical displays, and various smart systems.

In general, ML can be divided into fractoluminescence (destructive ML) and deformation luminescence (nondestructive ML); these correspond to the luminescence induced by fracture and mechanical deformation of solid, respectively. Roughly 50% of solid materials gives fractoluminescence by fracture (5): the well-known materials include sugar (6), molecular crystals (7,8), alkali halides (9,10), quartz (11), silica glass (12–14), phosphors (15), piezoelectric complex (16), metals (17), various minerals (18,19), and biomaterials (20). Recently, the fractoluminescence of rare-earth complexes was investigated

in order to build smart damage sensors capable of simple real-time detection of the magnitude and location of structural damage within materials (21). Deformation luminescence can be induced by mechanical deformation without fracture, and this is of interest in nondestructive evaluation. Deformation luminescence can be further divided into plasticoluminescence and elasticoluminescence. The former is produced during plastic deformation of solids, where fracture is not required, and the later is produced during the elastic deformation of solids where neither plastic deformation nor fracture is required. Nondestructive ML due to plastic deformation has been observed in several materials such as colored alkali halides (22,23), II–VI semiconductors (24), and rubbers (25). However, ML in the elastic region has been observed only for the irradiated alkali halides (4,26), and some piezoelectric materials (27). So far nondestructive luminescence intensities of materials have been reported to be too weak and difficult to repeat, and this has deferred any practical application of the phenomenon. For application of ML in developing new materials, repetitive ML must occur with undiminished intensity.

Devices for ML Measurement

Both mechanical and optical devices are being used to measure ML. The objective is to apply the measured mechanical energy to the ML sample, and then to detect the light induced by the mechanical energy. The various techniques already investigated include compression, bending, stretching, loading, piston impact, needle impact, cleaving and cutting, laser, shaking, air-blast, scratching, grinding and milling, and tribo- and rubbing (4). Figure 1 gives popular measurement devices for nondestructive ML; these devices measure compression, tension, bending, and shearing. Figure 1(a) shows a schematic diagram of an ML measurement device capable of measuring ML strain-stress relations simultaneously. Stress is applied on each sample by a materials test machine. The ML intensity is measured by a photon-counting system that consists of a photo multiplier tube (R464S, Hamamatsu Photonics) and a photon counter (C5410-51, Hamamatsu Photonics) controlled by a computer. The ML emission light is guided to the photo multiplier through a quartz glass fiber. The ML spectrum is obtained with a photon multichannel analyzer system (PMA 100, Hamamatsu Photonics). The ML images are recorded with an image intensified charge coupled device (ICCD) controlled by a computer system (C6394, Hamamatsu Photonics Corp.). Simultaneously, the stress and strain of the sample are measured by an in-situ sensor. In addition to compressive test, the materials test machine shown in Fig. 1(a) is able to apply tensile and bending stresses by exchanging the sample holder.

Figure 1(b) shows a schematic diagram of an ML measurement device for applying friction (shear stress); the same equipment as shown in Fig. 1(a) is used to measure the ML intensity and spectrum. The mechanical friction is applied by a friction rod under a load. The friction rod material, as well as the load, can be changed for different levels of mechanical stress applied to the test material. As

Figure 1. Schematic diagram of ML measurement devices (a) using a materials test machine for the compressive test and (b) using a friction test machine for the friction (shear stress) test.

the test sample is rotated at a controlled speed, as shown in Fig. 1(b), the friction rod draws a concentric circle on the test material. The ML emission light induced by friction is guided to the PM through a quartz glass fiber that is 3-mm in diameter; the distance between the glass fiber and the friction tip is set at 40 mm. The mechanical impact is applied by using a free-falling ball through a steel guide pipe. The impact velocity is adjusted by the height of the falling ball, and the impact energy can also be adjusted by both the weight of the ball and the falling height.

NONDESTRUCTIVE ML FROM ALKALINE ALUMINATES DOPED WITH RARE-EARTH IONS

As previously mentioned, development of materials with strong nondestructive ML intensity is an important goal in exploring applications of ML. Recently, systematic materials research has resulted in producing a variety of materials that emit an intensive and repeatable ML during elastic deformation without destruction: among these are ZnS: Mn, $\text{MAl}_2\text{O}_4\cdot\text{Re}$ ($M = \text{alkaline metals}$, $\text{Re} = \text{rare-earth metals}$), and $\text{SrMgAl}_{10}\text{O}_{17}\cdot\text{Eu}$ (28–32). So far the most promising ML materials are the rare-earth ions doped alkaline aluminates and the transition metal ions doped zinc sulfide. Remarkable upgrading in ML intensity has been achieved in the SrAl_2O_4 doped with europium by controlling the lattice defects in the material.

Preparation of Fine Particles of ML Materials and Their Smart Coatings

The luminescence powders are normally produced by a solid reaction process using a flux. In the solid reaction process, the starting materials of ultrafine powder of SrCO_3 , Al_2O_3 , and $\text{Eu}(\text{NO}_3)_3\cdot 2\text{H}_2\text{O}$, H_3BO_3 (flux) are thoroughly mixed. The mixture is calcined at 900°C for 1 h and then sintered at 1300°C for 4 h in a reducing atmosphere ($\text{H}_2 + \text{N}_2$). However, this process has the limitation that small particles cannot be obtained because of the growth of grains that occurs during the calcinations at high temperatures. To address this problem, a modified sol-gel method has been developed for preparing fine powders of SAO-E (33). In this modified sol-gel process, the starting materials of $\text{Sr}(\text{NO}_3)_2$, $\text{Al}(\text{O}-i\text{-C}_3\text{H}_7)_3$, and $\text{Eu}(\text{NO}_3)_3\cdot 2\text{H}_2\text{O}$ are dissolved in H_2O and thoroughly mixed with $\text{NH}_3\cdot\text{H}_2\text{O}$. The sol solution is then dispersed by $\text{HCON}(\text{CH}_3)_2$, followed by drying, calcining, and finally sintering in a reducing atmosphere at 1300°C for 4 h. In comparison with SAO-E powders synthesized by the solid reaction process, finer particles are obtained by the modified sol-gel process, their mean size being about $1\ \mu\text{m}$; the particles obtained by the solid reaction process are about $15\ \mu\text{m}$. The finer particles exhibit high ML, and as a result smart coating can be applied in uniform layers on the surfaces of the target objects by mixing it with binders and polymers. For example, standard coating techniques such as spin coating and spray

Figure 2. Dependence of ML intensity on defect concentration of Sr.

coating could then be used to create uniform layers (films) of SAO-E/epoxy on the surfaces of plastics, rubbers, glass, ceramics, and metals. The thicknesses of the resultant coating could be controlled from micrometer to millimeter.

Smart coatings made by mixing SAO-E fine powder with an optical epoxy can transfer mechanical energy into the photo energy of light emission, which in turn is capable of sensing the dynamic stress of substrate materials. To obtain the ML intensity and stress distribution, the composite samples of the SAO-E/epoxy have been included in the ML measurement together with the coated samples and the ceramics of SAO-E.

ML Response of SAO-E to Various Stresses

In upgrading the ML intensity of SAO-E for the smart coating application, the composition, the PH value, and the calcination conditions must be controlled. Significant

improvements in ML intensity can be made by optimizing the concentration of defects in the SAO-E system. Figure 2 shows the relationship of ML intensity to the defect concentration of Sr. The ML intensity is seen to strongly correspond to the defect concentration of Sr. The highest ML intensity is obtained by $Sr_{0.975}Al_2O_{3.985}:Eu_{0.01}$ with a lattice defect of 1.5 at% Sr vacancy. Such a nonstoichiometry system is found to produce one order of magnitude higher ML than a stoichiometry system. This is four orders of magnitude higher in intensity than that of the reported strong ML material of a quartz crystal. The luminescence of the defect-controlled SAO-E material gives a high enough ML to monitor the stress of the object it coats.

The influences of the stress and strain rates on the emitted light intensity are measured using the same strain rate but at different peak stresses, and then the same peak stress but at different strain rates. Figure 3(a) shows a time history of a luminescent object recorded during the application of a compressive stress with a constant strain rate for a SAO-E/epoxy composite with a dimension of $55 \times 29 \times 25 \text{ mm}^3$. As can be seen, over time a linearly increased load system results in linearly increased ML intensity. That is, the ML intensity emitted is linearly proportional to the magnitude of the applied stress. Figure 3(b) shows the ML intensity diminished during repetitive cycles of loading. The ML intensity decreased with the repetitive cycles of stress, reaching a stable level at about 20% of its initial strength. The ML intensity of SAO-E recovered completely after UV irradiation (365 nm) using a handy lamp. Such recoverability distinguished SAO-E from other nondestructive ML materials reported, for example, alkali halides which need γ -ray irradiation or very high energy irradiation to recover their intensivity (34). The linear relationship between ML intensivity and stress has been further demonstrated by the tests in which each test had the same strain rate but a different peak stress, as shown in Fig. 4. The ML intensity increased linearly with the increase of strain rate. Such a linear relation was also reported for γ -ray irradiated single crystals of alkali halides during the elastic deformation (35). It is evident that the ML of SAO-E is an elasticoluminescence. In a comparison test, the defect controlled SAO-E was found to give the most intense elasticoluminescence among the materials examined to date (36).

SAO-E was found also to exhibit ML during plastic deformation and fracture. In the region of plastic

Figure 3. (a) Typical time history of the luminescence intensity recorded during a compressive test for a SAO-E/epoxy composite with a dimension of $55 \times 29 \times 25 \text{ mm}^3$, (b) Diminishment in ML peak intensity during application of repetitive cycles of loading and its recoverability with UV irradiation of 365 nm.

Figure 4. Influence of applied stress on ML intensity (strain rate is 3.0×10^{-4} 1/s).

deformation, ML became intensified because of the stress that was concentrated in this region. Upon further load increases the ML intensity exhibited a sharp rise as the SAO-E material began to crack, revealing the maximum value in ML intensity at fracture. Similar results were obtained for ceramic samples of SAO-E. The results for alkali halide crystals confirmed the presence of intense ML in plastic deformation and that it sharply increases during fracture of the crystals (4,5). Clearly, the linear relation between strain and stress is an important factor in the application of ML stress sensors.

Figure 5 shows the relationship between the strain rate and ML intensity. The relationship is almost linear, as a higher strain rate produces greater ML intensity.

Figure 5. Influence of the strain rate on the ML intensity.

Figure 6. Dependence of ML intensity on tensile stress for a SAO-E/epoxy composite sample with a dimension of $100 \times 25 \times 5$ mm³. The ML intensity induced by compressive stress is also plotted for comparison.

Expressed mathematically, the ML intensity in terms of the stress and strain rate is

$$I - I_0 = K\sigma(t)\dot{\epsilon}(t), \quad (1)$$

where σ is the stress and $\dot{\epsilon}$ is the strain rate. Equation (1) indicates that the linear intensity of ML is consistent with the concept of an elastic (linear) region.

The dependence of ML on tensile stress is shown in Fig. 6 for a SAO-E/epoxy composite sample with measurements of $100 \times 25 \times 5$ mm³. For comparison, the ML intensity induced by compressive stress is also plotted. Note that the SAO-E exhibits the same ML intensity whether or not the stress is compressive or tensile. Figure 7 shows the dependence of ML on torsion measured by a shearing test machine for a SAO-E composite sample with dimensions of $\phi 10$ mm \times 110 mm. Note that the ML intensity increases linearly with the increase of torsion. Clearly, the nondestructive ML of SAO-E can detect shear stress and torsion changes without any volume changes. This is very different from the thermography technique that can detect stress based on the thermo-elastic effect when stress is accompanied by a volume change.

As previously mentioned, SAO-E ceramics and composites exhibit distinct ML behavior. Smart coating with SAO-E/epoxy can be applied to objects to sense changes of stress. Figure 8 shows the dependence of ML intensity on the stress for a plastic coated with an SAO-E/epoxy layer. The results are similar to those of composites and ceramics. The ML intensity almost linearly increases with the

Figure 7. Dependence of ML intensity on torsion measured by a shear test machine for a SAO-E composite sample with dimensions of $\phi 10 \text{ mm} \times 110 \text{ mm}$.

increase of stress when the strain rate is kept constant. Additionally, the ML intensity increases with the increase of the thickness in the ML layer. A thick layer is generally not suitable for stress detection because it produces strain or stress in the ML layer that differs from that of the object beneath it. As these results indicate, a uniform layer is necessary for an accurate display of the stress distribution of the object.

Figure 8. Dependence of ML intensity on the stress for a plastic block coated with SAO-E/epoxy layers with different thickness.

Contrary to the behavior of the destructive ML (37,38), the width of the ML emission band at the peak wavelength is independent of the stress level during elastic deformation. However, the ML intensity at peak emission increases linearly with the increase of stress level. Furthermore, the integrated intensity under the band also increases linearly with stress. As noted earlier, the ML of SAO-E can be induced by compressive, tensile, or shear stress. Smart coating using ML materials provides a simple way to detect these stresses dynamically and remotely.

ML Mechanism of SAO-E

The ML spectrum is measured by a photon multichannel analyzer. The broadband emission peaks at a wavelength of about 520 nm, which is the same as the photoluminescence (PL) spectrum measured by a fluorescence spectrometer. As shown in Fig. 9, the PL and ML spectra from SAO-E are characterized by emissions that peak near 520 nm. No other emission bands are found in the ML spectrum at 300 to 700 nm. This implies that ML is emitted from the same emission center of Eu ions as PL; both are produced by the transition of Eu^{2+} ions between $4f^7$ and $4f^65d^1$ (39,40). Emissions due to N_2 discharge have not been observed, which generally occur in destructive ML (fractoluminescence) (41). These results confirm that the ML of SAO-E described here is produced by a nondestructive deformation of SAO-E. Moreover, the recovery of ML intensity by UV irradiation suggests that the traps in SAO-E sample can be filled by UV irradiation. Measurements of the Hall effect of UV-activated SAO-E reveal traps of holes filled by UV, and this is consistent with other reports (39,44). The depths of these hole traps can be evaluated by the Hoogenstraaten method (42). This technique calls first for thermoluminescence glow curves to be measured at different rates of heating (β) to obtain the glow peak temperature (T_m) for each heating rate β , and then for the depth of trap (E_t) to be

Figure 9. ML and photoluminescence (PL) spectra of SAO-E.

Figure 10. (a) Glow curves of thermoluminescence from SAO-E at different heating rate of 0.091, 0.187, and 0.259 K/s for A, B, and C, respectively; (b) resultant Hoogenstraate plot, where β is a heating rate and T_m is a glow peak temperature.

calculated from the slope of the Hoogenstraaten plots using the equation

$$E_t = \frac{-k \log_e(\beta/T_m^2)}{1/T_m}, \quad (2)$$

where k is the Boltzmann constant. Figure 10(a) and (b) shows the glow curves of SAO-E and the resultant Hoogenstraaten plots, respectively. Two glow peaks are found for SAO-E as shown in Fig. 10 (a), implying that there are different kinds of traps in the material. The depth of the trap associated with lower T_m is about 0.2 ± 0.1 eV, which is much higher than the thermal energy of 350 K (0.03 eV). Consequently these hole traps can not be thermally activated at room temperature. On the other hand, it is evident that traps at levels near 0.1 eV can be activated by deformation to release electrons to the conduction band in the case of KCl (41). The ML kinetic model for SAO-E proposed in Fig. 11 takes these results into account. During deformation the strain energy excites the filled traps (T^+) to release holes to the valence band (process 1). The holes then excite Eu^+ to produce Eu^{2+*} (process 2), and return to ground state by emitting a green light of about 520 nm (process 3).

The hole traps in the model are attributable to the lattice defects of Sr^{2+} (44), which can greatly affect the ML intensity as was indicated in Fig. 12. For this reason the SAO-E is classified as a defect-controlled ML material whose intensity is substantially altered by the existence of the trap (defect). The well-known alkali halides also belong to this outgoing. However, ZnS:Mn is a piezoelectric-induced material as will be described in the next section.

Figure 11. ML kinetic model for SAO-E.

REPEATABLE ML OF TRANSITION METAL IONS DOPED ZINC SULFIDE

As was previously noted, the nondestructive ML of SAO-E showed diminished intensity during the application of a repetitive stress cycle, similar to that of alkali halides (45). ZnS-doped Mn has been found to give undiminished ML intensity during the elastic deformation, so it is the representative material to achieve the most repetitive ML.

Preparation of Highly Oriented ZnS:Mn Films

Thin films can be prepared from a ZnS pellet on various substrate materials, including quartz glass, stainless, carbon, and ceramics (Al_2O_3 , SiC, Si_3N_4), by physical vapor depositions of the ion plating method (46). The substrates

Figure 12. (a) ML response of ZnS:Mn to a friction (shear stress); (b) dependence of ML intensity on the friction load.

are kept at 160°C, and the deposition is carried out in a vacuum of 0.2 Pa in Ar atmosphere. The source pellet is prepared from $\text{Zn}_{0.985}\text{Mn}_{0.015}\text{S}$ powder by a cold isotropic press method followed by sintering in a vacuum-sealed quartz glass tube at 1000°C for 10 h. Such a pretreatment is applied to fabricate highly crystallized pellets whose deposition rate is very stable and easily controlled. A vacuum-sealed technique is used because ZnS begins to sublime at temperatures above 700°C. The as-grown films are annealed at 500 to 1000°C for 1 h in a vacuum-sealed quartz glass tube. Their chemical composition is determined by fluorescent X-ray spectrometric analysis. The Mn amount in the film showed the same as that in the source material, namely 1.5 at%. The XRD pattern exhibited a strong diffraction peak at 28.49° in the 2θ range of 10 to 90°, which was attributed to the (111) plane of the ZnS film was highly oriented.

ML Characteristics of ZnS:Mn Films

The luminescence intensity depends on the microstructure of film. Post-heat treatment in vacuum is effective for obtaining high ML in that it increases the crystallinity of ZnS:Mn and decreases the defects and residual stress in the film. Moreover, the connection between the film and substrate is strengthened by annealing, even for film thicker than 1 μm , and thus prevents deprivation due to moisture or mechanical attack. The ML intensity is enhanced by two magnitudes in order after annealing at 700°C, and the mechanical strength of the ZnS:Mn film is also remarkably strengthened (46). Surface observation shows that the film consists of ZnS grains with a mean size of several nano-meters.

Figure 12(a) shows the ML response of ZnS:Mn to friction (shear stress) measured by the device shown in

Fig. 1(b). The ML intensity increases steeply when the friction on the ZnS:Mn film is turned on, and the frequency of the oscillating change equals the rotating speed of the test sample. This oscillating change is also found in the friction force by a strain gauge attached to the friction rod. The oscillation may be caused by nonuniformity of the test material, as is similarly the case in bulk ceramics (47). The response curve is reproducible, and this indicates that the film is combined strongly onto the substrate, as is confirmed by the SEM image and adhesive strength test. This reproducibility distinguishes the ML of ZnS:Mn from the other destructive ML. It has been found that ZnS:Mn shows a repetitive ML response not only to friction but also to other types of stresses such as compressive stress (30). These results are substantially different from the other elasticoluminescent materials reported so far like gamma colored alkali halide crystals and the SAO-E, where the intensity decreased in a great deal during the application of repetitive stress. Apparently the reproducibility is essentially important for self-diagnosis materials and applications in various novel smart systems including stress sensors.

The ML intensity of ZnS:Mn increases with increasing the mechanical stress. Figure 12(b) shows that the intensity increases linearly with the increasing applied load. Correspondingly, the mechanical friction can be monitored without any mechanical contacts. The linear relation between ML and stress of the ZnS:Mn has also been found in the case of compressive stress.

Figure 13 shows the ML response to a mechanical impact. Note that the ML response transits of ZnS:Mn are similar to those of piezoelectric voltage responses, as reported previously (48). The energy conversion efficiency for converting mechanical energy to photon energy, roughly estimated from the experimental data, is on the order of

Figure 13. (a) ML response to a mechanical impact; (b) dependence of ML on the falling height.

10^{-2} and 10^{-6} for a slowly applied stress and impact cases, respectively; this is also on the same order as was reported previously for the piezoelectrics. The ML intensity increases linearly with the increase of the falling height of the free ball; that is, ML intensity increases with the increasing impact energy. Correspondingly, the mechanical impact can be remotely monitored using an ML film. More important, the ML intensity emitted by such a high-oriented films is much higher than that of the bulk material by more than one magnitude. The significant improvement in the ML intensity is attributed to the high orientation of the created film and the nano-sized grains of which it is composed.

Mechanism of ZnS:Mn

ZnS is both a piezoelectric and electroluminescent material. Figure 14 gives the spectrum of the ML for ZnS:Mn thin films, along with the photoluminescence (PL) and electroluminescence (EL). The ML exhibits a maximum emission band at 585 nm, which is consistent with the spectra for PL and EL of ZnS:Mn. No additional emissions due to the discharge of N_2 are found in the ML spectrum of ZnS:Mn. This indicates that the ML is introduced by stress and the emission arises from the emitting center of Mn^{2+} ions, due to the transition of ${}^4T_1 \rightarrow {}^6A_1$. The stress-activated mechanism is supported by other experiments; for example, when covering the ZnS:Mn film with a transparent film of AlN, similar emission is seen. Figure 15 shows the ML and PL intensities for ZnS:Mn films deposited on various substrates. It is seen that the ML intensities for conductor substrates like stainless and carbon are much lower than those for dielectric substrates such as quartz, alumina, silicon nitride, and silicon carbide. When

a shear stress is applied on the ZnS:Mn film, a piezoelectric voltage based on the piezoelectric coefficient of d_{14} will be generated between the opposite sides of the thin film surfaces. If the film is deposited on a conducting substrate, then electrical leakage may occur. The presence of such leakage is indicated by low ML intensity for ZnS:Mn on steel and carbon substrates as shown in Fig. 15.

Figure 14. Spectrum of the ML for ZnS:Mn thin films, along with the photoluminescence (PL) and electroluminescence (EL) spectra.

Figure 15. ML and PL intensities for ZnS:Mn films coated on various substrates.

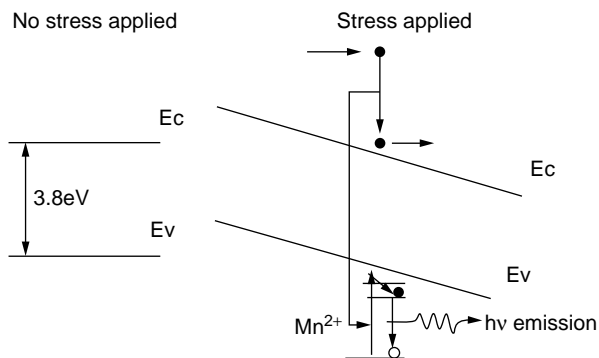

Figure 16. ML model of ZnS:Mn film, where the ML of ZnS:Mn is proposed to be based on the superposition of piezoelectric effect and electroluminescence.

Taking these results into account, the ML phenomenon of ZnS:Mn can be interpreted by a piezoelectric-induced electroluminescence model as shown in Fig. 16. In the figure the ML of ZnS:Mn is considered to be the superposition of piezoelectric effect and electroluminescence, and this can also be considered as the inverse effect of photostriction (49). The proposed ML model can well explain the distinguished behavior of ML. It is evident that the high orientation and crystallinity of the ZnS:Mn film give higher piezoelectric performance. The higher piezoelectric voltage produced on the opposite sides of the nano-sized grains of ZnS leads to a higher intensity of electroluminescence. Meanwhile, the EL efficiency is also improved with the increase in crystallinity (50–52). Therefore the total effect is higher ML intensity. The repeatable ML with an undiminished intensity of ZnS:Mn is attributed to the reproducibility of the piezoelectric effect.

APPLICATION OF SMART COATING WITH ML MATERIALS FOR NOVEL STRESS DISPLAY

Since ML intensity increases linearly with the increase of stress and strain rate in the elastic region, the ML layer is

believed to be able to display a stress distribution of any object that it covers.

Stress distribution is measured in solids to improve their reliability and extend their applications. The distribution of stress in a solid is conventionally evaluated using several techniques (53,54). Electric resistance strain gauges and piezoelectric sensors are typical techniques using electrical signals. The limitation to these methods becomes evident in analyzing the distribution on the micro scale because of their size. The sensors must maintain electrical contact to the target objects, so it is difficult to measure the stress distribution of a dynamic moving part such as cutting tool or gas turbine. Remote detection has permitted the use of optical signals in experimental stress analyses utilizing photoelastic and photoplastic effects, X-ray diffraction, optical fiber networks embedded in composites, and thermography based on thermoelastic analysis, for example. However, until recently there were no simple techniques for the direct visualization of the stress distribution in real time. Current studies to solve this problem have focused on building self-diagnosis systems using smart coatings of piezoelectric (55–57) and the ML materials (30,58,59).

Visualizing Stress Distribution

To view the stress distribution of an object, a smart coating of ML material is applied on the surface of the object. The ML images are recorded during the application of stress on the ML-layer/object. Figure 17 shows an example of a plastic disk coated with a SAO-E/epoxy film (50 μm). The intense green light emitted into the atmosphere from the two ends of the stressed sample can be clearly observed by the naked eye. Also various stress images can be simulated using the finite element method (60). It has been found that the strain energy distribution is in agreement with the ML image, as compared in Fig. 17(b) and (c). This is supported by the argument in the previous sections. In addition, since the strain rate is a constant in the measurement, this ML image is consistent with the stress distribution. Figure 18 illustrates the stressed sample and the line distribution of ML intensity and stress along CC' axis. The ML intensity distribution along $CO C'$, which was obtained experimentally by the ICCD camera, is given by a solid line, and the stress distribution of the sample, which was simulated theoretically based on elastics (61), is shown by a dotted line. As compared in Fig. 18(b), the simulated compressive stress along $CO C'$ increases exponentially with the increasing of r/R . This is consistent with the line profile of the ML image, indicating that the ML image reflects well the stress distribution (stress image) under the experimental conditions. Therefore, smart coating with ML materials can directly display the stress distribution of the object beneath the layer.

Monitoring in Dynamic Stress and Impact

Dynamic ML images have been successfully recorded during the application of different stresses, including bending, tension, compression, and impact (62). The ML images

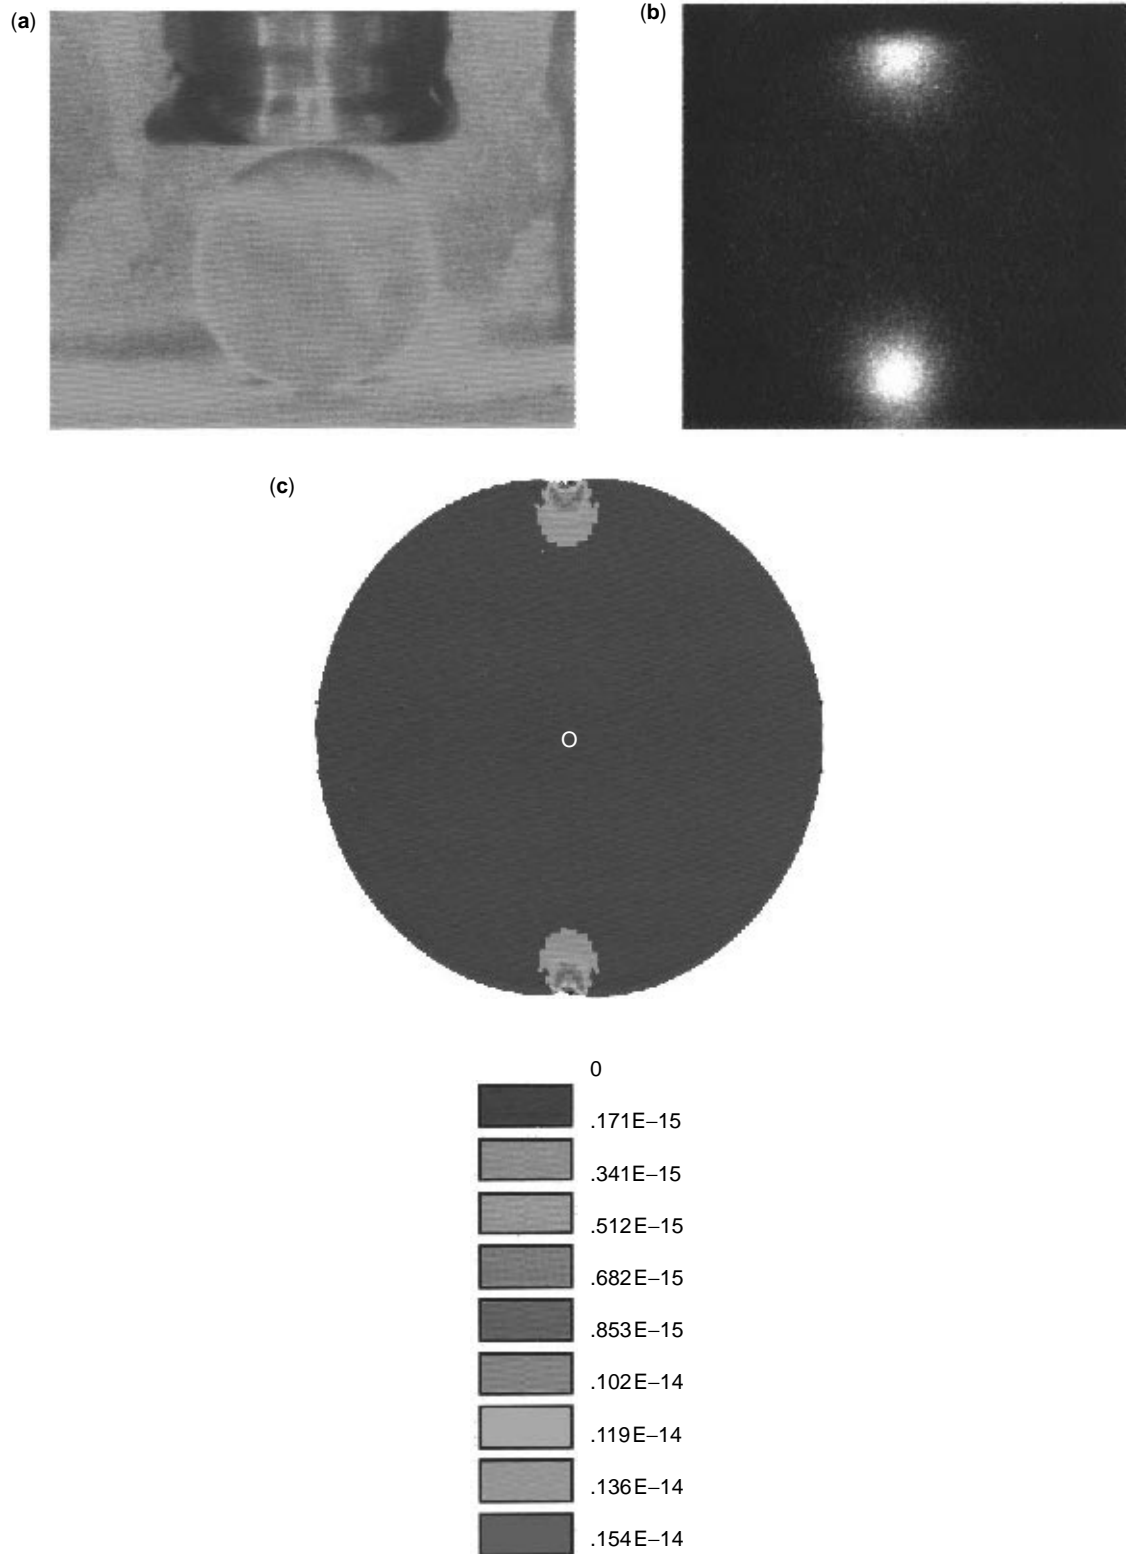

Figure 17. Stress distribution images for plastic disc ($\phi 25 \text{ mm} \times 10 \text{ t mm}$) coated with SAO-E/epoxy layer under compressive test: Stressed sample (a); ML image at a load of 500 N (b); simulated image of strain energy distribution using the finite element method (c).

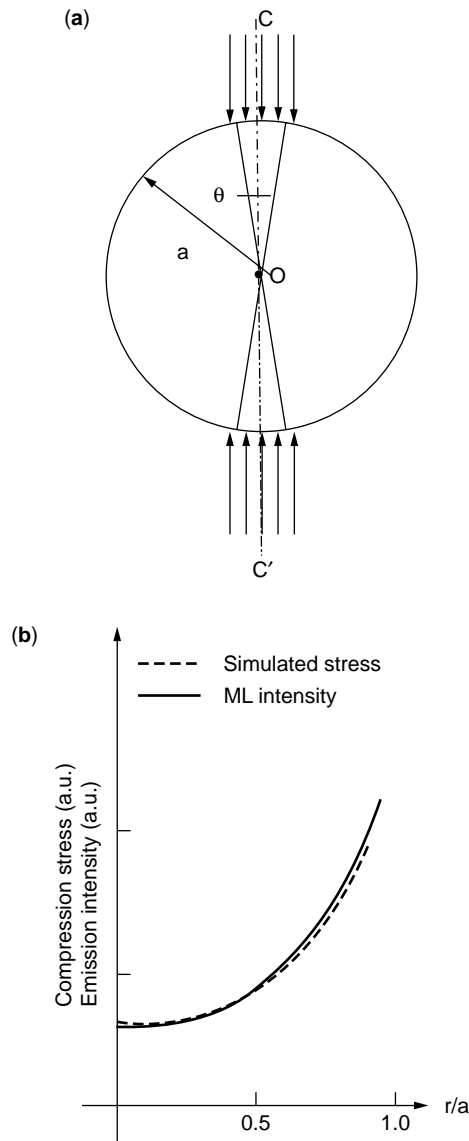

Figure 18. Stressed sample (a) and the line distribution profiles of ML intensity and stress along CC' axis (b).

dynamically changed with the loading, and were found to be in good agreement with the stress concentration results obtained by computer simulation and other experimental stress analyses. This imaging method gives the dynamic stress distribution in real time. It is distinguished from thermography, which requires repetitive cycles of stresses and thus is limited in evaluating stress during the fatigue process. Moreover, the present ML images are strong enough to be seen by the naked eye in a darkened room.

Photographs in Fig. 19(a) and (b) show the dynamic visualization of impact and friction, respectively, for a quartz substrate coated with the (111)-plane-oriented ZnS:Mn film. After applying mechanical impact caused by a free-falling ball, the yellow emission shown in Fig. 19(a) was recorded. Mechanical friction caused the strong ML

Figure 19. Photographs of the dynamic visualization of impact (a) and friction (b) for a quartz substrate coated with the (111)-plane-oriented ZnS:Mn film.

recorded in real time. The ML emission from the ZnS:Mn film was strong enough to be clearly seen by the naked eye.

The same method can be applied in an aqueous environment. Real-time ML images of stress distributions were obtained in water, ethanol, acetone, and 0.1 M HCl, for example, although the ML intensity values were dependent on the environment due to the different refraction and adsorption values. These results show the practicability of the present method in environment uses.

In particular, the ML smart coating technique holds much promise for observing the stress distribution with high spatial resolution using ML materials with nanoscale particles and the optical microscopy with high resolution. Although more experiments are needed, in the near future stress distributions in a scale smaller than micrometers should become observable as image techniques are combined with microscopy. Already the smart coating technique has enabled us to view stress distributions on both macro and micro scales.

The application of smart coating with an ML layer to analyze dynamic stress not only provides a new method for nondestructive evaluation of materials. In addition to the mechanical display, ML smart coating has opened a window on developing new smart systems and optomechanical devices.

COLOSSAL MAGNETORESISTIVE MATERIALS

A. MAIGNAN

Laboratoire CRISMAT, ISMRA
CAEN Cedex, FRANCE

INTRODUCTION

Magnetoresistance (MR) is defined as the relative change in the electrical resistivity of a material upon the application of a magnetic field and is generally given by $\%MR = 100 \times [(\rho(H) - \rho(0))/\rho(0)]$, where $\rho(H)$ and $\rho(0)$ are the resistivities at a given temperature in and in the absence of a magnetic field, respectively. MR is positive for most nonmagnetic metals, and its magnitude is limited to a few percent, whereas MR can be negative in magnetic materials because the magnetic field tends to reduce the spin disorder. For instance, the $\%MR$ of Co and Fe is $\sim -15\%$.

MR is of considerable technological interest. IBM is using the Permalloy (composition: 80% Ni and 20% Fe) MR of about 3% in a small magnetic field at room temperature for the magnetic storage of information. More recently, larger magnetoresistance also called giant MR (GMR) was observed in thin films of magnetic superlattices (for instance, Fe, Cr) for which metallic layers of a ferromagnet and a nonmagnetic material (or an antiferromagnet) are alternately deposited on a substrate (1,2). By doing so, the MR magnitude is increased by an order of magnitude. Small ferromagnetic particles deposited on a paramagnetic thin film also provide an alternative way to obtain GMR devices (3). For both material classes, small magnetic field applications (a few oersteds) are sufficient to align the magnetizations ferromagnetically and thus to induce a resistivity decrease originating in decreased scattering.

In hole-doped perovskite manganites $\text{Ln}_{1-x}\text{AE}_x\text{MnO}_3$ where $x \sim 0.3$, magnetoresistance values of $\sim -100\%$ in large magnetic fields (several teslas) have been discovered. These effects are called CMR to distinguish them from GMR (4–11). CMR has motivated a large number of experimental studies of these oxides in bulk (ceramics and crystals) and in thin films and also of theoretical work to understand the origin of the phenomenon. In the 1950s, the double-exchange model (DE) was proposed to explain the simultaneous appearance of ferromagnetism and metallicity when $\text{Mn}^{3+}/\text{Mn}^{4+}$ valency is created in $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ (12–14). However, after the CMR discovery, several theoretical studies have shown that double exchange alone cannot explain the magnitude of the resistivity drop upon the application of a magnetic field (15). The distorted Jahn–Teller Mn^{3+}O_6 octahedron introduces an interaction between the charge carriers and the crystal lattice so that the bound-state charge and a lattice called a “polaron” has been proposed and experimentally evidenced (15–19). Consequently, the Jahn–Teller distortion, static or dynamic, must be incorporated in any model, built to describe CMR. This time-dependent increasing complexity has been more recently confirmed by the relevancy of the phase-separation scenario for manganese oxides (20–25). Roughly, recent computational studies in which extended coulombic interactions are included have revealed

that, as the $\text{Mn}^{3+}/\text{Mn}^{4+}$ mixed valency is created by varying x in $\text{Ln}_{1-x}\text{AE}_x\text{MnO}_3$, the transition from the antiferromagnetic insulating state for $x = 0$ toward ferromagnetism for hole-doped compositions, where $x \gg 0$, does not occur via intermediate phases (canted phases) but rather through a mixed-phase process (20). An inhomogeneous electronic state should be stabilized, and several experimental studies have confirmed this phase-separation scenario (21–25). Consequently, the large dropping resistivity at the origin of the qualifying “colossal” magnetoresistance is interpreted in a percolation framework: a magnetic field increases the ferromagnetic metallic regions at the expense of the insulating antiferromagnetic areas, so that the macroscopic insulating state becomes metallic beyond the percolation threshold (26).

In this article, several representative examples of perovskite manganites are given to illustrate the richness of their phase diagrams. More particularly, the chemical key factor governing the CMR of hole-doped manganites that contain 30% Mn^{4+} and have the $\text{Ln}_{0.7}\text{AE}_{0.3}\text{MnO}_3$ formula are reviewed. The existence of $\text{Mn}^{3+}/\text{Mn}^{4+}$ charge ordering in the Mn lattice for half-doped manganites ($\text{Mn}^{3+}:\text{Mn}^{4+} = 50:50$, i. e., $x = 0.5$) and also for Mn^{4+} -rich compositions (electron-doped, $x > 0.5$) are discussed. Finally, the possibility of obtaining CMR properties in Mn^{4+} -rich manganites is shown.

CMR IN HOLE-DOPED $\text{Ln}_{0.7}\text{AE}_{0.3}\text{MnO}_3$ PEROVSKITES

Among the first compositions that were investigated, those where $x = 0.3$ in $\text{Ln}_{1-x}\text{AE}_x\text{MnO}_3$, have the best CMR properties (4–10). This is the case for $\text{Ln} = \text{Pr}^{3+}$ and $\text{AE} = \text{Ca}^{2+}/\text{Sr}^{2+}$ that have the formula $\text{Pr}_{0.7}\text{Ca}_{0.3-x}\text{Sr}_x\text{MnO}_3$ (27,28). Some of the latter compositions show resistivity (ρ) drops in a magnetic field ($\mu_0 H = 5\text{T}$) when the ratio $\rho(0)/\rho(5\text{T})$ is from 10^4 to 10^{11} , as shown in Fig. 1 for $\text{Pr}_{0.7}\text{Ca}_{0.25}\text{Sr}_{0.05}\text{MnO}_3$ ($x = 0.05$) and $\text{Pr}_{0.7}\text{Ca}_{0.26}\text{Sr}_{0.04}\text{MnO}_3$ ($x = 0.04$), respectively. By cooling the $x = 0.05$ sample from 300 K to 5 K in the absence of a field, the activated character of ρ observed till 90 K evolves to a metallic character below that temperature; ρ decreases by about four orders of magnitude at 20 K (Fig. 1a). Then, by registering the ρ data using the same process but in a 5-T magnetic field applied at 300 K before cooling, one can clearly see in Fig. 1a the dramatic ρ decrease induced by the field in the temperature vicinity of the insulator–metal (I–M) transition. Five orders of magnitude are obtained from the isothermal $\rho(0)/\rho(5\text{T})$ at 88 K and consequently, the magnetoresistance $\%MR = 100 \times [(\rho(H) - \rho(0))]$, reaches -100% , demonstrating the “colossal” character of this negative magnetoresistance. Furthermore, a composition shift of only 0.01 Ca for Sr (from $x = 0.05$ to $x = 0.04$) prevents the I–M transition (Fig. 1b), and high resistivities are measured at the lowest measurable temperature of ~ 30 K. Again, the field application seems to quench a quasi-T independent metallic state and the $\rho(0)/\rho(5\text{T})$ ratio reaches $\sim 10^{12}$. This behavior has also been confirmed by measuring isothermal field dependent $\rho(H)$ curves ($T = 50$ K, Fig. 2). At 50 K, the curve shows that a ρ drop of 10^7 is reached beyond the critical field of 0.6T.

Figure 1. T dependence of the resistivity ρ upon cooling in (5 T) and in the absence (0 T) of a magnetic field for (a) $\text{Pr}_{0.7}\text{Ca}_{0.25}\text{Sr}_{0.05}\text{MnO}_3$ and (b) $\text{Pr}_{0.7}\text{Ca}_{0.26}\text{Sr}_{0.04}\text{MnO}_3$.

These CMR properties are connected with the magnetic properties that show the great interplay between the carriers and the spins. Clear transitions from paramagnetic (PM) to ferromagnetic (FM) are observed from the T -dependent magnetization (M) curves of the $x = 0.05$ and $x = 0.04$ compositions (Fig. 3). The corresponding Curie temperatures (T_C) taken at the inflection point of the transition coincide with the I–M transition temperatures. Thus, for $\text{Pr}_{0.7}\text{Ca}_{0.25}\text{Sr}_{0.05}\text{MnO}_3$, the metallicity appears as the sample becomes ferromagnetic. For the other composition, $\text{Pr}_{0.7}\text{Ca}_{0.26}\text{Sr}_{0.04}\text{MnO}_3$, the $\rho(T)$ curve (Fig. 1b) does not show an I–M transition in the absence of a magnetic field, although this ceramic exhibits a ferromagnetic state (Fig. 3). However, the $M(T)$ curve has been obtained by measuring in an applied field of 1.45 T and a $\rho(T)$ curve registered in the same field shows the I–M transition.

This first set of data allows two important conclusions: high magnetic values are required to obtain CMR effects,

and small chemical changes are responsible for dramatic modifications in physical properties.

ORIGIN OF THE CMR EFFECT: MANGANESE MIXED VALENCY AND DOUBLE EXCHANGE

Manganese oxides $\text{Ln}_{1-x}\text{AE}_x\text{MnO}_3$ crystallize in a perovskite structure (Fig. 4), but their structures differ from that of the ideal cubic perovskite ABO_3 (29,30). The structure can be described as a tridimensional network of MnO_6 octahedra linked by their apexes, so that cages are formed and are filled by the Ln^{3+} and AE^{2+} cations (A site of the perovskite). The distortion of the structure in manganites is a consequence of the small size of the A-site cations

Figure 2. Field-dependent ρ curve for $\text{Pr}_{0.7}\text{Ca}_{0.26}\text{Sr}_{0.04}\text{MnO}_3$.

Figure 3. T -dependent magnetization curves found upon warming in 1.45 T after a zero-field-cooling process (ZFC) for $\text{Pr}_{0.7}\text{Ca}_{0.26}\text{Sr}_{0.04}\text{MnO}_3$ ($\text{Ca}_{0.26}$) and $\text{Pr}_{0.7}\text{Ca}_{0.25}\text{Sr}_{0.05}\text{MnO}_3$ ($\text{Ca}_{0.25}$).

Figure 4. Idealized structure of a $\text{Ln}_{1-x}\text{A}_x\text{MnO}_3$ distorted perovskite.

which gives rise to the tilting of the MnO_6 octahedra. This distortion is quantified by the Goldsmith tolerance factor $t = d_{\text{A-O}}/[\sqrt{2}(d_{\text{Mn-O}})]$, where $d_{\text{A-O}}$ and $d_{\text{Mn-O}}$ are the A cation–oxygen and Mn–oxygen bond lengths, respectively. Usually, for manganites t is ~ 1 or $t < 1$ and, consequently, because the tilting mode depends on t , several kinds of crystallographic space groups can be evidenced as the A-site average cationic size $\langle r_{\text{A}} \rangle$ changes or as the manganese valency (which controls the Mn–O distance) varies.

To understand ferromagnetic metallic properties (31), the electronic configurations of the Mn^{3+} ($3d^4$) and Mn^{4+} ($3d^3$) magnetic species must be considered. Full rotational invariance is broken in the octahedral environment, and this creates the splitting of 3d orbitals in two e_g and three t_{2g} . Due to the strong Hund coupling (J_{H}) for this system, the spins are aligned in the 3d shell (high-spin configuration): three localized electrons populate the t_{2g} orbitals (t_{2g}^3), whereas one electron (e_{g1}) or no electron (e_{g0}) populates the e_g orbital for Mn^{3+} and Mn^{4+} , respectively. Moreover, the e_g filling for Mn^{3+} creates a Jahn–Teller distortion that degenerates the e_g orbitals in two levels, d_{z^2} and $d_{x^2-y^2}$; only the former is occupied (Fig. 5). The e_g electrons of Mn^{3+} are mobile and they use the bridging orbitals of the oxygens to reach an empty e_g orbital of a Mn^{4+} nearest neighbor. This leads to the double-exchange model proposed by Zener (12): the e_g electron delocalization between nearest neighbor manganese ions that have t_{2g} parallel spins (Fig. 6) allows paying the energy J_{H} and gains some kinetic energy for the mobile carriers by minimizing

Figure 5. Electronic configuration of Mn^{4+} ($3d^3$) and Mn^{3+} ($3d^4$) cations.

Figure 6. Double-exchange mechanism according to Zener.

the hole–spin scattering. Consequently, the FM droplets around the holes start to overlap as holes (Mn^{4+}) are injected in the Mn^{3+} matrix, and a fully FM metallic state can be reached.

From this model, one can understand that the CMR effect in the T_{C} vicinity results from the field-induced ferromagnetic alignment, which creates delocalization and thus the resistivity decrease. But, several experimental results exist, for instance, coexistence of FM and charge ordering (21–26) that have suggested that more complex ideas are needed to explain CMR properties. At present, the phase-separation scenario (20) seems to be relevant for manganese oxides. Several examples that support this model are described in the following.

CHEMICAL FACTORS GOVERNING CMR PROPERTIES

Two important factors have to be considered to control the magnetism in these systems: the hole concentration and the overlap of the Mn and O orbitals (11,32,33). The first corresponds to the content of Mn^{4+} in the Mn^{3+} matrix and can be tuned by varying the A-site cationic $\text{Ln}^{3+}/\text{AE}^{2+}$ ratio. The best concentration for obtaining the highest T_{C} corresponds to about 30–40% Mn^{4+} ; far below this content, the FM regions do not percolate (FM insulating “FMI” state), and beyond, other complications arise from the closeness to the “half-doped” $\text{Ln}_{0.5}\text{AE}_{0.5}\text{MnO}_3$ compositions that are highly favorable for antiferromagnetism (AFM). This is clearly seen in Fig. 7 where the $\text{Pr}_{1-x}\text{Sr}_x\text{MnO}_3$ phase diagram (34) is given; if one concentrates on the hole region ($x < 0.5$), a clear T_{C} optimum of ~ 280 K is

Figure 7. Magnetic and electronic phase diagram of $\text{Pr}_{1-x}\text{Sr}_x\text{MnO}_3$ that shows the great complexity of these systems as the Mn valency varies. The magnetic transition temperatures Néel (T_N) and Curie (T_C) are symbolized by black triangles and circles, respectively. The gray curve (gray circles) corresponds to the magnetization values at 4.2 K in 1.45 T (ZFC). The highest T_C of 280 K is reached for $\text{Pr}_{0.6}\text{Sr}_{0.4}\text{MnO}_3$ ($x = 0.4$).

observed for $x \sim 0.4$. For the same Mn valency, the T_C maximum of $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ reaches 370 K (35), and the T_C of $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$ is 280 K (36).

The overlap of the 3d orbitals of the Mn species and of the oxygen p orbitals are controlled by varying the Mn–O–Mn angle, which can be done by changing $\langle r_A \rangle$. The effect of $\langle r_A \rangle$ on CMR properties was shown simultaneously by several groups (11,32,33). If we return to the $\text{Pr}_{0.7}\text{Ca}_{0.3-x}\text{Sr}_x\text{MnO}_3$ series and more especially to the $\rho(T)$ and $M(T)$ curves where x varies by 0.01 increments from 0.04 to 0.10 (Fig. 8), the following remarks can be made: (1) the resistivity drop at the I–M transition $\rho_{T_{I-M}}/\rho_{5\text{K}}$ increases as the strontium content decreases, from 170 for

$x = 0.10$ up to 3×10^5 for $x = 0.05$ (Fig. 8a); (2) both T_{I-M} and the Curie temperature T_C (Fig. 8b) increase as x increases. These are very important results because they demonstrate that the physical properties are highly sensitive to $\langle r_A \rangle$. The ionic radius of Sr^{2+} is larger than that of Ca^{2+} [1.31 Å versus 1.18 Å (37)], and thus as x increases, $\langle r_A \rangle$ increases; the Mn–O–Mn angle increases as x increases so that the bandwidth (W) increases. Consequently, T_C increases as $\langle r_A \rangle$ increases. The largest T_C of ~ 370 K is thus observed for the larger $\langle r_A \rangle$ such as for $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ (35).

Finally, a third important parameter exists that governs the T_C of these perovskites: the local disorder tends to weaken the DE process. Particularly, the same $\langle r_A \rangle$

Figure 8. (a) $\rho(T)$ and (b) $M(T)$ curves of $\text{Pr}_{0.7}\text{Ca}_{0.3-x}\text{Sr}_x\text{MnO}_3$. x values are labeled on the graphs.

Figure 9. T dependence of the real part of the AC susceptibility (χ') for several $\text{Th}_{0.35}\text{Ae}_{0.65}\text{MnO}_3$ samples characterized by a fixed $\langle r_A \rangle = 1.255 \text{ \AA}$ value but varying A-site mismatch (σ^2). The σ^2 values $\times 10^4$ in nm^2 are indicated on the graph. (a) $\sigma^2 = 1.96, 2.00,$ and 2.12 ; (b) $\sigma^2 = 2.20, 2.30, 2.47,$ and 2.80 .

value can be obtained by using different sets of cations: as shown by Rodriguez-Martinez and Attfield (38), both $\text{La}_{0.7}\text{Ca}_{0.11}\text{Sr}_{0.19}\text{MnO}_3$ and $\text{Sm}_{0.7}\text{Ba}_{0.3}\text{MnO}_3$ are characterized by the same $\langle r_A \rangle = 1.23 \text{ \AA}$ value, but their T_C s differ strongly, 360 K and 60 K for the former and the latter, respectively. This difference was ascribed to the size mismatch of the A site represented by the variance σ^2 , defined by $\sigma^2 = \sum y_i r_i^2 - \langle r_i \rangle^2$, where y_i and r_i are the fractional occupancies and the ionic radii of the i cations. As σ^2 increases, local distortions are generated that reduce T_C . This can be inferred from the results obtained for the highly mismatched $\text{Th}_{0.35}^{4+}\text{AE}_{0.65}^{2+}\text{MnO}_3$ samples (AE = Ba, Sr, Ca) which are characterized by $\langle r_A \rangle = 1.255 \text{ \AA}$, that is, large enough to attain a ferromagnetic state at a sufficiently small σ^2 and for which the mismatch can be varied across a wide range (39). Starting from a FMM sample

where $\sigma^2 = 1.96 \cdot 10^{-4} \text{ nm}^2$, the ferromagnetism can be reduced by increasing the A-site cationic size mismatch, as shown in Fig. 9 from the T -dependent AC-susceptibility [$\chi'(T)$] curves (Fig. 9a,b) and corresponding $\rho(T)$ curves (Fig. 10). Furthermore, for the highest mismatch values, the $\chi'(T)$ curves exhibit a cusp shape characteristic of spin-glass (Fig. 9b), and the $\rho(T)$ curves show insulating behavior (Fig. 10). Clearly, the A-site disorder is an important parameter that strongly affects the FMM state of perovskite manganites and can be controlled to induce a change from FMM samples to spin-glass insulators (SGI), as shown in the electronic and magnetic diagram proposed in Fig. 11.

Circles and squares are for the T_C (Curie) and T_g (glass) characteristic temperatures as a function of the mismatch (σ^2). The dotted line is the boundary between the FMM and SGI regions.

Figure 12. (a) 92-K electron diffraction pattern obtained by a transmission electron microscope for $\text{Sm}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$. The doubling of the a cell parameter observed at 92 K (extra peak indicated by the arrow) is induced by $\text{Mn}^{3+}/\text{Mn}^{4+}$ orbital ordering. (b) Corresponding lattice image that shows the alternation of Mn^{3+} and Mn^{4+} stripes.

CHARGE ORDERING IN PEROVSKITE MANGANITES

Charge carriers doped into antiferromagnetic insulators as in La_2NiO_4 and La_2CuO_4 tend to be arranged in stripes for favorable doping levels. An electronic phase separation is created by stripes of holes interspaced by antiferromagnetic electron-rich regions (40). A different kind of electronic phase separation also occurs in half-doped $\text{Ln}_{0.5}\text{AE}_{0.5}\text{MnO}_3$ manganites, where the e_g carriers $e_{g^0} - e_{g^1}$ are delocalized in the paramagnetic state but localized in alternating Mn^{4+} and Mn^{3+} planes below the characteristic charge-ordering temperature T_{CO} . This model was first proposed by J. B. Goodenough (41) after the pioneering work by Wollan and Koehler on $\text{La}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ (42). This charge-ordering phenomenon has been proved more recently by the electron diffraction patterns and lattice images collected below T_{CO} by transmission electron microscopy of several $\text{Ln}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ manganites (43,44). One typical pattern and corresponding lattice image are given in Fig. 12. On the one hand, additional peaks (indicated by an arrow), corresponding to the doubling of the a parameter (where $a \sim 5.5 \text{ \AA}$ in the primitive cell) as a $\text{Sm}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ sample is cooled down below T_{CO} , are observed in the diffraction pattern (Fig. 12a). On the other hand, the alternating bright and dark stripes of Mn^{3+} and Mn^{4+} are visible in the image that lead to an interfringe distance $2a \sim 11 \text{ \AA}$ (Fig. 12b). Besides the FMM state driven by the double-exchange mechanism, thus a second phenomenon exists that is driven by long-range coulombic repulsion which tends to separate the Mn^{3+} and Mn^{4+} species. The Jahn–Teller distortion of Mn^{3+} plays a crucial role in the CO process, because the d_{z^2} orbitals of Mn^{3+} are

arranged in 90° zigzag chains in the CO phase (as shown in the drawn projection of Fig. 13): thus CO (T_{CO}) and orbital ordering (T_{OO}) occur simultaneously (41). In Fig. 13, the Mn^{3+} and Mn^{4+} stripe of charges are planes running along the (b, c) planes that alternate in the a direction. The size difference between Mn^{3+}O_6 and Mn^{4+}O_6 octahedra in this checkered pattern is responsible for the doubling of the a parameter, as this CO manganite is cooled below the T_{CO} .

Here again, $\langle r_A \rangle$ is a crucial parameter that governs T_{CO} (and/or T_{OO}): as $\langle r_A \rangle$ decreases, T_{CO} increases, as shown in Fig. 14 by the $\text{Ln}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ compositions (44). In other words, as the Mn–O–Mn angle decreases, the charge ordering is favored at the expense of the FMM state. For all of the CO $\text{Ln}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$, the spin order in a CE-type AFM

Figure 13. 2-D drawing obtained by projecting the 3-D charge-ordered structure of a $\text{Ln}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ perovskite. The 90° zigzag chains of the Mn^{3+} d_{z^2} orbitals are clearly visible. The bright octahedra correspond to Mn^{4+}O_6 . The distortion of the Mn^{3+}O_6 octahedron is not shown.

Figure 14. Charge-ordering (T_{CO}) as a function of $\langle r_A \rangle$ determined from the study of several $\text{Ln}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ charge-ordered manganites by electron microscopy or magnetization.

structure (Fig. 15) below the Néel temperature T_N (42), and the T_N value is always such that $T_N \leq T_{\text{CO}}$. To sum up, the CO process in $\text{Ln}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ half-doped manganites induces a structural transition [see the doubling of one cell parameter in the CO structure (Fig. 12 and 13)] and an AFM arrangement of the spins, confirming the important interplay between the lattice, the charges, and the spins. The strong electron–phonon coupling in the CO phase has been confirmed in the CO $\text{La}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ half-doped manganite by an oxygen isotopic effect (18).

At first glance, the robustness of the low temperature CO-AFMI state to a high magnetic field does not seem very attractive for the CMR effect because, for instance, 30T are necessary to melt the CO state of $\text{Pr}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ (45). However, several possibilities exist for weakening the CO for the benefit of the FMM state.

Figure 15. CE-type AFM structure of $\text{Ln}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ charge-ordered manganites. The bright and black circles are for the Mn^{3+} and Mn^{4+} cations, respectively. The small arrows are for the magnetic moments. The solid line and dotted line are for the nuclear and magnetic cells, respectively.

The first is controlling $\langle r_A \rangle$; for sufficiently large $\langle r_A \rangle$ values, as for $\text{Nd}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ (46), the FMM state exists above T_{CO} , and consequently, these half-doped manganites are such that $T_C > T_{\text{CO}}$. One example of such a realization is the $\text{Pr}_{0.5}\text{Sr}_{0.5-x}\text{Ca}_x\text{MnO}_3$ series (47): starting from the end member $\text{Pr}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$, which is a CO-AFM compound without CMR properties (48), a FMM state can be obtained by increasing $\langle r_A \rangle$ by substituting Sr for Ca, as shown (Fig. 16a,b) by the $M(T)$ and $\rho(T)$ curves of $\text{Pr}_{0.5}\text{Sr}_{0.5-x}\text{Ca}_x\text{MnO}_3$. The closeness of both CO-AFMI and FMM states creates the metastability of these phases. The

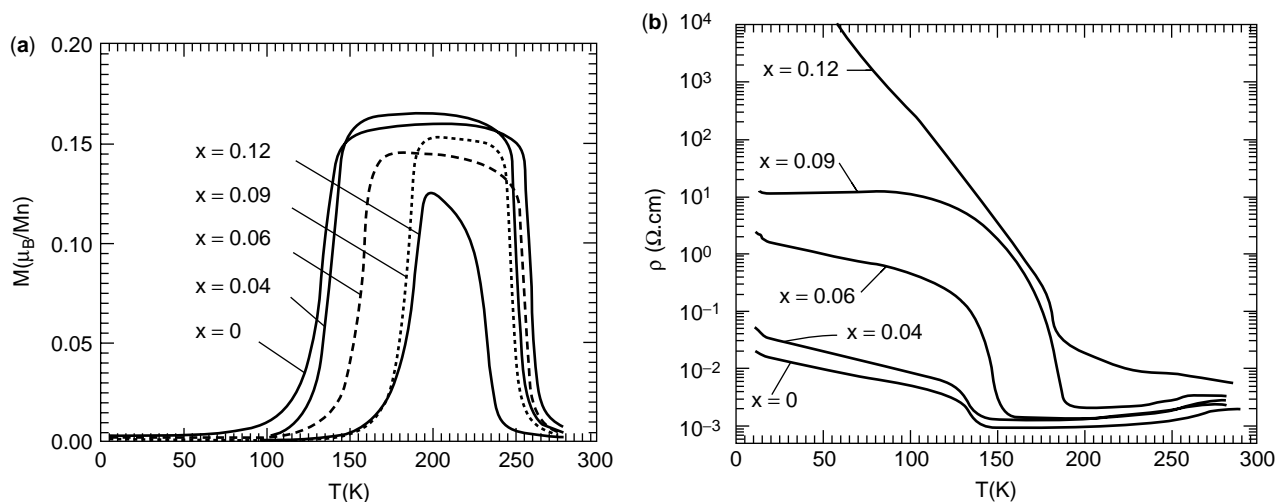

Figure 16. $\text{Pr}_{0.5}\text{Sr}_{0.5-x}\text{Ca}_x\text{MnO}_3$ samples. (a) $M(T)$ curves at $\mu_0 H = 10^{-2}$ T and (b) corresponding $\rho(T)$ curves.

Figure 17. $\rho(T)$ curve of the CO compound $\text{Pr}_{0.5}\text{Sr}_{0.41}\text{Ca}_{0.09}\text{MnO}_3$ ($x = 0.09$) at 0 and 7 T. ZFC and FC are for zero-field-cooling and field-cooling, respectively.

application of a 7-T magnetic field on $\text{Pr}_{0.5}\text{Sr}_{0.41}\text{Ca}_{0.09}\text{MnO}_3$ (47) is sufficient to destabilize the CO state and thus to restore a FMM state as shown in Fig. 17. A resistivity ratio $\rho(0)/\rho(7\text{ T})$ of 10^4 can be reached. Thus, the CO phase can be a “precursor” to CMR effects. The CO CE-type AFM phase can be transformed into the FMM by applying a magnetic field. Direct evidence from a neutron diffraction study as a function of magnetic field has been given for $\text{Nd}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ (49): at 125 K and under 6 T, the monoclinic CO CE phase collapses into the FMM orthorhombic phase. This field-induced structural transition is facilitated by the coexistence of electronic and magnetic phase segregation at nearly comparable free energies.

A second route to obtaining CMR effects starting from CO compounds is to act on the B site of the perovskite. This impurity effect, it has been shown, is the most efficient when substituting metals such as Cr, Co, and Ni (50). As one can judge from the $\rho(T)$ curve that shows a I–M transition and the $M(T)$ curve that shows ferromagnetic behavior (Fig. 18a and b), 2% of Cr per Mn site in $\text{Pr}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$

is sufficient to induce a FMM. Accordingly, a CMR effect is obtained in the T_{I-M} vicinity. Induced long-range ferromagnetism for $\text{Pr}_{0.5}\text{Ca}_{0.5}\text{Mn}_{0.95}\text{Cr}_{0.05}\text{O}_3$ has been probed by neutron powder diffraction (51). However, the low-temperature electron microscopy study revealed a more complex situation; small charge-ordered monoclinic (AFM) regions of few tens of a nanometer that still remain in the orthorhombic matrix are responsible for the FM observed by neutron diffraction. This coexistence makes all interpretations of the physical properties very complex (26,52). Very recently, some authors proposed that the metallic state observed in the Cr-doped $\text{Nd}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ phase originates in the percolation of FMM clusters (26). Finally, it should be emphasized that nonmagnetic doping cations—divalent, trivalent, and tetravalent—such as Mg^{2+} , Al^{3+} , Ga^{3+} , Ti^{4+} , Sn^{4+} substituted for Mn, destabilize the CO but do not induce the I–M transition observed for magnetic cations such as Cr^{3+} (50).

It is of prime importance for understanding CMR to realize that the CO tendency is not restricted to the half-doped $\text{Ln}_{0.5}\text{AE}_{0.5}\text{MnO}_3$ compositions, but that it can be observed far from the $\text{Mn}^{3+}:\text{Mn}^{4+} = 50:50$ ratio. Several types of $\text{Mn}^{3+}/\text{Mn}^{4+}$ arrangements below the T_{CO} have been observed by transmission electron microscopy (53–55). Some examples, electron diffraction pattern and corresponding lattice image, are shown in Fig. 19 for $\text{Sm}_{1/4}\text{Ca}_{3/4}\text{MnO}_3$ and $\text{Sm}_{1/3}\text{Ca}_{2/3}\text{MnO}_3$ together with $\text{Sm}_{1/2}\text{Ca}_{1/2}\text{MnO}_3$ [from (55)]. From these contrasts, schematic drawings for the Mn^{3+} and Mn^{4+} planes can be proposed (Fig. 20). They underline the lack of cation intermixing; the extra Mn^{4+} compared to $\text{Sm}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ forms new Mn^{4+} planes between the Mn^{3+} planes (blocks of 1, 2, and 3 Mn^{4+} planes for Mn valencies of 3.5, 3.66, and 3.75, respectively). For these commensurate $\text{Mn}^{3+}:\text{Mn}^{4+}$ ratios, the doubling of the a cell parameter observed for $\text{Mn}^{3+}:\text{Mn}^{4+} = 50:50$ evolves toward a tripling and a quadrupling for $\text{Sm}_{1/3}\text{Ca}_{2/3}\text{MnO}_3$ and for $\text{Sm}_{1/4}\text{Ca}_{3/4}\text{MnO}_3$, respectively. Obviously, as the charges order, the samples become insulators and antiferromagnetic. The antiferromagnetic structure, CE-type for $\text{Ln}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ (Fig. 15), changes into a C-type structure (Fig. 21) for $\text{Ln}_{1-x}\text{Ca}_x\text{MnO}_3$ where $0.5 < x$ (CE and C are for AFM structures described

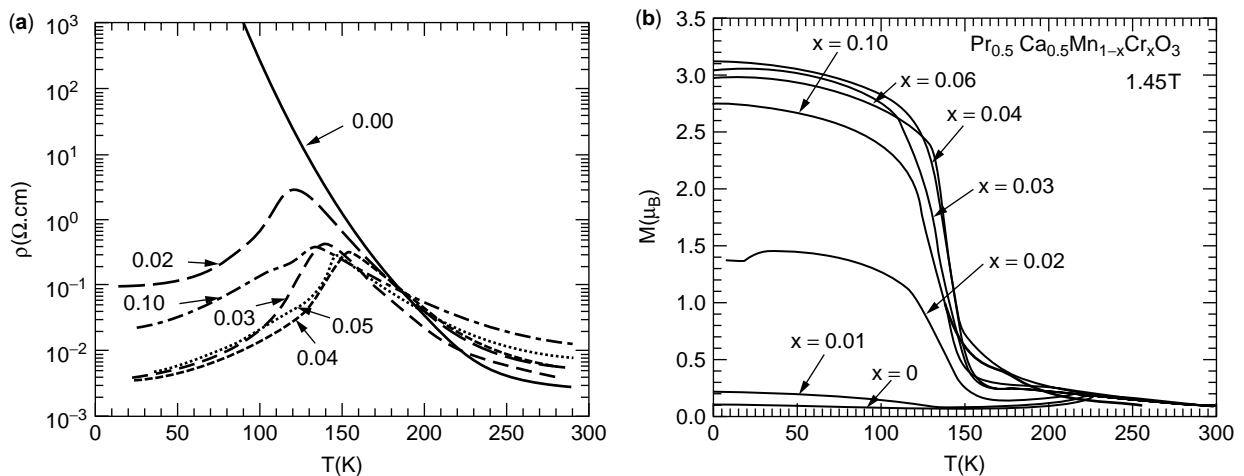

Figure 18. (a) $\rho(T)$ and (b) $M(T)_{1.45\text{T}}$ curves of the $\text{Pr}_{0.5}\text{Ca}_{0.5}\text{Mn}_{1-x}\text{Cr}_x\text{O}_3$ series.

by octants as explained in Ref. 42). At low temperature, incommensurate values of the $\text{Mn}^{3+}:\text{Mn}^{4+}$ ratio lead to extra reflections in the system of intense reflections, observed at room temperature for the $Pnma$ structure, in incommensurate positions on the electron diffraction patterns. In that case, the lattice images show the absence of long-range charge ordering: the alternating $\text{Mn}^{3+}/\text{Mn}^{4+}$ planes cannot order regularly manner in all of the microcrystal. For each lanthanide (Ln), the properties of $\text{Ln}_{1-x}\text{Ca}_x\text{MnO}_3$ manganites, characterized by small $\langle r_A \rangle$ values, can be summarized by a magnetic phase diagram where all of the characteristic transitions are indicated. An example is given in Fig. 22 for the $\text{Sm}_{1-x}\text{Ca}_x\text{MnO}_3$ series (34).

One can see in this graph that a broad composition range exists where charge ordering occurs. However, this

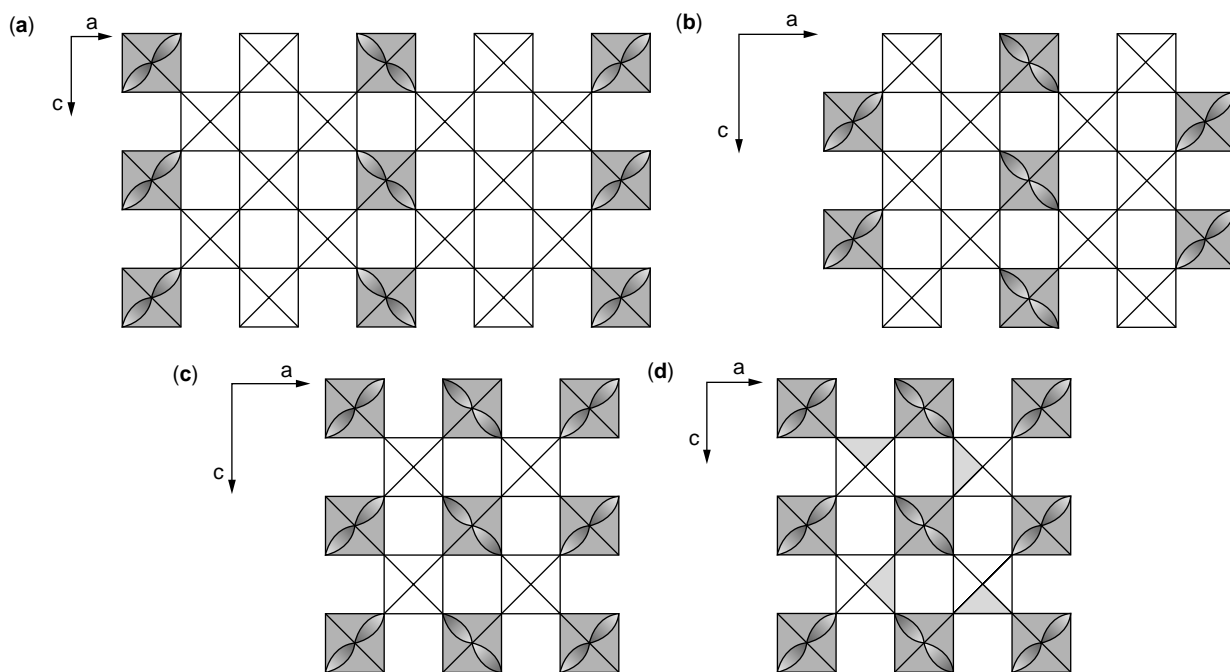

Figure 20. Corresponding $\text{Mn}^{3+}/\text{Mn}^{4+}$ arrangements (a) $x = 1/4$, (b) $x = 1/3$, (c) $x = 1/2$, and (d) the schematic drawing for $\text{Mn}^{3+}/\text{Mn}^{4+} > 1$ is also given.

region covers a part of the Mn^{3+} compositions because CO is detected for $0.35 < x \leq 0.8$ in $\text{Sm}_{1-x}\text{Ca}_x\text{MnO}_3$. In fact, a mixture of two phases is obtained for $0.3 \leq x \leq 0.4$, where CO regions coexist with FM regions. For these hole-doped compositions, the extra reflections characteristic of the CO in the electronic diffraction patterns are in commensurate positions and indicate a doubling of the structural parameter similar to $\text{Sm}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$. This result is not intuitive if one considers that the $\text{Mn}^{3+} : \text{Mn}^{4+}$ ratio is far from the 50:50 value of the half-doped manganites. Most probably, the extra Mn^{3+} species tend to be substituted for Mn^{4+} so that the CO can be viewed as alternating 1:1 planes of Mn^{3+} and mixed $\text{Mn}^{4+}/\text{Mn}^{3+}$ planes (Fig. 20d).

The existence of hole-doped compositions characterized at low temperature by the coexistence of CO and FM regions is very important for CMR. Recent observations by electron microscopy (90 K) of CMR manganites $\text{Pr}_{0.7}\text{Ca}_{0.3-x}\text{Sr}_x\text{MnO}_3$ where $0 \leq x \leq 0.05$, discussed earlier, showed the presence of short-range charge-ordered domains in these FM manganites. Consequently, the application of a magnetic field tends to transform the CO regions in FM regions and thus to generate CMR effects.

Finally, it should be mentioned, that no CO is observed for half-doped manganites of larger (r_A), such as $\text{Pr}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ (56,57). The low-temperature AFM structure is A type, that is, antiferromagnetically coupled FM planes (Fig. 23). According to the large (r_A) value of this compound, 1.24 Å, the Mn^{3+} octahedron is more flattened than in the CO phases because the $d_{x^2-y^2}$ orbitals are filled rather than the d_{z^2} . The $d_{x^2-y^2}$ orbitals (half-filled and empty for Mn^{3+} and Mn^{4+} , respectively), form MnO_2 FM planes in which the charges can be delocalized. In the out-of-plane direction, the empty d_{z^2} orbitals prevent any charge delocalization. The conductive nature of the FM planes of the A-type AFM structure has been probed by (in-plane and out-of-plane) resistivity measurements of $\text{Nd}_{0.45}\text{Sr}_{0.55}\text{MnO}_3$ (58) which show large anisotropy in transport properties. This anisotropic character can be made more isotropic by field application which restores

3-D FM metallic behavior in $\text{Pr}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ (56). Such half-doped manganites that have no CO but have an A-type AFM state can also show an I–M transition in a magnetic field and thus are CMR compounds.

OTHER CMR MANGANITES

CMR is also found in compositions very close to the G-type AFMI CaMnO_3 manganite, that is, for Mn valency close to four (59–61). Inspection of the $\text{Sm}_{1-x}\text{Ca}_x\text{MnO}_3$ phase diagram of Fig. 22 reveals the existence of “cluster-glass” (CG) compositions (62). The latter exhibit metallic behavior in the paramagnetic state that, it is believed, are connected with the small content of Jahn–Teller Mn^{3+} species, as contrasted to hole-doped manganites. Surprisingly, these compositions exhibit a G-type AFM structure below $T_N \sim 110$ K (G-type: each Mn moment is antiferromagnetically coupled to its six Mn nearest neighbors, Fig. 24) but also a nonnegligible FM moment ($M_{5K} \sim 1 \mu_B/\text{mole}$ of Mn for $\text{Sm}_{0.1}\text{Ca}_{0.9}\text{MnO}_3$) supposed to be the

Figure 23. A-type AFM structure. The $d_{x^2-y^2}$ are ordered in the FM planes.

Figure 24. G-type AFM structure of CaMnO_3 .

signature of FM regions that coexist with the G-type AFM matrix that has very close T_N and T_C (63). Percolative pathways between these FM regions, as Mn^{3+} increases from CaMnO_3 , are responsible for the metallic behavior observed below T_N in $\text{Sm}_{0.1}\text{Ca}_{0.9}\text{MnO}_3$. However, at higher Mn^{3+} content, the materials are insulators at low temperature; they exhibit a C-type AFM structure (Fig. 21) with CO as in $\text{Sm}_{1-x}\text{Ca}_x\text{MnO}_3$ where $0.6 \leq x \leq 0.8$. At the boundary between CG and CO compositions, a very narrow composition range exists where CMR effects are observed (61). This is exemplified in Fig. 25 by the comparison of the $\rho(T)$ curves of $\text{Sm}_{0.15}\text{Ca}_{0.85}\text{MnO}_3$, registered upon cooling in and in the absence of a 7-T magnetic field, which show a ρ decrease by several orders of magnitude upon application of a magnetic field.

It should be pointed out that the CMR of these electron-doped compositions (Mn valency is greater than 3.5) is controlled by the valency and also by $\langle r_A \rangle$. First, for the $\text{Ln}_{1-x}\text{AE}_x\text{MnO}_3$ series, characterized by large $\langle r_A \rangle$ such as $\text{Pr}_{1-x}\text{Sr}_x\text{MnO}_3$, the electron-doped compositions lying close to SrMnO_3 crystallize in a hexagonal phase and are thus

Figure 25. $\rho(T)$ curve of $\text{Sm}_{0.15}\text{Ca}_{0.85}\text{MnO}_3$ upon cooling at 0 and 7 T.

very difficult to prepare as pure cubic perovskite. Second, if cubic perovskites are stabilized by using a different synthetic approach, their magnetic properties show an absence of any FM component, in contrast to $\text{Ln}_{1-x}\text{AE}_x\text{MnO}_3$ manganites of small $\langle r_A \rangle$ (64). Moreover, the AFM state (C- or G-type) is much stronger according to their higher T_N (Fig. 7 and 22). Thus, the $\langle r_A \rangle$ effect on magnetism is opposite to that observed for hole-doped compounds. For the latter, the larger $\langle r_A \rangle$ values favor FM but are unfavorable in electron-doped manganites.

Besides 3-D perovskite manganites, other manganites exist that crystallize in layered structures, as in the Ruddlesden–Popper phases (SrO) $(\text{La}_{1-x}\text{Sr}_x\text{MnO}_3)_n$ (65–67) or pyrochlore as $\text{Tl}_2\text{Mn}_2\text{O}_7$ (68) that exhibit CMR properties. For the former, the $n = 2$ member $\text{La}_{1.8}\text{Sr}_{1.2}\text{Mn}_2\text{O}_7$ is a CMR compound consistent with its FMM state below T_C (67). Interestingly, when the current flows through the $[\text{La}/\text{SrO}]_\infty$ insulating layer, the out-of-plane transport properties are governed by inter-layer tunneling which is of particular interest for its low magnetic field magnetoresistance (69). Their properties (structural, magnetic, electronic) are also very sensitive to the size of the Ln/AE cations and to the Mn valency (70) as in the perovskite but are more complicated by the existence of two structural sites for Ln/AE cations (70)—perovskite between the two $[\text{MnO}_2]_\infty$ layers and NaCl-type in the $[(\text{Ln}/\text{AE})_2\text{O}_2]_\infty$ separating layers. By choosing a $\text{Mn}^{3+} : \text{Mn}^{4+} = 1 : 1$ ratio, CO in the planes has also been observed as in $\text{La}_{0.5}\text{Sr}_{1.5}\text{MnO}_4$ ($n = 1$) (71) and $\text{LaSr}_2\text{Mn}_2\text{O}_7$ ($n = 2$) (72).

The second example is the pyrochlore $\text{Tl}_2\text{Mn}_2\text{O}_7$ manganite (68). This structure has already attracted considerable attention: it is made of Mn–O–Mn angles of only 133° ; there is no mixed valency (it is a pure Mn^{4+} phase), but it is a ferromagnetic (by superexchange) metal below 142 K. Its conductivity is much larger than that of other $\text{A}_2\text{Mn}_2\text{O}_7$ pyrochlores ($A = \text{Y}, \text{Sc}, \text{In}$) and arises from the contribution of Tl ($6s^2$) states to the density of states as has been proposed (73).

CONCLUSION

The goal of this paper was to emphasize the complexity of the underlying phenomena governing the CMR properties of manganites. These compounds have attracted a lot of scientific interest and numerous papers on the topic have been published. It is very difficult and too ambitious to give an exhaustive overview of the state of the art. For more informations and details, the readers can refer to books (74,75) and review articles (76–80). However, a few important notions emerge in the examples given in this article.

The strong interplay among charge, spin, and structure in manganese oxides should always be considered in apprehending the properties of these fascinating materials. Note that this guideline can be extended to other transition-metal oxides such as the high T_C superconducting cuprates, the $\text{La}_2\text{NiO}_{4+\delta}$ nickelates, the charge-ordered ferrites [for instance $(\text{La}/\text{Sr})\text{FeO}_3$], etc.

A second important parameter is the competition between the charge-ordering process that leads to a localized

antiferromagnetic state and a ferromagnetic state that allows charge delocalization. Subtle changes in composition can be used to change their respective proportions and induce dramatic effects on structural, magnetic, and electronic properties. In this context, percolation models become more and more pertinent for describing experimental observations.

Finally, one actual limitation for the application is a magnetic field too high to obtain magnetoresistance effects at room temperature. Several technological approaches are possible for overcoming this problem, such as control of grain-boundary quality and growth of multilayered heterostructures.

COMPOSITES, FUTURE CONCEPTS

BRIAN S. THOMPSON

Michigan State University
East Lansing, MI

INTRODUCTION

The composite materials considered here are solid objects with a macrostructure. The constituents of these, solids can be observed with the naked eye. Solid objects are said to be *smart* if they embody additional functionality capabilities beyond their inherent structural attributes. These capabilities might be attributed to an embedded network of interconnected sensors, actuators and computers, for example. Synthetic inhomogeneous materials with these capabilities comprise the basis for a new generation of materials. These materials have the potential to revolutionize many types of products, and usher into existence unforeseen manufactured goods.

Humankind's traditional quest for superior materials may be satisfied in the near future by ideas furnished by Mother Nature. The design and manufacturing methodologies needed for creating new generations of materials will come from a meticulous study of flora and fauna. The future lies with the development of synthetic materials that mimic naturally occurring biological materials.

HISTORICAL PROLOGUE

Materials science has come the full circle. The evolution of this important field began with humankind's use of naturally occurring materials. Materials have had a profound impact on the evolution of world civilizations. Historians have classified periods in this evolution by the materials that were the state-of-the-art during these periods. Thus the vocabulary now contains phrases like the Stone Age, the Bronze Age, and the Iron Age. Each of these eras, illustrated in Fig. 1, is characterized by the material that was the most advanced of its time. An alternative classification is presented in Fig. 2. Here the eras are classified by the type of properties embodied by each material.

Homo habilis chose unrefined naturally occurring materials for weapons and tools during the Paleolithic period, some one million years ago. This decision was responsible for the selection of flint, a fine-grained very hard abrasion-resistant siliceous rock, rather than sandstone or bone to be lashed to a long shaft of wood to create an innovative weapon system for hunting: namely the spear. About 3500 BC, *Homo sapiens sapiens* began to create bronzes by smelting ores. This accomplishment required metallurgical prowess, and it also exploited the ability to generate and control heat. These new nonferrous materials were alloys of copper and tin, and they were instrumental in creating superior classes of weapons, tools, and utensils.

The development of foundry technology enabled higher furnace temperatures to be generated, and a different class of ores to be smelted. This new technology was responsible for the demise of nonferrous alloys as the materials of choice. They were superseded by a new class of

Figure 1. Historical eras of materials science.

state-of-the-art materials that were more versatile and harder than their predecessors. These new ferrous materials were the irons. The irons were exploited in many aspects of life to generate innovative classes of products, ranging from domestic articles to military systems and agricultural implements.

The societal consequences of these new materials were immeasurable. For example, Archimedes, Ctesibius, and Hero exploited the properties of these new materials to create numerous mechanical devices. These included the pulley, the lever and the screw, hydraulic devices, compressed air devices and screw-cutting machines. In addition, plough shares wrought in iron facilitated the development of deeper plowing techniques and the cultivation of inferior quality soils. Consequently this new capability enabled human settlement to occur in these less desirable regions, thereby leading to the growth of different civilizations. Clearly, the cascading consequences of this new generation of ferrous materials were immeasurable.

In 1856 the demise of iron was initiated by Henry Bessemer's design of a converter to create steel by inexpensively refining iron. The consequences of this new class of materials were titanic. Steel fueled the Industrial Revolution, and at that significant technological, socio-economic, and cultural changes. These changes increased confidence in exploiting the properties of new materials, and utilizing scientific data; this has resulted in new generations of industrial machines, new organizational structures for the human component of the enterprises, and improved communications and transportation technologies. A nexus of mass production environments was created and consequently a dramatic increase in the consumption of raw materials.

These cascading phenomena were far reaching. They included an increase in international trade. Employees were required to develop machine-oriented skills while being subjected to the discipline of an industrial environment, and industrialization mandated that the legal system respond with new legislation. Suburban areas flourished, wealth was distributed more uniformly, agriculture was mechanized to feed the industrial communities, and finally humankind received a psychological boost from this new-found success in further exploiting natural resources in a controlled manner. Thus at the dusk of the nineteenth century, there were complex interactions between the naturally occurring materials that fueled the industrialization, technological innovations, and rapid changes in society.

By the twentieth century an embryonic technology involving synthetic materials had emerged. This was a profound departure from the traditional approach of exploiting natural materials with their known defects and limitations. The new generation of materials was the plastics. The early successes included celluloid, xylonite, cellophane, and bakelite. The growth of the plastics field was astronomical. Indeed, by 1979, the volume of plastics manufactured in the United States exceeded steel production for the first time. There were thousands of different plastics in the marketplace to satisfy a diverse range of design requirements for materials with appropriate stiffness, strength, hardness, wear resistance, heat resistance, transparency, and so on. This diversity was achieved by carefully synthesizing the appropriate atomic structure from primarily the chemical elements carbon, hydrogen, oxygen, and nitrogen.

Synthetic plastic materials replaced the traditional materials in a diverse range of industries from transportation

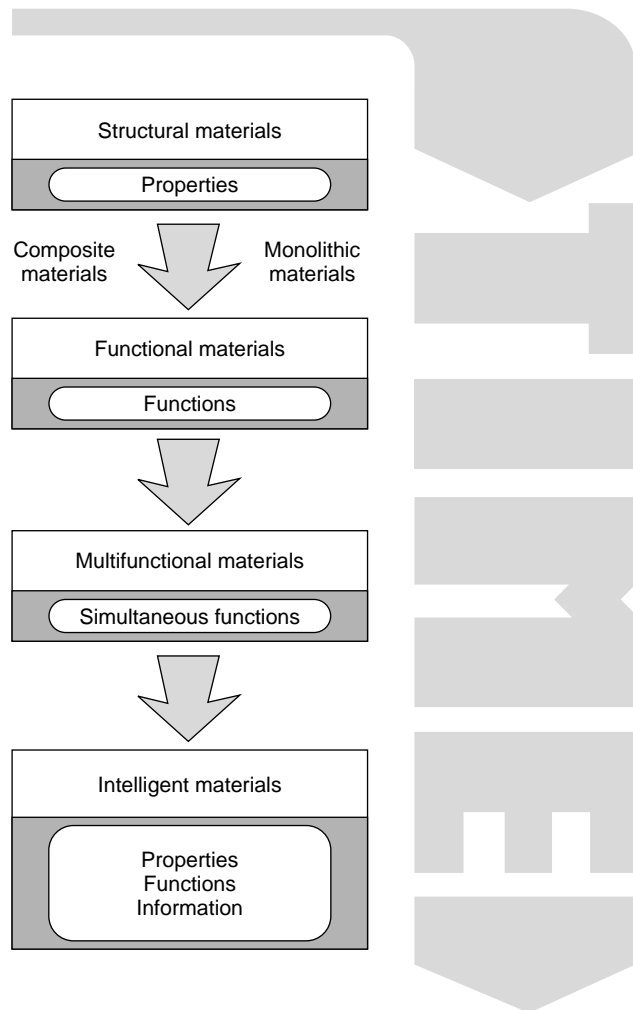

Figure 2. Evolution of the design of materials with macrostructure and microstructure.

to domestic appliances and the medical supply industry. The reason for this universal utilization of these new materials is their extensive range of physical properties. Their physical properties could comply precisely with the design specification of a product. In the past, metallurgists were primarily responsible for the development of new materials. Now these new materials are synthesized by eclectic teams of specialists.

The trend of employing eclectic teams of specialists was responsible for the explosive development during the latter half of the twentieth century of a plethora of material classifications too numerous to discuss here. These include the development of a variety of functional materials, such as gallium arsenide or magnetostriuctive materials where the functional properties are exploited in practice instead of the structural properties as in traditional practice. However, there is one classification worthy of mention because it is important commercially and is central to chronicling the evolution of a branch of materials science.

This class of modern materials is the advanced composites. These engineered materials are synthesized within

two distinct phases comprising a load-bearing material housed in a relatively weak protective matrix. The reinforcement is typically particles, whiskers, or fibers, while the matrix can be polymeric, ceramic, or metallic materials. A characteristic of these composite materials is that the combination of two or more constituent materials creates a material with engineering properties superior to those of the constituents—albeit at the expense of more challenging fabrication technologies.

As an aside, it should be noted that the field of fibrous composite materials technologies is not entirely new. Consider the recording in Exodus, chapter 5 of the Bible, of the Israelites manufacturing bricks from a mixture of clay and straw for the pharaoh in Egypt in 450 BC. Over a thousand years later, the French used a combination of horse hair and plaster to create ornate ceilings in stately homes.

Advanced polymeric composite materials have afforded the engineering community the opportunity to fabricate products with the strongest and stiffest parts per unit weight. Furthermore, by appropriately designing the macrostructure of these materials, the engineer can develop composites with different properties in different directions, or alternatively, different properties in different domains of a structural member. Thus, not only are the geometrical and surface attributes of the part being designed, but in addition the material's macrostructure is being design too. The infusion of these materials into numerous industries has been responsible for the creation of many generations of products in the defense, automotive, biomedical, and sporting goods industries, for example.

Thus at the dusk of the twentieth century the creation of materials with an engineered macrostructure was the state-of-the-art. In the context of advanced fibrous composite materials, materials science had come the full circle. In the beginning, naturally occurring materials were studied by *Homo habilis* to select the appropriate mineral for the tip of the spear or arrow. Now, one million years later, *Homo sapiens sapiens* is studying naturally occurring fibrous composite materials in order to emulate the placement of fibers for the creation of synthetic composite parts. One of the primary motivations for the growth of this field of scientific endeavor is that naturally occurring fibrous composites are embodied in numerous species of flora and fauna. They are one of the basic building blocks of life. They are an intrinsic design of Nature's. Clearly, if these biological systems have evolved to these mature states through the millennia, then they are indeed worthy of study and perhaps emulation in an engineering context. This observation provides the underpinning of the subsequent section: biologically inspired materials.

Historically, then, each era during the evolution of humankind was motivated by the insatiable demand for superior weapons and more innovative products. In turn, this demand propelled the maturing of materials science, because the triumvirate of product design comprises materials, manufacturing and conceptual design. And of course this quest is very evident to this day. Currently the age of synthetic materials has been driven by the same motives. While plastics shall undoubtedly remain an increasingly dominant component of modern lifestyles, the new millennium shall witness the emergence of a superior class

of advanced materials. These smart materials, or intelligent materials, materials with diverse characteristics that mimic flora and fauna, shall be responsible for historians classifying it as *The Age of Smart Materials*, because they will dominate the materials selection process when technologists are seeking state-of-the-art materials.

BIOLOGICALLY-INSPIRED CREATIVITY IN ENGINEERING

Although human genius through various inventions makes instruments corresponding to the same ends. It will never discover an invention more beautiful nor more ready nor more economical than does Nature, because in her inventions nothing is lacking and nothing is superfluous.

Leonardo da Vinci

(Ms RL 19115v; K/P 114r; Royal Library, Windsor)

These profound words penned some 500 years ago by Leonardo, that brilliant painter, sculptor, draftsman, architect and visionary engineer, are the earliest that formally recognize the power of Nature's creativity in the fields of natural science such as botany, zoology, and entomology. The naturally occurring materials and systems associated with these academic disciplines have developed their properties and characteristics over millions of years through processes of Darwinian evolution. They have been required to survive when subjected to dynamically changing environmental conditions. Indeed, these conditions demand that only the most adaptable and fittest survive. Therefore, these biological systems are truly optimal designs engineered by Mother Nature in response to a set of unwritten design specifications. Hence they merit meticulous scrutiny and potential emulation by humankind.

Since Charles Darwin's seminal work in 1859, entitled "On the Origin of Species by Means of Natural Selection," the notion of natural selection has remained the central theme of evolutionary biology. Thus the proposition is that all life forms evolved because organisms with traits that promoted reproduction and survival somehow passed on those traits to future generations. Organisms without those traits simply became extinct. They failed to survive. Indeed, this powerful assertion has motivated theories in several disciplines beyond the central theme of materials science. Hence the proposition of learning from biological systems to advance the field of engineering has credence. Evolutionary psychology, for example, proposes that the human mind is not a vacuous medium, but instead comprises specialized mental protocols that were honed by the solving of problems faced long ago. Sociobiology, on the other hand, employs natural selection and other biological phenomena to explain the social behavior of animals.

This emulation, or mimicking, of biological systems is often called *biomimetics*. The name is derived from the Greek *bios* (life) and *mimesis* (imitation). It can be employed by creative designers to develop solutions to engineering problems through the use of a direct analogy between a naturally occurring system and an engineering system. Thus a meticulous and comprehensive study of a living organism can yield invaluable insight into the subtleties of its refined design attributes developed by a lengthy process of evolution and optimization.

Already during recent centuries Nature's creative prowess has been recognized and exploited by many gifted individuals. Consider, for example, Sir George Cayley's work in 1810 when he was designing a low-drag shape for his fixed wing flying machine. He exploited his knowledge of ichthyology to propose that the geometry of the wing cross section should mimic the streamlined low-drag cross section of the trout. Sir Marc Isambard Brunel proposed the use of caissons to facilitate the underwater construction of civil engineering structures by the serendipitous observation of a shipworm tunneling in timber. George de Mistral developed the hook-and-loop fastener, such as those manufactured by Velcro USA, Inc, by studying how cocklebur plants tenaciously adhered to his trousers after he had walked through woodland thickets. Of course, there are many others too who have used a direct analogy between a biological system and an engineering system in order to create a new artifact for the betterment of humankind.

In the context of the development of advanced materials from studies of naturally occurring systems with fibers, such as the stalks of celery or the skin of a banana, the fibrous composites of engineering practice are an obvious consideration. They emulate the fibrous structures of muscles or plants. For example, the structure of the humble tree comprises flexible cellulose fibers in a rigid lignin matrix. On the other hand, the insect cuticle comprises chitin fibers in a proteinaceous matrix.

On a separate level of comparison between materials engineered by humankind and those created by Mother Nature, consider the variety of materials in both classifications. In 1990, it was estimated that the marketplace contained about 60,000 different plastics. This contrasts sharply with the observation that there are only two groups of substances from which almost all skeletal tissues of animals and plants are formed. These groups are the amino-acid-based proteins and polysaccharides that occur together in different proportions in the vast majority of biological materials. Clearly, the apparently limited chemistry of these naturally occurring materials is compensated for by the tremendous diversity of their microstructure. In addition, the creation and manufacture of these diverse microstructures is accomplished when subjected to a small range of temperature, humidity, and pressure. These limited conditions contrast markedly with the extreme thermodynamic environments employed to produce plastics. Finally, these processes of design and manufacture occur simultaneously. They occur in unison. Again, this contrasts sharply with the protocols implemented in a large percentage of industrial enterprises where design departments and manufacturing departments function autonomously. They do not practice simultaneous engineering.

SMART MATERIALS AND STRUCTURES: CURRENT NONCOMMERCIAL TECHNOLOGIES

Biological systems are extremely complex, and in the context of biomimetics, it is therefore only inevitable that an eclectic team of specialists must be assembled to prosecute the research if progress is to be assured in the

creation of new materials. Teams of trained professionals are mandatory because biomimetics lies at the boundaries of numerous artificial disciplines that have been created by the academic community in order to study the phenomenological problems of life. Thus a team with expertise in materials science, biological sciences, biotechnology, nanotechnology, molecular electronics, artificial intelligence, data-processing, microprocessors, automatic control theory, manufacturing, applied mathematics, chemistry, physics and the like, is required, along with the associated equipment. The best configuration would be a blend of academics, industrialists, and government employees. The creation of this type of infrastructure is often a challenging undertaking. Thus there is a need for large grants and perhaps centers of excellence.

Unfortunately, in many academic institutions the traditional research philosophy is for each professor to seek their own funding. Interdisciplinary collaboration is minimal. Unfortunately, this is an outcome of the academic system where professors are promoted because of their individual accomplishments and natural phenomena are broken down into distinct fields and the artificial interfaces are well defined. This infrastructure hinders potential interactions between individuals in adjacent fields. Thus the conventional model is of a single investigator guiding graduate students and postdoctoral fellows. Therefore there needs to be a major shift in the current research paradigm if progress in this field is to proceed effectively.

However, using the typical single-discipline non-embracing philosophy, humankind has indeed created a multitude of macroscopically smart materials that mimic naturally occurring materials. While these material systems are still quite crude relative to Nature's materials, they do exhibit, at the most advanced level, the behavior of muscles (by using actuators), nerves (by using sensors), and brains (by using control schemes, microprocessors, fuzzy logic, artificial intelligence, etc.) at various levels of sophistication.

The diverse structural materials, functional materials, and multifunctional materials can be combined in building-block style, as shown in Fig. 3. The materials that mimic naturally occurring materials can have, at the most advanced levels sensors, actuators, information pathways, control schemes, and microprocessors. Some people classify these materials as *intelligent materials* because they can respond effectively to dynamically changing environmental conditions.

An intelligent material could comprise a graphite-epoxy fibrous polymeric structural material that houses some embedded fiber optic Mach Zender interferometric strain sensors and conventional surface-mounted electrical resistance strain gauge strain sensors. The signals from these sensors could be processed by a microprocessor that employs an appropriate control algorithm to activate an array of actuators exploiting piezoelectric and shape-memory phenomena to create an optimal performance under variable external stimuli.

It should be noted that there are naturally several levels of complexity in this field. At the lowest level, a material might feature only sensors to emulate the nerves of a

Figure 3. Classification of materials design.

biological material: photonic, piezoelectric, or conventional strain gauges, for example, depending on the design specification. Alternatively, the smart material might only feature actuators that are controlled manually to emulate the muscles of a biological material. These actuators include a variety of functional materials that demonstrate the diverse phenomena associated with piezoelectricity, electro-rheology, magnetorheology, magnetostriction, and electrostriction, for example. They are typically excited by an electrical stimulus that changes the geometrical configuration, stiffness, or energy dissipation characteristics in a controlled manner. At the highest level, the material might include the brains of a biological system. These complex entities can be imperfectly represented by the exploitation and integration of diverse theories and technologies associated with neural networks, rule-based systems, a multitude of control schemes, signal processing, nanotechnology, and microprocessors, for example. Figure 4 illustrates some of the primary components of these materials.

The last decade has witnessed an explosion of articles on smart materials, and the first book dedicated to the field was published in 1992 by the author. While two journals are dedicated to this field—namely the *Journal of Intelligent Material Systems and Structures* and the *Journal of Smart Materials and Structures*—the eclectic nature of this field, coupled with the importance of materials science in the product realization process, mandates that most academic journals now publish regularly articles on some aspect of the field. The World Wide Web is an obvious source of information on these activities, but the

Figure 4. Ingredients of the premier class of smart materials.

professional wishing to enter this rapidly evolving field would be well advised to attend the SPIE's international symposium on smart materials and structures for an overview of current thinking.

SMART MATERIALS AND STRUCTURES: THE FUTURE

Predicting the future of a technical field with any certainty is fraught with errors and subsequent embarrassment. Therefore I will refrain from peering to the horizon with binoculars, preferring to view the future without an optical aid. After all, there are numerous records of truly gifted individuals failing to accomplish this task of predicting the evolution of a scientific disciplines or a technological field. For example, the famous British scientist Lord Kelvin, who was president of the Royal Society in 1895, stated that "Heavier than air flying machines are impossible." Four years later, Charles H. Duell, commissioner of the U.S. Office of Patents, commented that "Everything that can be invented has been invented." More recently, in 1977, Ken Olsen, the founder of Digital Equipment Corporation, said "There is no reason for any individuals to have a computer in their home." Thus the evidence is clear. Nevertheless, future objectives will be explored on the tenet that engineers and scientists should mimic naturally occurring systems as one method of advancing the state-of-the art.

The most sophisticated class of smart materials in the foreseeable future will be that which emulates biological systems. This class of multifunctional materials will possess the capability to select and execute specific functions intelligently in order to respond to changes in the local environment. Furthermore, these materials could have the ability to anticipate challenges based on the ability to recognize, analyze, and discriminate. These capabilities should include self-diagnosis, self-repair, self-multiplication, self-degradation, self-learning, and homeostasis.

Environmental Design Issues

The maturing nexuses between professionals in the biological and engineering communities have been responsible for a deeper appreciation of the awesome prowess of Nature's creations. This appreciation should be used to establish new operating procedures for the design and manufacture of the next generation of materials. They canon can be distilled from studies of complex ecosystems that have evolved through the millennia. These winning strategies have been adopted by diverse organisms; therefore, they have been employed by both animals and plants comprising diverse organs and parts. This diversity nevertheless does not defer their harmonious functioning together to sustain life and its activities. Indeed, these diverse organisms provide a set of rules that are worthy of analysis and potential implementation in engineering practice by humankind. After all, *Homo sapiens sapiens* is an organism too. They are presented in Table 1.

The information in Table 1 has very broad ramifications in terms of environmental design protocols for the engineering profession, in addition to the creation of new classes of smart materials.

Health Monitoring of Smart Materials

There is a cycle in all ecosystems. Biological systems experience life and death. Thus there is a recycling of the material. Mature trees in a forest absorb nutrients from the soil, but they eventually die and collapse to the forest floor. There they crumble and decompose, providing enrichment to the soil. This enrichment provides nourishment for the next generation of trees and, of course, other forms of vegetation too.

It appears therefore that materials that emulate this natural cycle could be developed. Indeed, there are already a number of biodegradable materials on the market that decompose after serving their useful purpose. In addition this philosophy has been responsible for new engineering protocols concerning the environment. Thus parts are being recycled, others are being re-manufactured, and there is great concern for reducing the consumption of natural resources.

The continuous monitoring of the health of a part or product is one of the many new ideas set for development based on the re-evaluation of practices in the context of naturally occurring systems. The engineering approach

Figure 5. Health monitoring of *Homo sapiens sapiens*.

requires sensors to be embedded in a material, or attached to the surface of a part, in order to provide information on the behavior of the engineering artifact or its structural integrity. It is called “health monitoring” or the cradle-through-grave” approach. This approach of continually monitoring the status of a part during manufacturing, service, and failure mimics the spasmodic health-monitoring activities of *Homo sapiens sapiens*. Noninvasive techniques are often employed to monitor the health of individuals before appropriate medical action is prescribed. These techniques, illustrated in Fig. 5, often begin in the womb and continue throughout life in response to various stimuli and conditions.

The analogous engineering situations employ in situ sensors to monitor the behavior of the part during its manufacture, the service life, and at failure as shown in Fig. 6. Thus the sensing system would be employed initially to monitor the state of cure of a smart part during the fabrication process, in an autoclave perhaps. Subsequently, the same system would monitor continuously the health of the part during the service life. For example, dynamical stresses could be monitored and compared with limits imposed by the design specification. If limits are exceeded,

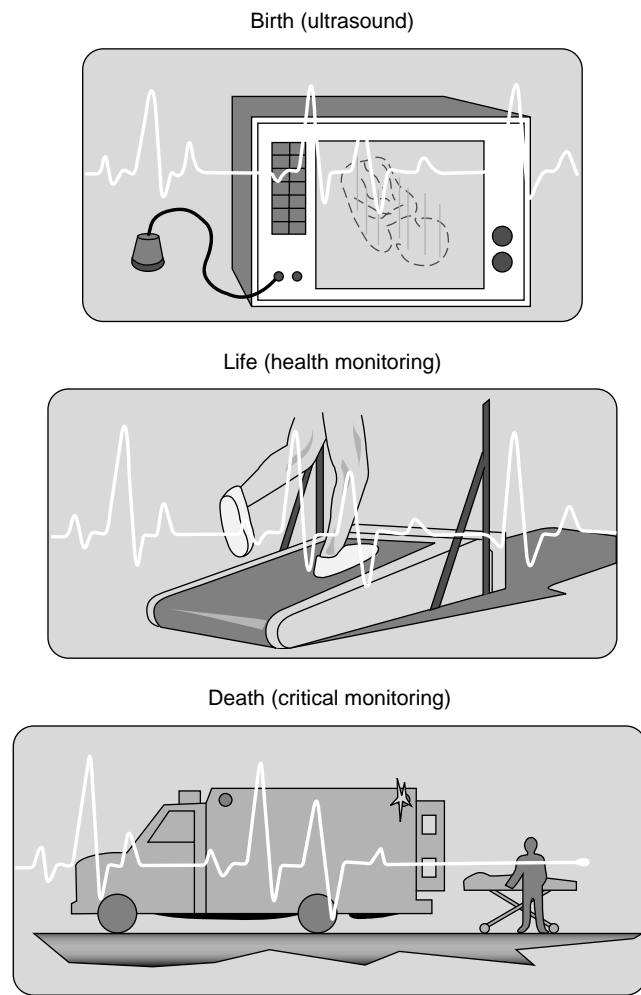

Figure 6. Health monitoring of smart structures.

then the operational envelope of the machine could be automatically changed to restore it to the desired domain.

Critical parts, subjected to complex fatigue environments, could be monitored for structural integrity and impending failure. These would include primary structures of aircraft and large civil engineering structures such as dams, pipelines, and highway bridges. The task of maintaining these structures by maintenance and inspection would be greatly enhanced by this health-monitoring capability.

Intelligence in Biological Materials

The intelligence to be imbued in a synthetic material developed by humankind should emulate the intelligent attributes found in biological systems. These attributes do not require human involvement, and they function autonomously, as evidenced by self-learning, self-degradation, and regeneration. Thus the rusting of iron in a humid environment could be considered to be a simple form of self-degradation. Other functions could include the availability to recognize and subsequently discriminate, redundancy, hierarchical control schemes, and the

election of an appropriate action based on sensory data. Furthermore, a material that has been damaged and is undergoing a process of self-repair would reduce its level of performance in order to survive.

Intelligence that should be inherent in future generations of smart materials can comprise several categories that are derived from studies of biological systems. These are highlighted, with some of the consequences, for the variety of terms listed below.

Crystal Structure. Changes occur in the orientation of crystals, in the atomic configuration, and in the interatomic spacings: These changes are responsible phase transformations, and in polymeric materials, the molecular chain can be re-configured from a folded state to an extended state.

Molecular Structure. Changes occur in the molecular structure caused by molecular chains breaks, re-configured intramolecular bonds, three-dimensional intramolecular spacings, and antigenic or enzymatic reactions.

Macroscopic Structure. Global changes occur in the macroscopic structure after the diffusion and bulk transfer of fluids and ultra-fine powder.

Composition. The interaction between a material and the neighboring environment at the interface results in a change in the material composition at the surface because of the attendant chemical reactions.

Interfaces. Interfacial changes typically pertain to grain boundary phenomena and also reactions at the surface of a material resulting from interactions with the adjacent environment.

Energy. The interaction between a material and the adjacent environment at the interface trigger an energy change or the release of electrons or photons.

Ion Transfer. Ions become transformed ion materials and in addition radicals are transferred along polymer chains.

Charge Transfer. Charge transfer occurs by conductivity in metals and charges are transferred along polymer chains in organic materials.

Electronic Structure. The magnetic properties of materials are changed by changes in the orientation of electronic spin vectors.

This is the main vocabulary being used as attention shifts to the attributes of biological materials and how they can relate to the development of intelligence in smart materials. The following paragraphs highlight some of the primary attributes of biological systems and their interpretation in the context of materials science. Some are illustrated in Fig. 7.

Mitosis. Self-multiplication, self-breeding, or growth in a biological system involves a cell creating similar cells by mitosis to replicate itself. To mimic these processes, smart materials will be self-producing with the additional implicit constraint of terminating the process when a prescribed state has been achieved.

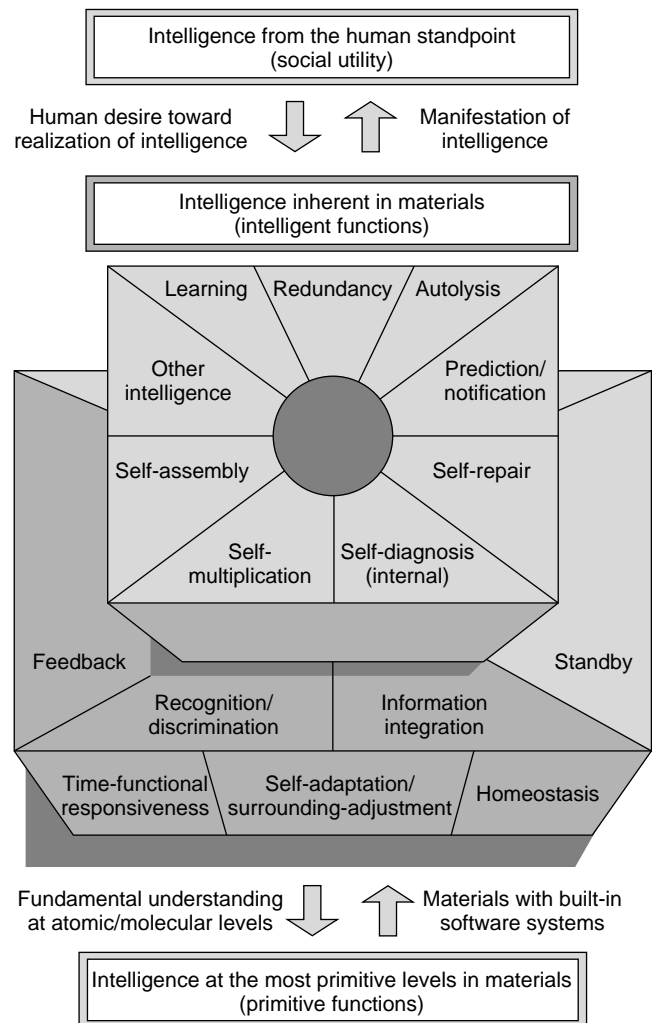

Figure 7. Intelligent functions inherent in biological materials.

This might require changes in their molecular or crystalline structure through the absorption of substances from the neighboring environment or other regions of the material.

Self-repair. This biological activity is closely related to the self-multiplication function or growth. It requires the identification of damage and the extent of the damage before the repair process is initiated and the material restored to its state of normality. The state is manifest in materials that undergo changes in crystalline structure and in the interfacial conditions at the surface of the material or at grain boundaries. Future classes of smart materials could autonomously regain their original shape through phase transformation, even after the material has suffered permanent deformation from surface impact.

Autolysis. Biological systems die and decompose when they sustain severe injuries or damage, or they cease to receive nutrition. Smart materials with these attributes would decompose upon completion of their

useful life and be assimilated within the environment. Smart materials with this attribute would be able to change their molecular structure or their macrostructure.

Redundancy. To enhance survivability, biological systems possess some degree of redundancy in their structures and functions in order to survive. Smart materials with this attribute would feature redundant functions that would be dormant under normal conditions. However, as the material structure changes in response to dynamic environmental conditions, the microstructure would be reconfigured to maintain equilibrium through the activation of new functions. These functions would trigger a change of the molecular structure of the crystalline structure. For example, a stress-induced transformation might be triggered at the tip of a crack in order to reduce the stress concentration in that region and hinder the crack propagation. Alternatively, parts that demand high reliability and are being subjected to very high loads could embody an innovative function that triggers a phase transformation in order to develop higher strength properties.

Learning. The ability to learn is fundamental to many aspects of the behavior of biological systems. Learning would be manifest in smart materials through changes in their physical constants, and changes in the molecular or crystalline structure. The associated knowledge-base is associated with some innate attributes; others are acquired through experience and through interactions with the local environment. These may involve inductive logic where general conclusions are distilled from the observations of an event. Smart materials would benefit from this ability and respond more appropriately to external stimuli through the recollection of previous experiences. Some of the underpinnings would include sensory abilities, data processing, control schemes, and actuators.

Autonomous Diagnosis. Some biological systems contain a self-diagnosis health-monitoring capability that permits the identification of problems, degradations, malfunctions, and judgmental errors. This is facilitated by a comparison between the current conditions and the past. Classes of smart materials would be able to monitor their own welfare so that the effects of damage on the performance of the material could be ascertained and corrective measures implemented.

This class of functions would be achieved by molecular structural changes, changes in the crystalline structure, or changes in the interfacial properties at the surface or the grain boundaries. Typically changes occur in materials that are traditionally used in nonequilibrium states, and their functional properties change when they reach a state of equilibrium. In addition, changes are found in materials that determine autonomously the appropriate time to quickly terminate their functional behavior in response to the ambient environmental conditions, and

in materials that detect degradation before they trigger a stress-induced transformation that reveals the damaged state, perhaps using energy.

Prediction. Some biological systems can predict the immediate future and take appropriate action by exploiting sensory data and by learning from their past experiences. Classes of smart materials designed to emulate these biological systems would need to use a combination of sensors, control algorithms, and knowledge. This is manifest in materials that undergo an energy change, a change in their molecular structure, or a change in the crystalline structure. Examples include the change in the crystalline structure associated with a phase change, the transfer of electrons precipitated by the re-configuring of the crystalline structure and stress induced transformations.

Standby. Smart materials should embody the state of readiness for action displayed by biological systems. This state would probably require several subfunctions such as sensing, diagnosis, prediction, learning, and some class of actuators. This responsiveness could be governed by the role of the material and the ability to analyze the dynamically changing external environmental conditions. It would be manifest by changes in energy, molecular structure, and crystalline structure.

Information Integration. Biological systems generally evolve by storing the integrated experiences of previous generations extending over a great period of time before it is transferred to subsequent generations. Thus the emulation of genes or DNA would provide the basis for the creation of materials with innovative functions that integrate and maintain memory banks.

Recognition. Organisms frequently possess the ability to recognize and discriminate when evaluating information. Smart materials with this ability would not only embody analytical skills but also some measure of fuzzy logic to interpret the data from sensing functions.

Homeostasis. Biological systems are generally subjected to dynamically changing environmental conditions that cause internal systems and structures to change continually. Such systems survive and maintain stable physiological states by coordinated responses that autonomously compensate for these ever-changing external conditions. Innovative functions would need to be established to accomplish these tasks. These functions would require closed-loop feedback systems where sensory information from both the input and the output states need to be compared. Furthermore, the desired conditions would require the careful orchestration of sensors, processors and actuators.

Feedback is manifest in a variety of forms including the transfer of charges, the change in composition, the change in molecular structure, the transfer of radicals and ions, and the change in the crystalline structure. Thus, for example, materials

with a transformation temperature would undergo changes when external conditions subject the material to an elevated temperature.

Adaptation. Biological systems adapt to ever-changing environmental conditions through the evolution of their physiological state. These abilities would have great utility in engineering practice. Examples of this class of materials include films of lubricants that assume solid or fluidic states depending on the local thermal or dynamic conditions. Others include materials that control their optical properties in response to changes in external stimuli like magnetic fields, electrical fields, or heat.

There are probably other biological attributes that are worthy of emulation in the design and manufacture of smart materials that mimic naturally occurring materials, but this list provides a beginning. The road ahead will have many positive and negative undulations and many winding turns. The primary provinces will include theoretical studies, experimental studies, and computational studies, followed by design and manufacture, the creation of primitive functions, assembly and integration of these functions, material characterization, and the development of the supporting technologies.

CONCLUDING COMMENTS

With the passing of time, the technologies associated with materials are becoming ever more sophisticated. It is unreasonable to contemplate the receding of this tide of knowledge and complexity because it is motivated by both commercial and military demands for superior materials. Composite materials, based on ideas emulating from naturally occurring materials, could be considered the most sophisticated class of materials created by humankind. If this is true, then it is only natural to invoke induction and suggest that biological materials are the basis from which new generations of materials will be developed.

COMPOSITES, INTRINSICALLY SMART STRUCTURES

D.D.L. CHUNG
State University of New York at Buffalo
Buffalo, NY

INTRODUCTION

Smart structures are important because of their use in hazard mitigation, structural vibration control, structural health monitoring, transportation engineering, and thermal control. Research on smart structures has emphasized incorporating of various devices in a structure to provide sensing, energy dissipation, actuation, control, or other functions. Research on smart composites has emphasized incorporating of a smart material in a matrix to enhance smartness or durability. Research on smart materials has

emphasized the study of materials (e.g., piezoelectric materials) used for making the devices. However, relatively little attention has been given to the development of structural materials (e.g., concrete and composites) that can inherently provide some of the smart functions, so that the need for embedded or attached devices is reduced or eliminated, thereby lowering cost, enhancing durability, increasing the smart volume, and minimizing mechanical property degradation (which is usually caused by embedded devices).

Smart structures are structures that can sense certain stimuli and respond to the stimuli appropriately, somewhat like a human being. Sensing is the most fundamental aspect of a smart structure. A structural composite, which is itself a sensor, is multifunctional.

This article focuses on structural composites for smart structures. It addresses cement-matrix and polymer-matrix composites. The smart functions addressed include strain sensing (for structural vibration control and traffic monitoring), damage sensing (both mechanical and thermal damage related to structural health monitoring), temperature sensing (for thermal control, hazard mitigation, and structural performance control), thermoelectricity (for thermal control and saving energy), and vibration reduction (for structural vibration control). These functional abilities of the structural composites have been shown in the laboratory. Applications in the field are forthcoming.

CEMENT-MATRIX COMPOSITES FOR SMART STRUCTURES

Cement-matrix composites include concrete (containing coarse and fine aggregates), mortar (containing fine aggregate but no coarse aggregate), and cement paste (containing no aggregate, whether coarse or fine). Other fillers, called admixtures, can be added to the mix to improve the properties of the composite. Admixtures are discontinuous, so that they can be included in the mix. They can be particles such as silica fume (a fine particulate) and latex (a polymer in the form of a dispersion). They can be short fibers such as polymer, steel, glass, or carbon fibers. They can be liquids such as aqueous methylcellulose solutions, water reducing agents, and defoamers. Admixtures to render the composite smart while maintaining or even improving the structural properties are the focus of this section.

Background on Cement-Matrix Composites

Cement-matrix composites for smart structures include those that contain short carbon fibers (for sensing strain, damage, and temperature and for thermal control), short steel fibers (for sensing temperature and for thermal control), and silica fume (for vibration reduction). This section provides background on cement-matrix composites and emphasizes the carbon-fiber cement-matrix composite due to its dominance among intrinsically smart cement-matrix composites.

Carbon-fiber cement-matrix composites are structural materials that are gaining in importance quite rapidly due

to the decrease in carbon-fiber cost (1) and the increasing demand for superior structural and functional properties. These composites contain short carbon fibers, typically 5 mm long; the short fibers can be used as an admixture in concrete (whereas continuous fibers cannot be simply added to the concrete mix), and short fibers are less expensive than continuous fibers. However, due to the weak bond between carbon fiber and the cement matrix, continuous fibers (2–4) are much more effective than short fibers in reinforcing concrete. Surface treatment of carbon fiber [e.g., by heating (5) or by using ozone (6,7), silane (8), SiO₂ particles (9), or hot NaOH solution (10)] is useful for improving the bond between fiber and matrix, thereby improving the properties of the composite. Surface treatment by ozone or silane improves the bond due to the enhanced wettability by water. Admixtures such as latex (6,11), methylcellulose (6), and silica fume (12) also improve the bond.

The effect of carbon fiber addition on the properties of concrete increases with fiber volume fraction (13), unless the fiber volume fraction is so high that the air void content becomes excessively high (14). (The air void content increases with fiber content and air voids tend to have a negative effect on many properties, such as compressive strength.) In addition, the workability of the mix decreases with fiber content (13). Moreover, the cost increases with fiber content. Therefore, a rather low volume fraction of fibers is desirable. A fiber content as low as 0.2 vol.% is effective (15), although fiber contents exceeding 1 vol.% are more common (16–20). The required fiber content increases with the particle size of the aggregate, because flexural strength decreases as particle size increases (21).

The effective use of carbon fibers in concrete requires dispersing of the fibers in the mix. Dispersion is enhanced by using silica fume (a fine particulate) as an admixture (14,22–24). Typical silica fume content is 15% by weight of cement (14). The silica fume is usually used along with a small amount (0.4% by weight of cement) of methylcellulose to help the dispersion of the fibers and the workability of the mix (14). Latex (typically 15–20% by weight of cement) is much less effective than silica fume in helping fiber dispersion, but it enhances the workability, flexural strength, flexural toughness, impact resistance, frost resistance, and acid resistance (14,25,26). The ease of dispersion increases with decreasing fiber length (24).

The structural properties improved by carbon fiber addition are increased tensile and flexible strengths, increased tensile ductility and flexural toughness, enhanced impact resistance, reduced drying shrinkage, and improved freeze–thaw durability (13–15,17–25,27–38). Tensile and flexural strengths decrease as specimen size increases, so that the size effect becomes larger as the fiber length increases (39). Low drying shrinkage is valuable for large structures, for repair (40,41), and in joining bricks in a brick structure (42,43). The functional properties created by carbon fiber addition are strain sensing (7,44–58) (for smart structures), temperature sensing (59–62), damage sensing (44,48,63–65), thermoelectric behavior (60–62), thermal insulation (66–68) (to save energy for buildings), electrical conduction (69–78) (to facilitate cathodic protection of embedded steel and to provide electrical grounding or connection), and radio wave reflection/absorption

(79–84) (for electromagnetic interference or EMI shielding, for lateral guidance in automatic highways, and for television image transmission).

In relation to structural properties, carbon fibers compete with glass, polymer, and steel fibers (18,27–29,32,36–38,85). Carbon fibers (isotropic pitch-based) (1,85) are advantageous in their superior ability to increase the tensile strength of concrete, even though the tensile strength, modulus, and ductility of isotropic pitch-based carbon fibers are low compared to most other fibers. Carbon fibers are also advantageous in relative chemical inertness (86). PAN-based carbon fibers are also used (17,19,22,33), although they are more commonly used as continuous fibers than short fibers. Carbon-coated glass fibers (87,88) and submicron diameter carbon filaments (77–79) are even less commonly used, although the former are attractive for the low cost of glass fibers and the latter are attractive for their high radio wave reflectivity (which results from the skin effect). C-shaped carbon fibers are more effective for strengthening than round carbon fibers (89), but their relatively large diameter makes them less attractive. Carbon fibers can be used in concrete together with steel fibers; the addition of short carbon fibers to steel-fiber-reinforced mortar increases the fracture toughness of the interfacial zone between the steel fiber and the cement matrix (90). Carbon fibers can also be used in concrete together with steel bars (91,92) or together with carbon-fiber-reinforced polymer rods (93).

Carbon fibers are exceptional in most functional properties, compared to the other fiber types. Carbon fibers are electrically conducting, in contrast to glass and polymer fibers, which are not conducting. Steel fibers are conducting, but their typical diameter ($\geq 60 \mu\text{m}$) is much larger than the diameter of a typical carbon fiber ($15 \mu\text{m}$). The combination of electrical conductivity and small diameter makes carbon fibers superior to the other fiber types in the strain sensing and electrical conduction. However, carbon fibers are inferior to steel fibers for thermoelectric composites, due to the high electron concentration in steel and the low hole concentration in carbon.

Although carbon fibers are thermally conducting, the addition of carbon fibers to concrete lowers the thermal conductivity (66), thus allowing applications for thermal insulation. This effect of carbon fiber addition is due to the increase in air void content. The electrical conductivity of carbon fibers is higher than that of the cement matrix by about eight orders of magnitude, whereas the thermal conductivity of carbon fibers is higher than that of the cement matrix by only one or two orders of magnitude. As a result, electrical conductivity is increased upon carbon fiber addition despite the increase in air void content, but thermal conductivity is decreased upon fiber addition.

The use of pressure after casting (94) and extrusion (95, 96) can result in composites that have superior microstructure and properties. Moreover, extrusion improves the shapability (95).

Cement-Matrix Composites for Strain Sensing

The electrical resistance of strain-sensing concrete (without embedded or attached sensors) changes reversibly with

Figure 1. Variation of the fractional change in volume electrical resistivity and of the strain (negative for compressive strain) with time during dynamic compressive loading at increasing stress amplitudes within the elastic regime for a carbon-fiber latex cement paste after 28 days of curing.

strain, such that the gauge factor (fractional change in resistance per unit strain) is up to 700 under compression or tension (7,44–58). The resistance (dc/ac) increases reversibly under tension and decreases reversibly upon compression due to fiber pull-out upon microcrack opening ($<1\ \mu\text{m}$) and the consequent increase in fiber–matrix contact resistivity. The concrete contains as little as 0.2 vol.% short carbon fibers, which are preferably those that have been surface-treated. The fibers do not need to touch one another in the composite. The treatment improves wettability with water. The presence of a large aggregate decreases the gauge factor, but the strain-sensing ability remains sufficient for practical use. Strain-sensing concrete works even when data acquisition is wireless. The applications include structural vibration control and traffic monitoring.

Figure 1 shows the fractional change in resistivity along the stress axis, as well as the strain during repeated compressive loading at an increasing stress amplitude for carbon-fiber latex cement paste after 28 days of curing. The strain varies linearly with the stress up to the highest stress amplitude. The strain returns to zero at the end of each loading cycle. The resistivity decreases upon loading in every cycle (due to fiber push-in) and increases upon unloading in every cycle (due to fiber pull-out). The resistivity has a net increase after the first cycle, due to damage. Little further damage occurs in subsequent cycles; the resistivity after unloading does not increase much after the first cycle. The greater the strain amplitude, the more the resistivity decreases during loading, although the resistivity and strain are not linearly related. The effects in Fig. 1 were also observed in carbon-fiber silica-fume cement paste after 28 days of curing.

Figures 2 and 3 show the fractional changes in the longitudinal and transverse resistivities, respectively, for carbon-fiber silica-fume cement paste after 28 days of curing during repeated uniaxial tensile loading at increasing strain amplitudes. The strain essentially returns to zero at

Figure 2. Variation of the fractional change in longitudinal electrical resistivity (solid curve) and of strain with time (dashed curve) during dynamic uniaxial tensile loading at increasing stress amplitudes within the elastic regime for a carbon-fiber silica-fume cement paste.

Figure 3. Variation of the fractional change in transverse electrical resistivity (solid curve) and of strain with time (dashed curve) during dynamic uniaxial tensile loading at increasing stress amplitudes within the elastic regime for a carbon-fiber silica-fume cement paste.

the end of each cycle, indicating elastic deformation. The longitudinal strain is positive (i.e., elongation); the transverse strain is negative (i.e., shrinkage due to the Poisson effect). Both longitudinal and transverse resistivities increase reversibly under uniaxial tension. The reversibility of both strain and resistivity is more complete in the longitudinal direction than in the transverse direction. The gauge factor is 89 and -59 for the longitudinal and transverse resistances, respectively.

Figures 4 and 5 show corresponding results for silica-fume cement paste. The strain is essentially totally reversible in both the longitudinal and transverse directions, but the resistivity is only partly reversible in both directions, in contrast to the reversibility of the resistivity when fibers are present (Figs. 2 and 3). As with fibers, both longitudinal and transverse resistivities increase under uniaxial tension. However, the gauge factor is only 7.2 and -7.1 for Figs. 4 and 5, respectively.

Comparison of Figs. 2 and 3 (with fibers) with Figs. 4 and 5 (without fibers) shows that fibers greatly enhance the

Figure 4. Variation of the fractional change in longitudinal electrical resistivity (solid curve) and of strain with time (dashed curve) during dynamic uniaxial tensile loading at increasing stress amplitudes within the elastic regime for a silica-fume cement paste.

magnitude and reversibility of the resistivity effect. The gauge factors are much smaller when fibers are absent.

The increase in both longitudinal and transverse resistivities under uniaxial tension for cement pastes, whether with or without fibers, is attributed to defect (e.g., microcrack) generation. In the presence of fibers, fiber bridging across microcracks occurs, and slight fiber pull-out occurs under tension, thus enhancing the possibility of microcrack closing and causing more reversibility in the resistivity change. The fibers are much more electrically conductive than the cement matrix. The presence of the fibers introduces interfaces between fibers and matrix. The degradation of the fiber-matrix interface due to fiber pull-out or other mechanisms is an additional type of defect generation which will increase the resistivity of the composite. Therefore, the presence of fibers greatly increases the gauge factor.

The transverse resistivity increases under uniaxial tension, even though the Poisson effect makes the transverse strain negative. This means that the effect of transverse

Figure 5. Variation of the fractional change in transverse electrical resistivity (solid curve) and of strain with time (dashed curve) during dynamic uniaxial tensile loading at increasing stress amplitudes within the elastic regime for a silica-fume cement paste.

resistivity increase overshadows the effect of transverse shrinkage. The increase in resistivity is a consequence of uniaxial tension. In contrast, under uniaxial compression, the resistance in the stress direction decreases after 28 days of curing. Hence, the effects of uniaxial tension on transverse resistivity and of uniaxial compression on longitudinal resistivity are different; the gauge factors are negative and positive for these cases, respectively.

The similarity of the resistivity change in the longitudinal and transverse directions under uniaxial tension suggests similarity for other directions as well. This means that the resistance can be measured in any direction to sense the occurrence of tensile loading. Although the gauge factor is comparable in both longitudinal and transverse directions, the fractional change in resistance under uniaxial tension is much higher in the longitudinal direction than in the transverse direction. Thus, the use of the longitudinal resistance for practical self-sensing is preferred.

Cement-Matrix Composites for Damage Sensing

Concrete, with or without admixtures, can sense major and minor damage—even damage during elastic deformation—due to the increase in electrical resistivity that accompanies damage (44,48,63–65). That both strain and damage can be sensed simultaneously through resistance measurement means that the strain/stress condition (during dynamic loading) under which damage occurs can be obtained, thus facilitating damage origin identification. Damage is indicated by an increase in resistance, which is larger and less reversible when the stress amplitude is higher. The increase in resistance can be sudden during loading. It can also be a gradual shift of the baseline resistance.

Figure 6 (64) shows the fractional change in resistivity along the stress axis, as well as the strain during repeated compressive loading at increasing stress amplitude for silica-fume cement paste after 28 days of curing. The strain varies linearly with stress up to the highest stress amplitude. The strain returns to zero at the end of each loading

Figure 6. Variation of the fractional change in electrical resistivity and of strain (negative for compressive strain) with time during dynamic compressive loading at increasing stress amplitudes within the elastic regime for a silica-fume cement paste after 28 days of curing.

Figure 7. Fractional change in resistance and strain during repeated compressive loading at increasing and decreasing stress amplitudes, the highest of which was 60% of the compressive strength, for carbon-fiber concrete after 28 days of curing.

cycle. During the first loading, the resistivity increases due to damage initiation. During the subsequent unloading, the resistivity continues to increase, probably due to opening of microcracks generated during loading. During the second loading, the resistivity decreases slightly as the stress increases up to the maximum stress of the first cycle (probably due to the closing of microcracks) and then increases as the stress increases beyond this value (probably due to the generation of additional microcracks). During unloading in the second cycle, the resistivity increases significantly (probably due to the opening of microcracks). During the third loading, the resistivity essentially does not change (or decreases very slightly) as the stress increases to the maximum stress of the third cycle (probably due to the balance between microcrack generation and microcrack closing). Subsequent unloading causes the resistivity to increase very significantly (probably due to the opening of microcracks).

Figure 7 shows the fractional change in resistance and strain during repeated compressive loading at increasing and decreasing stress amplitudes for carbon-fiber (0.18 vol.%) concrete (with fine and coarse aggregates) after 28 days of curing. The highest stress amplitude is 60% of the compressive strength. A group of cycles in which the stress amplitude increases cycle by cycle and then decreases cycle by cycle back to the initial low stress amplitude is here referred to as a group. Figure 7 shows the results for three groups. The strain returns to zero at the end of each cycle for any of the stress amplitudes, indicating elastic behavior. The resistance decreases upon loading in each cycle, as in Fig. 1. An extra peak at the maximum stress of a cycle grows as the stress amplitude increases, resulting in two peaks per cycle. The original peak (strain induced) occurs at zero stress, and the extra peak (damage induced) occurs at maximum stress. Hence, during loading from zero stress within a cycle, the resistance drops, then increases sharply, and reaches the maximum resistance of the extra peak at the maximum stress of the cycle. Upon subsequent unloading, the resistance decreases, then increases as unloading continues, and reaches the maximum resistance of the original peak at zero stress. In the part of

this group where the stress amplitude decreases cycle by cycle, the extra peak diminishes and disappears, leaving the original peak as the sole peak. In the part of the second group where the stress amplitude increases cycle by cycle, the original peak (peak at zero stress) is the sole peak, except that the extra peak (peak at the maximum stress) returns in a minor way (more minor than in the first group) as the stress amplitude increases. The extra peak grows as the stress amplitude increases, but, in the part of the second group in which the stress amplitude decreases cycle by cycle, it quickly diminishes and vanishes, as in the first group. Within each group, the amplitude of the variation in resistance increases as the stress amplitude increases and decreases as the stress amplitude subsequently decreases.

The greater the stress amplitude, the larger and the less reversible the damage-induced increase in resistance (the extra peak). If the stress amplitude has been experienced before, the damage-induced increase in resistance (the extra peak) is small, as shown by comparing the result of the second group with that of the first group (Fig. 7), unless the extent of damage is large (Fig. 8 for the highest stress amplitude of >90% of the compressive strength). When the damage is extensive (as shown by a decrease in modulus), a damage-induced increase in resistance occurs in every cycle, even at a decreasing stress amplitude, and it can overshadow the strain-induced decrease in resistance (Fig. 8). Hence, the damage-induced increase in resistance occurs mainly during loading (even within the elastic regime), particularly at a stress above that in prior cycles, unless the stress amplitude is high and/or damage is extensive.

At a high stress amplitude, the damage-induced increase in resistance, cycle by cycle, as the stress amplitude increases, causes the baseline resistance to increase irreversibly (Fig. 8). The baseline resistance in the regime of major damage (that decreases in modulus) provides a measure of the extent of damage (i.e., condition monitoring). This measure works in the loaded or unloaded state. In

Figure 8. Fractional change in resistance and strain during repeated compressive loading at increasing and decreasing stress amplitudes, the highest of which was >90% of the compressive strength, for a carbon-fiber concrete after 28 days of curing.

Figure 9. Current-voltage characteristic of a carbon-fiber silica-fume cement paste at 38°C during stepped heating.

contrast, the measure using the damage-induced increase in resistance (Fig. 7) works only during an increase in stress and indicates the occurrence of damage (whether minor or major), as well as the extent of damage.

Cement-Matrix Composites for Temperature Sensing

A thermistor is a thermometric device that consists of a material (typically a semiconductor, but in this case a cement paste) whose electrical resistivity decreases with a rise in temperature. The carbon-fiber concrete described previously for strain sensing is a thermistor because its resistivity decreases reversibly as temperature increases (59); the sensitivity is comparable to that of semiconductor thermistors. (The effect of temperature will need to be compensated for in using the concrete as a strain sensor.)

Figure 9 (59) shows the current-voltage characteristic of carbon-fiber (0.5% by weight of cement) silica-fume (15% by weight of cement) cement paste at 38°C during stepped heating. The characteristic is linear below 5 V and deviates positively from linearity beyond 5 V. The resistivity is obtained from the slope of the linear portion. The voltage at which the characteristic starts to deviate from linearity is called the critical voltage.

Figure 10 shows a plot of resistivity versus temperature for carbon-fiber silica-fume cement paste during heating and cooling. The resistivity decreases upon heating, and the effect is quite reversible upon cooling. That the resistivity increases slightly after a heating/cooling cycle is probably due to thermal degradation of the material. Figure 11 shows the Arrhenius plot of log conductivity (conductivity = 1/resistivity) versus the reciprocal of the absolute temperature. The slope of the plot gives the activation energy, which is 0.390 ± 0.014 and 0.412 ± 0.017 eV during heating and cooling, respectively.

Results similar to those of carbon-fiber silica-fume cement paste were obtained with carbon-fiber (0.5% by weight of cement) latex (20% by weight of cement) cement paste, silica-fume cement paste, latex cement paste, and plain cement paste. However, for all of these four types of cement paste, (1) the resistivity is higher by about an order of magnitude, and (2) the activation energy is lower

Figure 10. Plot of volume electrical resistivity vs. temperature during heating and cooling for a carbon-fiber silica-fume cement paste.

by about an order of magnitude, as shown in Table 1. The critical voltage is higher when fibers are absent (Table 1).

The Seebeck (60–62,97) effect is a thermoelectric effect which is the basis for using thermocouples for temperature measurement. This effect involves charge carriers that move from a hot point to a cold point within a material, thereby resulting in a voltage difference between the two points. The Seebeck coefficient is the negative of the voltage difference (hot minus cold) per unit temperature difference between the two points (hot minus cold). Negative carriers (electrons) make it more negative, and positive carriers (holes) make it more positive.

The Seebeck effect in carbon-fiber-reinforced cement paste involves electrons from the cement matrix (62) and holes from the fibers (60,61), such that the two contributions are equal at the percolation threshold, a fiber content from 0.5–1.0% by weight of cement (62). The hole contribution increases monotonically as fiber content changes above and below the percolation threshold (62).

Due to the free electrons in a metal, cement that contains metal fibers such as steel fibers is even more negative in thermoelectric power than cement without fiber (97).

Figure 11. Arrhenius plot of log electrical conductivity vs. reciprocal absolute temperature for a carbon-fiber silica-fume cement paste.

Table 1. Resistivity, Critical Voltage, and Activation Energy of Five Types of Cement Pastes

Formulation	Resistivity at 20°C (Ω cm)	Critical Voltage at 20°C (V)	Activation Energy (eV)	
			Heating	Cooling
Plain	$(4.87 \pm 0.37) \times 10^5$	10.80 ± 0.45	0.040 ± 0.006	0.122 ± 0.006
Silica fume	$(6.12 \pm 0.15) \times 10^5$	11.60 ± 0.37	0.035 ± 0.003	0.084 ± 0.004
Carbon fibers + silica fume	$(1.73 \pm 0.08) \times 10^4$	8.15 ± 0.34	0.390 ± 0.014	0.412 ± 0.017
Latex	$(6.99 \pm 0.12) \times 10^5$	11.80 ± 0.31	0.017 ± 0.001	0.025 ± 0.002
Carbon fibers + latex	$(9.64 \pm 0.08) \times 10^4$	8.76 ± 0.35	0.018 ± 0.001	0.027 ± 0.002

The attainment of a very negative thermoelectric power is attractive because a material whose thermoelectric power is positive and a material whose thermoelectric power is negative are two very dissimilar materials; their junction is a thermocouple junction. The greater the dissimilarity, the more sensitive the thermocouple.

Table 2 and Fig. 12 show the thermoelectric power results. The absolute thermoelectric power is much more negative for all of the steel-fiber cement pastes compared to all of the carbon-fiber cement pastes. An increase in the steel fiber content from 0.5% to 1.0% by weight of cement makes the absolute thermoelectric power more negative, whether or not silica fume (or latex) is present. An increase in the steel fiber content also increases the reversibility and linearity of the change in Seebeck voltage with the temperature difference between the hot and cold ends, as shown by comparing the values of the Seebeck coefficient obtained during heating and cooling in Table 2. The values obtained during heating and cooling are close for the pastes that have the higher steel-fiber content but are not so close for the pastes that have the lower steel-fiber content. In contrast, for pastes that have carbon fibers in place of steel fibers, the change in Seebeck voltage with temperature difference is highly reversible for both carbon-fiber contents of 0.5 and 1.0% by weight of cement, as shown in Table 2 by comparing the values of the Seebeck coefficient obtained during heating and cooling.

Table 2 shows that the volume electrical resistivity is much higher for the steel-fiber cement pastes than the corresponding carbon-fiber cement pastes. This is attributed to the much lower volume fraction of fibers in the former (Table 2). An increase in the steel-or carbon-fiber content from 0.5 to 1.0% by weight of cement decreases the resistivity, though the decrease is more significant for the carbon-fiber cement than for the steel-fiber cement. That the resistivity decrease is not large when the steel fiber content is increased from 0.5 to 1.0% by weight of cement and that the resistivity is still high at a steel-fiber content of 1.0% by weight of cement suggest that a steel-fiber content of 1.0% by weight of cement is below the percolation threshold.

With or without silica fume (or latex), the change of the Seebeck voltage with temperature is more reversible and linear at a steel-fiber content of 1.0% by weight of cement than at a steel fiber content of 0.5% by weight of cement. This is attributed to the larger role of the cement matrix at the lower steel-fiber content and the contribution of the cement matrix to the irreversibility and nonlinearity. Irreversibility and nonlinearity are particularly significant when the cement paste contains no fiber.

From the practical point of view, the steel-fiber silica-fume cement paste that contains 1.0% steel fibers by weight of cement is particularly attractive for use in temperature sensing because the absolute thermoelectric

Figure 12. Variation of the Seebeck voltage (with copper as the reference) vs. the temperature difference during heating and cooling for a steel-fiber silica-fume cement paste containing 1.0% steel fibers by weight of cement.

power is the highest ($-68 \mu\text{V}/^\circ\text{C}$) and the variation of the Seebeck voltage with the temperature difference between the hot and cold ends is reversible and linear. The absolute thermoelectric power is as high as that of commercial thermocouple materials.

Joints between concretes that have different values of thermoelectric power, made by multiple pouring, provide concrete thermocouples (98).

Cement-Matrix Composites for Thermal Control

Concretes that can inherently provide heating through Joule heating, provide temperature sensing, or provide temperature stability through a high specific heat (high thermal mass) are highly desirable for thermal control of structures and energy saving in buildings. Concretes of low electrical resistivity (69–78) are useful for Joule heating, concrete thermistors and thermocouples are useful for temperature sensing, and concretes of high specific heat (66–68,99) are useful for heat retention. These concretes involve the use of admixtures such as fibers and silica fume. For example, silica fume introduces interfaces that promote the specific heat (66); short carbon fibers enhance electrical conductivity (74) and produce p-type concrete (62). Plain concrete is n-type (62).

Figure 13 (74) gives the volume electrical resistivity of composites after 7 days of curing. The resistivity decreases a lot as the fiber volume fraction increases, whether or not a second filler (silica fume or sand) is present. When sand is absent, the addition of silica fume decreases the resistivity at all carbon-fiber volume fractions except the highest volume fraction of 4.24%; the decrease is most significant at the lowest fiber volume fraction of 0.53%. When sand is present, the addition of silica fume similarly decreases the resistivity; the decrease is most significant at fiber volume fractions below 1%. When silica fume is absent, the addition of sand decreases the resistivity only when the fiber volume fraction is below about 0.5%; at high fiber volume fractions, the addition of sand even increases the resistivity due to the porosity induced by the sand. Thus, the addition of a second filler (silica fume or sand) that is essentially

Figure 13. Variation of the volume electrical resistivity of cement-matrix composites with carbon-fiber volume fraction. (a) without sand, with methylcellulose, without silica fume; (b) without sand, with methylcellulose, with silica fume; (c) with sand, with methylcellulose, without silica fume; (d) with sand, with methylcellulose, with silica fume.

nonconducting decreases the resistivity of the composite only at low volume fractions of the carbon fibers, and the maximum fiber volume fraction for decreased resistivity is larger when the particle size of the filler is smaller. The decrease in resistivity is attributed to the improved fiber dispersion that results from the presence of the second filler. Consistent with improved fiber dispersion is increased flexural toughness and strength due to the presence of the second filler.

Table 3 (67,100) shows the specific heats of cement pastes. The specific heat is significantly increased by adding of silica fume. It is further increased by the further addition of methylcellulose and defoamer. It is still further increased by the still further addition of carbon fibers. The effectiveness of fibers in increasing the specific heat increases in the following order: as-received fibers, O_3 -treated fibers, dichromate-treated fibers, and silane-treated fibers. This trend applies whether the silica fume is as-received or silane-treated. For any of the formulations, silane-treated silica fume gives higher specific heat than as-received silica fume. The highest specific heat is exhibited by the cement paste that contains silane-treated silica fume and silane-treated fibers. The specific heat is 12% higher than that of plain cement paste, 5% higher than that of the cement paste containing as-received silica fume and as-received fibers, and 0.5% higher than that of the cement

Table 3. Specific Heats (J/g · K, ± 0.001) of Cement Pastes. The Value for Plain Cement Paste (with Cement and Water only) Is 0.736 J/g · K

Formulation ^a	As-Received Silica Fume	Silane-Treated Silica Fume
A	0.782	0.788
A ⁺	0.793	0.803
A ⁺ F	0.804	0.807

^aA⁺S: A⁺ + silane-treated fibers.

paste containing as-received silica fume and silane-treated fibers. Hence, silane treatment of fibers is more valuable than treatment of silica fume to increase the specific heat.

Table 4 (67,100) shows the thermal diffusivities of cement pastes. The thermal diffusivity is significantly decreased by adding silica fume. The further addition of methylcellulose and defoamer or the further addition of fibers has relatively little effect on thermal diffusivity. Surface treatment of the fibers by ozone or dichromate slightly increases the thermal diffusivity, whereas surface treatment of the fibers by silane slightly decreases the thermal diffusivity. These trends apply whether the silica fume is as-received or silane-treated. For any of the formulations, silane-treated silica fume gives slightly lower (or essentially the same) thermal diffusivity than as-received silica fume. Silane treatments of silica fume and of fibers are about equally effective in lowering the thermal diffusivity.

Table 5 (67,100) shows the densities of cement pastes. The density is significantly decreased by adding silica fume. It is further decreased slightly by the addition of methylcellulose and defoamer. It is still further decreased by the addition of fibers. The effectiveness of

fibers in decreasing the density decreases in the following order: as-received fibers, O₃-treated fibers, dichromate-treated fibers, and silane-treated fibers. This trend applies whether the silica fume is as-received or silane-treated. For any of the formulations, silane-treated silica fume gives slightly higher (or essentially the same) specific heat than as-received silica fume. Silane treatment of fibers is more valuable than treatment of silica fume to increase density.

Table 6 (67,100) shows the thermal conductivities of cement pastes. They are significantly decreased by adding silica fume. The further addition of methylcellulose and defoamer or the still further addition of fibers has little effect on density. Surface treatment of fibers by ozone or dichromate slightly increases the thermal conductivity, whereas surface treatment of the fibers by silane has a negligible effect. These trends apply whether the silica fume is as-received or silane-treated. For any of the formulations, silane-treated silica fume gives slightly lower (or essentially the same) thermal conductivity than as-received silica fume. Silane treatments of silica fume and of fibers contribute comparably to reducing the thermal conductivity.

Sand is a much more common component in concrete than silica fume. It differs from silica fume in its relatively large particle size and negligible reactivity with cement. Sand gives effects that are opposite from those of silica fume; sand addition decreases the specific heat and increases the thermal conductivity (99).

Table 7 (99) shows the thermal behavior of cement pastes and mortars. Comparison of the results on cement paste without silica fume and those on mortar without silica fume shows that sand addition decreases the specific heat by 13% and increases the thermal conductivity by 9%. Comparison of the results on cement paste with silica fume and those on mortar with silica fume shows that sand addition decreases the specific heat by 11% and increases the thermal conductivity by 64%. That sand addition has more effect on the thermal conductivity when silica fume is present than when silica fume is absent is due to the low value of the thermal conductivity of cement paste that contains silica fume (Table 7).

Comparison of the results on cement paste without and with silica fume shows that silica fume addition increases the specific heat by 7% and decreases the thermal conductivity by 38%. Comparison of the results on mortar without and with silica fume shows that silica fume addition increases the specific heat by 10% and decreases the thermal conductivity by 6%. Hence, the effects of silica fume addition on mortar and cement paste are in the same direction. That the effect of silica fume on the thermal conductivity is much less for mortar than for cement paste is mainly due to the fact that silica fume addition increases the density of mortar but decreases the density of cement paste (Table 7). That the fractional increase in specific heat due to silica fume addition is higher for mortar than cement paste is attributed to the low value of the specific heat of mortar without silica fume (Table 7).

Comparison of the results on cement paste with silica fume and those on mortar without silica fume shows that sand addition gives a lower specific heat than silica fume addition and a higher thermal conductivity than silica fume addition. Because sand has a much larger particle size than silica fume, sand has much less interfacial area than silica fume, though the interface may be more diffuse for silica fume than for sand. The low interfacial area for sand is believed responsible for the low specific heat and

the higher thermal conductivity because slippage at the interface contributes to the specific heat and the interface acts as a thermal barrier.

Silica fume addition increases the specific heat of cement paste by 7%, whereas sand addition decreases it by 13%. Silica fume addition decreases the thermal conductivity of cement paste by 38%, whereas sand addition increases it by 22%. Hence, silica fume addition and sand addition have opposite effects. The cause is believed to be associated mainly with the low interfacial area for sand and the high interfacial area for silica fume, as explained in the last paragraph. The high reactivity of silica fume compared to sand may contribute to the observed difference between silica fume addition and sand addition, though this contribution is believed to be minor because the reactivity should have tightened up the interface, thus decreasing the specific heat (in contrast to the observed effects). The decrease in specific heat and the increase in thermal conductivity upon sand addition are believed to be due to the higher level of homogeneity within a sand particle than within cement paste.

Cement-Matrix Composites for Vibration Reduction

Vibration reduction requires high damping capacity and high stiffness. Viscoelastic materials such as rubber have high damping capacity but low stiffness. Concretes that have both high damping capacity (two or more orders higher than conventional concrete) (Table 8) (101) and high stiffness (Table 9) (101) can be obtained by adding surface-treated silica fume to concrete. Steel-reinforced concretes that have improved damping capacity and stiffness can be obtained by surface treating the steel (say, by sand blasting) before incorporating it in concrete (Table 10) (102) or by using silica fume in concrete (101). Due to its small

particle size, silica fume in concrete introduces interfaces that enhance damping. Sand blasting of a steel rebar increases the interfacial area between steel and concrete, thereby enhancing damping. Carbon-fiber addition has relatively small effects on damping capacity and stiffness (103).

POLYMER-MATRIX COMPOSITES FOR SMART STRUCTURES

Polymer-matrix composites for structural applications typically contain continuous fibers such as carbon, polymer, and glass fibers because continuous fibers tend to be more effective as a reinforcement than short fibers. Polymer-matrix composites that contain continuous carbon fibers are used for aerospace, automobile, and civil structures. In contrast, continuous fibers are too expensive for reinforcing concrete. Because carbon fibers are electrically conducting, whereas polymer and glass fibers are not, carbon-fiber composites are predominant among polymer-matrix composites that are intrinsically smart.

Background on Polymer-Matrix Composites

Polymer-matrix composites that contain continuous carbon fibers are important structural materials due to their high tensile strength, high tensile modulus, and low density. They are used for lightweight structures such as satellites, aircraft, automobiles, bicycles, ships, submarines, sporting goods, wheel chairs, armor, and rotating machinery (such as turbine blades and helicopter rotors). Due to the recent emphasis on repair of civil infrastructural systems,

composites are beginning to be used to repair concrete structures and bridges, even though they are much more expensive than concrete. Because the price of carbon fibers has been dropping steadily during the last two decades, the spectrum of applications has been widening tremendously.

The continuous carbon fibers used are primarily based on either polyacrylonitrile (PAN) or mesophase pitch. Mesophase-pitch-based carbon fibers, if heat treated to high temperatures exceeding 2500°C, can be graphitized and attain very high values of tensile modulus and thermal conductivity (in-plane), in addition to improved oxidation resistance. The high thermal conductivity is attractive for thermal management, which is particularly important for electronics (i.e., heat sinks, etc.). However, graphitized fibers tend to have relatively low strength due to the ease of shear between the graphite layers, and they are very expensive. On the other hand, PAN-based fibers cannot be graphitized, though they compete well with mesophase-pitch-based fibers which have not been graphitized, both materials exhibit reasonably high values of both strength and modulus and are not very expensive. These fibers are the most widely used among carbon fibers. The fabrication of both pitch-based and PAN-based carbon fibers involves stabilization (infusibilization) and then carbonization (conversion from hydrocarbon molecules to a carbon network). Graphitization optionally follows carbonization.

Due to the importance of carbon-fiber polymer-matrix composites for structural applications, the mechanical behavior of these materials has been much investigated. Much less work has been done to study the electrical behavior (104–111). On the other hand, due to the fact that carbon fibers are much more conductive than the polymer matrix, the electrical behavior gives much information on the microstructure, such as the degree of fiber alignment, the number of fiber–fiber contacts, the amount of delamination, and the extent of fiber breakage. Such information is useful for scientific understanding of the properties of the composite and is also valuable for giving the composite the ability to sense its strain, damage, and temperature in real time via electrical measurement. In other words, the strain, damage, and temperature affect the electrical

behavior, such as electrical resistance, which thus serves to indicate strain, damage, and temperature. In this way, the composite is self-sensing, that is, intrinsically smart, without the need for attached or embedded sensors (such as optical fibers, acoustic sensors and piezoelectric sensors), which raise the cost, reduce the durability and, in the case of embedded sensors, weaken the structure.

Carbon fibers are electrically conductive, whereas the polymer matrix is electrically insulating [except for the rare situation in which the polymer is electrically conductive (112)]. The continuous fibers in a composite laminate are in the form of layers called laminae. Each lamina comprises many bundles (called tows) of fibers in a polymer matrix. Each tow consists of thousands of fibers. There may or may not be twist in a tow. Each fiber has a diameter that typically ranges from 7–12 μm . The tows within a lamina are usually oriented in the same direction, but tows in different laminae may or may not be in the same direction. A laminate whose tows in all of the laminae are oriented in the same direction is said to be unidirectional. A laminate whose tows in adjacent laminae are oriented at a 90° angle is said to be crossply. In general, an angle of 45° and other angles may also be involved in the various laminae, as desired to attain the mechanical properties required for the laminate in various directions in the plane of the laminate.

Within a lamina whose tows are in the same direction, the electrical conductivity is highest in the fiber direction. In the transverse direction in the plane of the lamina, the conductivity is not zero, even though the polymer matrix is insulating because there are contacts between fibers of adjacent tows (113). In other words, a fraction of the fibers of one tow touch a fraction of the fiber of an adjacent tow here and there along the length of the fibers. These contacts result from the fact that fibers are not perfectly straight or parallel (even though the lamina is said to be unidirectional) and the flow of the polymer matrix (or resin) during composite fabrication can prevent a fiber from being completely covered by the polymer (even though, prior to composite fabrication, each fiber may be completely covered by the polymer, as in the case of a prepreg, a fiber sheet impregnated with polymer). Fiber waviness is known as marcelling. Thus, the transverse conductivity gives information on the number of fiber–fiber contacts in the plane of the lamina.

For similar reasons, the contacts between fibers of adjacent laminae make the conductivity in the through-thickness direction (direction perpendicular to the plane of the laminate) nonzero. Thus, the through-thickness conductivity gives information on the number of fiber–fiber contacts between adjacent laminae.

Matrix cracking between the tows of a lamina decreases the number of fiber–fiber contacts in the plane of the lamina, thus decreasing the transverse conductivity. Similarly, matrix cracking between adjacent laminae [as in delamination (114)] decreases the number of fiber–fiber contacts between adjacent laminae, thus decreasing the through-thickness conductivity. This means that the transverse and through-thickness conductivities can indicate damage as matrix cracking.

Fiber damage (as distinct from fiber fracture) decreases the conductivity of a fiber, thereby decreasing the

longitudinal conductivity (conductivity in the fiber direction). However, due to the brittleness of carbon fibers, the decrease in conductivity due to fiber damage before fiber fracture is rather small (115).

Fiber fracture causes a much larger decrease in the longitudinal conductivity of a lamina than fiber damage. If there is only one fiber, a broken fiber results in an open circuit, i.e., zero conductivity. However, a lamina has a large number of fibers and adjacent fibers can make contact here and there. Therefore, the portions of a broken fiber still contribute to the longitudinal conductivity of the lamina. As a result, the decrease in conductivity due to fiber fracture is less than it would be if a broken fiber did not contribute to conductivity. Nevertheless, the effect of fiber fracture on longitudinal conductivity is significant, so that longitudinal conductivity can indicate damage as fiber fracture (116).

The through-thickness volume resistance of a laminate is the sum of the volume resistance of each of the laminae in the through-thickness direction and the contact resistance of each of the interfaces between adjacent laminae (i.e., the interlaminar interface). For example, a laminate that has eight laminae has eight volume resistances and seven contact resistances, all in the through-thickness direction. Thus, to study the interlaminar interface, it is better to measure the contact resistance between two laminae rather than the through-thickness volume resistance of the entire laminate.

The contact resistance between laminae can be measured by allowing two laminae (strips) to contact at a junction and using the two ends of each strip to make four electrical contacts (117). An end of the top strip and an end of the bottom strip serve as contacts for passing current. The other end of the top strip and the other end of the bottom strip serve as contacts for voltage measurement. The fibers in the two strips can be in the same direction or in different directions. This method is a form of the four-probe method of measuring electrical resistance. The configuration is illustrated in Fig. 14 for crossply and unidirectional laminates. To make sure that the volume resistance within a lamina in the through-thickness direction does not contribute to the measured resistance, the fibers at each end of a lamina strip should be electrically shorted together by using silver paint or other conducting media. The measured resistance is the contact resistance of the junction. This resistance, multiplied by the area of the junction, gives the contact resistivity, which is independent of the area of the junction and depends only on the nature of the interlaminar interface. The unit of contact resistivity is $\Omega\text{ m}^2$, whereas that of the volume resistivity is $\Omega\text{ m}$.

The structure of the interlaminar interface tends to be more prone to change than the structure within a lamina. For example, damage as delamination is much more common than damage as fiber fracture. Moreover, the structure of the interlaminar interface is affected by the interlaminar stress (whether thermal stress or curing stress), which is particularly significant when the laminae are not unidirectional (because the anisotropy within each lamina enhances the interlaminar stress). The structure of the interlaminar interface also depends on the extent of consolidation of the laminae during composite fabrication.

Figure 14. Specimen configuration for measuring of the contact electrical resistivity between laminae. (a) Crossply laminae. (b) Unidirectional laminae.

The contact resistance provides a sensitive probe of the structure of the interlaminar interface.

The volume resistivity in the through-thickness direction can be measured by using the four-probe method, in which each of the two current contacts is a conductor loop (made by silver paint, for example) on each of the two outer surfaces of the laminate in the plane of the laminate, and each of the two voltage contacts is a conductor dot within the loop (114). An alternate method is to have four extra long laminae in the laminate, extend out to serve as electrical leads (118). The two outer leads are for current contacts, and the two inner leads are for voltage contacts. The use of a thin metal wire inserted at an end into the interlaminar space during composite fabrication to serve as an electrical contact is not recommended because the quality of the electrical contact between the metal wire and carbon fibers is hard to control and the wire is intrusive in the composite. The alternate method is less convenient than the method involving loops and dots, but it approaches the ideal four-probe method more closely.

To attain zero conductivity in the through-thickness direction of a laminate, it is necessary to use an insulating layer between two adjacent laminae (119). The insulating layer can be a piece of writing paper. Tissue paper is ineffective in preventing contacts between fibers of adjacent laminae due to its porosity. The attainment of zero conductivity in the through-thickness direction allows the laminate to serve as a capacitor. This means that the structural composite stores energy by serving as a capacitor.

Polymer-Matrix Composites for Strain Sensing

Smart structures that can monitor their own strain are valuable for structural vibration control. Self-monitoring of strain (reversible) has been achieved in carbon-fiber

epoxy-matrix composites without using embedded or attached sensors (118,120–123) because the electrical resistance of the composite in the through-thickness or longitudinal direction changes reversibly with longitudinal strain (gauge factor up to 40) due to a change in the degree of fiber alignment. Tension in the fiber direction of the composite increases the degree of fiber alignment, thereby decreasing the chance for fibers of adjacent laminae to touch one another. As a consequence, the through-thickness resistance increases, and the longitudinal resistance decreases.

Figure 14 (121) shows the change in longitudinal resistance during cyclic longitudinal tension in the elastic regime for a unidirectional continuous-carbon-fiber epoxy-matrix composite that has eight fiber layers (laminae). The stress amplitude is equal to 14% of the breaking stress. The strain returns to zero at the end of each cycle. Because of the small strains involved, the fractional resistance change $\Delta R/R_0$ is essentially equal to the fractional change in resistivity. The longitudinal $\Delta R/R_0$ decreases upon loading and increases upon unloading in every cycle, such that R irreversibly decreases slightly after the first cycle (i.e., $\Delta R/R_0$ does not return to zero at the end of the first cycle). At higher stress amplitudes, the effect is similar, except that both of the reversible and irreversible parts of $\Delta R/R_0$ are larger.

Figure 15 (121) shows the change in the through-thickness resistance during cyclic longitudinal tension in the elastic regime for the same composite. The stress amplitude is equal to 14% of the breaking stress. The through-thickness $\Delta R/R_0$ increases upon loading and decreases

Figure 15. Longitudinal stress and strain and fractional resistance increase ($\Delta R/R_0$) obtained simultaneously during cyclic tension at a stress amplitude equal to 14% of the breaking stress for a continuous-fiber epoxy-matrix composite.

Figure 16. Longitudinal stress and strain and the through-thickness $\Delta R/R_0$ obtained simultaneously during cyclic tension at a stress amplitude equal to 14% of the breaking stress for a continuous-fiber epoxy-matrix composite.

upon unloading in every cycle, such that R irreversibly decreases slightly after the first cycle (i.e., $\Delta R/R_0$ does not return to zero at the end of the first cycle). Upon increasing the stress amplitude, the effect is similar, except that the reversible part of $\Delta R/R_0$ is larger.

The strain sensitivity (gauge factor) is defined as the reversible part of $\Delta R/R_0$ divided by the longitudinal strain amplitude. It is negative (from -18 to -12) for the longitudinal $\Delta R/R_0$ and positive (17 – 24) for the through-thickness $\Delta R/R_0$. The magnitudes are comparable for the longitudinal and through-thickness strain sensitivities. As a result, whether the longitudinal R or the through-thickness R is preferred for strain sensing depends only on the convenience of electrical contact application for the geometry of the particular smart structure.

Figure 16 (121) shows the compressive stress, strain, and longitudinal $\Delta R/R_0$ obtained simultaneously during cyclic compression at stress amplitudes equal to 14% of the breaking stress for a similar composite that has 24 rather than eight fiber layers. The longitudinal $\Delta R/R_0$ increases upon compressive loading and decreases upon unloading in every cycle, such that resistance R irreversibly increases very slightly after the first cycle. The magnitude of the gauge factor is lower in compression (-1.2) than in tension (from -18 to -12).

A dimensional change without any resistivity change would have caused longitudinal R to increase during tensile loading and decrease during compressive loading. In contrast, the longitudinal R decreases upon tensile loading

and increases upon compressive loading. In particular, the magnitude of $\Delta R/R_0$ under tension is 7–11 times that of $\Delta R/R_0$ calculated by assuming that $\Delta R/R_0$ is due only to dimensional change and not due to any change in resistivity. Hence, the contribution of $\Delta R/R_0$ from the dimensional change is negligible compared to that from the change in resistivity.

Though the irreversible behavior is small compared to the reversible behavior, it is such that R (longitudinal or through-thickness) under tension is irreversibly decreased after the first cycle. This behavior is attributed to the irreversible disturbance to the fiber arrangement at the end of the first cycle, such that the fiber arrangement becomes less neat. A less neat fiber arrangement means that there is more chance for the adjacent fiber layers to touch one another.

Polymer-Matrix Composites for Damage Sensing

Self-monitoring of damage (whether due to stress or temperature, under static or dynamic conditions) has been achieved in continuous-carbon-fiber polymer-matrix composites because the electrical resistance of the composite changes with damage (114,120,124–137). Minor damage in the form of slight matrix damage and/or disturbance to the fiber arrangement is indicated by the irreversible decrease of the longitudinal and through-thickness resistance due to an increase in the number of contacts between fibers, as shown after one loading cycle in Figs. 15–17.

Figure 17. Longitudinal stress, strain, and $\Delta R/R_0$ obtained simultaneously during cyclic compression (longitudinal) at a stress amplitude equal to 14% of the breaking stress for a continuous-fiber epoxy-matrix composite.

Figure 18. Variation of longitudinal $\Delta R/R_0$ with cycle number during tension–tension fatigue testing for a carbon-fiber epoxy-matrix composite. Each cycle of reversible decrease in resistance is due to strain. The irreversible increase in resistance at around cycle number 218,281 is due to damage as fiber breakage.

More significant damage as delamination or interlaminar interfacial degradation is indicated by the increase in the through-thickness resistance (or more exactly the contact resistivity of the interlaminar interface) due to a decrease in the number of contacts between fibers of different laminae. Major damage as fiber breakage is indicated by the irreversible increase of the longitudinal resistance.

During mechanical fatigue, it was observed that delamination begins at 30% of the fatigue life, whereas it was observed that fiber breakage begins at 50% of the fatigue life. Figure 18 (124) shows an irreversible increase in resistance at about 50% of the fatigue life during tension–tension fatigue testing of a unidirectional, continuous-carbon-fiber epoxy-matrix composite. The resistance and stress are in the fiber direction. The reversible changes in resistance are due to strain, which makes the resistance decrease reversibly in each cycle, as in Fig. 15.

Figure 19 shows the variation in contact resistivity with temperature during thermal cycling. The temperature is repeatedly increased to various levels. A group of cycles in which the temperature amplitude increases cycle by cycle and then decreases cycle by cycle back to the initial low temperature amplitude is called a group. Figure 19a shows the results of the first 10 groups, whereas Fig. 19b shows only the first group. The contact resistivity decreases upon heating in every cycle of every group. At the highest temperature (150°C) of a group, a spike of increase in resistivity occurs, as shown in Fig. 19b. It is attributed to damage at the interlaminar interface. In addition, the baseline resistivity (i.e., the top envelope) gradually and irreversibly shifts downward as cycling progresses, as shown in Fig. 19a. The baseline decrease is probably due to matrix damage within a lamina and the resulting decrease in modulus and hence decrease in residual stress.

Polymer-Matrix Composites for Temperature Sensing

Continuous-carbon-fiber epoxy-matrix composites provide temperature sensing by serving as thermistors (117,138) and thermocouples (139).

The thermistor function stems from the reversible decrease of contact electrical resistivity at the interface between fiber layers (laminae) from temperature change.

Figure 20 shows the variation in contact resistivity ρ_c with temperature during reheating and subsequent cooling, both at 0.15°C/min, for carbon-fiber epoxy-matrix composites cured at zero and 0.33 MPa. The corresponding Arrhenius plots of log contact conductivity (inverse of contact resistivity) versus the inverse of absolute temperature during heating are shown in Fig. 21. The activation energy can be calculated from the slope (negative) of the Arrhenius plot, which is quite linear. The linearity of the Arrhenius plot means that the activation energy does not change throughout the temperature variation. This activation energy is the energy of electrons jumping from one lamina to the other. Electronic excitation across this energy enables conduction in the through-thickness direction.

The activation energies, thicknesses, and room temperature contact resistivities for samples made at different curing pressures and composite configurations are shown in Table 11. All of the activation energies were calculated on the basis of the data at 75–125°C. In this temperature regime, the temperature change was very linear and well controlled. From Table 11, it can be seen that, for the same composite configuration (crossply), the higher the curing pressure, the smaller the composite thickness (because more epoxy is squeezed out), the lower the contact resistivity, and the higher the activation energy. A smaller composite thickness corresponds to a higher fiber volume fraction in the composite. During curing and subsequent cooling, the matrix shrinks, so a longitudinal compressive stress develops in the fibers. The modulus of carbon fibers in the longitudinal direction is much higher than that in the transverse direction. Moreover, the carbon fibers are continuous in the longitudinal direction. Thus, the overall shrinkage in the longitudinal direction tends to be less than that in the transverse direction. Therefore, there will be a residual interlaminar stress in the two crossply layers in a given direction. This stress accentuates the barrier for electrons to jump from one lamina to another. After curing and subsequent cooling, heating will decrease the thermal stress. Both thermal stress and curing stress contribute to residual interlaminar stress. Therefore, the higher the curing pressure, the larger the fiber volume fraction, the greater the residual interlaminar stress, and the higher the activation energy, as shown in Table 11. Besides the residual stress, thermal expansion can also affect contact resistance by changing the contact area. However, calculation shows that the contribution of thermal expansion is less than one-tenth of the observed change in contact resistance with temperature.

The electron jump occurs primarily at points where direct contact occurs between fibers of adjacent laminae. Direct contact is possible due to the flow of epoxy resin during composite fabrication and due to the slight waviness of the fibers, as explained in Wang and Chung (114) in relation to the through-thickness volume resistivity of a carbon-fiber epoxy-matrix composite.

The curing pressure for the sample in the unidirectional composite configuration was higher than that of any of the crossply samples (Table 11). Consequently, the thickness was the lowest. As a result, the fiber volume fraction was the highest. However, the contact resistivity of the unidirectional sample was the second highest rather

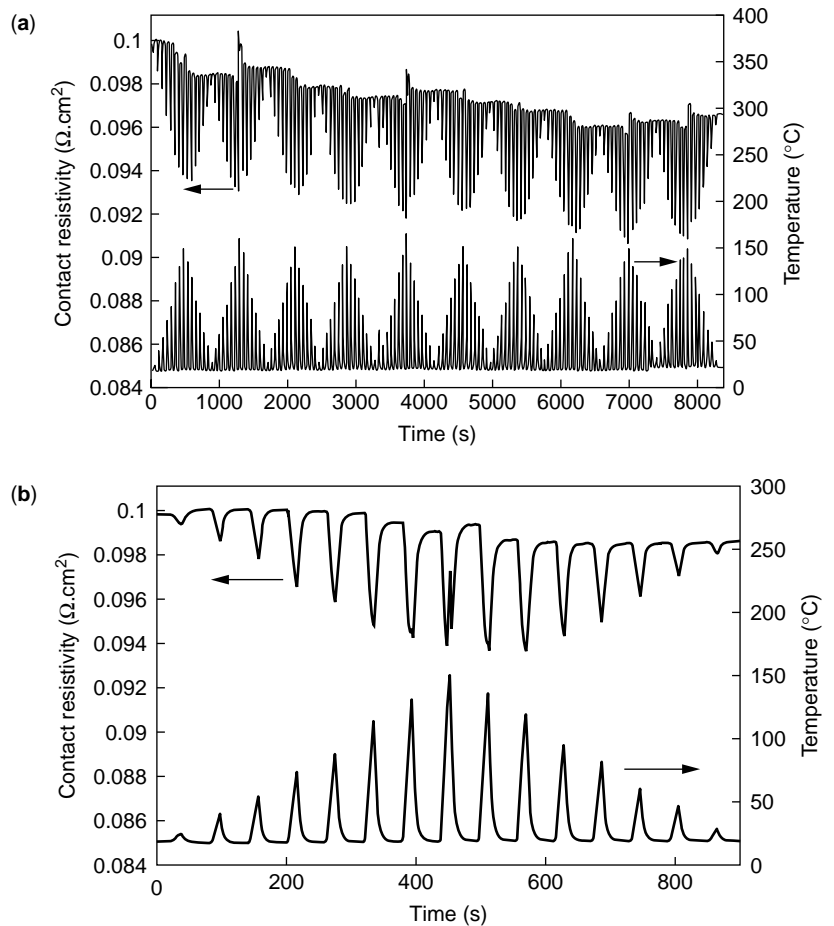

Figure 19. Variation in contact electrical resistivity and of temperature with time during the thermal cycling of a carbon-fiber epoxy-matrix composite. (b) the magnified view of the first 900 s of (a).

than the lowest, and its activation energy was the lowest rather than the highest. The low activation energy is consistent with the fact that there was no mismatch of CTE or curing shrinkage between the two unidirectional laminae and, as a result, no interlaminar stress between the

laminae. This low value supports the notion that interlaminar stress is important in affecting activation energy. The high contact resistivity for the unidirectional case can be explained in the following way. In the crossply samples, the pressure during curing forced the fibers of the

two laminae to press onto one another and hence contact tightly. In the unidirectional sample, the fibers of one of the laminae just sank into the other lamina at the junction, so pressure helped relatively little in the contact between fibers of adjacent laminae. Moreover, in the crossply, every fiber at the lamina–lamina interface contacts many fibers of the other lamina, whereas, in the unidirectional situation, every fiber has little chance to contact the fibers of the other lamina. Therefore, the number of contact points between the two laminae is less for the unidirectional sample than for the crossply samples.

The thermocouple function stems from the use of n-type and p-type carbon fibers (as obtained by intercalation) in different laminae. The sensitivity and linearity of the thermocouple are as good as or better than those of commercial thermocouples. By using two laminae that are crossply, a two-dimensional array of thermistors or thermocouple junctions is obtained, thus allowing temperature distribution sensing.

Table 12 shows the Seebeck coefficient and the absolute thermoelectric power of carbon fibers and the thermocouple sensitivity of epoxy-matrix composite junctions. A positive value of the absolute thermoelectric power indicates p-type behavior; a negative value indicates n-type behavior. Pristine P-25 is slightly n-type; pristine

T-300 is strongly n-type. A junction that comprises pristine P-25 and pristine T-300 has a positive thermocouple sensitivity that is close to the difference in the Seebeck coefficients (or the absolute thermoelectric powers) of T-300 and P-25, whether the junction is unidirectional or crossply. Pristine P-100 and pristine P-120 are both slightly n-type. Intercalation with sodium makes P-100 and P-120 strongly n-type. Intercalation with bromine makes P-100 and P-120 strongly p-type. A junction comprising bromine-intercalated P-100 and sodium-intercalated P-100 has a positive thermocouple sensitivity that is close to the sum of the magnitudes of the absolute thermoelectric powers of the bromine-intercalated P-100 and the sodium-intercalated P-100. Similarly, a junction comprising bromine-intercalated P-120 and sodium-intercalated P-120 has a positive thermocouple sensitivity that is close to the sum of the magnitudes of the absolute thermoelectric powers of the bromine-intercalated P-120 and the sodium-intercalated P-120. Figure 22 shows the linear relationship of the measured voltage with the temperature difference between hot and cold points for the junction comprising bromine-intercalated P-100 and sodium-intercalated P-100.

A junction comprising n-type and p-type partners has a thermocouple sensitivity that is close to the sum of the

Table 12. Seebeck Coefficient ($\mu\text{V}/^\circ\text{C}$) and Absolute Thermoelectric Power ($\mu\text{V}/^\circ\text{C}$) of Carbon Fibers and Thermocouple Sensitivity ($\mu\text{V}/^\circ\text{C}$) of Epoxy-Matrix Composite Junctions. All Junctions are Unidirectional Unless Specified as Crossply. The Temperature Range is 20–110°C

	Seebeck Coefficient with Copper as the Reference ($\mu\text{V}/^\circ\text{C}$)	Absolute Thermoelectric Power ($\mu\text{V}/^\circ\text{C}$)	Thermocouple Sensitivity ($\mu\text{V}/^\circ\text{C}$)

^aPristine (i.e., not intercalated).

Figure 22. Variation of the measured voltage with the temperature difference between hot and cold points of the epoxy-matrix composite junction comprised of bromine-intercalated P-100 and sodium-intercalated P-100 carbon fibers.

magnitudes of the absolute thermoelectric powers of the two partners because the electrons in the n-type partner, as well as the holes in the p-type partner, move away from the hot point toward the corresponding cold point. As a result, the overall effect on the voltage difference between the two cold ends is additive.

By using junctions comprising strongly n-type and strongly p-type partners, a thermocouple sensitivity as high as $+82 \mu\text{V}/^\circ\text{C}$ was attained. Semiconductors are known to exhibit much higher values of the Seebeck coefficient than metals, but the need to have thermocouples in the form of long wires makes metals the main materials for thermocouples. Intercalated carbon fibers exhibit much higher values of the Seebeck coefficient than metals. Yet, unlike semiconductors, their fiber form and fiber composite form make them convenient for practical use as thermocouples.

The thermocouple sensitivity of carbon-fiber epoxy-matrix composite junctions is independent of the extent of curing and is the same for unidirectional and crossply junctions. This is consistent with the fact that the thermocouple effect hinges on the difference in the bulk properties of the two partners and is not an interfacial phenomenon. This behavior means that the interlaminar interfaces in a fibrous composite serve as thermocouple junctions in the same way, irrespective of the layup configuration of the dissimilar fibers in the laminate. Because a structural composite typically has fibers in multiple directions, this behavior facilitates using a structural composite as a thermocouple array.

It is important to note that the thermocouple junctions do not require any bonding agent other than the epoxy, which serves as the matrix of the composite and is not an electrical contact medium (because it is not conductive). Despite the presence of the epoxy matrix in the junction area, direct contact occurs between a fraction of the fibers of a lamina and a fraction of the fibers of the other lamina, thus resulting in a conduction path in the direction perpendicular to the junction.

Polymer-Matrix Composites for Vibration Reduction

Polymer-matrix composites that contain continuous carbon fibers and exhibit both high damping capacity and high stiffness have been attained by using interlayers in the form of discontinuous $0.1 \mu\text{m}$ diameter carbon filaments (140). The damping enhancement is due to the large interfacial area between filaments and matrix. Viscoelastic constrained interlayers, though common, degrade the strength and modulus and become less effective as the temperature increases (141). Surface treatment of the filaments helps, at least in a thermoplastic matrix (141). Other techniques for damping enhancement are matrix modification (142,143), fiber coating (143), and filament winding angle optimization (144).

CONCLUSION

Intrinsically smart structural composites for strain sensing, damage sensing, temperature sensing, thermal control, and vibration reduction are attractive for smart structures. They include cement-matrix and polymer-matrix composites, particularly cement-matrix composites that contain short carbon fibers and polymer-matrix composites that contain continuous carbon fibers. The electrical conductivity of the fibers enables the dc electrical resistivity of the composites to change in response to strain, damage, or temperature, thereby allowing sensing. In addition, the conduction enables the Seebeck effect, which is particularly large in cement-matrix composites that contain short steel fibers and in polymer-matrix composites that contain intercalated, continuous, carbon fibers. By using the interfaces in composites to enhance damping, cement-matrix and polymer-matrix composites that have both enhanced damping capacity and increased stiffness are obtained. By using composite interfaces, cement-matrix composites that have increased specific heat for thermal control are also obtained.

COMPOSITES, SURVEY

K.H. SEARLES

Oregon Graduate Institute of
Science and Technology
Beaverton, OR

INTRODUCTION

The definition of a composite material, loosely translated, could point to any material having more than a single phase such that the multiple phases act in a synergistic manner to provide a behavior or set of behaviors more desirable than exhibited singularly. By this definition, a significant amount of creative space is available for scientists and engineers alike to develop exciting new materials, structures, processes, and applications to meet the demands dictated by the evolution of new technologies. As this evolution progresses, the traditional distinction made between the five classes of materials (i.e., metals, ceramics, polymers, elastomers, and glasses) tends to fade. It is here where many new possibilities arise to intelligently process and “smear” these classes together to produce new, smarter composite materials and engineering structures that “think” and respond to stimuli. The paradigm for this is by way of the tailorable structure-performance relationships for composites based on interactions between constituent materials, which may encompass any of the five material classes.

ENGINEERING MATERIALS

The number of materials available to scientists and engineers for translating ideas into usable products and markets is vast, if not almost overwhelming. Current estimations give a range somewhere on the order of between 40,000 and 80,000 engineering materials at our disposal (1). As new materials are developed having novel and exploitable characteristics (properties and responses), the number of choices further expands. The appropriate choice(s) of material(s) for design can be just as overwhelming as the number of materials available. How does one appropriately choose from the vast menu? Through proper rationalizations and design considerations, the search and selection processes can be drastically minimized. Many of

the important product and market design considerations are as follows: safety, strength, weight, cost, reliability, life cycle, processing, wear resistance, corrosion resistance, friction, lubrication, stiffness, flexibility, volume, shape, styling, surface finish (appearance), control, maintenance, utility, and liability.

An adequate methodology of materials selection for design cannot be addressed without considering the function, material, process, and shape. The function, ultimately governed by material behavior, is confined by shape. Restrictions on the ability to achieve desired shapes are placed by limitations in material processing. Considerations in shape and geometry include both the micro- and macroscales. Internal two-dimensional and three-dimensional structures such as interleaves, cells, and honeycombs collectively determine, to an extent, the external shape. In most materials, presence or absence of these structures also influences material behavior (response), ultimately leading back to the desired function or set of functions. As illustrated by Fig. 1, the interactions between function, material, process, and shape are bidirectional. At the center of these interactions, an iterative design process utilizes the processing, materials, and design optimization sciences in forming an integrated system to arrive at a final product and market.

Materials Evolution

Prior to 5000 BC, the engineering materials that defined the peak of technology were natural composites, polymers, ceramics, and glasses. Little metal was consumed and only in the form of naturally occurring gold and silver. Between 5000 BC and AD 500 the increased consumption of copper, bronze, and iron served to mark respective technological ages. However, wood, skins, natural fibers, rubber, flint, and pottery were still the primary sources for materials usage. A perspective given by Ashby (1986) illustrates the relative importance and evolution of advanced materials for mechanical and civil engineering purposes (1).

It is evident from Fig. 2 that engineering steels did not gain prominence until 1850, and from then to the mid-1900s, steels and their alloys had been the preeminent material sources for design. Nonmetal materials were rarely thought of for use as structural materials, perhaps with the exceptions being refractories and Portland cement. Even so, their consumption compared to that of total material consumption was small. Within the last 20 to 30 years though, newly developed materials belonging to the other classes (polymers and elastomers, ceramics, composites) have surfaced due to their increasing technological importance. The growth rate of many of these materials is on par with (if not exceeding) the growth rate enjoyed by steel during the height of the Industrial Revolution.

Demand for New Materials

Several factors must be taken into account regarding the choice of material substitution when designing a part. A considerable driving force behind this is weight savings. However, part functionality must be critically reviewed if weight reduction is obtained through the substitution of a lightweight material for a conventional one. For example,

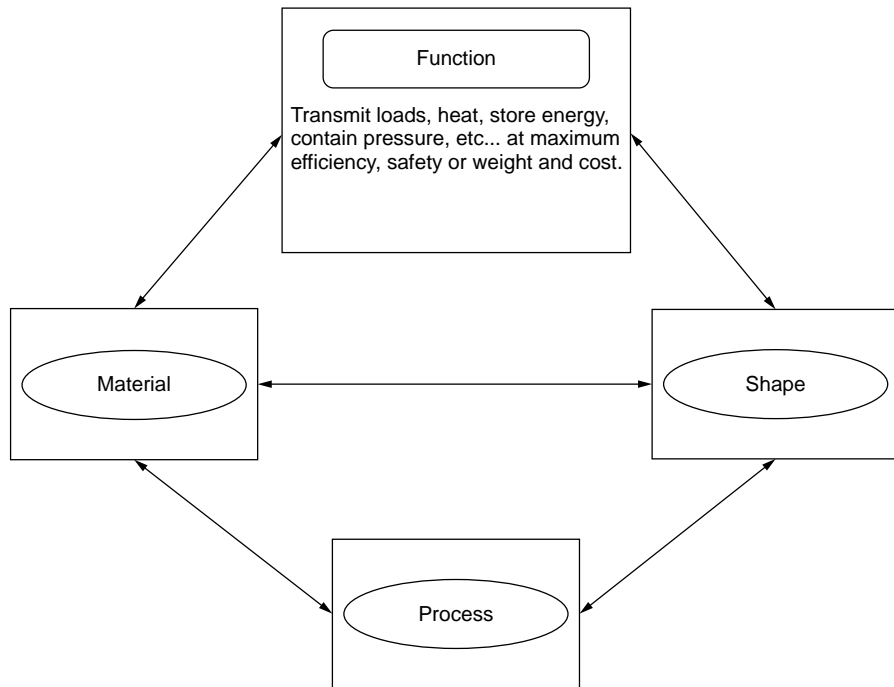

Figure 1. Bidirectional interactions between function, material, shape and process (1).

in a study of materials for ground transportation discussed by Compton and Gjostein (2,3), substitution of a hypothetical aluminum part of the same volume for a cast iron part would result in a 63% weight savings. If equal load sharing were maintained, then weight savings dropped from 63% to 56%. A similar comparison made between mild steel and high-strength steel revealed a weight savings of 18% where structural strength was the main concern, though mild steel is really no lighter than high strength steel by volume.

For high-strength steel replacements using aluminum or fiber-reinforced plastics (FRPs), savings in weight is much smaller when equivalent tensile, compressive, and bending stiffnesses are necessary. Additional to weight savings, another technological aspect of functionality as equally important pertains to the demand of elevated temperature environments. In particular to the commercial aircraft, military aircraft, and aerospace sectors, “skin” temperatures from friction with air have risen 20 fold,

Figure 2. Relative importance and evolution of civil and mechanical engineering materials (1).

from a modest 50°C (120°F), as exhibited by early 1900s trainers, to in excess of 1000°C (1800°F), as exhibited by the space shuttle. Many of the aircraft and aerospace powerplant temperatures have risen by similar magnitudes. In both of these examples, the boundaries of functionality were obviously broadened and more ingenuity in the application and consolidation of materials was required.

Bulk metals and metallic alloys possess high elastic moduli and can be made extremely strong through various heat-treating and mechanical processes. They also remain relatively ductile, permitting shaping operations by deformation. However, they are the most susceptible materials to corrosion attack, and their ductility exposes them to failure by fatigue.

Ceramics and some glasses have relatively high elastic moduli, but unlike bulk and alloyed metallics, they are very brittle. The strengths of structural ceramics and glasses are statistically dependent on volume, consequently these materials are termed “net shape” meaning little tolerance is available for changes in geometry without manufacturing an entirely new component. They do function very well in hostile environments where temperatures, wear, and corrosion are excessive, but brittle behavior tends to foster catastrophic failure from concentrated stresses.

Elastomeric and polymeric materials have elastic moduli 40 to 50 times lower than metals, but they are as strong, if not stronger than metals. They usually exhibit much higher strain to failure and properties that are much more dependent on temperature with a useful limit of 200°C (390°F). Some thermosets and thermoplastics can extend the limit by an additional 100°C (200°F), but this is typically accompanied by increased brittle behavior. There are added benefits associated with processing and designing with polymers in that additional surface finishing is usually not necessary, resistance to corrosion is favorable, more complicated shapes are easy to form, and large deflections foster component designs that are flexible yet geometrically stable.

Contrary to the other material classes, composites tend to exhibit microscopic and macroscopic heterogeneity and behave anisotropically. That is, composite mechanical properties vary from point to point due to the intrinsic properties of the reinforcements and their orientations. From the standpoint of design, predicting responses to external mechanical and thermal loads becomes more complicated. With the exception of mainly thermosetting polymer or nonpolymer matrices specifically tailored for elevated temperature environments, composites are also of limited use structurally above 250°C (480°F). Given this, composites do avoid some of the drawbacks associated with the other material classes while necessarily combining the attractive properties.

By incorporating various materials from principally diverse classes into the synthetically derived composite materials, several essential characteristics may be drawn upon: the corrosion resistance of polymers, the high strength and ductility, the light weight and lower cost of fabrication, the high temperature performance of ceramics and the thermal-electrical conductivity of metals (3). As shown by Fig. 3, there is merit in grouping materials that show commonalities in properties and process.

Figure 3. Commonality of composite material processing and properties to the principal classes of engineering materials (1).

COMPOSITE MATERIALS

What are composite materials? If we adopt the generality that a composite material is any material consisting of some combination of two or more phases, then almost every material in the universe that exists naturally or synthetically may be referred to as a composite. This generality leads to a very broad classification of materials that are composites. For example, wood can be classified as a composite, since its honeycomb microstructure consists of arrays of fibers (cellulose) encompassed and held together by a polymer matrix (lignin) as shown in Fig. 4. At the macroscale, numerous combinations of the 60 native and 30 imported species of wood are possible for tailoring performance to suit a particular need (4). In many cases, the macroscale wood composites serve as excellent bulk engineering materials (plywood, particle board, etc.).

Other, less-tailorable, natural composite materials and biomaterials might also include bamboo, bone, and muscular tissues. Bamboo, referred to as “nature’s own fiberglass,” has an aligned fibrillar structure and exhibits a “broomed” fracture morphology similar to a failed glass fiber composite (5). The microstructure of muscular tissues is such that flexibility occurs along with a high degree of strength. Fast- or slow-twitch fibers (collagen) are aligned in the general directions of loading along the bone axes and surrounded by a continuous matrix having lower stiffness, thus allowing neighboring fibers to slide past one another.

Bulk engineering materials such as metal alloys and plastics are traditionally not thought of as composite materials. However, on the microscale, these materials do lie well within the bounds given by the previous generality. Consider a heavily utilized bulk engineering material like plain carbon, hypoeutectoid steel (up to 0.8% carbon). Although the separable phases require some form of microscopy to resolve, they exist as fine dispersions that

Figure 4. Lamellar composite structure of wood cell composed of the primary wall cellulose fibers, a linear polymer in an irregular network, and the 3-layer secondary wall: S_1 —crisscross network, S_2 —spiral-type network, S_3 —irregular network. The matrix is formed from the lignin and hemicellulose deposits.

act synergistically with temperature to control structural behavior under equilibrium conditions. Upon cooling to below 800°C (1472°F), pearlite forms, which is a *lamellar* composite of the polyphases α + carbide. The layers of soft ductile alpha iron are interleaved with the layers of hard brittle iron carbide (cementite or Fe_3C), yielding a tough, strong steel. Similarly, an engineering plastic like acrylonitrile-butadiene-styrene (ABS) is a prominent copolymer with rubber particles finely dispersed within the styrene-acrylonitrile (SAN) phase and, thus, is a microscale composite material. The acrylonitrile provides surface hardness and heat resistance, while styrene contributes to strength and butadiene improves toughness and resistance to impact.

A succinct definition in the classical sense of what composite materials are is a prerequisite to understanding the structure-performance relationships that are possible and benefiting from the ability to tailor material performance through processing to suit end-use requirements. Essentially, particulate and filamentary, namely fibrous, composite materials may be viewed as selective arrangements of hybrid materials of which their performance in structural and nonstructural applications is controlled through calculated variations of internal compositions and architectures. More adequately defined, acceptable composites possess the following characteristics (5):

- Consist of two or more physically distinct and mechanically separable phases.
- Can be dispersed or mixed in a controlled manner to achieve a desired behavior.

- Have properties that are necessarily superior to those of the constituents and possibly unique.

Clearly, from the foregoing definition, differentiating between the constituents (e.g., particulates, short fibers, and continuous fibers), individual composite layers (laminae), and laminated composite structures ultimately becomes a matter of scale.

Fundamental to the treatment of composite material and structure behaviors, it is often convenient to study the material interactions in terms of three scales, namely the microscale (fibers, matrices, fiber-matrix interface), mesoscale (lamina architectures), and macroscale (geometric arrangement of laminae). At the macroscale, the laminated composite and structural engineering or nonstructural components are often synonymous. What follows is a review of composite principles and behaviors in terms of the material interactions occurring at each of these scales, beginning with the microscale interactions.

MICROSCALE BEHAVIOR

Fibers, Fillers, and Matrix

Composites are nominally a synergistic combination of two phases, the reinforcing phase and the matrix phase, with likely combinations of polymer matrix and polymer (e.g., epoxy-Kevlar), polymer matrix and ceramic (e.g., fiberglass), ceramic matrix and ceramic (e.g., Al_2O_3 -SiC), or metal matrix and ceramic (e.g., WC-Co). The matrix phase is a continuous medium wherein the reinforcing phase is uniformly dispersed. The majority of reinforcements are in the form of either continuous aligned fibers or chopped random fibers and dispersions or particles. Other, less frequently used reinforcing materials include ribbons and flakes. Reinforcements vary in cross-sectional shape, with characteristic sizes ranging from circa $1.0\ \mu\text{m}$ (3.94×10^{-2} mils) to $20.0\ \mu\text{m}$ (0.78 mils). Since their diameters are small, the fibers, ribbons, or particulates cannot form a structure singularly unless bounded by a matrix that is geometrically stable.

Composites are often categorized according to the form of the reinforcements: *dispersion-strengthened*, *particle-reinforced*, and *fiber-reinforced*. Dispersion-strengthened composites have small particles dispersed in a matrix which is the primary load-bearing constituent. Particle-reinforced composites have larger particles incorporated within the matrix and the load is shared equally between the particles and matrix. Fiber-reinforced composites have either continuous (perhaps practically continuous) or chopped fibers incorporated in a matrix and the fibers are the primary load-bearing constituent.

Several materials are common to each form of composite reinforcement. For fiber-reinforcements the available selection of traditionally utilized materials includes tungsten, titanium, aluminum, boron, carbon [graphite from polyacrylonitrile (PAN) precursors], aramid [Kevlar (polyphenylene terephthalamide)], and glass (E, S, C, and ECR grades) with compositions of SiO_2 , Al_2O_3 , Fe_2O_3 , CaO, MgO, Na_2O , K_2O , BaO, and Ba_2O_3 . For ribbon, flake, and particle reinforcements, the available selection of

Sources: Data after Courtney (p. 224); Hull (5, p. 14).

materials includes glass, boron and graphite films, silicon carbide, and mica and aluminum of boride. The list of usable materials for selection of a constituent matrix phase is vast, and composites are usually grouped into the material classes in which the constituent matrix belongs.

Many polymer matrix composites (PMCs) incorporate the following thermoplastic and thermoset polymers as constituent matrices: polyethylenes (PE), polyurethanes (PU), polyamides (PA-Nylon 6,6), polyether-etherketones (PEEK), polycarbonates (PC), epoxies, polyesters, and polyimides (PI), and bismaleimides (BMI). Ceramic matrix composites (CMCs) may incorporate the following advanced structural ceramics as constituent matrices: silica oxides (SiO₂), alumina (Al₂O₃), metallic carbides (W, Ta, Hf, Zr, Mo, V, Ti, Cr), nonmetallic carbides (B, Si), borides (Ta, V, Cr, W, Ti, C), metallic nitrides (Zr, Y, Mo, Ti, Cr), and nonmetallic nitrides (Al, B, Si). For metal matrix composites (MMCs), materials incorporated as constituent matrices include titanium, copper, aluminum, and nickel.

Specific material properties for some of the most common reinforcing and matrix constituents are given in Tables 1 and 2, respectively.

Fiber-reinforced PMC's are achieving widespread acceptance, particularly in the aerospace industry. Composites based on polymer epoxy matrices currently account for about 4% by weight of commercial aircraft and about 10% of military aircraft with forecasts spanning the next decade of 65% by weight (6). These composites possess a high specific strength, stiffness, and very large endurance to fatigue. The room temperature specific strengths of epoxy PMCs are higher than aluminum, titanium alloys, and some super alloys. The upper service temperature of these materials is limited to approximately 150°C (302°F). In many aerospace PMC applications such as aircraft skins and engines, however, temperatures often exceed 200°C (392°F) and could reach 427°C (800°F). The strength of epoxy-based PMCs would begin to diminish far below these temperatures, hence there is a growing demand for other

Table 2. Selected Material Properties for Several Materials Commonly Used as Constituent Matrix Phases in MMCs, CMCs, and PMCs

candidate PMCs with much higher upper service temperature capabilities.

PMCs consolidated with thermosetting polyimides such as PMR (polymerization of monomer reactants), Avimid-R, AMB-21 and VCAP-75 are replacing epoxies for elevated temperature applications. PMR (e.g., PMR-15, PMR-II-50) and the other aforementioned polyimide-based composites have extremely good specific properties and are stable up to temperatures approaching 360°C (680°F).

Some of the more common applications for advanced PMR compositions include aer propulsion system components such as turbine engine thruster rings, reversers, compressor casings, bearings, and external structural surfaces for supersonics. Materials used in these applications must possess a good balance of mechanical properties over a wide temperature range, withstand thermal shock and experience a low percentage of weight loss (thermal-oxidative stability, TOS) even after long-term exposure (60,000 h) at or near upper service temperatures. To maintain sufficient mechanical properties, the polymer glass transition temperature (T_g) must be at least 25°C (77°F) higher than its intended use temperature. Currently, the PMR compositions are limited for use in applications operating in the 200 to 300°C (392 to 572°F) temperature range (7).

Fiber-Matrix Interface

In any composite system where one phase is completely dispersed within another phase, continuity between phases is extremely important. When a continuum does not exist, the benefits associated with the combination of phases may not be fully realized. In fiber-reinforced and many particulate-reinforced systems, the matrix acts as a "conduit" for transporting load and sharing stresses equally within the reinforcing phase. Whether or not an equivalent distribution occurs or concentrations arise becomes highly dependent on the structure and properties of the interphase, namely the fiber-matrix interface (particulate is referred to as a fiber from this point on).

The interface acts as the medium by which stresses in the matrix are transported to the fiber, or alternatively, the significant differences between the elastic properties of the fibers and the matrix are communicated through the interface (5). How efficiently this communication occurs is governed primarily by the degree of bonding that takes place between the fibers and the matrix. Fiber pullout may result if the interfacial bonding is poor and if the interfacial bonding is too good, then energy absorption subsequent to the debonding process will be insufficient.

Ideally, debonding of the fiber-matrix interface should follow fracturing of the matrix (8). The nature and efficiency of bonding between a fiber and matrix will be dependent on the molecular conformation and chemistry of both constituents. Even though the interface is specific to each fiber-matrix system, insight can be given toward the origins of bond strength by way of the principal mechanisms governing adhesion, chiefly wetting, interdiffusion, electrostatics, chemical bonding and mechanical interlocking.

Contact and Wetting. Central to the study and application of adhesion wetting mechanisms, the Dupre equation

defines the work of adhesion in terms of the respective surface energies of two materials in intimate contact and is given by

$$W_A = \gamma_1 + \gamma_2 - \gamma_{12},$$

where W_A is the work of adhesion, γ_1 is the surface energy of material 1, γ_2 is the surface energy of material 2, and γ_{12} is the interfacial energy, that is, the energy necessary to create a unit area of interface (9). The surface energy γ of a material is highly dependent on the magnitude of intermolecular forces and can be defined as

$$\gamma = \frac{\pi n^2 A}{32r_0^2},$$

where A is a constant which scales the attractive interactions, n is the surface molecular density on either side of the interface, and r_0 is the equilibrium distance between the mating surfaces near intimate contact. For fiber-matrix interactions, it is also useful to consider the relationship between the stiffness of the material and its surface energy in terms of the isothermal Young's modulus:

$$E = \frac{32\gamma}{r_0}.$$

The isothermal Young's modulus E of a material may also be expressed by the following relationship:

$$E = r_0 \left(\frac{\partial \phi^{L-J}(r)}{\partial r} \right)_{T, r=r_0},$$

where ϕ^{L-J} represents the potential energy according to Lennard-Jones proposed interactions between atoms and molecules. While the work of adhesion W_A can be regarded as a thermodynamic parameter that describes the work necessary for two mutual surfaces to remain in intimate contact, the work of cohesion W_{COH} may be regarded as the work required to create two new surfaces of the same material as in the case of crack origination. If a monolithic material is broken such that the separated materials are completely nonenergy dissipating nor absorbing (perfectly brittle), then the work of cohesion is simply 2γ .

One might now discern that cohesion is adhesion with consideration for the respective materials in contact and their interfacial energy existing prior to a separation. By extending the concept of surface energies further, the wetting adhesion mechanism can be understood in terms of the Dupre equation and the Young equation. The Young equation relates the physical occurrence of a liquid drop on a solid surface. It states that

$$\gamma_{LV} \cos \theta = \gamma_{SV} - \gamma_{SL},$$

where γ_{ij} are the appropriate interfacial tensions between the liquid L , solid S , and vapor V and θ is the contact angle as shown in Fig. 5. The solid-vapor interfacial energy is not the true surface-free energy of the solid, but it is related

Figure 5. Schematic of contact angle representation where a liquid drop is perfectly placed on a smooth, rigid solid. The contact angle θ is measured at A: the three points between the liquid, the solid, and the vapor.

by the following equation:

$$\gamma_{SV} = \gamma_S - \pi_e.$$

Here γ_S is the true surface free energy and π_e is referred to as the equilibrium spreading pressure, a measure of released energy through adsorption of the vapor onto the solid surface. If combined, the Dupre equation with the Young equation yield a simple expression (Dupre-Young) that relates a thermodynamic parameter to two readily determined quantities:

$$W_A = \gamma_{LV}(1 + \cos \theta).$$

Knowing the liquid–vapor interfacial tension and the contact angle, the work of adhesion is easily calculated. In considering the wetting of a fiber by a matrix, only liquids with γ_{LV} less than the critical surface tension of wetting will spontaneously spread on the fiber. For example, epoxy has a surface energy of $.042 \text{ J m}^{-2}$ ($0.100 \times 10^{-1} \text{ cal in}^{-2}$), glass a surface energy of 0.560 J m^{-2} ($1.337 \times 10^{-1} \text{ cal in}^{-2}$), and graphite a surface energy of 0.077 J m^{-2} ($0.184 \times 10^{-1} \text{ cal in}^{-2}$). Although epoxy will wet both glass and graphite, the glass will wet more readily due to a much lower contact angle between the epoxy and glass. When fibers are considered for use with matrices having a greater surface energy, coatings and sizings are often introduced via polymers with lower energies to promote better wetting and adhesion characteristics.

Interdiffusion. The mechanism of adhesion by interdiffusion is thought to occur when the two surfaces that are brought into intimate contact are at least partially soluble in one another. If we adopt the philosophy that “like dissolves like,” then only a limited number of adhesive examples are applicable to a mechanism of adhesion by interdiffusion, unless coatings are used that are very similar as in some fiber-reinforced composite applications. In any case, diffusive bonding implies that an interphase forms between two materials that is a mixture of both materials as shown in Fig. 6. The extent to which the interphase is equally apportioned and continuous between the two materials depends on the solubility parameter criterion, defined as

$$\delta = \sqrt{\frac{E_{COH}}{V}},$$

where V is the molar volume and the cohesive energy E_{COH} , in this case, is the energy required to separate all of the

Figure 6. Schematic of diffusive bonding showing that material A and material B are at least partially soluble in each other, resulting in formation of an interphase mixture of both A and B.

atoms or molecules in a material an infinite distance (9). In terms of the enthalpy of vaporization ΔH_{vap} , the gas constant R , and the absolute temperature T , the cohesive energy is given by the following relationship:

$$E_{COH} = \Delta H_{vap} - RT.$$

This equation implies that the extent of energy of cohesion is indicated by the energy required for vaporization. Spontaneous formation of a solution is dependent upon the magnitude and sign of the Gibbs free energy of mixing:

$$\Delta G_{mix} = \Delta H_{mix} - T\Delta S_{mix}.$$

Polymer materials are limited to a few states that exist because of their high molecular weight. Therefore the entropy change ΔS is small and the enthalpy change ΔH is either zero or positive, meaning that dissolution and mixing between polymers is not likely. Complete interphase formation requires a larger entropy change leading to a negative Gibbs free energy of mixing. Perfect adhesion by diffusion requires two materials that are completely soluble in one another, giving the most negative value for change in enthalpy of mixing which would be zero. In polymer materials, autohesion (interdiffusion) may be assisted by the addition of plasticising agents or solvents ultimately affecting the degree of molecular entanglement and bond strength.

Electrostatic Interactions. Adhesion by electrostatic interaction appears to be an unlikely contributor to direct bond strength in composite materials. However, this mechanism of adhesion provides a reasonable justification for acid–base interactions and the use of coupling agents. In theory, it can be stated that surfaces that are basic are electropositive in character, whereas surfaces that are acidic are electronegative in character. Accordingly, there should be some strength of attraction between these two surfaces, with the greatest adhesion by electrostatic interaction occurring when one material is the most basic while the other material is the most acidic. Coupling agents such as silane can be introduced to couple an organic phase with an inorganic phase. These agents possess chemical functions that are twofold: they are reactive with both the inorganic and organic phases. Fiberglass utilizes such coupling agents to protect the glass fiber–matrix interface against attack by moisture and subsequent debonding. A monolayer is formed between the glass fiber and styrenated

polyester that bonds covalently, and it is here where the electrostatic interactions are most relevant and may lead to adhesion by chemical bonding mechanisms.

Chemical Bonding. The chemical bonding mechanism offers a solid explanation for using coupling agents on glass fibers and for the bond strength between carbon fibers and polymer matrices (5). Covalent bonding at interfaces is desirable because of kinetics limitations in the presence of water. That is, adhesion due to primarily covalent bonding mechanisms offers resistance to debonding at the fiber–matrix interface when exposed to moisture, since water must first hydrolyze the bonds. When a chemical bond is formed between compatible chemical groups on the fiber surface and matrix, the bond strength will depend highly on the number of bonds as well as the types. The energy required to separate the two materials at their interface will need to be greater than the covalent bond energy. The bond energy is attributable not only to the activity of the chemical groups but also to the surface area, since a larger area can provide a greater number of chemical bond sites.

The silane coupling agents R–SiX₃ added to the surface of glass fibers ensure good wetting of the fibers in the presence of a hydrated water layer, which tends to greatly reduce the glass fiber surface energy. These agents also provide a strong chemical link between the glass surface oxides and the polymer matrix, leading to a strong, water-resistant bond. Strong bonds between carbon fibers and matrices occur due to the highly reactive surface structure and large surface area (a large surface microroughness) of carbon fibers. If the carbon fiber surface is treated in thermal and acidic environments, ranges of functional groups can be produced that bond directly with unsaturated matrix groups and unsaturated thermoplastic matrix groups.

Mechanical Interlocking. Adhesion by the mechanism of mechanical interlocking is possible, provided that a sufficient surface roughness exists in conjunction with a high degree of wetting. The higher the surface wetting, the more likely the matrix is to conform with the existing fiber surface topography. The lower the surface wetting, the more likely the matrix is to fill interstices lending a smooth surface and little adhesion by mechanical interlocking. The existence of sharply transitioning topography does two things to promote adhesive strength between materials: roughness increases the effective area of contact, and developing cracks are forced to propagate along a tortuous path. Whether or not the matrix fills the pores and smooths topography can be described by Poiseuille's law, which states that

$$x \left(\frac{dx}{dt} \right) = \frac{r^2 P}{8\eta},$$

where x is the distance of pore penetration by the matrix, t is time, r is the pore radius, P is the capillary pressure, and η is the polymer viscosity. The capillary pressure can also be related to the liquid–vapor interfacial energy and the wetting contact angle in terms of the pore radius by

the following relationship:

$$P = \frac{2\gamma_{LV} \cos \theta}{r}.$$

MESOSCALE BEHAVIOR

In composites, the reinforcing constituent materials (fibers) take up nearly all of the applied load as previously outlined. Since the reinforcements cannot support a load directly, the matrix must act as a conduit for transferring the load to the reinforcements. The overall response of individual composite laminae is influenced by the strengths and stiffnesses of the constituent materials. At the micro- and mesoscales, the transfer of load, and elastic and failure behaviors of composites involve many factors besides the constituent material properties. Generally speaking, the primary factors that influence lamina behavior are (10):

- The properties of the constituent reinforcement and matrix materials.
- The properties of the interphase bonding the constituent materials (previous section).
- The volume fractions of the constituent materials.
- The geometry of packing (aligned, random, textile, etc.).
- The cross-sectional shapes and aspect ratios of the reinforcements.

A single composite lamina may have mesoscale properties and exhibit behavior that are far removed from the properties and behavior of the constituents. For example, the constituents can be isotropic while the lamina exhibits orthotropy of strength and modulus. As a result composite mechanical behavior is often categorized as being either fully isotropic or plane orthotropic with transverse anisotropy. That is, the properties are considered to exhibit orthotropic behavior in the principal reinforcing plane and to be equivalent in planes transverse to the reinforcing plane. Because of their complexity, they are usually never considered to be fully anisotropic as 21 constants are required to completely describe fully anisotropic, elastic behavior. The number of possible composite architectures (classes), with textile classes defined to a large extent by NASA Langley Research Center's (LaRC) Advanced Composites Program (ACT), fall into one of the categories and are presented in Fig. 7 (11).

When evaluating orthotropic composite behavior, it is useful to establish a coordinate system relative to a Cartesian or polar coordinate system and coincident to the reinforcing direction. This principal material coordinate system (1–2–3) serves to establish the nine elastic constants that apply for orthotropic behavior, namely the longitudinal tensile modulus, the shear modulus, and Poisson's ratio (E_{11} , G_{12} , ν_{12}) and the transverse tensile moduli, shear moduli, and Poisson's ratios (E_{22} , E_{33} , G_{13} , G_{23} , ν_{13} , ν_{23}). However, by assuming orthotropic symmetry, one can reduce the number of effective elastic constants required to describe orthotropic behavior from nine to five as shown in Fig. 8 for a unidirectional (UD) composite lamina. This

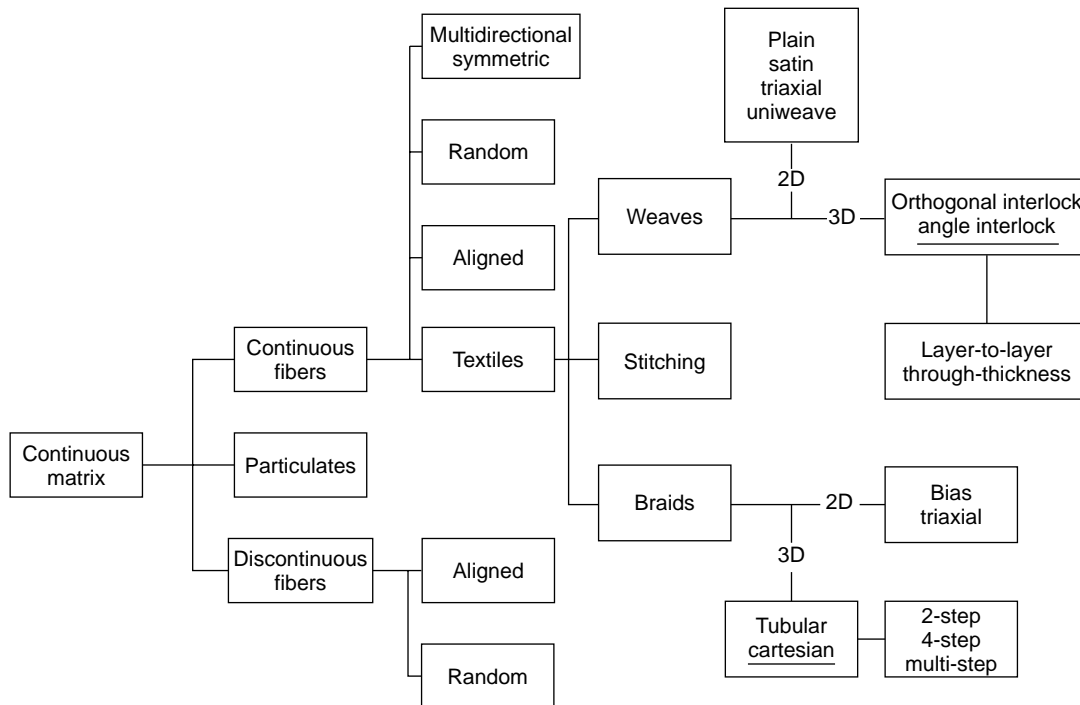

Figure 7. Possible fiber and textile composite architectures (classes) for general and advanced structural high-performance use categorized, in large part, by NASA LaRC's ACT program established in 1989.

leads to the following relations:

$$E_{22} = E_{33}, \quad \nu_{12} = \nu_{13},$$

$$G_{23} = \frac{E_{22}(\text{or } E_{33})}{2(1 + \nu_{23})}, \quad G_{12} = G_{13}.$$

Continuous Fiber Reinforcement

The elastic behavior of a composite lamina having continuous fiber reinforcements is evaluated on the basis of the constituent material properties and their associated volume fractions. In a continuous fiber, UD composite lamina (Fig. 8), all fibers are assumed to be aligned in parallel and extend to the boundaries of the matrix. For the purposes of theoretical analysis, the fibers are considered to be arranged in an ideal square or hexagonal array (analogous to the Kepler conjecture) giving a fiber volume fraction V_f according to

$$V_f = 0.25\pi \left(\frac{r}{R}\right)^2 : \text{square}, \quad V_f = 0.29\pi \left(\frac{r}{R}\right)^2 : \text{hexagonal},$$

where $2R$ is the center-to-center fiber spacing and $2r$ is the fiber diameter. In practice, however, the fiber volume fraction is usually determined by ASTM standardized acid digestion techniques or image analysis using some form of microscopy.

On the premise of linear elasticity, when a load is applied parallel to the lamina fibers, the strain experienced by both the fibers and matrix is the same (*isostrain* condition). Since the fiber stress is $\sigma_f = E_f \varepsilon_1$ and the matrix

stress is $\sigma_m = E_m \varepsilon_1$, it follows that the fiber stress is greater in the fibers than in the matrix ($E_f > E_m$). If we assume that a total load P_c is applied and the bonding between constituents is continuous, then $P_c = P_f + P_m$, where the subscripts c, f, and m denote the composite, fiber, and matrix, respectively. Knowing that the strain in the composite is the same as the strain in the fibers and matrix, and the stresses are a function of the applied load and area fractions, the isostrain condition can be explained by

$$\frac{\sigma_c}{\varepsilon_c} = \frac{\sigma_f}{\varepsilon_f}(V_f) + \frac{\sigma_m}{\varepsilon_m}(V_m).$$

Upon substitution of the definitions for the fiber and matrix tensile moduli in this equation, the traditional "rule of mixtures" equation based on an isostrain loading condition is defined:

$$E_{11} = E_{\parallel} = E_f V_f + E_m (V_m \text{ or } (1 - V_f)).$$

Loads applied to the composite lamina that are perpendicular or transverse to the fiber direction follow a similar derivation, but the loading is referred to as an isostress condition (see Fig. 9 for isostrain vs. isostress). Under the isostress assumption, the stresses are assumed to be the same in the lamina, fibers, and matrix. However the strains become a function of the area fractions of fibers and matrix to that of the total composite. It follows that the isostress condition can be explained by

$$\varepsilon_c = \frac{\sigma_2}{E_m}(V_m) + \frac{\sigma_2}{E_f}(V_f).$$

Figure 8. Representation of the principal material coordinate system in a UD composite lamina exhibiting orthotropic symmetry and the effective elastic constants derived from the basic loading schemes.

Upon substitution of the definition for stress (Hooke's law) in the preceding equation, a more traditional equation for the transverse tensile composite modulus is defined:

$$E_{22} = E_1 = \frac{E_f E_m}{E_f(1 - V_f) + E_m V_f}.$$

Composite lamina elastic properties derived on the basis of the isostress loading condition provide only marginal agreement with actual results. The isostress derivation does not take into account the effects of the Poisson contraction. Therefore other mesomechanics approaches are necessary for evaluating lamina elastic constants from constituent materials that exhibit highly anisotropic elastic behavior.

According to more realistic assumptions that account for the Poisson contraction and nonuniform stress distributions due to strain magnification between neighboring fibers, additional solutions obtained from elasticity theory and finite element analysis have been offered for predicting transverse and longitudinal elastic properties. One such set of solutions that are generally more applicable are the Halpin-Tsai equations (12). These equations can be written in the general form as:

$$\frac{(\bullet)_c}{(\bullet)_m} = \frac{1 + \xi \eta V_f}{1 - \psi \eta V_f},$$

Figure 9. Schematic of isostrain versus isostress loading for a composite material, indicating that less fiber is required according to isostrain assumption for yielding the same elastic modulus. The isostress assumption approaches the isostrain assumption as the ratio of elastic constituent moduli $E_f/E_m \rightarrow 1$.

where (\bullet) is the elastic constant, ξ depends on the characteristics of the reinforcing phase such as fiber aspect ratio, packing geometry, shape, and loading conditions, and ψ is a factor that accounts for the maximum packing possible. The other factor η is given by

$$\eta = \frac{r - 1}{r + \xi}, \quad r = \frac{(\bullet)_f}{(\bullet)_m}.$$

When the factor ψ is properly evaluated for maximum packing fraction, the general form of the Halpin-Tsai equations for UD lamina elastic properties can be given in expanded notation as

$$\begin{aligned} E_{11} &= E_{\parallel} = E_f V_f + E_m(1 - V_f), \\ \nu_{12} &= \nu_{\parallel+} = \nu_f V_f + \nu_m(1 - V_f), \\ \frac{M}{M_m} &= \frac{(1 + \xi \eta V_f)}{(1 - \eta V_f)}, \quad \eta = \frac{(M_f/M_m) - 1}{(M_f/M_m) + \xi}, \end{aligned}$$

in which M is the elastic modulus of interest, E_{22} , G_{12} , or ν_{23} ; M_f the constituent reinforcing fiber modulus E_f , G_f , ν_f ; and M_m the constituent matrix modulus E_m , G_m , ν_m . The reinforcement factor ξ is determined empirically by curve-fitting the experimental results. When $\xi \rightarrow \infty$, the Halpin-Tsai formulas lead to the classical rule-of-mixtures relation, and when $\xi \rightarrow 0$, the Halpin-Tsai formulas lead to the inverse form of the rule-of-mixtures:

$$(\bullet)_c = V_f (\bullet)_f + (1 - V_f) (\bullet)_m,$$

$$\frac{1}{(\bullet)_c} = \frac{V_f}{(\bullet)_f} + \frac{(1 - V_f)}{(\bullet)_m}.$$

For reinforcing fibers such as carbon or Kevlar, which exhibit anisotropic behavior but are considered transversely isotropic, the following expressions from Chamis (13)

describe the elastic properties of a UD lamina composed of anisotropic fibers in an isotropic matrix:

$$E_{11} = E_{1f}V_f + E_m V_m, \quad E_{22} = E_{33} = \frac{E_m}{1 - V_f [1 - (E_m/E_{2f})]},$$

$$G_{12} = G_{13} = \frac{G_m}{1 - V_f [1 - (G_m/G_{12f})]},$$

$$G_{23} = \frac{G_m}{1 - V_f [1 - (G_m/G_{23f})]},$$

$$\nu_{12} = \nu_{13} = \nu_{12f}V_f + \nu_m V_m,$$

$$\nu_{23} = \frac{E_{22}}{2G_{23}} - 1,$$

where the subscripts f , m , ij_f and ij_m ($i, j = 1, 2$) denote the elastic properties of the reinforcing fibers and matrix.

Composite cylinder assemblage (CCA) theory also provides simple, closed-form analytical solutions for the effective composite moduli and the fiber and matrix are also considered to be transversely isotropic (14–16). CCA yields close-bounded solutions for the transverse tensile and shear moduli and models the composite as an assemblage of long, circular fibers surrounded by concentric matrix shells.

The dependence of the effective elastic moduli on fiber volume fraction is presented in Fig. 10 and 11 for two different composite systems, a E-glass-epoxy composite lamina and a carbon-epoxy lamina. It is apparent from the results that packing densities and constituent material elastic behaviors can readily be used as parameters in the design of composite materials when tailoring the performance characteristics.

Textile Architectures. Many of the woven, braided, and stitched fabric-reinforced (textile) composite laminae also

Figure 10. Effect of fiber volume fraction (packing density) on the effective elastic modulus ratios for a E-glass-epoxy composite system (solution of Halpin-Tsai). Constituent properties: $E_{11f} = E_{22f} = 72.0$ GPa (10.4 Msi), $G_{12f} = 27.7$ GPa (4.02 Msi), $\nu_{12f} = 0.30$, $E_{11m} = E_{22m} = 3.5$ GPa (0.51 Msi), $G_{12m} = 1.3$ GPa (0.19 Msi), $\nu_{12m} = 0.35$.

Figure 11. Effect of fiber volume fraction (packing density) on the effective elastic modulus ratios for a carbon-epoxy composite system (solution of Chamis). Constituent properties: $E_{11f} = 230.0$ GPa (33.4 Msi), $E_{22f} = 40.0$ GPa (5.8 Msi), $G_{12f} = 24.0$ GPa (3.48 Msi), $G_{23f} = 14.3$ GPa (2.07 Msi), $\nu_{12f} = 0.30$, $E_{11m} = E_{22m} = 3.5$ GPa (0.51 Msi), $G_{12m} = 1.3$ GPa (0.19 Msi), $\nu_{12m} = 0.35$.

fall under the umbrella of continuous fiber reinforcements. However, nearly all of the textile architectures are not aligned within the reinforcing plane. These fiber architectures provide reinforcement in two or three directions, with the disadvantage of having somewhat lower in-plane stiffnesses due to the textile geometries. Textile reinforcing phases do afford better shaping capabilities over curved surfaces (drape) and the possibility for through-thickness reinforcement as with three-dimensional architectures.

In contrast to aligned fiber, UD laminae, textile reinforcements consist of many filaments grouped together to act as primary braiders, weavers, and fillers (warp and weft tows). Fiber bundling influences not only the packing arrangement and density but also the cross-sectional shapes and aspect ratios. Such variations in these factors combined with different textile architectures require alternate methods to evaluate the mechanical response of the composites. For example, consider the eight harness satin (8HS) weave architecture shown in Fig. 12. The bundled filamentary tow cross-sectional shapes are biconvex (lenticular); that is, thickness variation exists. Additionally, the warp tows interlace at every eighth mutually orthogonal weft or fill tow (hence, 8HS). The periodic interlacings and orthogonal tows permit shapability, but increase the in-plane compliances. Because of these factors and others, it is necessary to evaluate the effective composite properties on the basis of transformed reduced stiffnesses and through-thickness homogenization schemes that smear thickness properties into an effective continuum.

The complete evaluation of elastic and thermoelastic behavior of woven and braided composite materials is involved and beyond the scope of this review. (However, the reader is encouraged to study references 17 to 23 for thorough analytical and numerical treatments on the subjects of textile composite elastic and nonlinear behaviors).

Figure 12. Unit cell of an 8-harness satin (8HS) woven reinforcing architecture consisting of weaver (warp) tows interlaced with filler (weft) tows. Maximum width of the filamentary bundles is given by a and the cross-sectional shape is lenticular.

Randomly Oriented Fiber Reinforcement

Continuous Fibers. As with laminae constructed using continuously aligned fibers, a lamina may also be made by impregnating a polymer matrix into continuous and discontinuous fiber mats having fibers at various orientations. For the case of continuous fibers, lamina elastic properties can be considered isotropic in plane so long as a uniform probability exists over the entire range of fiber angles from $-\pi/2$ to $+\pi/2$. Neglecting fiber end effects, it is only necessary to determine the average composite longitudinal tensile and shear moduli. Akasaka derived the following expressions for the averaged effective elastic constants of composites based on randomly oriented, continuous fibers (24):

$$\begin{aligned}\bar{E}_c &= \left[\frac{E_{11} + E_{22} + 2\nu_{12}E_{22}}{1 - \nu_{12}\nu_{21}} \right] \\ &\times \left[\frac{E_{11} + E_{22} - 2\nu_{12}E_{22} + 4(1 - \nu_{12}\nu_{21})G_{12}}{3(E_{11} + E_{22}) + 2\nu_{12}E_{22} + 4(1 - \nu_{12}\nu_{21})G_{12}} \right], \\ \bar{G}_c &= \left[\frac{E_{11} + E_{22} - 2\nu_{12}E_{22}}{8(1 - \nu_{12}\nu_{21})} \right] + \frac{1}{2}G_{12}; \\ \bar{\nu}_c &= \frac{\bar{E}_c}{2\bar{G}_c} - 1.\end{aligned}$$

A simpler approach that produces similar results can be used the above equations for random fiber orientation in two dimensions:

$$\begin{aligned}\bar{E}_c &= \frac{3}{8}E_{11} + \frac{5}{8}E_{22}, \\ \bar{G}_c &= \frac{1}{8}E_{11} + \frac{1}{4}E_{22},\end{aligned}$$

where E_{11} and E_{22} are the longitudinal and transverse tensile moduli along and across the fibers in a UD composite having the same fiber volume fraction. These two approaches are equivalent to assuming that there is an equal

probability of fiber angles (θ) ranging from 0 to 360° in a composite such that the averaged equivalent longitudinal tensile modulus can be obtained by integrating the expression $\bar{E} = 2\pi \int E(\theta) d\theta$ over the range from 0 to $+\pi/2$. The orientation dependence of the tensile modulus $E(\theta)$ of a UD lamina with the same fiber volume fraction is expressed as

$$\begin{aligned}E(\theta) &= \left[\frac{1}{E_{11}} \cos^4 \theta + \left(\frac{1}{G_{12}} - \frac{2\nu_{12}}{E_{11}} \right) \cos^2 \theta \sin^2 \theta \right. \\ &\quad \left. + \frac{1}{E_{22}} \sin^4 \theta \right]^{-1}.\end{aligned}$$

These sets of equations infer the possibility of tailormaking composite laminae with fiber distributions known *a priori* so that mechanical, thermal, and other physical properties can meet the specified requirements of a given design.

Discontinuous Fibers. Behavior of composite laminae made from randomly oriented, discontinuous (chopped) fibers present a more complex problem in so far as evaluating mechanical response because of the existence of fiber-end effects. The assumption of isostrain does not hold as with continuous fiber systems because the strain transfer from the fiber-end-matrix interface is not the same as the transfer borne by continuous fibers along their length. Under an applied tensile force, the matrix displaces relative to the fiber along the fiber-matrix interface resulting in interfacial shear stress. The relative displacement is zero at the fiber midpoint and maximum at either end of fiber termination. The relationship between the fiber tensile and shear stress is $(d/d_x)\sigma_x = (4\tau_m/d_f)$, and the variation with distance along the fiber is shown for the case of elastic tensile deformation in Fig. 13.

The load transfer from the matrix to the fiber occurs over a given length of fiber called the critical length (l_c) that is just enough to allow for complete transfer. This critical length is such that complete transfer takes place without fiber breakage or matrix failure and is defined as:

$$l_c = d_f \left(\frac{E_f \epsilon_m}{2\tau_{ym}} \right),$$

where the subscripts f, m, and ym denote the fiber, matrix, and yield of matrix, respectively. The critical aspect ratio of fiber length-to-fiber diameter (l_c/d_f) increases with composite stress and strain according to the previous equation. If we define longer fibers to be $l > l_c$ and shorter fibers to be $l < l_c$, then the shorter fiber, composite effective longitudinal tensile, and shear elastic moduli become

$$\begin{aligned}E_c &= \frac{1}{3}V_f E_f \left(1 - \frac{l_c}{2l} \right) + (1 - V_f)E_m, \\ G_c &= \frac{1}{8}V_f E_f \left(1 - \frac{l_c}{2l} \right) + (1 - V_f)E_m,\end{aligned}$$

for the two-dimensional consideration. For random orientations of longer fibers in two-dimensions, the composite

Figure 13. The tensile load transfer process by interfacial shear and the resulting variation of tensile and shear stresses along the length of a discontinuous fiber.

effective moduli are given by

$$E_c = \frac{1}{3}V_f E_f \left(\frac{l}{2l_c} \right) + (1 - V_f)E_m,$$

$$G_c = \frac{1}{8}V_f E_f \left(\frac{l}{2l_c} \right) + (1 - V_f)E_m.$$

Particulate Reinforcement

Composite materials based on particle reinforcements usually contain fillers that are spherical. It is reasonable to consider these composites as mesoscopically isotropic. Therefore only two effective elastic properties are necessary to fully describe composite elastic behavior. In evaluating these elastic properties, the modified Halpin-Tsai solution set is applicable:

$$\frac{(\bullet)_c}{(\bullet)_m} = \frac{1 + \xi \eta V_f}{1 - \psi \eta V_f}, \quad \eta = \frac{r - 1}{r + \xi}$$

$$r = \frac{(\bullet)_f}{(\bullet)_m}, \quad \xi = \frac{7 - \nu_m}{8 - 10\nu_m}$$

$$\psi = 1.$$

Again, (\bullet) is the elastic constant of interest, ξ depends on the characteristics of the reinforcing phase such as filler

aspect ratio, packing geometry, shape, and loading conditions, and ψ is a factor that accounts for the maximum packing possible. For particle reinforcement, the filler and matrix are both assumed to be isotropic and the packing factor is taken as 1.

Statistics and Strength Theories

Up to this point, the assumption was that stress-induced fiber failure would occur at the same level for all fibers within a composite lamina, suggesting that a simple rule-of-mixtures (ROM) approach would give a sufficient first-order approximation to composite longitudinal tensile strength according to

$$\sigma_{11} = E_f \varepsilon_{11} V_f + E_m \varepsilon_{11} (1 - V_f).$$

In practice, the stress levels reached to cause fiber failure will vary from point to point because of the various distributions of inherent flaws that exist within the constituent matrix and on the surface of the reinforcing fibers as well as the distributions of fiber lengths. For a given tensile stress, weaker fibers within a group may fail, giving rise to perturbations in the local stress fields near the fiber termination and resulting in the high interfacial shear stresses as previously discussed in regard to discontinuous fiber reinforcements. The interfacial shear stresses transfer the load across the interfaces and may introduce stress concentrations into adjacent, unbroken fibers.

Several possible failure events may arise due to the stress distribution at each broken fiber end. If the interfacial bond strength is weak, separation of the matrix and fiber at the termination will rapidly advance along the fiber–matrix interface. If the interfacial bonding is strong or the matrix is a soft ductile material, shear stresses are redistributed and fibers may fail before the surrounding matrix fails completely. Progression of undesirable modes of failure results in the development of damage zones (see Fig. 14), eventually leading to a strength reduction such that the composite strength is no greater than that of the weakest fiber or “link.”

Prior to composite material failure, increased loading produces a statistical accumulation of dispersed damage zones until a sufficient number interact to provide a weakened surface. At the point of failure, the weakened surface becomes quite large in comparison to the undamaged material and the composite can no longer support additional tensile loading.

The experimentally measured tensile strengths of brittle fibers are subject to significant amounts of scatter that can be described by the Weibull distribution function. A schematic illustration of this is given in Fig. 15, where the fraction of fibers of uniform length that fail are plotted against the given failure stress. The Weibull cumulative probability distribution function $G(\sigma)$ represents the probability of fiber and fiber bundle fracture at a stress level that is equal to or less than σ , and it is given by

$$G(\sigma) = 1 - \left[1 - \left(\frac{\sigma - \sigma_I}{\sigma_o} \right)^m \right]^\omega,$$

where σ_o is the difference between the upper strength limit

Figure 14. Schematic of the evolution of tensile fiber damage in aligned fiber composites: (a) fiber break with interfacial debonding, (b) fiber break expanding matrix crack, (c) matrix crack with fiber bridging, and (d) a compilation of a, b, and c resulting in a damage zone.

Figure 15. Weibull cumulative probability distribution function $G(\sigma)$ describing variations in fiber strength: (1) Fibers do not exhibit a wide variability in fracture strength between 0 and 1, where 0.5 is the occurrence of tensile failure in 50% of fibers, and (2) a wide variation exists and is statistically described by a standard deviation as indicated with vertical lines.

σ_u and the lower strength limit σ_l , ω is a function of the test sample aspect ratio and m depends on the amount of scatter. The exponent m is approximately $1.2\bar{\sigma}/s$, where $\bar{\sigma}/s$ is the inverse of the coefficient of variation given by

$$\frac{\bar{\sigma}}{s} = \left(\frac{\sum_{i=1}^N \sigma_i}{N} \right) \left(\left[\frac{\sum_{i=1}^N (\sigma_i - \bar{\sigma})^2}{N} \right]^{1/2} \right)^{-1}$$

Below the lower strength limit, all fibers undergo the same amount of elongation and remain unbroken. As the lower strength limit is exceeded, the weakest fibers (those containing internal flaws leading to reduced effective cross sections) break in succession, and the load must be transferred to the surviving fibers. Complete fracture of the bundle occurs when the upper strength limit is reached.

Several tensile dominated failure modes adopted to consider the fiber-and-fiber bundle failure processes when they are bound by a matrix include the weakest link failure mode, cumulative weakening failure mode, fiber break propagation failure mode, and cumulative group failure mode. The weakest link failure mode associates catastrophic failure with the occurrence of a single or isolated small number of independent fiber breaks. Realistically, this mode of failure is an unlikely characterization because the stress level at which weakest link events occur would not be sufficient enough to invoke composite material failure.

The cumulative weakening failure mode is necessarily an extension of the weakest link failure mode. Within characterization of this mode, a fiber fracture site inhibits redistribution of stress near the site. As more sites develop along a fiber, they tend to have a statistical strength distribution that is equivalent to the distribution of flaws along the fiber. Failure is thought to occur when a layer across the section of a lamina is weakened to the point of not being able to support any further increments in load. A critical argument to acceptance of this mode entirely as a characterization of failure is that no consideration is given to the effects on neighboring fibers and flaws.

It is well known that the effects of stress perturbations at terminations are significant to neighboring fibers. The fiber break propagation failure mode is more realistic in the sense that the effects of perturbations on the progressive weakening of adjacent fibers are considered. As redistribution of stress occurs, the stresses on adjacent fibers are magnified, increasing the probability that failure will occur in these fibers. With increased loading, the failure probability increases until sequential fiber failure occurs.

Under auspices of the fiber break propagation model, it is difficult to achieve a meaningful strength estimate, and lamina tensile strength predictions generally depend on the micromechanisms of deformation and fracture at fiber termination points. For the smaller damaged volumes of material, strength predictions are acceptable, but predicted failure stresses are lower for larger volumes. The cumulative group mode failure model considers the effects of variability in fiber strengths, stress concentrations in adjacent fibers arising from stress redistributions, and the interfacial debonding process due to increased matrix shear stresses. It is more likely that fiber breaks

will progressively accumulate in groups between the stress level necessary to initiate the first fiber break to the stress level necessary to cause composite material failure. Composite failure will occur when the distributed groups of damage zones are of a sufficient number and size that their cumulative effect reduces the material stiffness by an amount sufficient enough to prohibit any additional load-carrying capability. Weakening mechanisms by this mode could be thought of in a couple of different manners. In one way, the number of developed damage zones would grow to such a number that the summed interactions exceeded the critical material stress. In another, the size and number of zones would reach such magnitude that catastrophic and rapid crack propagation ensue due to the lack of both intact material and crack tip blunting mechanisms between zones. Although the cumulative group model suggests a generalization of the cumulative weakening model, the practicality of use is complicated by its complexity in considering mostly all of the singular fiber longitudinal tensile failure mechanisms.

The longitudinal compressive strength, like the longitudinal tensile strength, is highly dependent on many factors and is particularly sensitive to constituent matrix properties and fiber volume fraction. Several failure mechanisms have been proposed, but the most dominant mechanism is microbuckling, analogous to the buckling of a beam on an elastic foundation. The surrounding matrix resists fiber microbuckling, but there are several factors that can lead to a reduction in the support given by the matrix and neighboring fibers. At a low fiber volume fraction, the out-of-phase or extensional buckling mode is suggested with the lamina compressive strength predicted by the following equation:

$$\sigma_{11,c}^{cr} = 2V_f \sqrt{\frac{V_f E_m E_f}{3(1 - V_f)}}.$$

At higher, more industrially practicable fiber volume fractions, the in-phase or shear buckling mode is suggested with the lamina compressive strength predicted by the following equation:

$$\sigma_{11,c}^{cr} = \frac{G_m}{(1 - V_f)}.$$

Given a constant fiber volume fraction, any factors contributing to reduction in the matrix shear modulus will lead to a reduction in composite compressive strength, since the mode is in-phase. More specifically, the identified factors that influence reduced support from the surrounding media include: (25)

- Fiber bunching and waviness, which leads to preferential buckling, local matrix rich regions and matrix instability.
- The presence of voids, which tend to have a greater effect than the matrix rich regions.
- Interfacial debonding, due to circumferential tensile stresses that arise principally from a difference in Poisson's ratios between the fibers and surrounding matrix or the opposite effect induced by thermal curing stresses.

Figure 16. Progression of compressive fiber failure resulting from longitudinal compressive in-phase buckling (a). In polymeric aramid fibers, compressive yielding is common (b) during formation of a kink zone, while more pronounced kinking often leads to fiber fracture at two locations (c) after (25).

- A lower effective matrix shear modulus, compared to the instantaneous matrix shear modulus, as a result of viscoelastic deformation processes.

Another longitudinal compressive failure mechanism specific to the structurally oriented, wholly aromatic polyamide polymer fiber (Kevlar aramid) and carbon/graphite fiber families, is the formation of kink-bands as illustrated in Fig. 16. The highly anisotropic behavior of these fibers leads to massive fiber rotation at one zone and counter-rotation at another zone. In the extreme case, compressive failure at the kink zones results in complete fiber fracture at two locations. Compressive yielding without complete failure is more typical of the polymeric Kevlar aramids such as Kevlar 49.

The transverse tensile, compressive, shear, and longitudinal shear strengths can be regarded as matrix dominated, so the failure modes can be thought of as matrix-modes of failure. Transverse tensile strength is governed by the same factors as longitudinal compression, but with one added detail. Unlike longitudinal tension where composite strength is prescribed primarily on the basis of fiber strength, the presence of fibers in transverse tension have a negative effect. Transverse strength is often lower than the strength of the constituent neat matrix material because of the stress magnification effects from fibers. Without regard to the presence of stress magnification from fiber ends and

matrix voids, the transverse strength is dictated primarily by the interfacial bond strength. The interface is made weaker when cohesive failure occurs prior to the cohesive failure in either the constituent matrix or fibers.

Where interface bonding is weak, stress magnification from fiber ends and voids tends to promote transverse cracking more readily along the common edges of adjacent fiber ends. These same factors also affect the transverse and longitudinal shear strengths, depending on the direction of shear displacements and the viscoelastic properties of the matrix. The only real differences here may be the direction of crack propagation and the failure mode(s) of the matrix, unless the fiber volume fraction is sufficiently higher. If a large number of fibers are present and the interfacial bonding is good, the fibers will offer reinforcement, provided the shearing plane is normal to the fibers. If the shearing plane contains the fibers, then little fiber reinforcement is available and the strength is determined by the properties of the matrix.

Identification of a predominant failure mechanism, whether a fiber or matrix mode, is important from the perspective of designing composite structures. Knowledge of the different failure mechanisms and the nature of single-stress component damage initiation can be used to evaluate the predominant mode of failure through formulation of practical failure criteria. In establishing the failure criterion, a fundamental assumption is that a failure criterion exists to characterize failure in a UD composite and is of the following form:

$$F(\sigma_{11}, \sigma_{22}, \tau_{12}) = 1,$$

where some function F is defined in terms of the principal stresses. A suitable failure criterion generally takes the form of a quadratic polynomial because this is the simplest form that has been found to adequately describe experimental data. The advantages are that several failure criteria can be defined in terms of uniaxial strengths, and a predominant mode of failure can be identified from the criterion that is initially satisfied.

If a certain mode of failure is identified and deemed undesirable for a given load, the designer can tailor the composite properties and re-evaluate the failure criteria until some other mode is predicted that is less detrimental to the design. For UD fiber composites, the general quadratic failure criterion is a two-dimensional version of the Tsai-Wu criterion given by

$$\begin{aligned} & \left(\frac{1}{S_1^t S_1^c} \right) \sigma_{11}^2 + \left(\frac{1}{S_1^t} - \frac{1}{S_1^c} \right) \sigma_{11} + \left(\frac{1}{S_2^t S_2^c} \right) \sigma_{22}^2 \\ & + \left(\frac{1}{S_2^t} - \frac{1}{S_2^c} \right) \sigma_{22} - \frac{1}{2} \left(\left(\frac{1}{S_1^t S_1^c} \right) \left(\frac{1}{S_2^t S_2^c} \right) \right)^{1/2} \sigma_{11} \sigma_{22} \\ & + \left(\frac{1}{(S_{12}^s)^2} \right) \tau_{12}^2 = 1, \end{aligned}$$

where the S_{ij} denote the single-component strengths and the superscripts t, c, and s denote tension, compression, and shear, respectively. The biggest drawback of this criterion is that it ignores the diversity in the possible failure modes.

Each of the failure modes previously mentioned can be modeled as a specific criterion and, as such, evaluated and identified independently. The following set of equations provides a reasonable set of criteria for each of the dominant fiber and matrix failure modes (26):

- Tensile Fiber Failure

$$\left(\frac{\sigma_{11}}{S_1^t} \right)^2 + \left(\frac{\tau_{12}}{S_{12}^s} \right)^2 = 1.$$

- Compressive Fiber Failure

$$\left(\frac{\sigma_{11}}{S_1^c} \right)^2 + \left(\frac{\tau_{12}}{S_{12}^s} \right)^2 = 1.$$

- Tensile Matrix Failure

$$\left(\frac{\sigma_{22}}{S_2^c} \right)^2 + \left(\frac{\tau_{12}}{S_{12}^s} \right)^2 = 1.$$

- Compressive Matrix Failure

$$\left(\frac{\sigma_{22}}{2S_{23}^s} \right)^2 + \left(\left(\frac{S_2^c}{2S_{23}^s} \right)^2 - 1 \right) \left(\frac{\sigma_{22}}{S_2^c} \right) + \left(\frac{\tau_{12}}{S_{12}^s} \right)^2 = 1.$$

Since the transverse shear strength S_{23} is difficult to obtain without performing thickness shear tests, the matrix shear strength is used as an approximation. Upon evaluating each of the failure criteria for a given circumstance, the predominant mode or modes of failure can be determined. Necessarily, no biaxial tests are required, and a mode of failure is identified by the criterion that is satisfied first.

MACROSCALE BEHAVIOR

On the macroscale, the effective composite elastic properties are evaluated on the basis of a composite laminate that is composed of several laminae bonded together at various orientations to one another. It was previously stated that the composite structure or component and the laminae may, in some cases, coincide on the same structural scale. This being the case, tailoring laminate properties will also coincide directly with influencing component behavior.

One of the most important aspects relating to the effective design of composite laminates and structures is knowledge of composite lamina off-axis behavior and associated limitations with particular fiber orientations. Aligned fiber composite laminae are highly anisotropic in-plane, and commonly varying degrees of coupling between extension and shear occur when the direction of loading is not coincident with a principal material direction. The designer must have some knowledge *a priori* of the lamina response to off-axis loading conditions in order to determine a suitable lamina lay-up sequence that provides optimum reinforcement. An accurate prediction of laminate elastic properties, which are highly dependent on the orientation, properties, and distribution of individual laminae, is essential for understanding the response of the resulting structure to external loading and environmental conditions.

Elastic Behavior Off-Axis

Hooke's law can be generalized using a contracted form of tensor notation and expressed concisely by the following equation:

$$\sigma_i = \sum_{j=1}^6 C_{ij} \varepsilon_j,$$

where $i, j = 1, \dots, 6$, σ_i are the components of stress, C_{ij} is the stiffness matrix, and ε_j are the components of strain. Since the stiffness constants are symmetrical (i.e., $C_{ij} = C_{ji}$), the expanded form of the previous equation is given in matrix notation by

$$\begin{bmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_3 \\ \tau_{23} \\ \tau_{31} \\ \tau_{12} \end{bmatrix} = \begin{bmatrix} C_{11} & C_{12} & C_{13} & C_{14} & C_{15} & C_{16} \\ & C_{22} & C_{23} & C_{24} & C_{25} & C_{26} \\ & & c_{33} & C_{34} & C_{35} & C_{36} \\ & & & C_{44} & C_{45} & C_{46} \\ & & & & C_{55} & C_{56} \\ & & & & & C_{66} \end{bmatrix} \begin{bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \varepsilon_3 \\ \gamma_{23} \\ \gamma_{31} \\ \gamma_{12} \end{bmatrix}.$$

(SYM)

The constitutive relations that link stress to strain in terms of the stiffness matrix may also be inverted to relate strain to stress in terms of the compliance matrix. The constitutive relations for a UD composite lamina, which exhibits orthotropic symmetry and transverse isotropy in the x_2 - x_3 material principal coordinate plane, can be simplified if the dimension in the x_3 (thickness) direction is considered to be sufficiently smaller than both of the in-plane dimensions. This consideration reduces the problem to two dimensions, either of the plane stress or plane strain form. Clearly, the implication is that the nonzero stresses are arbitrarily restricted to in-plane; hence the nonzero quantities are not functions of x_3 ($\sigma_3 = \tau_{23} = \tau_{31} = 0$). For this, the stress-strain relation for a UD lamina given in terms of the matrix of mathematical moduli $[Q_{ij}]$ becomes

$$\begin{bmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_6 \end{bmatrix} = \begin{bmatrix} Q_{11} & Q_{12} & 0 \\ Q_{12} & Q_{22} & 0 \\ 0 & 0 & Q_{66} \end{bmatrix} \begin{bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \varepsilon_6 \end{bmatrix},$$

where Q_{11} , Q_{22} , Q_{12} , and Q_{66} are identified as the *reduced stiffnesses*.

The equation above suggests that no coupling exists between tensile and shear strains; that is, orthotropic composite materials exhibit no shearing strains when applied loads act coincident to the principal material directions. The Q_{ij} components of the reduced stiffness matrix from this equation are given in terms of the engineering constants as

$$Q_{11} = C_{11} = \frac{E_{11}}{1 - \nu_{12}\nu_{21}},$$

$$Q_{22} = C_{22} = \frac{E_{22}}{1 - \nu_{12}\nu_{21}},$$

$$Q_{66} = \frac{1}{2}(C_{11} - C_{12}) = G_{12},$$

$$Q_{12} = C_{12} = \frac{\nu_{12}E_{22}}{1 - \nu_{12}\nu_{21}} = \frac{\nu_{21}E_{11}}{1 - \nu_{12}\nu_{21}}.$$

Figure 17. Representation of a UD composite lamina with the principal material direction (fibers) oriented at some arbitrary in-plane angle λ to the Cartesian coordinate X - Y plane.

When the direction of applied load does not coincide with a principal material direction, then coupling between tensile and shear strains exists. Consider the sufficiently thin, UD lamina with fibers oriented at an angle λ to the principal coordinate axis shown in Fig. 17. From classical theory of elasticity, the stress-strain relation becomes

$$\begin{bmatrix} \sigma_x \\ \sigma_y \\ \tau_{xy} \end{bmatrix} = \begin{bmatrix} \bar{Q}_{11} & \bar{Q}_{12} & \bar{Q}_{16} \\ \bar{Q}_{12} & \bar{Q}_{22} & \bar{Q}_{26} \\ \bar{Q}_{16} & \bar{Q}_{26} & \bar{Q}_{66} \end{bmatrix} \begin{bmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{bmatrix},$$

where the \bar{Q}_{ij} components of the matrix are referred to as the *transformed reduced stiffness components*. In terms of the reduced stiffness matrix components and λ , the transformed reduced stiffness components have the following values:

$$\bar{Q}_{11} = Q_{11} \cos^4 \lambda + 2(Q_{12} + 2Q_{66}) \sin^2 \lambda \cos^2 \lambda + Q_{22} \sin^4 \lambda,$$

$$\bar{Q}_{22} = Q_{11} \sin^4 \lambda + 2(Q_{12} + 2Q_{66}) \sin^2 \lambda \cos^2 \lambda + Q_{22} \cos^4 \lambda,$$

$$\bar{Q}_{66} = (Q_{11} + Q_{22} - 2Q_{12} - 2Q_{66}) \sin^2 \lambda \cos^2 \lambda + Q_{66}(\sin^4 \lambda + \cos^4 \lambda),$$

$$\bar{Q}_{12} = (Q_{11} + Q_{22} - 4Q_{66}) \sin^2 \lambda \cos^2 \lambda + Q_{12}(\sin^4 \lambda + \cos^4 \lambda),$$

$$\bar{Q}_{16} = (Q_{11} - Q_{12} - 2Q_{66}) \sin \lambda \cos^3 \lambda + (Q_{12} - Q_{22} + 2Q_{66}) \sin^3 \lambda \cos \lambda,$$

$$\bar{Q}_{26} = (Q_{11} - Q_{12} - 2Q_{66}) \sin^3 \lambda \cos \lambda + (Q_{12} - Q_{22} + 2Q_{66}) \sin \lambda \cos^3 \lambda.$$

If the local elastic properties of the UD composite lamina are known with respect to the material coordinate system, the engineering elastic constants can be determined for the Cartesian coordinate system as follows:

$$E_x = \left[\frac{1}{E_1} \cos^4 \lambda + \left(\frac{1}{G_{12}} - \frac{2\nu_{12}}{E_1} \right) \sin^2 \lambda \cos^2 \lambda + \frac{1}{E_2} \sin^4 \lambda \right]^{-1},$$

$$E_y = \left[\frac{1}{E_1} \sin^4 \lambda + \left(\frac{1}{G_{12}} - \frac{2\nu_{12}}{E_1} \right) \sin^2 \lambda \cos^2 \lambda + \frac{1}{E_2} \sin^4 \lambda \right]^{-1},$$

Figure 18. Variations of the engineering elastic constants E_x , G_{xy} , and v_{xy} with the fiber orientation angle λ for a UD carbon-epoxy composite of the following elastic properties: $E_{11} = 139.4$ GPa (20.2 Msi), $E_{22} = 7.7$ GPa (1.1 Msi), $G_{12} = 3.0$ GPa (0.44 Msi), $v_{12} = 0.3$, and $V_f = 0.6$.

$$G_{xy} = \left[2 \left(\frac{2}{E_1} + \frac{2}{E_2} + \frac{4v_{12}}{E_1} - \frac{1}{G_{12}} \right) \sin^2 \lambda \cos^2 \lambda + \frac{1}{G_{12}} (\sin^4 \lambda + \cos^4 \lambda) \right]^{-1}$$

$$V_{xy} = E_x \left[\frac{v_{12}}{E_1} (\sin^4 \lambda + \cos^4 \lambda) - \left(\frac{1}{E_1} + \frac{1}{E_2} - \frac{1}{G_{12}} \right) \sin^2 \lambda \cos^2 \lambda \right]$$

The variations of E_x , G_{xy} , and v_{xy} that result from these equations, with the fiber orientation angle λ relative to the principal material direction, are shown in Fig. 18 for a UD carbon-epoxy composite. It is possible in some cases that the predicted value of E_x may exceed the values of E_{11} and E_{22} depending on the differences among between G_{12} , E_{11} , and E_{22} . By carefully examining Fig. 18, one could envisage how the engineering elastic constants of a composite laminate might be modified according to the orientations of stacked laminae, hence allow performance tailoring characteristics with composites.

Classical Lamination Theory

The most established theory for analysis of laminates takes the form of the Kirchhoff hypothesis for thin plates or classical, linear, thin plate theory. Following the adaptation of this theory for analysis of composite laminates, commonly referred to as classical lamination theory (CLT), the subsequent four assumptions are made:

- Upon application of a load to a plate with a through-thickness, lineal element normal to the plane of the plate, the element undergoes at most a translation

and rotation with respect to the initial coordinate system, but remains normal to the plate.

- The plate resists in-plane and lateral loads only by in-plane action, bending and transverse shear stress, and not by through-thickness, blocklike tension or compression.
- There is a neutral plane, on which extensional strains may not be zero but bending strains are zero in all directions.
- The laminate midplane is analogous to the neutral plane of the plate.

According to the foregoing assumptions for adaptation of the Kirchhoff hypothesis for thin plates, the strain components can be derived from the midplane strains and curvatures. The midplane strains are expressed as $\varepsilon^{\circ xx} = \partial u^{\circ} / \partial x$, $\varepsilon^{\circ yy} = \partial v^{\circ} / \partial y$ and $\gamma^{\circ xy} = (\partial u^{\circ} / \partial y) + (\partial v^{\circ} / \partial x)$, where u° and v° are expressed in terms of the x and y coordinate directions. The midplane curvatures are expressed as $\kappa_{xx} = -\partial^2 w^{\circ} / \partial x^2$, $\kappa_{yy} = -\partial^2 w^{\circ} / \partial y^2$, and $\kappa_{xy} = -\partial^2 w^{\circ} / \partial x \partial y$ and are related to the z coordinate direction. Here κ_{xy} refers to the curvature of twist about the plane of the plate. The strain components are expressed in matrix form as

$$\begin{Bmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{Bmatrix} = \begin{Bmatrix} \varepsilon_{x,0} \\ \varepsilon_{y,0} \\ \gamma_{xy,0} \end{Bmatrix} + z \begin{Bmatrix} -\frac{\partial^2 w}{\partial x^2} \\ -\frac{\partial^2 w}{\partial y^2} \\ -2\frac{\partial^2 w}{\partial x \partial y} \end{Bmatrix}$$

$$\{\varepsilon\} = \{\varepsilon\}_0 + z\{\kappa\}_0$$

The equation above implies that the strains vary linearly with z , meaning that through-thickness sections remain plane and normal after deformation relative to the original coordinate system with its origin at the midplane. If the strains vary linearly, then lamina (ply) stresses must vary in proportion to lamina stiffnesses. In terms of the laminate, the ply stress components are given by

$$\begin{aligned} \{\sigma\}_k &= [Q_{xy}]_k \{\varepsilon\}_k \\ &= [Q_{xy}]_k \{\varepsilon\}_0 + z_k [Q_{xy}]_k \{\kappa\}_0 \end{aligned}$$

where the subscript k denotes the contribution from the k th ply within the composite laminate. According to the plate shown in Fig. 19, the forces and moments have a lineal distribution. In reference to the stress components for the k th ply in the previous equation, force and moment equilibrium are considered. The forces and moments that are responsible for producing in-plane ply stresses are denoted by N_x , N_y , N_{xy} , M_x , M_y , and M_{xy} , where the N 's are the ply-level forces and the M 's are the ply-level moments. For force equilibrium, the integrated, through-thickness laminate stress must be equivalent to the corresponding force that produces it. The total force and moment, determined from contributions of all plies within the laminate,

Figure 19. In-plane force and the moment resultants of a laminated plate subjected to extensional forces and bending moments.

can be expressed as

$$\begin{Bmatrix} N_x \\ N_y \\ N_{xy} \end{Bmatrix} = \sum_{k=1}^n \int_{h_{k-1}}^{h_k} (\sigma_{x,k}, \sigma_{y,k}, \tau_{xy,k}) dz,$$

$$\begin{aligned} \{N\} &= \begin{bmatrix} \sum_{k=1}^n [Q_{xy}]_k \int_{h_{k-1}}^{h_k} dz \\ \sum_{k=1}^n [Q_{xy}]_k \int_{h_{k-1}}^{h_k} z dz \end{bmatrix} \{\varepsilon\}_0 + \begin{bmatrix} \sum_{k=1}^n [Q_{xy}]_k \int_{h_{k-1}}^{h_k} dz \\ \sum_{k=1}^n [Q_{xy}]_k \int_{h_{k-1}}^{h_k} z dz \end{bmatrix} \{\kappa\}_0 \\ &= \begin{bmatrix} \sum_{k=1}^n (h_k - h_{k-1}) [Q_{xy}]_k \\ \sum_{k=1}^n \frac{1}{2} (h_k^2 - h_{k-1}^2) [Q_{xy}]_k \end{bmatrix} \{\varepsilon\}_0 \\ &\quad + \begin{bmatrix} \sum_{k=1}^n [Q_{xy}]_k \int_{h_{k-1}}^{h_k} dz \\ \sum_{k=1}^n [Q_{xy}]_k \int_{h_{k-1}}^{h_k} z dz \end{bmatrix} \{\kappa\}_0 \\ &= [A]\{\varepsilon\}_0 + [B]\{\kappa\}_0, \end{aligned}$$

$$\begin{Bmatrix} M_x \\ M_y \\ M_{xy} \end{Bmatrix} = \sum_{k=1}^n \int_{h_{k-1}}^{h_k} (\sigma_{x,k}, \sigma_{y,k}, \tau_{xy,k}) z dz,$$

$$\begin{aligned} \{M\} &= \begin{bmatrix} \sum_{k=1}^n [Q_{xy}]_k \int_{h_{k-1}}^{h_k} z dz \\ \sum_{k=1}^n [Q_{xy}]_k \int_{h_{k-1}}^{h_k} z^2 dz \end{bmatrix} \{\varepsilon\}_0 + \begin{bmatrix} \sum_{k=1}^n [Q_{xy}]_k \int_{h_{k-1}}^{h_k} z dz \\ \sum_{k=1}^n [Q_{xy}]_k \int_{h_{k-1}}^{h_k} z^2 dz \end{bmatrix} \{\kappa\}_0 \\ &= \begin{bmatrix} \sum_{k=1}^n \frac{1}{2} (h_k^2 - h_{k-1}^2) [Q_{xy}]_k \\ \sum_{k=1}^n \frac{1}{3} (h_k^3 - h_{k-1}^3) [Q_{xy}]_k \end{bmatrix} \{\varepsilon\}_0 \\ &\quad + \begin{bmatrix} \sum_{k=1}^n [Q_{xy}]_k \int_{h_{k-1}}^{h_k} z dz \\ \sum_{k=1}^n [Q_{xy}]_k \int_{h_{k-1}}^{h_k} z^2 dz \end{bmatrix} \{\kappa\}_0 \\ &= [B]\{\varepsilon\}_0 + [D]\{\kappa\}_0. \end{aligned}$$

The peculiar mechanical behavior of composite laminates can be discerned by examining the two previous equations. The first equation implies that changes in curvature (bending strains), stretching and squeezing are brought about by the tensile forces and compressive forces given by $\{N\}$. Also the second equation implies that the moments given by $\{M\}$, in addition to changes in curvature, can produce squeezing and stretching strains. From the

force and moment equilibrium analysis, the constitutive relations for laminated composites can be expressed in a condensed form as follows:

$$\begin{Bmatrix} N \\ M \end{Bmatrix} = \begin{bmatrix} A & B \\ B & D \end{bmatrix} \begin{Bmatrix} \varepsilon_0 \\ \kappa_0 \end{Bmatrix},$$

where the A , B , and D matrices are the extension, extension-bending coupling and bending stiffnesses, respectively. Upon expansion of the condensed form, the solution to the stiffnesses can be written in terms of summations of transformed, reduced stiffnesses belonging to individual laminae having h_k th thicknesses:

$$[A] = \sum_{k=1}^n (h_k - h_{k-1}) [Q_{xy}]_k,$$

$$[B] = \sum_{k=1}^n \frac{1}{2} (h_k^2 - h_{k-1}^2) [Q_{xy}]_k,$$

$$[D] = \sum_{k=1}^n \frac{1}{3} (h_k^3 - h_{k-1}^3) [Q_{xy}]_k.$$

Evaluation of the extension, extension-bending coupling and bending stiffnesses, or more simply, the $[ABD]$ matrix serves many purposes in the analysis of composite laminates. This matrix has many uses from the standpoint of designing composite laminates and engineering structures, and it may be used for the following (27):

- Calculating the effective composite laminate elastic properties.
- Calculating the ply-level stresses and ply-level strains for a given load on the laminate.
- Calculating the ply-level stresses and laminate load for a given mid-plane strain.
- Evaluating whether bending strains would result from an extensional load, and vice versa.
- Comparative evaluations of different lay-ups followed by optimization.
- Determining the variation of laminate properties along different directions.
- Calculating the thermal expansion and swelling coefficients of the laminate.
- Estimating the laminate residual stresses due to curing.
- Calculating the ply-level hygral and thermal stresses.

Effects of Orientation and Stacking

The derivation of the $[ABD]$ matrix suggests that the elastic behavior of a composite laminate made from UD laminae is influenced by the constituent fiber and matrix properties as well as the orientations and locations of individual laminae with respect to the geometric midplane of the laminate. The extensional $[A]$ matrix relates the stress resultants with the midplane strains, and the normal stress resultant-to-midplane shear strain coupling and shear stress resultant-to-midplane normal strain coupling

are due to the A_{16} and A_{26} components, respectively. The B_{16} and B_{26} components of the extension-bending coupling $[B]$ matrix relate the normal stress resultants with laminate twisting, and the $[B]$ matrix also suggests the coupling between the moment resultants and the in-plane strains. Finally, the interaction between the laminate bending moment and laminate twisting are related through the D_{16} and D_{26} terms of the bending $[D]$ matrix (28). A physical sense of the coupling effects that exist in relation to the laminate midplane can be seen in Fig. 20(a–b).

If an isostrain condition is assumed for the laminae shown in Fig. 20(a), different stresses will result normal and transverse to the laminae due to their orthotropic behavior. Then, upon bonding and releasing of applied stress, the laminate will distort and bend favorably toward the lamina with higher in-plane stiffness. For the laminate to remain flat, an additional force normal to the plane would be necessary. Similarly, if a uniaxial stress were applied to a laminate having laminae oriented at $+/-\lambda$ and lacking end constraints as shown in Fig. 20(b), twisting about the axis would result due to the extensional-shear coupling arising from anti-symmetry about the midplane.

From a practical standpoint, it is useful to minimize or eliminate these coupling effects, since most engineering structures are required to maintain dimensional stability for long periods of time under various loading and environmental conditions. According to the premises of the $[ABD]$ matrix, coupling can be minimized by selecting the appropriate sequences in which to lay-up individual laminae having various materials, thicknesses, and orientations. This may be referred to as the design of composite laminates and engineering structures.

Two of the most important classes of composite laminate designs from an engineering perspective are symmetric laminates and quasi-isotropic laminates. In symmetric laminates, laminae (plies) on opposing sides of the laminate geometric midplane have the same material, thickness, and orientation. Symmetry about the midplane eliminates the undesirable effects of extension-bending coupling; that is, all of the elements in the $[B]$ matrix become zero and unknown residual stresses from warping deformation are avoided. Except for the cases of cross-ply, all 0° , or all 90° , bending moments in symmetric laminates still produce torsional deflections ($[D]$ matrix). However, the magnitudes can be reduced by increasing the number of plies, for example, in cross-ply configurations.

The notation often adopted in describing a lay-up that is symmetric is as follows: a six-layered stacking sequence expressed as $[0^\circ/-45^\circ/+45^\circ_2/-45^\circ/0^\circ]$ is equivalent to the sequence denoting symmetry expressed as $[0^\circ/-45^\circ/+45^\circ]_s$ provided that the thicknesses and materials are matched below the midplane. The term “quasi-isotropic” as used to describe laminate behavior suggests the same $[A]$ matrix in all directions. Quasi-isotropic laminates exhibit very little variation in apparent elastic moduli with direction, and this becomes useful when the load-direction is unknown or variable.

From the perspective of designing laminates, a laminate can be made isotropic, or nearly isotropic, by having a number of plies greater than four that are equal in thickness and oriented by $2\pi/n$ (n is the total number of plies) to

Figure 20. Interpretation of the coupling effects between two bonded composite laminae at various orientations with respect to the geometric midplane: (a) Extensional-bending coupling in well-bonded laminae oriented at 0 and 90° under isostrain conditions, and (b) extensional-shear coupling, which produces twisting in well-bonded laminae oriented at $+\lambda$ and $-\lambda$ to the principal material axis.

adjacent plies. Ideally, quasi-isotropic laminates are symmetric, and symmetric or unsymmetric laminates are at least balanced in thickness, since these designs will tend to be most well-behaved structurally and at least somewhat predictable in response. Examples of symmetric and unsymmetric composite laminate lay-up sequences are shown in Fig. 21.

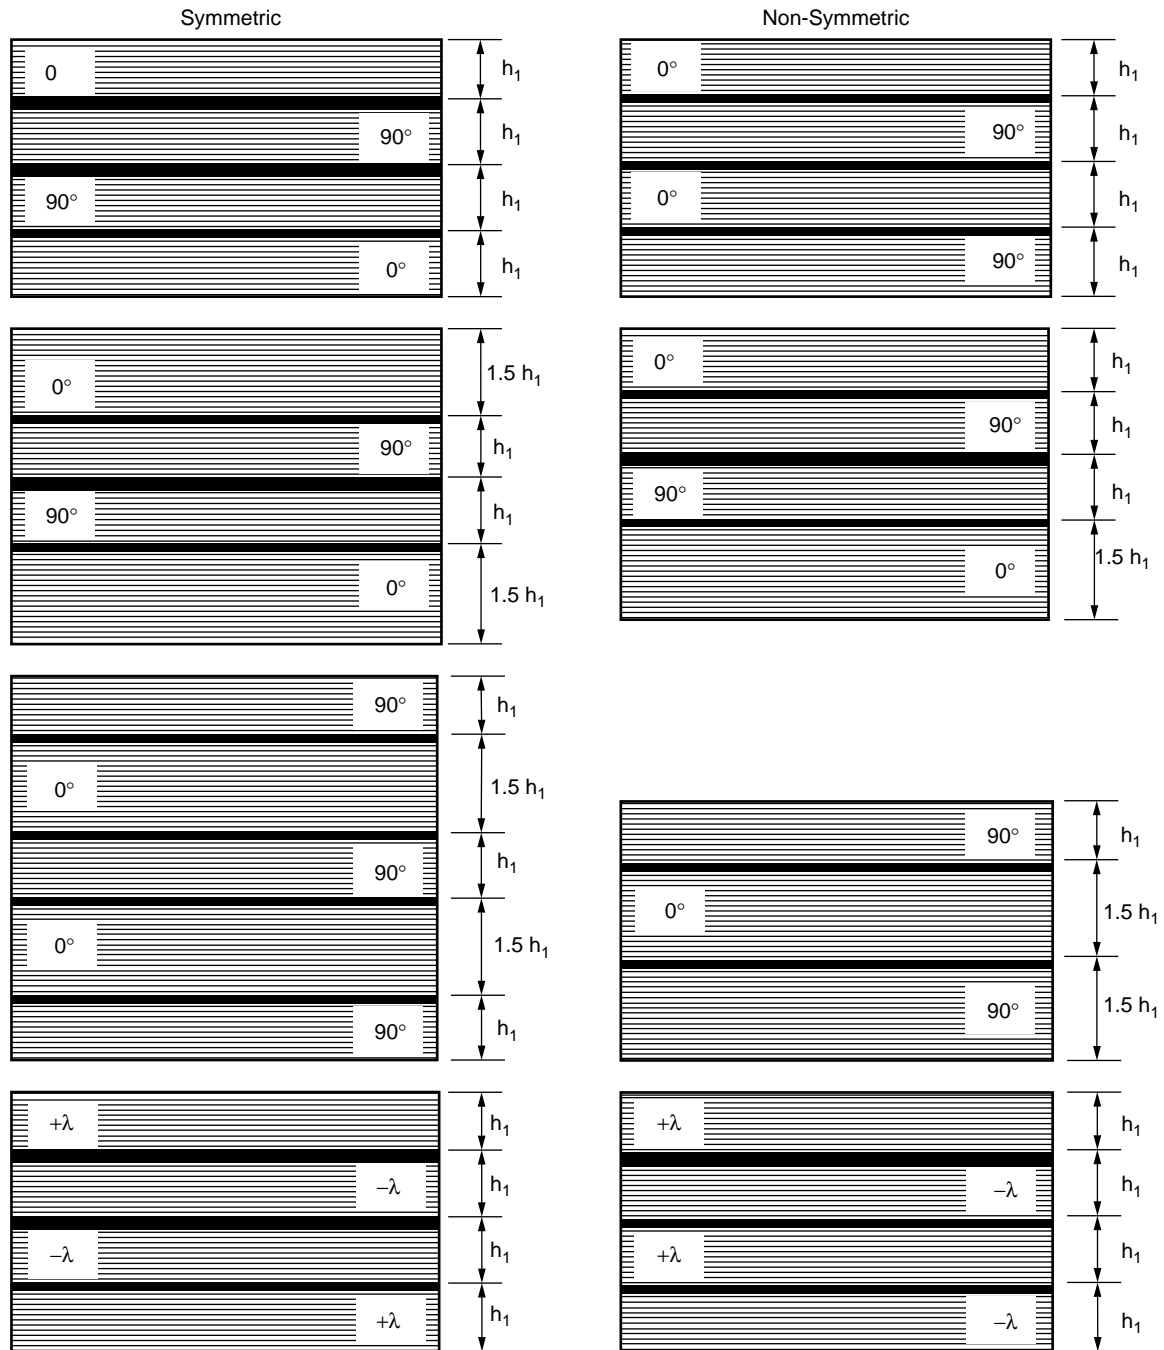

Figure 21. Examples of symmetric and nonsymmetric laminates for the general $0^\circ/90^\circ$ cross-ply and $+\lambda/-\lambda$ angle-ply configurations.

Laminate Failure

Identification of the precise manner in which a composite may fail depends not only on the composite architecture but also on the conditions to which it is exposed. For the purposes of engineering design, it is somewhat less of an arduous task to at least estimate when the composite may fail rather than how it will fail. Failure of a composite may be restrictively considered when failure of the first lamina occurs or more realistically considered when the

composite can no longer support any additional load. The first situation is often referred to as the first-ply-failure (FPF) philosophy, and the second situation is referred to as the ultimate-laminate-failure (ULF) philosophy. With FPF, the inverted $[ABD]$ matrix is used to evaluate the midplane strains and curvature changes in accordance with the applied load vector. Upon evaluating the strains, the stresses in the principal material coordinate system can be calculated and used with any of the composite failure criteria to determine if the applied load vector satisfies a failure

condition. Knowledge of when the first ply failure occurs can lead to appropriate choices for laminate safety factors in design.

ULF extends the application of FPF to the entire laminate. Rather than considering the composite as "failed" once the FPF load is reached, the properties of the failed ply are reduced to values incapable of sustaining load. The "new" composite is re-evaluated, whereby the process is repeated in an iterative fashion until the plies remaining can no longer support any load. At this point, the composite is considered to have failed. Although less conservative than the FPF approach, the ULF approach does offer merit in the sense of capturing the progressive stiffness changes that occur prior to ultimate failure. In this manner, the ULF approach is similar to the classical techniques available for metals.

OTHER CONSIDERATIONS

The particular mechanical behavior associated with composite laminates and structures involves the interactions of many materials on distinct geometric scales. Principles fundamental to the treatment of composite performance in the elastic regime have been presented, notwithstanding considerations for environmental conditions and that new material technologies must also be ascertained. Many applications that are emerging where composite materials may be employed as suitable replacements involve long-term durability in hot and wet conditions. Here knowledge of the hygrothermal effects in a specific composite becomes critical to the design process.

Stresses can be developed in individual plies when they are constrained by neighboring plies against dimensional changes due to thermal and hygroscopic expansions. The distribution of stresses from hygrothermal effects are a function of ply orientation, and the resulting deformation due to these effects may be evaluated by considering the total strain minus the mechanical strain. Since thermal diffusion takes place in composites at a much faster rate than moisture diffusion, the nonmechanical strains due to thermal and moisture exposure may be treated as component effects.

In addition to the continued development of techniques for evaluating the behavior of composites exposed to various environmental conditions, further understanding of the peculiarities with composites is also necessary for future growth toward that of "smarter" structures. That is, such composite structures would not only receive external stimuli in a positive manner but also provide predictable and measurable feedback to those stimuli. To capitalize on the benefits from these structures, designers must explore many of the unresolved issues within the regimes of understanding nonlinear behavior, new (hybrid) material interactions, and constitutive material relations. For example, if we want a material that exhibits piezoelectric, electrostrictive, or magnetostrictive characteristics, then we would introduce phases that exhibit these behaviors. However, the presence of these phases could also result in more complicated predictions of composite behavior due to their interactions and resulting stress redistributions. Since these phases might be incorporated to inhibit some

type of linear or nonlinear response to external stimuli in the first place, the current framework of linear elastic theory may not offer reasonable answers. Consequently, much greater opportunity now exists to offer new theories and ideas to the already established and rapidly progressing comprehension of composite material behavior.

COMPUTATIONAL TECHNIQUES FOR SMART MATERIALS

MANUEL LASO
 JUAN L. CORMENZANA
 ETSII / Polytechnic University of Madrid
 Madrid, Spain

INTRODUCTION

In the following sections, we will use the term “design” in a rather restricted sense. Specifically, we will refer to the calculations, simulations, or in general to any quantitative approach necessary to specify a structure, part, mechanism, processing operation, or function, in which a smart material is used.

In a large number of cases, the design with smart materials relies on well-known and established principles of thermodynamics and continuum mechanics, such as the theories of elasticity (1), fluid mechanics (2), classical electromagnetic field theory (3), chemical equilibrium and kinetics, and solid state physics (4). These theoretical frameworks typically result in a consistent set of equations, of which at least one relates the stimulus and the response of the system. The design task consists often in specifying dimensions of structures or operating conditions of devices that guarantee satisfactory function. A typical example is the design of a smart structure that, under changes in temperature, deforms in a controlled way, possibly operating a valve or tripping a relay switch. The design of such a component, involves a straightforward application of the laws of thermoelasticity, provided that the thermomechanical properties of the material are known.

The controlling principles can often be expressed as very concise and elegant partial differential equations (PDEs) that must be satisfied in domains of complicated shape that have rather involved boundary and initial conditions. This combination of highly nonlinear PDEs, boundary, and initial conditions makes an analytical approach impossible in most cases. Approximate numerical techniques like finite differences (FD), finite elements (FE), finite volumes (FV), spectral methods (SM) and the like are then resorted to often with spectacular success in mechanical and electrical engineering and fluid mechanics (5–7).

In other cases, the difficult part of the design task is not the structural, fluid-mechanical, optical or thermal design itself, but the description of the behavior of the smart material (8). The behavior of a material has been traditionally represented by a so-called constitutive equation (CE) that, put in very broad terms, links stimulus and response. Constitutive equations are used daily in design tasks, sometimes even without our realizing it. For example, one

of the simplest CEs is the linear relationship between the tensorial magnitudes strain and stress for a linearly elastic material, which in its more general form, that is, valid also for anisotropic materials and using the convention of summation over repeated indexes (1), has the following aspect:

$$\sigma_{ik} = \lambda_{iklm} u_{lm}. \quad (1)$$

This expression basically makes the deformation of a material proportional to the cause (stress) and includes, as a special case, Hooke’s law

$$u_{zz} = \frac{\sigma_{zz}}{E}, \quad (2)$$

where E is Young’s modulus.

This very simple CE can be said to be the basis of the vast majority of isothermal linear elastic structural designs. Similarly, most of computational fluid dynamics (CFD) makes use of Newton’s relationship between stress and a velocity gradient:

$$\underline{\tau} = -\eta \dot{\gamma}, \quad (3)$$

where $\dot{\gamma} = (\nabla \underline{v}) + (\nabla \underline{v})^T$ is the strain rate and η is the viscosity.

Again, this very simple CE has extremely wide applicability, smart materials included. A key point worth emphasizing in this context is the fact that constitutive equations are postulates and therefore have a certain degree of arbitrariness. They do not follow from general fundamental principles, as conservation laws do, although they have to conform to certain deeply rooted requirements. Thus, a design problem involves typically a set of fundamental laws, expressed in one of several possible and more or less general ways (thermodynamic, chemical or mechanical equilibrium, conservation of energy, mass and momentum, minimization of action, and minimization of free energy) together with one or more CEs that characterize the material used. The fundamental conservation or variational laws are universal and have to be obeyed by any material we care to consider (Fig. 1).

By way of example, consider now the design of an isothermal flow process of a smart material that behaves as an incompressible memory or viscoelastic fluid. In this case, the fundamental laws that must be satisfied so that the design has physical sense are just two:

$$(\nabla \cdot \underline{v}) = 0 \text{ (conservation of mass),} \quad (4)$$

$$\rho \frac{\partial}{\partial t} \underline{v} + [\nabla \cdot \rho \underline{v} \underline{v}] + [\nabla \cdot \underline{\pi}] = 0 \text{ (conservation of linear momentum),} \quad (5)$$

where $\underline{\pi}$ is the total momentum-flux or total stress tensor which can be split in the following way:

$$\underline{\pi} = -p \underline{\delta} + \underline{\tau},$$

where p is the pressure and $\underline{\tau}$ is the stress tensor due to the fluid. $\underline{\tau}$ is as yet unspecified. We need a CE to define it and close the system of equations. The goodness of our

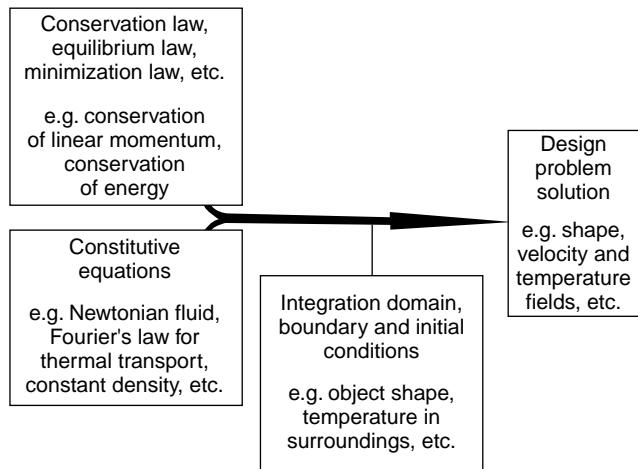

Figure 1. Basic structure of the design task. Conservation laws form an incomplete set of equations that must be closed by one or more constitutive equations.

design will depend critically on the precise form we give to τ , that is, on the way the stress in the fluid is going to depend on its velocity or on the history of the flow.

This CE, on the other hand, is entirely specific for our material. For example, if the material seems to behave as a Newtonian fluid during processing, the most reasonable CE would be Eq. (3). But this is not, of course, our only choice. Within certain boundaries, we are free to specify any relationship between stimulus and response (between strain rate and stress in this case). Even the roles of stimulus and response are interchangeable under some circumstances.

It is often useful to think of the CE as a kind of “calculator” that, when fed a value of the stimulus (say, a strain rate), gives us back the response of the material (say, a stress). This calculator typically contains one or more free parameters that are obtained from a fit to experimental measurements and are specific for the material under consideration. These free parameters are often referred to as “material properties.” Typical material properties are viscosity, elastic modulus, diffusion coefficient, thermal diffusivity, and optical linear and nonlinear susceptibility. In this discussion, it is assumed that material properties are known. In many cases, this assumption entirely eliminates the difficulty of the problem, which often is the characterization of the material. We are dealing here with design problems in which the material is perfectly known, but its behavior in a complex situation has to be determined.

The conservation, equilibrium, or minimization laws form a consistent but incomplete set of equations that require so-called “closure” to become solvable. The CE is the closure. CEs are so often taken for granted, that their very special nature is easily forgotten. It suffices to think of the Navier–Stokes equations, on which most CFD is based: the Navier–Stokes equations are almost automatically taken for granted as the foundation of fluid mechanics. But in fact they are already a combination of the momentum conservation equation and the CE for the Newtonian fluid: they can be obtained by plugging Eq. (3) into Eq. (5) and assuming that the fluid has constant density. Consequently,

whenever we use them to design a flow system, we are automatically and tacitly assuming that the flowing material obeys a very special and simple Newtonian CE. Furthermore, looking beyond the fact that different Newtonian fluids have different numerical values of viscosity, there is only one Newtonian fluid. The same is true for a perfectly elastic solid. All Newtonian fluids, all linear elastic solids, all linear optical materials behave in essentially one and the same way. Therefore, as soon as it is postulated that a smart material obeys one of these simple CEs, the design task becomes relatively simple. It will require only the same standard techniques used for non-smart materials. Such techniques may, of course, be very involved themselves (think of turbulent CFD), but they do not differ fundamentally from the techniques used to design for less smart materials. We will informally call such “standard” cases “design problems of the first kind.” They probably constitute 75% of all design tasks in which smart materials are involved. Because the techniques used for problems of the first kind are the same as those for non-smart materials, they will not be dealt with here in any depth.

In the remaining 25% of the design problems for smart materials, the sophisticated numerical machinery developed during the last four decades is not sufficient to provide reliable solutions in a reasonable time. We will call these “design problems of the second kind.”

The coming sections will be devoted to the two main aspects in which the design and calculation for smart materials departs significantly from standard design techniques. Both aspects are intimately related to the CE or, somewhat ironically, to its nonexistence. We have already seen that the conservation equations are the same for smart and less smart materials. It is the additional complication brought about by the CE that distinguishes these special design or calculation problems.

The first aspect specific of CEs for smart materials has to do with the existence of memory effects. As a matter of fact, some of the most spectacular effects that smart materials display are related to what is somewhat vaguely called memory. The next section discusses some general aspects of memory in materials and its mathematical formulation. In the following section, we consider the question how to handle materials that have memory in practical calculations. Finally, the subsequent section deals with the more fundamental question how to postulate a constitutive equation for smart materials. These last two sections reflect some recent developments in fields that are rapidly developing. A tentative outlook into the future of designing smart materials is presented in the closing section.

SMART MATERIALS, MEMORY EFFECTS, AND MOLECULAR COMPLEXITY

Frequently, complicated material behavior is closely related to the concept of memory, a key word very often heard in the context of smart materials. For example, form or shape memory materials constitute one of the best known classes of smart materials mainly due to the spectacularity of some of its applications (9). Less widely known, but also capable of displaying a stunning range of

nontrivial and often counterintuitive behavior, the large family of complex fluids has found numerous applications as smart materials. Smart materials based on complex fluids include gels, polymeric melts and solutions, colloidal dispersions, electro- and magnetorheological fluids, and liquid crystalline materials among others (10–13). All of these materials share some or all of the following characteristics, which are in many cases responsible for their smart behavior:

- They possess the ability to react to external excitations (fields, pH changes, strain) in a highly nonlinear way and often undergo a phase change.
- They display their most interesting behavior when driven strongly away from equilibrium.
- They typically possess either a very wide spectrum of relaxation times or else a main relaxation time, whose order of magnitude is comparable with the timescale of the physical process in which they find application (14).
- They often have a complicated small-scale structure, either at the molecular level (polymers) or at some mesoscopic scale (dispersions, emulsions, polycrystalline materials).

Although there is no single mechanism responsible for memory, several of these characteristics are responsible for phenomena such as hysteresis and memory. In some cases, a material appears to have a fading memory of past events because its internal structure (e.g., molecular) requires a certain time to adapt to a changing environment. Thus, memory is also a question of the timescale in which the relevant material property is observed. We can take water as an example. It is a low molecular weight fluid that behaves as a simple Newtonian fluid in most cases because its characteristic molecular relaxation time is very short compared with the characteristic times of flow in everyday life. Thus, it can adapt instantly to changes in the velocity field and therefore displays no memory effect. On the other hand, a high molecular weight polymer has a spectrum of relaxation times that can reach well into seconds. Any stimulus, for example, a change in an electric field, that tries to change its orientation will be followed by an observably slow response, during which the material retains information about the past state.

In other cases, memory is due to a kinetically frozen-in state, for example, due to a martensitic–austenitic phase transition, which can be unlocked by applying an external stimulus. The material is then forced to revert to a previous state and thus appears to possess memory.

There have been several attempts to capture these phenomena in a mathematical formulation. At this point, instead of addressing the question in an all-encompassing and general way, we will rather continue with our specific example, which is a representative example of materials that have complex behavior. We will address the family of high molecular weight polymers, which are considered by many as memory fluids par excellence.

Polymers display strong memory effects that are a consequence of their non-Newtonian nature and ultimately of their complex molecular structure and of the

entanglements they form, either in solution or as melts. Whereas there is just one CE for Newtonian fluids, literally dozens of CEs for non-Newtonian fluids have been proposed (13,15). Most of them directly or indirectly attempt to take into account memory effects. One of the simplest CEs that attempts to take into account both viscous and elastic behavior is that of the so-called Oldroyd-B fluid (16):

$$\underline{\tau} + \lambda_1 \underline{\dot{\tau}} = -\eta_0(\dot{\gamma}_{(1)} + \lambda_2 \dot{\gamma}_{(2)}), \quad (6)$$

in which $\dot{\gamma}_{(1)}$ and $\dot{\gamma}_{(2)}$ are kinematic tensors defined by

$$\begin{aligned} \dot{\gamma}_{(1)} &= (\nabla \underline{v}) + (\nabla \underline{v})^T \text{ (rate of strain tensor),} & (7) \\ \dot{\gamma}_{(2)} &= \frac{\partial}{\partial t} \dot{\gamma}_{(1)} + \{\underline{v} \cdot \nabla \dot{\gamma}_{(1)}\} - \{(\nabla \underline{v})^T \cdot \dot{\gamma}_{(1)} + \dot{\gamma}_{(1)} \cdot (\nabla \underline{v})\}, & (8) \end{aligned}$$

where η_0 is the zero-shear-rate viscosity, λ_1 is the relaxation time, and λ_2 is the retardation time. The first remarkable aspect of this CE is its complication, although it is one of the simplest CEs for non-Newtonian fluids. It is also worth noting that, written in this differential way, the memory aspect is not very obvious. It is possible, however, to rewrite this CE in a different but entirely equivalent way:

$$\underline{\tau}(r) = \eta \dot{\gamma}_{(1)} + \int_{-\infty}^t \left\{ \frac{nkT}{\lambda_H} e^{-\frac{(t-t')}{\lambda_H}} \right\} \dot{\gamma}_{(1)}(r, t, t') dt', \quad (9)$$

in which $\dot{\gamma}_{(1)}(t, t')$ is the finite strain tensor defined by

$$\dot{\gamma}_{(1)}(r, t, t') = \underline{\delta} - \left(\frac{\partial}{\partial r'^r} \right)^T \left(\frac{\partial}{\partial r'^r} r \right), \quad (10)$$

and $r = r(r', t, t')$ tells us where (r) a particle is located at time t knowing that it was located at r' at time t' . This superficially harmless last sentence is notoriously perverse: first of all, the instantaneous value of the stress no longer depends in any explicit way on the velocity. Nowhere in Eq. (9) or in Eq. (10) is the velocity to be seen (compare this to Eq. (3) where the stress and velocity gradient appear explicitly in the same equation). Instead, the stress depends on the whole history of the deformation of the fluid, as expressed in a deviously indirect way by Eq. (10). Second, to determine the present value of the stress, we must know the entire past of the flow. But we will know the past history of the flow only if we can compute previous stresses also, that in turn requires the knowledge of *their* flow past, and so on. This kind of infinite regress is unheard of in nonmemory materials: given a strain rate, the Newtonian fluid produces a given stress that depends only on that instantaneous strain rate and not on any other aspect of the past. The Newtonian fluid reacts infinitely fast to an external stimulus and consequently has no memory. Our memory fluids react to the present strain rate in a way that depends on their whole flow history through equations like Eqs. (9) and (10) or even more complicated ones.

This alternative integral way of writing the CE, although not much more transparent, does show how memory effects can be formulated mathematically: the stress at any given time and position $\underline{\tau}(r)$ depends on all of the previous history of the flow (through the term $\dot{\gamma}_{(1)}(r, t, t')$ and through the integration). Recent flow or deformation

events influence more the resulting $\tau(r)$ than long past ones, due to the exponential memory function. Thus, the material has a fading memory.

Flow properties and memory of smart materials are characterized by the numerical values of the parameters in this and other similar but more complex CEs. More complex CEs make more physically correct predictions of material behavior but at the cost of greater complexity. It is useful now to realize that the whole field of Newtonian CFD is based on the mass, energy, and momentum conservation equations closed by the very simple Newtonian CE given in Eq. (3). The fluid mechanics of non-Newtonian memory fluids is controlled by the same conservation laws but augmented by a CE similar to or more complicated than Eq. (9). In practice, this complication makes any calculations of memory fluids in realistic three-dimensional geometries quite complex and extraordinarily time-consuming. In the previous example of the Oldroyd-B fluid, the conservation equations can be expressed in a FE calculation in a weak Galerkin form together with the CE either in differential Eq. (6) or in integral Eq. (9) forms; the latter is generally more cumbersome. Other CEs admit only an integral form (17), and until now, its use in practical calculations has been very limited.

Furthermore, the very mathematical nature of the problem is changed by the CE, so that unexpected and fundamental mathematical difficulties appear that often represent an insurmountable barrier. To the shock of the rheological community, many deceptively simple non-Newtonian flow problems still resist all attempts at solution.

The reader may get the impression that the mathematical complexity of the CE for memory fluids must reflect some deep-lying complicated physical behavior. The astonishing fact is that a mathematical formulation as intricate as Eq. (9) and those even much more complex can be deduced from or correspond to any one of several extremely simple molecular descriptions of the material (one of which we will show in the next section). In the following, we will refer to this game of postulating a molecular picture of a material and extracting a CE from it, as “solving the kinetic theory of the material.”

Although the previous paragraphs refer to a specific type of smart material behavior, namely, memory fluids, the discussion has general validity. Any material property (mechanical, optical, or chemical) that somehow depends on the past history of the excitation will lead to a similar situation. For example, for a shape memory material, the elastic constants will depend on the history of the strain or of the temperature or both.

Because smart materials can be expected to be complicated or structured, the natural question now arises what happens when we want to put more realism into the underlying molecular picture. If an extremely simple model leads to quite a complex CE, what kind of CE will we obtain for a more physically correct molecular picture of the smart material? The answer is that almost immediately the kinetic theory of the material becomes unsolvable. In other words, it is very easy to develop not too sophisticated a molecular model of a material for which we cannot obtain a CE, no matter how hard we try. Lacking a CE, that is, if

one of the equations is missing, how can we possibly expect to solve the set of equations that describe smart material behavior? Smart materials easily outsmart us if we follow the strategy of a frontal attack. But not everything is lost: there are alternative and very straightforward ways to bypass the difficulty of the nonexistent CE. The next section is devoted to them.

CONTINUUM AND MOLECULAR DESCRIPTIONS OF SMART MATERIALS

In the previous section, we introduced the idea that smart material behavior almost always stems from underlying microscopic or mesoscopic complexity. Expressing this complexity in mathematical form, that is, solving the kinetic theory of the material, is very often impossible. Even in those cases where it is possible, predicting material behavior is a tough challenge. We will now further use our example of one of the simplest memory fluids, the Oldroyd-B fluid, to show how the apparent conundrum presented in the previous section can be approached.

Thermoplastic polymers are a class of materials whose behavior can be approximately represented by a CE like Eq. (9). These polymers are made of very long molecules, and have a backbone comprising several thousand atoms bonded covalently. These bonds have the possibility of rotating at the cost of some torsional energy, either by spontaneous thermal agitation or by the application of some external field (e.g., electrical) or deformation. Once the external effect disappears, these huge molecules tend to regain their average shape by releasing the torsional energy stored in the backbone of the molecule and adopting molecular conformations similar to the statistical coil (18). This tendency to go back to states of minimum free energy results in an approximately linear restoring force that acts on the whole molecule. This spring-like force opposes molecular stretching. If suspended in a liquid, that is, if the polymer molecule is in solution, it will also be subjected to random thermal bombardment by small solvent molecules and the effect of any velocity field of the solvent. This additional effect of the solvent is a double one: a tendency to deform the polymer molecule and a drag due to the relative motion between the molecule in solution and the solvent.

Treating all of these effects and the chemical structure of the molecule in a fully detailed way is completely beyond our current capabilities. Instead, a coarse-graining procedure is invoked: most of the details of the molecule are discarded, and only those most relevant are kept. A very coarse-grained picture of the molecule is shown in Fig. 2. The whole macromolecule in its fully detailed chemistry is represented by a dumbbell that consists of two masses joined by a Hookean spring. This dumbbell is fully characterized by specifying only three numbers: the components of the connector vector Q . The dynamics of this simplified mesoscopic object, which we will almost unjustifiably still call “molecule” can be written quite easily. The differential change in the connector Q in a very short time dt is

Figure 2. Coarse graining a polymer molecule in solution.

given by

$$d\mathbf{Q} = \left([\boldsymbol{\kappa} \cdot \mathbf{Q}] - \frac{2H}{\zeta} \mathbf{Q} \right) dt + \sqrt{\frac{4kT}{\zeta}} d\mathbf{w} \quad (11)$$

(see the end of the article for a list of symbols). In Eq. (11), we can recognize the spring restoring force (term containing $2H\mathbf{Q}/\zeta$), the effect of the flow field of the solvent ($[\boldsymbol{\kappa} \cdot \mathbf{Q}]$), the random buffeting by solvent molecules ($\sqrt{\frac{4kT}{\zeta}} d\mathbf{w}$), and the solvent drag ($\frac{2H}{\zeta}$). Thus, in a coarse-grained sense, our polymer solution consists of a suspension of these highly simplified objects in a Newtonian solvent.

The obvious question now is what has this absurdly simple picture of a polymer solution got to do with a CE like Eq. (9), that predicts non-Newtonian behavior, memory included. The unexpected answer is that if we rigorously solve the kinetic theory of a suspension of dumbbells in a Newtonian solvent, we end up with a relationship between stress and strain history that is precisely our Eq. (9) (15). We were referring to this exact equivalence in the previous section when it was stated that extremely simple molecular models lead to very complicated and often intractable CEs. Therefore, for example, when designing a polymer solution process using Eq. (9), we know we face serious computational difficulties. But we are willing to invest additional time and effort in the hope that a complex CE will reflect a very complex material structure and dynamics. However, whether or not we are aware of it, we are implicitly assuming that the polymer is nothing else than a suspension of Hookean dumbbells. In spite of their extreme simplicity, it is the presence of the dumbbells that endows the solution with memory. Dumbbells are not that dumb after all.

This interesting equivalence between simple mesoscopic molecular models and extremely complicated CEs can be established for most of the CEs used nowadays. But there still remains the immensely larger class of not-so-simple molecular models for which there never will be a CE, but which, nevertheless, are much better at capturing smart material behavior. We are naturally interested in tapping the resources of these more advanced molecular models. But how can we use advanced models for smart materials, if it is not even possible to write a CE for them?

The answer lies in a further connection between the micro- or mesoscopic molecular picture and the macroscopic response of the system. This missing ingredient is actually the simplest. In Eq. (11), the dynamics of the simplified molecular model was written in full detail. If we knew the initial state (its initial \mathbf{Q}) of a given molecule, we could predict its evolution, that is, its future states, by integrating Eq. (11) for as many time steps as we like. In this way, we would know how a single molecule evolves. This is clearly not enough because a polymer solution contains a very large number of such objects swimming in a Newtonian fluid. Furthermore, the stress $\boldsymbol{\tau}$ is a collective property of this large number of molecules (we call this population of molecules an “ensemble”). A single molecule does not allow us to determine the stress. What if we had a large, ideally infinite, collection of different dumbbells? Would it then be possible to obtain the stress from this ensemble? Fortunately enough, the answer is yes: the following simple formula tells us how to compute the macroscopic response of the material, the stress in this case, for an ensemble of molecules:

$$\boldsymbol{\tau} = -nkT \overline{(\mathbf{Q}\mathbf{Q} - \delta)}, \quad (12)$$

where the overbar means an ensemble average, that is, we compute the simple arithmetic average $nkT [\frac{1}{N} (\sum_{i=1}^N \mathbf{Q}_i \mathbf{Q}_i) - \delta]$ using an ensemble of N molecules and, within the statistical error bars due to finite ensemble size, the result is precisely $\boldsymbol{\tau}$. It is quite unexpected at first that we can obtain the same result for the stress of the material either using the idea of the ensemble or integrating Eq. (9). The connection between these two ways of obtaining the macroscopic response of the material is completely rigorous and stands on sound mathematical footing. But even without going into its details, this connection is not totally unexpected. Because Eq. (9) is an exact result of the kinetic theory of Hookean, noninteracting dumbbells, its predictions should be identical to those obtained from a direct simulation of a large number of such objects (Fig. 3).

Now, we know how to describe the behavior of a memory material at both the continuum level, Eq. (9), and at the microscopic level, Eqs. (11) and (12). We have also gained a great deal of insight into the mechanisms of memory or smart material behavior: in the continuum mechanical version, memory is introduced as an integral across the

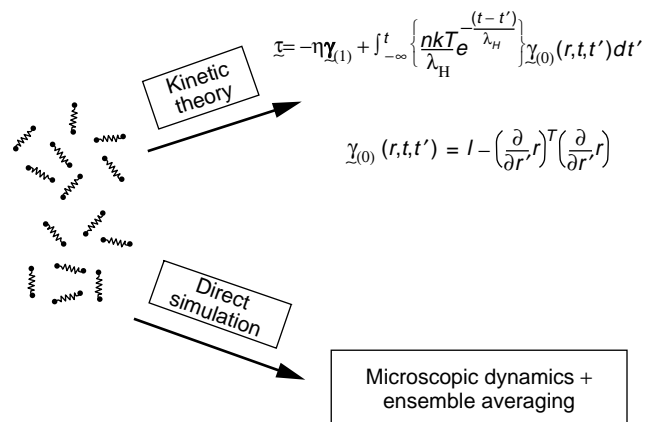

Figure 3. Correspondence between analytical constitutive equation for a memory fluid and direct simulation of an ensemble.

history of the flow, but it does not shed any light on the molecular mechanism responsible for memory. In the microscopic dynamic view, memory is stored in the present configurations of the dumbbells. If the memory fluid has been at rest, the \underline{Q} will be distributed isotropically and will yield, on average, a value of $\underline{\tau} = 0$. If the polymer has been subjected to a long period of shear or elongation, again on average, its molecules will be stretched and oriented. Their connectors \underline{Q} will be large and highly oriented and thus will make an important contribution to $\underline{\tau}$. If a change in the flow field takes place, for example, if flow ceases, the molecules will still be in predominantly stretched configurations for a period of time controlled by the typical relaxation time of the molecules (e.g., λ_1 for the Oldroyd-B fluid). The stress will drop to zero, not instantly, but over a timescale of the order of λ_1 . This gradual loss of information about previous events (shear or elongational flow in this example) is what we recognize as memory in a material. Thus, we see that the very simple fact that the internal structure of the molecule needs time to adapt to a new external stimulus is already sufficient to produce memory effects. Other, more advanced molecular models for smart materials have notoriously more complicated microscopic dynamics which take into account other relaxation processes of the individual polymer molecule and also of the surrounding molecules. The basic ingredient of memory, namely, the existence of a comparatively slow relaxation mechanism, is not very different, however.

Although we have seen some of the niceties of the equivalence between the continuum and microscopic pictures of our memory fluid, we still have to address the question how to solve design problems for smart materials in complex situations (shapes, boundary conditions).

Because there is no CE for the vast majority of consistent microscopic material models, with which we can close the design equations (4) and (5), it seems that there would be no hope of ever performing a design using a reasonably advanced CE. Recently, however, a number of approaches have been proposed that use the equivalence between the continuum and microscopic pictures of a material (19–21). Continuing with our example of the flow of a memory fluid, assume that we want to determine the amount of swelling

this material experiences upon exit from a cylindrical channel. The unknowns of the problem in this case are the velocity field and the free surface. We will further assume that we will be using a finite-element technique. In this method, the unknown fields are discretized on a mesh, and the solution sought consists of the values of the velocity at the nodes of the mesh and the coordinates of the free surface.

Solving the problem means obtaining a velocity field and a shape of the boundary that satisfies $(\nabla \cdot \underline{v}) = 0$ and $\rho \frac{\partial}{\partial t} \underline{v} + [\nabla \cdot \rho \underline{v} \underline{v}] + [\nabla \cdot \underline{\pi}] = 0$ where $\underline{\pi} = -p \underline{\delta} + \underline{\tau}$ and $\underline{\tau}(r)$ and comes from the CE [e.g., Eq. (9)]. There are additional free surface boundary conditions for the velocity and the stress which are not important for our discussion. In a standard FE (Finite Element) formulation, a large nonlinear set of equations is set up in which some of the unknowns are the components of the velocity and the coordinates of the boundary. The stress is evaluated at several integration points within each element of the grid by using Eq. (9). This value of the stress is then used to complete the momentum conservation equation, which is solved for velocity. This is fine so long as we have a CE, but what are we to do when there is no CE to describe the material? In the light of the correspondence between the continuum level and the microscopic levels, an alternative suggests itself naturally: we can fill all of the elements that make up the integration domain with a large number of molecules, dumbbells in our example, and use them to compute the stress in each element by using Eq. (12). The dumbbells in an element form a local ensemble. This local ensemble serves as a stress calculator that closes the mass and momentum conservation equation, just as an analytical CE does. Dumbbells are entrained and deformed by the fluid. The strong coupling between macroscopic flow and microscopic molecules is then very obvious: the macroscopic flow carries and distorts the dumbbells, which in turn produce the correct response (stress) that modifies the velocity field. This cycle is repeated as many times as we wish or until we reach a steady state. The general scheme of such a micro/macro method is illustrated in Fig. 4.

For our example of the flow of a memory material out of a cylindrical pipe, Fig. 5 illustrates a typical FE grid, a schematic representation of the “molecules” and the solution given as values of the velocity vector at the nodes of the grid.

Following this idea, we can have as complicated a molecular model as we want without worrying about its kinetic theory, that is, whether or not we can obtain a CE for it. This basic idea of combining a macroscopic formulation of the conservation equations with a direct simulation of a large ensemble of microscopic molecules is extremely powerful. It opens the way to the development and practical use of much more realistic molecular models than was possible until now. There is, of course, a price to pay for this extra power: because our ensembles can never be infinitely large, the computed $\underline{\tau}(r)$ will contain statistical noise and so will the velocity field. Besides, the calculation will be more expensive now, because we have to follow the dynamics of hundreds of thousands or millions of simple molecules. Some very recent advances in the area aim precisely

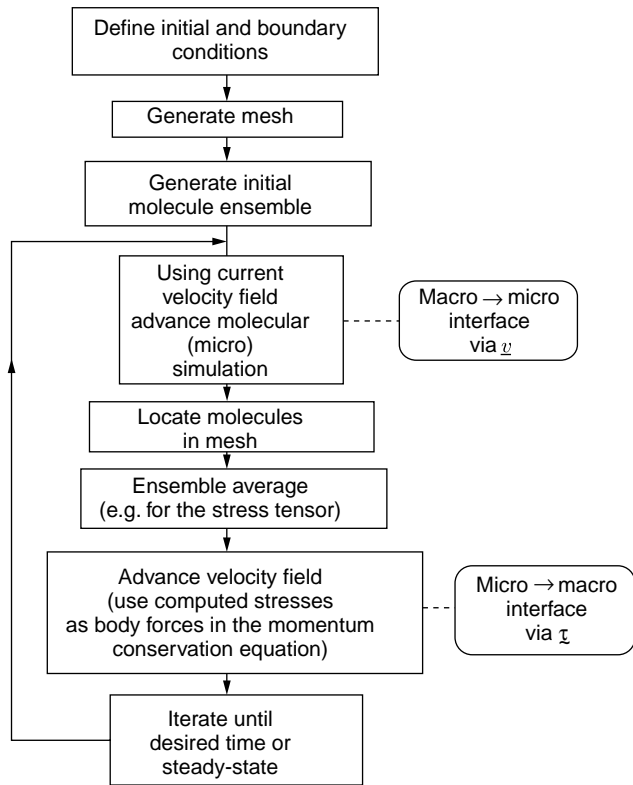

Figure 4. Basic time-marching scheme in a micro/macro method.

at reducing both the statistical noise and the computational effort by resorting to variance reduction techniques (20).

The basic idea behind all of these schemes is actually very simple and has been around under several disguises for quite some time (22). The degree of sophistication and the range of applications of such combined methods are truly phenomenal. In (23), an atomistic simulation taken from the field of fracture mechanics at a very basic level (density functional theory actually solves Schrödinger's equation for a fairly large collection of atoms of the material being investigated) has been successfully combined with higher level methods to predict crack propagation very satisfactorily. Needless to say, the microscopic model need not reside at the most basic level: some very significant and also spectacular applications come from the field of solidification and casting of metallic alloys (24). In this kind of micro/macro model, the microscopic level resolves metallic crystalline structures such as dendrites, and the macroscopic level has a typical length scale of centimeters. Clearly, the term "microscopic" in alloy casting picks up where the macroscopic level of fracture propagation leaves off. In both cases, the basic idea is the same: try and bridge the gap in time- and space scales by hierarchical modeling.

In spite of this additional extra cost, micro/macro methods are starting to find widespread application whenever the behavior of a material is too complex to be tackled by standard continuum mechanical techniques. Coupling very detailed microscopic descriptions of the

Figure 5. Calculation of the flow of a memory fluid using finite elements in an integration domain. The conservation and CE equations are discretized and solved on the grid. The solution is the velocity field shown and the shape of the domain (free liquid surface).

material with macroscopic methods allows making design calculations that were unthinkable as recently as a decade ago.

SMART MATERIALS AND NONEQUILIBRIUM THERMODYNAMICS

As already mentioned, one of the key features of smart materials is that they frequently have to operate far away from equilibrium. There is considerable freedom in the process of establishing a microscopic model of the smart material and extracting a relevant macroscopic property from it [for example, when obtaining the stress from an ensemble of dumbbells via Eq. (12)]. This freedom is not complete, however, because any micro- or mesoscopic model that we set up must comply with the rules of nonequilibrium thermodynamics. Major developments in the field of nonequilibrium thermodynamics or nonequilibrium statistical mechanics have been few and far apart (25). The application of nonequilibrium thermodynamics to complex materials is by no means obvious. At present, there

are a staggering number of different theories and a wide variety of approaches: classical nonequilibrium thermodynamics with internal variables, Lagrangian methods, bracket formulations, continuum or rational thermodynamics, variational formulations, extended irreversible thermodynamics, the matrix model, network thermodynamics, and the recent GENERIC formalism. In the last few years, however, there is a growing consensus that it should be possible now to combine the various approaches in some kind of common generalized theory. The final goal is to bring nonequilibrium thermodynamics to the same level of clarity and usefulness as equilibrium thermodynamics.

Unless it can be shown that the microscopic models we develop for a smart material satisfy the rules of equilibrium thermodynamics, there is no guarantee that they will be consistent, let alone able to make consistent predictions. However, given the lack of a unified formulation of nonequilibrium thermodynamics, microscopic models have been proposed based largely on intuition and have been used in practical work. Dynamic equations have been postulated directly with varying degrees of success. The unavoidable consequence is that the required self-consistency is missing in some of these models.

Given the fundamental importance of thermodynamic consistency in smart material modeling, this chapter would not be complete without at least mentioning these very recent advances. We will limit ourselves to summarily sketching one of the most recent theories of nonequilibrium thermodynamics (GENERIC is an acronym for general equation for nonequilibrium reversible-irreversible coupling). Although it is not possible to go into a detailed discussion of any of the current frameworks of nonequilibrium thermodynamics, it is important to give at least an idea of their structure, their main building blocks, and the kind of predictions they can make.

For example, in the GENERIC framework (26,27), the temporal evolution of any isolated thermodynamic system is given in the form,

$$\frac{dx}{dt} = L(x) \cdot \frac{\delta E(x)}{\delta x} + M(x) \cdot \frac{\delta S(x)}{\delta x}, \quad (13)$$

where x represents a set of independent state variables required to describe a given nonequilibrium system completely. $\delta/\delta x$ is to be understood as a functional derivative and the application of the operators implies summations over discrete labels and also integrations over continuous labels. The functionals E and S represent the total energy and entropy expressed in terms of the state variables x , and L and M are certain matrices. The two contributions to the temporal evolution of x generated by energy E and entropy S in Eq. (13) are called the reversible and irreversible contributions, respectively. Using the energy as the generator of reversible dynamics is inspired by Hamilton's description of a conservative system. Using the entropy as the generator of irreversible dynamics is inspired by the Ginzburg–Landau formulation of relaxation equations. The use of these two generators is a key aspect

of GENERIC. It has special importance and makes it capable of treating systems far from equilibrium.

In GENERIC, Eq. (13) is supplemented by the two degeneracy requirements:

$$L(x) \cdot \frac{\delta S(x)}{\delta x} = 0$$

and

$$M(x) \cdot \frac{\delta E(x)}{\delta x} = 0. \quad (14)$$

Furthermore, the matrix L is required to be antisymmetric, whereas M is symmetrical and positive-semidefinite. The positive-semidefiniteness of M together with the first degeneracy condition imply a strong implementation of the second law of thermodynamics. Both the complementary degeneracy requirements and the symmetry properties of L and M are extremely important in formulating proper L and M matrices when modeling nonequilibrium materials. Finally, it is assumed that the Poisson bracket $\{\dots, \dots\}$ associated with the antisymmetric matrix L ,

$$\{A, B\} = \frac{\delta A}{\delta x} \cdot L(x) \cdot \frac{\delta B}{\delta x}, \quad (15)$$

satisfies the Jacobi identity,

$$\{\{A, B\}, C\} + \{\{B, C\}, A\} + \{\{C, A\}, B\} = 0, \quad (16)$$

for arbitrary functionals A , B , and C . The Jacobi identity severely restricts convection mechanisms for structural variables and expresses the time-structure invariance of the reversible dynamics implied by L .

The power of any such formulation of nonequilibrium thermodynamics resides precisely in the ability to define which micro- or mesoscopic models are permissible and consistent. Until recently, due to the lack of a general framework, any ad hoc or intuitively proposed microscopic dynamics run the risk of violating the degeneracy requirements or the Jacobi identity. Using a consistent framework such as GENERIC to constrain our microscopic material models automatically guarantees consistency.

The GENERIC formulation of nonequilibrium thermodynamics has led, among others, to fully consistent generalized reptation models and to new models for liquid crystal polymers, both of great importance for applications in the area of advanced materials. The tremendous advantage of having a framework of nonequilibrium thermodynamics at our disposal in which to formulate microscopic models is that consistency is guaranteed by construction. Furthermore, such a formalism acts as a helpful guide in improving and refining microscopic material models, that is, ultimately in the quality of the resulting CEs (when it is possible to write one) or of the resulting stimulus–response behavior.

Nonequilibrium thermodynamics is probably an even more important tool for engineers than equilibrium thermodynamics, for example, in connection with the design

and processing of all kinds of memory materials. Nonequilibrium thermodynamics is obviously important if phase transitions, such as phase separation of crystallization, take place under deformation or flow. The successful application of a formalism such as GENERIC to such problems depends on the possibility of obtaining the four building blocks of GENERIC: the two generators, energy E and entropy S , and the matrices L and M . Thermodynamic modeling in terms of these basic building blocks is strongly advocated, rather than the direct formulation of temporal-evolution equations. The situation is analogous to that in equilibrium thermodynamics: it is more advantageous to work with a thermodynamic potential as a basic building block than with several equations of state. Experience with empirical expressions for the GENERIC building blocks for different design and material cases needs to be collected by reformulating and generalizing existing theories. Although microscopic expressions for the building blocks do exist, they will become useful only when the numerical methods for handling these formal expressions are developed. Just as Monte Carlo simulations allow us an atomistic understanding of equilibrium physics, molecular and stochastic dynamics will be the key to applying non-equilibrium thermodynamics to practical cases. The basic tools for understanding structure–property relationships are available now.

OUTLOOK

To summarize, the “smartness” of smart materials almost always has its origin in a complex structure at the microscopic or mesoscopic level. Attempts to capture this complexity mathematically are successful in some simple cases but soon run into fundamental difficulties. Having no constitutive equation to close the system of equations that are the basis of any design calculation, the task of describing smart material behavior seems to be hopeless. Fortunately, recent methodological and computational advances have reopened the road to successful design and prediction of smart material behavior.

On one hand, micro/macro methods are reaching a state now where they can compete with classical methods based on a continuum mechanical description of the material. Micro/macro methods make it possible to model a smart material at a very high level of sophistication without worrying about the solvability of the corresponding kinetic theory.

On the other hand, very recent advances in nonequilibrium thermodynamics are starting to yield their first truly groundbreaking results. Due to them, we can now postulate and develop microscopic models for smart materials certain that they are correct and consistent at the most fundamental level.

These two avenues of research are essential and complementary in process or part design for smart materials: nonequilibrium thermodynamics is the tool of choice to guide the development and the validation of the microscopic models used in micro/macro calculations.

Micro/macro methods and nonequilibrium thermodynamics are two of the most promising paths along which future advances in smart material design are likely to come.

CONDUCTIVE POLYMER COMPOSITES WITH LARGE POSITIVE TEMPERATURE COEFFICIENTS

C. P. WONG
SHIJIAN LUO
Georgia Institute of Technology
Atlanta, GA

INTRODUCTION

Conductive polymer composites (1,2) that contain conductive fillers such as metal powder, carbon black, and other highly conductive particles in a nonconductive polymer matrix have been widely used in electrostatic dissipation (ESD) and electromagnetic interference shielding (EMIS). A special group among electrically conductive polymer composites are conductive polymer composites that have large positive temperature coefficients (PTC), which in some cases are called positive temperature coefficient resistance (PTCR). The resistivity of this kind of composite increases several orders of magnitude in a narrow temperature range, as shown in Fig. 1. The transition temperature T_t is defined by the intersection of the tangent to the point of inflection of the resistivity versus temperature curve which is horizontal from the resistivity at 25°C (ρ_{25}). This kind of smart material can change from a conductive material to an insulating material or vice versa upon heating or cooling, respectively. The smartness of this kind material lies in this large PTC amplitude (defined as the ratio of maximum resistivity at the peak or the resistivity right after the sharp increase to the resistivity at 25°C), and also in its reversibility, its ability to adjust the transition temperature, its low-temperature resistivity, and high-temperature resistivity. PTC behavior in a polymer composite was first discovered by Frydman in 1945 (3), but not much attention was paid to it originally. Because Kohler obtained a much higher PTC amplitude from high density polyethylene loaded with carbon black in 1961 (4), this kind of temperature-sensitive materials has aroused wide research interest and also led to many very useful applications. In this review, the general theories

Figure 1. Resistivity versus temperature behavior of a conductive polymer composite that has a large positive temperature coefficient.

of PTC conductive polymer are introduced. Carbon-black-filled conductive polymer composites and their PTC behavior are discussed in more detail, in regard to the effects of fillers, the polymer matrix, and processing conditions, and additives. At the end, applications of this kind of smart temperature-sensitive material are presented.

BASIC THEORY OF CONDUCTIVE POLYMER COMPOSITES AND PTC BEHAVIOR

The conductivity of polymer composites that contain conductive particles dispersed in a polymer matrix may result from direct contact between conductive particles and electron tunneling. The conductivity of a highly filled conductive adhesive is due to the former mechanism. Matsushige used atomic force microscopy (AFM) to study the conduction mechanism in a PTC composite on a nanoscale (5). It was proposed that electron tunneling or hopping through the conductive carbon particles in the polymer matrix might be the governing mechanism for organic PTC materials.

There are two very simple mechanisms for small PTC behavior of conductive polymer composites: reduction of the contact area of neighboring conductive particles and an increase in the junction distance in electric tunneling when heated. Although the large PTC phenomenon is well known, its mechanism has not been fully understood. Different theories have been proposed (4,6,7) to explain the large PTC behavior.

Kohler (4) suggested that the PTC is due to the difference in thermal expansion of the materials. His theory was supported by some other researchers in percolation theory (1). The conductivity of conductive polymer composites increases as the volume fraction of the conductive filler increases. For a polymer filled with conductive particles, a critical volume fraction of filler may exist, which is called the percolation volume fraction. The resistance of the conductive polymer composite whose filler volume fraction is higher than the percolation volume fraction is several orders of magnitude less than that of the composite whose filler volume fraction is less than the percolation volume fraction. In the region of low filler concentration, the filler particles are distributed homogeneously in the insulating polymer matrix. There is no contact between adjacent filler particles. The resistance decreases slowly as the volume fraction of filler particles increases. As filler concentration increases further, filler particles begin to contact other particles and agglomerate. At a certain filler concentration, the growing agglomerates form a one-, two-, or three-dimensional network of the conducting phase within the insulating polymer matrix. At this range, the resistivity of the mixture shows a deep decrease to the low value of the conductive network. After the formation of the continuous conductive network, the resistivity of the mixture increases slowly as the filler content increases due to the slightly improved quality of the conductive network.

Many models have been proposed (8) to explain the electrical conductivity of mixtures composed of conductive and insulating materials. Percolation concentration is the

most interesting of all of these models. Several parameters, such as filler distribution, filler shape, filler/matrix interactions, and processing technique, can influence the percolation concentration. Among these models, the statistical percolation model (9) uses finite regular arrays of points and bonds (between the points) to estimate percolation concentration. The thermodynamic model (10) emphasizes the importance of interfacial interactions at the boundary between individual filler particles and the polymeric host in network formation. The most promising are structure-oriented models, which explain conductivity on the basis of factors determined from the microlevel structure of the as-produced mixtures (11).

Because the thermal expansion coefficient of a polymer matrix is generally higher than that of the conductive particles, the volume fraction of conductive filler in a conductive polymer composite decreases as temperature increases; thus, the resistivity increases. If a conductive polymer composite is made of semicrystalline polymer as an insulator and a filler of conducting particles, whose concentration is just above the percolation volume fraction, the relatively large change in specific volume of the polymer at its melting temperature may bring the volume fraction of the conductive filler down below the critical volume fraction when the composite is heated beyond the melting temperature of the polymer crystal. Thus, the resistivity increases greatly. Kohler's theory cannot explain the very small rise in resistance exhibited by such filled polymer systems when they are strained to an amount equivalent to that found at the crystalline melting point. And the PTC amplitude should be a direct function of volume change according to Kohler's theory; however, it is not the case in reality.

Ohe proposed a more complex theory (6). He stated that PTC phenomenon could be explained by the increasing intergrain gap among the carbon black particles caused by thermal expansion. He visualized that the distribution of the intergrain gaps in a conductive composite is rather uniform at low temperature, and the gap is small enough for extensive tunneling to occur, but the distribution at high temperature becomes random due to thermal expansion. Although the average gap distance does not change greatly, the presence of a significant amount of gap distance too large to allow electron tunneling will result in a great increase in resistance.

Meyer's theory (7) was based on the assumption that a thin (300 Å) crystalline film of polymer is much more conductive than an amorphous film of polymer. It was shown that carbon black particles remain in the amorphous region between crystallites in a conductive composite. The high conductivity at low temperature is due to tunneling through the thin crystallite, and the PTC phenomenon is caused by a preliminary change in state of these crystallites just before the crystalline melting point that leads to a sharp reduction in the ease of tunneling and thus much higher resistivity.

The authors of this article propose a new theory for PTC behavior. Large thermal expansion during crystal melting surely will contribute to a large amplitude of PTC behavior. But it contributes only to a limited level. Ohe's

vision of the change from uniform distribution of carbon particle to random distribution is groundless and cannot be justified. Actually, as is shown later, cross-linking can eliminate the redistribution of carbon black after melting and stabilizes PTC behavior. PTC behavior takes place at the same time as melting, rather than before crystalline melting, as stated by Meyer. It probably is true that tunneling is easier in a crystalline region than in an amorphous region. The difference is probably due to polymer chain mobility. The work function of the conductive particle at the interface between the conductive particle and polymer matrix may increase after crystal melting due to the high mobility of the polymer chain. The same theory can explain PTC behavior in conductive polymer composites as well as the conductivity phenomenon in an electrically conductive adhesive after curing (12). Before the conductive adhesive is cured, the resin matrix has high mobility and prohibits tunneling between conductive particles. After curing, the mobility of the polymer chain is greatly reduced and thus allows tunneling between conductive particles.

EFFECT OF CONDUCTIVE FILLERS ON PTC CONDUCTIVE POLYMER

Different conductive fillers have been used as in PTC conductive polymers. Metallic powders that are stable at high temperature, such as tin, gold, and silver were suggested as conductive fillers in PTC materials (13a). In addition, ceramic powder such as tungsten carbide was also used as a filler in PTC conductive polymer composites (13b). It was found that V_2O_3 has several phase transitions (1). At 160 K, it is transformed from an antiferromagnetic insulator (AFI) to a paraelectric metallic conductor (PMC), accompanied by a resistivity change from $10^5 \Omega\cdot\text{cm}$ to $10^{-2} \Omega\cdot\text{cm}$. At 400 K, it changes from a PMC to a paraelectric insulator (PI) whose resistivity is $10^3\text{--}10^4 \Omega\cdot\text{cm}$. Most interestingly, low density polyethylene (LDPE) filled with V_2O_3 shows a square well in the resistivity versus temperature profile by combining a sharp negative temperature coefficient (NTC) around -110°C and a sharp PTC around 100°C (1,14–16). A PTC transition temperature of conductive polymer composites filled with V_2O_3 was also reported in other polymer systems (17). The T_i of a V_2O_3 -filled system changes in the following manner: LDPE (100°C) < polypropylene (150°C) < polytetrafluoroethylene (260°C). However, the fillers mentioned before are expensive. Work has been done to develop alternative less expensive PTC conductive polymer composites. Most of the conductive polymers for ESD and EMIS applications are thermoplastics filled with carbon black or carbon graphite because of their very low cost. Carbon black is also one of the major fillers used in so-called PTC conductive polymers (18–20).

There are several important parameters of carbon black (21): particle size (surface area), aggregate structure (carbon black particles aggregate to form a grapelike structure), porosity, crystallinity, and surface functionality. Small particle size and high structure lead to more difficult dispersion. The initial grapelike structure of carbon black formed during the manufacturing of carbon black

is highly stable and can be destroyed only by very intensive processing such as grinding in a ball mill. For a given loading of carbon black, a smaller particle size would add more particles to the composite than that using carbon black of larger particle size. Thus, carbon blacks of smaller particle size would produce a composite that has a smaller separation between carbon particles (as well as the probability of more carbon particles in contact), resulting in greater conductivity. Small particle size gives a low critical volume for a carbon-black-filled polymer system (1). However, for fiberlike conductive fillers, large filler particles favor the formation of conducting paths at a low percolation concentration. High-structure carbon blacks tend to produce a larger number of aggregates in contact, as well as, smaller separation distances, that result in greater conductivity. For a given carbon black loading, the more porous carbon black generally provides a larger number of aggregates to the composite. This results in a smaller interaggregate distance and higher conductivity. The increase in the degree of carbon black structuring is found more efficient than the increase of the specific surface of carbon black in conductive polymers. Carbon particles that have higher oxygen content have higher resistance. Removal of the surface oxides increases the conductivity of the original carbon black much more than heat treatment to produce graphitization. Higher graphite content in carbon black leads to higher electrical conductivity.

Although the small particle size and the highly aggregated structure of carbon black (such as BP2000 manufactured by Cabot Corp.) can give polymer composites that have low resistance, this kind of composite does not show a large PTC amplitude because the aggregated structure cannot be broken down by the thermal expansion of the polymer (Fig. 2). On the contrary, a polymer composite filled with carbon black that has a large particle size and low aggregate structure (such as N660 manufactured by Columbia Chemicals) shows high room temperature resistance but high PTC amplitude (22). To obtain a PTC

Figure 2. Resistivity versus temperature of HDPE filled with different carbon blacks (the loading is 30% by weight). BP2000: small particle size and high aggregated structure; N660: large particle size and low aggregated structure.

conductive polymer composite that has both lower room temperature resistance and high PTC transition amplitude, porous carbon black is much better than nonporous carbon black. Ueno et al. reported that etching a carbon black at an elevated temperature to remove the less crystalline portion and therefore to increase the surface area can improve the PTC characteristics of a conductive polymer filled with carbon black, and this material was suitable for use as a resettable fuse (20).

The PTC amplitude depends on the loading of carbon black. It was shown that for different carbon blacks, a different loading exists at which the composite has a maximum PTC amplitude (23). The carbon black concentration that gives the optimum PTC intensity can be predicted approximately from room temperature data (17).

EFFECT OF POLYMER MATRIX ON PTC BEHAVIOR

Polymers used as the matrix in electrically conductive polymer composites can vary from elastomers to thermoplastics and thermosets that have crystallinity varying between 0 and 80%. As mentioned in the previous paragraph, the large PTC anomaly is due to the large thermal expansion of the polymer matrix, especially during melting of a polymer crystal. The PTC transition temperature is determined by the melting point of the polymer matrix. Because polymers that have low and high melting points are available for use in conductive polymer composites, the transition temperature can be controlled by selecting and compounding the matrix polymer for different applications that require different transition temperatures (24). A PTC conductive composite based on high-density polyethylene whose melting peak temperature is 129–131°C and whose specific volume increases by approximately 10% due to melting across a narrow temperature range, showed maximum resistivity as a matrix at 129–131°C (22). The transition temperature can be slightly adjusted by using a copolymer or polymer blend that has more than one homopolymer. A compound of 40 parts by weight of carbon black, 60 parts of a melted olefin copolymer (ethylene-ethyl acrylate copolymer) (EEA), and an organic peroxide, had a T_i at 82°C (5). Another reported recipe (25) is a composite of carbon black dispersed in high-density polyethylene (HDPE) and poly(ethylene vinyl acetate) (EVA), whose T_i is 120°C. Ultra high molecular weight polyethylene (UHMWPE) reportedly enhances PTC behavior (18). Thermosetting material such as thermosetting polyester resin that was cross-linked by a free radical reaction, was also reportedly used as a polymer matrix for a PTC conductive polymer composite (25).

The PTC amplitude depends on crystallinity. Meyer showed (26) that crystalline *trans*-polybutadiene filled with carbon black has low room temperature resistivity and a significant anomaly, whereas the amorphous *cis*-polybutadiene filled with same amount of carbon black has much higher resistivity and no anomaly. Within a polymeric family, a polymer that is more crystalline has higher PTC amplitude. But also note that different classes of polymers that have the same crystallinity do not exhibit identical PTC behavior and no relationship was correlated. PTC

Figure 3. Resistivity vs. temperature for a PTC conductive polymer during heating and cooling cycles.

amplitude depends on polymer type. PTC amplitude increases in the following order with respect to the matrix polymer: nylon 66 < polypropylene < polyethylene oxide < low-density polyethylene < high-density polyethylene.

As mentioned before, the mechanism for the PTC anomaly in semicrystalline polymer composites is accompanied by a relatively large change in the specific volume of the polymer at its melting temperature. The resistivity versus temperature curve can be well matched by the specific volume–temperature curve. Crystallization during cooling of a polymer is the reverse of melting of a polymer crystal during heating. The PTC transition of this kind of smart material is reversible. During cooling, the same material shows a sharp decrease in resistivity, as shown by Fig. 3. The thermal expansion of a polymer depends on its heating and cooling cycle. Because the melting temperature of a polymer crystal is always higher than the recrystallization temperature, the PTC transition of a conductive polymer composite is always higher in the heating cycle than that during the cooling cycle (1). The difference is about 18 K for polyethylene, 34 K for polyoxymethylene, and 50 K for polypropylene. Actually, all factors that affect the melting and recrystallization behavior such as pressure and heating and cooling rates influence the PTC behavior of a conductive polymer composite. Meyer showed that the PTC transition temperature increases and PTC amplitude decreases as pressure increases (26).

In some conductive polymer composites, the negative temperature coefficient (NTC) effect follows, for example, the resistivity decreases as the temperature increases further after a PTC transition. The NTC effect is probably due to the reorientation, reaggregation, or reassembling of carbon black. Initially dispersed particles may become mobile in the temperature range of polymer melting to repair the broken percolation network. The measurement of resistance versus the temperature behavior of the conductive composite was repeated for the same sample (27,28). Tang (27) observed that the PTC intensity and the base resistance decrease with thermal cycles. The reason is obviously reorganization of carbon black at the high temperature.

Radiation was used to cross-link a carbon-black-filled conductive polymer composite. The NTC effect can be alleviated or reduced by cross-linking, and the PTC

amplitude is stabilized (the resistance at lower temperature is stabilized) after cross-linking (1, 27). The organization of carbon black is hampered in a cross-linked polymer network.

EFFECT OF PROCESSING CONDITION AND ADDITIVES

The effect of mixing time on the resistance-temperature behavior was also investigated (27). Both the PTC effect and the reproducibility were improved greatly when the sample was mixed for a long time. It was suggested that the improvement is due to increasing absorption of the polymer on the carbon black surface and this absorption forms a polymer layer outside the carbon black particle. The room temperature resistivity increases with mixing time at constant carbon black concentration. It can also be explained that structures are broken down during mixing, thus the resistivity increases. If the power consumption during mixing is too great, the composition would have too high resistivity at a low temperature and have unsatisfactory electrical stability on aging at elevated temperature. If the power consumption is too low, it can also result in a composition that has low PTC amplitude.

Tang (27) studied the effect of the interaction between carbon black and the polymer on electrical behavior. The absorption of polymer on the carbon black surface may be physical or chemical. The latter is caused by free radical reaction between the polymer and carbon black, and it can occur during radiation or the preparation of the composite. In carbon-black-filled HDPE, the cross-linked network of the polymer restrict the freedom of movement of carbon black. The free radical reaction enhances the binding force between the polymer and carbon black.

Polymeric materials may be broken down under high voltage. The voltage stability of a cross-linked PTC conductive polymer is improved by incorporating a polymerizable monomer such as triallylisocyanurate before it is cross-linked (28). Antimony oxide, which does not degrade PTC resistance, can be used as a flame retardant (13a). A semiconductive inorganic substance such as silicon carbide or boron carbide was used to improve the high voltage stability (29). Alumina trihydrate can be added to a PTC conductive polymer composite to prevent dielectric breakdown, arcing, and carbon tracking under high voltage (19).

APPLICATION OF PTC CONDUCTIVE POLYMER COMPOSITE

There are many applications for PTC conductive polymer composites, including thermistors (13b), circuit protection devices (30), and self-regulating heaters (31). Because the material both heats and controls the temperature, it can be used to manufacture a self-regulating heating device. As the temperature increases, the resistance increases, and thus the power decreases. This kind of self-regulating heater can be used to prevent freezing of water and pipes used in chemical processing. It has also been used to manufacture a heater for heating a hot-melt adhesive to seal a

cable splice case (32) and a hair curler (33). Self-regulating heaters can be manufactured into different forms. The blank form of PTC conductive polymer composite can allow precise temperature control across larger areas. This kind of device has been used to repair thermally complex aircraft structures (31,34).

Another application of PTC conductive polymers is in over-temperature and over-current protection. A device manufactured from a PTC conductive polymer composite has low resistance and much less resistance than the rest of the circuit at normal temperature; thus it has no influence on normal performance. But at high temperature, these devices become highly resistant or insulators; thus, they dominate the circuit, reduce the current, and protect the circuit. For large abnormal current, the device can rapidly self-heat to a high resistance state and thus reduces the current. The smartness lies in the over-temperature and over-current protection and also in its resetability. After the current drops and the temperature of the device decreases, the device returns to a low resistance state and allows current to pass. A resettable fuse made from a PTC conductive polymer has been on the market. This kind of resettable fuse has been used in battery chargers to terminate the charging function based on the battery temperature and protect the battery from overheating. It is also used in telecommunication equipment, computers, and power supplies.

SUMMARY

A temperature-sensitive PTC conductive polymer composite is a true smart material. Its property can also be tailored by selecting the filler, polymer matrix, and processing conditions. Its transition temperature is determined by the melting point of the polymer matrix. Its room temperature resistivity, high-temperature resistivity, and PTC transition amplitude can be adjusted by the filler and its combination with the polymer matrix. PTC transition behavior can be stabilized by cross-linking the polymer matrix. This kind of smart material can be used in many temperature-sensitive applications such as thermistors, self-regulating heaters, and circuit protection devices.

University of Wollongong
Wollongong, Australia

INTRODUCTION

Intelligent polymer systems have the capacity to sense a variety of stimuli in the operational environment. They can further process this information and then actuate responses (Fig. 1). The stimuli utilized may be chemical (e.g., chemical imbalance in a living system) or physical (e.g., structure exceeds a stress limit). Likewise the response actuated may be chemical (e.g., controlled release of drugs) or physical (e.g., increase in stiffness of material).

The intelligent polymer structure will require energy to implement these functions, so energy conversion/storage

Figure 1. Function required in an intelligent polymer system.

capabilities are desirable. These latter functions could be achieved, for example, by utilizing the photovoltaic properties of polymer structures. Ideally, all of the above mentioned functions would be integrated at the molecular level.

While a number of classes of polymers are capable of providing one or more intelligent functions, inherently conducting polymers (ICPs) may provide all of them (1,2).

SYNTHESIS AND PROPERTIES

The ability of ICPs to provide the range of functions required for intelligent polymer systems will be illustrated with examples that utilize polypyrroles (I), polythiophenes (II), and polyanilines (III).

For polypyrroles and polythiophenes, n is usually about 3 or 4 for optimal conductivity; that is, there is a positive charge on every third or fourth pyrrole or thiophene unit along the polymer chain, close to where the dopant anion A^- is electrostatically attached. For polyanilines, the ratio of reduced (amine) and oxidized (imine) units in the polymer is given by the $y/(1 - y)$ ratio. The conducting emeraldine salt form of polyaniline has $y = 0.5$; that is, there are equal numbers of imine and amine rings present.

Each of these materials may be produced via chemical or electrochemical oxidation of the appropriate monomer (1).

Figure 2. Steps involved in polypyrrole formation.

The polymerizations involve formation of lower molecular weight oligomers that are further oxidized (at lower potentials than the initial monomer) to form a polymer that eventually precipitates or electrodeposits as a critical molecular weight is exceeded. For example, the steps involved in polypyrrole formation are shown in Fig. 2 ($X=\text{NH}$).

A counterion (A^-) is incorporated during synthesis to balance the charge on the polymer backbone. Common chemical oxidants are FeCl_3 and $(\text{NH}_4)_2\text{S}_2\text{O}_8$, which provide Cl^- and $\text{HSO}_4^-/\text{SO}_4^{2-}$, respectively, as the dopant anions. Electrochemical oxidation provides greater flexibility in terms of the anion that can be incorporated from the electrolyte (MA salt or HA acid) added to the polymerization medium. Acidic conditions (pH generally ≤ 3) are required for aniline polymerization in order to solubilize the monomer, while pyrrole and thiophene polymerizations may be carried out in neutral solution.

In general, chemical oxidation provides ICPs as powders, while electrochemical synthesis leads to films deposited on the working electrode. A wide range of working electrodes may be employed, including platinum, gold, reticulated vitreous carbon (RVC), and indium-tin-oxide coated glass. The last-mentioned ITO-glass electrodes,

being transparent in the visible near-infrared region, are very useful for recording absorption or circular dichroism spectra for the deposited conducting polymer films. Both the chemical and electrochemical oxidation approaches can be modified to produce soluble or dispersible conducting polymers.

An important additional feature is that all of these polymer structures are amenable to facile oxidation/reduction processes that can be initiated at moderate potentials. For polypyrroles, and polythiophenes, two oxidation states can be reversibly switched, as shown in Eq. (1) where $Z=\text{NH}$ or S , respectively. The doped oxidized forms exhibit good electrical conductivity ($\sigma = 1 - 100 \text{ s cm}^{-1}$), while the reduced forms have very low conductivity ($\sigma \sim 10^{-8} \text{ s cm}^{-1}$). This ability to conduct electrons is important in that information can be readily relayed within an intelligent polymer system. However, this feature alone is not sufficient for intelligent performance. The dynamic character of these polymer systems is equally important, with chemical, physical, and mechanical properties being a function of applied potential. Both polypyrroles and polythiophenes can be reversibly reduced/oxidized according to Eq. (1) and (2). Polyaniline undergoes similar transitions, although its

redox chemistry is slightly more complex.

If the dopant anion (A^-) is small and mobile (e.g., Cl^-), and the polymer has a high surface area to volume ratio, then upon reduction, the anion will be efficiently ejected from the polymer. However, extensive studies with polypyrroles have shown (3) that if the dopant is large and immobile (e.g., if A^- is a polyelectrolyte such as polystyrene sulfonate), then an electrically induced cation exchange process occurs, according to Eq. (2); where the cation (X^+) is incorporated from the supporting electrolyte solution. This reduction process has a dramatic effect on the physical and chemical properties of the polymer. For example, conductivity will decrease, color will be altered, anion exchange capacity will diminish, cation exchange capacity may increase, and hydrophobicity will be altered in a manner determined by which ion exchange process predominates (2). Some of the changes accompanying these redox reactions are summarized in Fig. 3. These changes are important in determining the sensing, information processing, and actuation capabilities of the systems.

The situation with polyanilines is more complex, with the polymer able to exist in three different oxidation states: leucoemeraldine, emeraldine and pernigraniline (Fig. 4) (4,5). In addition, protonation/deprotonation equilibria occur for two of these oxidation states, depending on the pH. Thus, the emeraldine salt form (ES), which is the only electrically conducting form of polyaniline, is typically dedoped at $\text{pH} > 4$ to give nonconducting emeraldine base (EB). Reversible redox and pH switching between these different forms of polyaniline leads to important changes in their physical and chemical properties (Fig. 3), which may be exploited in a range of applications for intelligent polymer systems.

Polymer reduced	$\xrightarrow{\hspace{1cm}}$ $\xleftarrow{\hspace{1cm}}$	Polymer oxidised

Besides responding to direct electrical stimulation or a change in the redox environment, ICPs may be sensitive to other stimuli such as temperature, humidity, and inorganic and organic vapors. For example, substituted polythiophenes, show a marked blue shift of the highest wavelength absorption band when films or solutions are heated (6–8). These reversible color changes have been attributed to a twisting of the polymer backbone to a less ordered nonplanar conformation. Less dramatic thermochromic effects have also been reported for polyanilines (9–11) where circular dichroism studies of chiral polyaniline salts (9), as with related studies on chiral polythiophenes (12), have provided further insights into the nature of the thermochromism.

The response of ICPs to exposure to various compounds has been reported by many authors. Among these are investigations of changes in the conductivity of polyaniline doped with hydrochloric and sulfonic acids (13). The conductivity of both polyaniline films was at a minimum in dry air and increased over time with increasing humidity. The interaction between water and polypyrrole has also been employed as the driving force in an ICP motor, where a band of this polymer is alternately wetted and dried in order to generate motion (14). Volume changes were reported in polypyrrole perchlorate when it was exposed to ammonia gas and in substituted polythiophenes exposed to iodine vapor (15). These volume changes are utilized as sensors or chemically driven bending beam actuators.

CHEMICAL AND PHYSICAL STIMULI

Chemical Stimuli

Nature has developed chemical recognition systems that are able to discriminate on the basis of highly specific molecule–molecule interactions generating a unique signal. Alternatively, nature utilizes arrays of less specific chemical sensors to collect information that is deciphered using pattern recognition processes carried out in the brain. Both approaches have also been pursued using ICPs in the development of synthetic sensors.

Specific Molecular Recognition Approach

Immobilization of Biologically Active Agents on ICPs.

Chemical specificity has been induced in conducting polymers by borrowing elements of the sensor from nature. For example, the ICP may be used as an immobilization platform for enzymes (16–20), antibodies (21,22) or even whole living cells (23,24). Generally, the bioactive component is

Figure 3. Some changes accompanying polymer oxidation/reduction.

Figure 4. Chemical transitions observed in the oxidation/reduction of polyaniline.

simply incorporated during the polymerization process. The ICP plays a dual role in that it provides a biocompatible matrix that does not destroy the bioactivity of the incorporated species and also provides signal transduction and transmission capabilities.

The majority of enzyme-containing ICP sensors generate a signal because of the increase in concentration of an electroactive product (e.g., H_2O_2) generated by the enzymatic reaction, or because of the decrease of an electroactive product (e.g., O_2) consumed by this reaction. Some others utilize the fact that the bioevent triggers a change in pH that results in a change in resistance of the polymer (25).

The mechanism of signal generation with antibody-containing conducting polymer sensors (21,22) is not so clear. This is also the case for sensors that rely on antibody-antigen reactions that occur on mammalian red blood cell membranes immobilized on a conducting polymer (23). However, both amperometric (21,22) and resistometric (23) measurement techniques have been explored and give rise to useful analytical signals.

Selectivity in the detection process can be increased further by the use of an appropriately designed sensor configuration (26), for example, the use of an electromembrane sensor (Fig. 5).

With this configuration the conducting polymer serves as an immobilization platform for the enzyme. The potential applied to one side of the membrane (the reaction zone) can be independently optimized to ensure maximum

enzyme activity. The electroactive product generated, H_2O_2 , is then selectively transported across the support (PVDF) membrane for detection in an electrically insulated detection zone. Potential interferences such as ascorbic acid and glutathione are not transported and hence not detected. The area covering the use of conducting polymers as biosensors has recently been reviewed (27).

Figure 5. The Electromembrane Sensor

Covalent Attachment of Specific Binding Groups to ICP Backbones. The selective detection of a wide range of target analytes, both chemical and biochemical, has also been achieved by the covalent attachment of molecular recognition moieties to the ICP backbone. The usual approach has been to synthesize a monomer or dimer containing the appropriate recognition group, and this is then oxidized to produce the conducting polymer (28). Subsequent binding of the target analyte to the recognition site is usually accompanied by an electrochemical response in the ICP (e.g., a change in resistance) although other physicochemical responses such as a change in color are sometimes employed.

A drawback with this approach to functionalized ICPs is that the synthesis of the initial substituted monomer may be complex and time-consuming. In addition subsequent oxidation to the desired polymer may prove difficult because of steric hindrance by the functional group or electronic effects that shift the oxidation potential of the monomer. A significant recent development, therefore, is a route involving the facile modification of pre-formed polypyrroles containing good leaving groups such as N-hydroxysuccinamide (29). Using this approach, crown-ethers and electroactive groups such as ferrocene have been covalently attached to the pyrrole rings. This generic approach should be extendable to analogous polythiophenes and polyanilines.

Metal Ion and Organic Cation Sensing. Swager et al. (30) have prepared polythiophenes containing crown-ethers and calix[4]arenes, covalently bound to the bithiophene repeat units (e.g., structure IV below), that exhibit tunable selectivities toward Li^+ , Na^+ , and K^+ ions. Electrochemical detection is facilitated in these cases by electrostatic and conformational perturbations caused by the coordination of the metal ions to these chemical receptors. Swager's group has also developed real-time sensors for viologen dications such as paraquat (V), using conducting polymers based on poly(bi- and trithiophene)s to which cyclophane receptors have been covalently attached to the thiophene rings (31). These form self-assembled pseudorotaxane complexes with paraquat, causing a large decrease in conductivity for the polymer system as a sensitive sensor signal.

More recently, pyrrole monomers VI ($n = 2$ or 4) have also been prepared with calix[4]arenes grafted to the N

atom of the pyrrole ring (32). Electropolymerization to give films of the corresponding N-substituted polypyrroles was more facile for the monomer with the longer alkyl spacing arm length ($n = 4$) (33). However, no change was observed in the electroactivity of these films upon cyclic voltammetry in the presence of Li^+ , Na^+ , or K^+ ions (34).

Sensing Biological Molecules. Covalent attachment of simple functional groups has also been used to promote electron transfer with biocomponents in solution. For example, Cooper et al. (35) produced the functionalized polypyrrole (VII shown below) and demonstrated the ability to mediate in the electrochemical oxidation/reduction of cytochrome c.

Garnier et al. (36) have similarly oxidized pyrrole monomers bearing a range of dipeptide substituents, producing substituted polypyrrole materials with specific recognition properties toward proteolytic enzymes.

A recent exciting advance involves the incorporation of oligonucleotide chains into polypyrrole backbones. This approach has been used to produce DNA-biochips (37–39) applicable in a number of important sensing applications.

Sensing Enantiomeric Molecules/Ions—Chiral Recognition. ICPs with chiral discrimination capabilities have recently been developed via the covalent attachment of optically active groups, such as amino acids, to the β -ring position of pyrrole and thiophene monomers prior to oxidation to the corresponding polymers. The presence of the chiral substituents is believed to induce a one-handed helical structure on the polymer backbones of the polypyrroles and polythiophenes formed. Polypyrroles with main chain chirality have also been generated via the covalent attachment of chiral groups (e.g., sugars) to the N center of the pyrrole monomer prior to polymerization.

In some cases, (e.g., polymers VIII–X) these optically active polypyrroles and polythiophenes were shown to possess the ability to discriminate between the enantiomers of chiral molecules and ions (40–43). The first demonstration of such chiral discrimination was with polymer (VIII).

Cyclic voltammetric studies on the (2*S*)-(+)-enantiomer of VIII in the presence of (+)- and (-)-camphorsulfonic acid (HCSA) showed substantially higher doping with the (+)-HCSA enantiomer (40). The reverse discrimination was shown by the (2*R*)-(-)- polymer.

Use of Dopant Anions Containing Molecular Recognition Groups. An alternative and often facile route to appropriately functionalized ICPs, which avoids the synthetic problems outlined above, is the use of sulfonated species containing the desired molecular recognition/receptor site as the dopant anion for the conducting polymer chains. For example, calixarene-containing polypyrroles (44) and polyanilines (45) for selective metal ion detection have been recently prepared via the use of the sulfonated calixarenes (VIII, $n = 4$ or 6) as dopant anions. We have similarly found that the incorporation of metal complexing agents such as sulfonated 8-hydroxyquinoline as dopants in polypyrroles provides a simple route to metal ion-selective ICPs (46).

Similarly, chiral recognition properties have been introduced into polyanilines via the use of optically active acids such as (+)- or (-)-camphorsulfonic acid (HCSA) (47–49) or (+)- or (-)-tartaric acid (50) to acid dope emeraldine base, producing optically active emeraldine salts. The chiral dopant anions are believed to induce a preferred one-handed helical chirality into the polyaniline chains.

We (51) and others (52) have recently shown that films of optically active polyaniline salts such as PAN(+)-HCSA, or the optically active emeraldine base (EB) derived from them, exhibit chiral discrimination toward chiral compounds such as the enantiomers of CSA⁻ and amino acids.

Specificity can also be controlled to some extent by the introduction of electrocatalytic properties in the polymer. For example, the incorporation of Fe(CN)₆⁴⁻ as a counterion (53) or the use of a prussian blue coating on a conducting polymer inner layer (54) can promote electron exchange with Cytochrome C.

Electrocatalytic dopants (heteropolyanions) have also been incorporated into conducting polymers with a view to developing sensors for detection of nitrite (55) or nitrogen monoxide (56).

Pattern Recognition Approach

Microsensing arrays of ICPs have been assembled with a view to collecting less specific data and using pattern recognition software to decipher it. The so-called electronic noses are based on this principle (57–62). A range of conducting polymers with differing molecular selectivity respond to a complex mixture to produce a unique pattern of responses. This approach has been used to differentiate beers (57) and olive oils (58), as well as to detect microorganisms (59,61) among other applications.

Normally the sensing chips are produced using microlithography and a four-point measuring technique is used to achieve high accuracy in measurement (63). Signal generation is achieved via changes in resistance (increase or decrease), since the sensor works in the dry state. The origin of a particular ICP film's response is uncertain and could include factors such as changes in polymer conformation, volume, and/or screening between the counterions and carriers induced by the analyte.

The means of polymer deposition on the tip of the four-track sensing device is critical. Electrodeposition of the ICP is preferred over chemical polymerization, since the device to be coated is small and deposition can be localized using the electrochemical method. While growth on the gold tracks is readily initiated, lateral growth across the insulating silicon surface is necessary to form a thin coherent film—the structure required for optimal sensitivity. Such lateral growth can be encouraged by silanizing the nonconducting substrate to render it more hydrophobic, enhancing polymer deposition.

The array approach has also been developed for amperometric sensing when used in solution. This has been used by us recently to discriminate between simple ions (64) and even proteins (65). The approach used is similar to the electronic nose in that none of the sensing elements is specific, however, each polymer has a different selectivity

series giving rise to a unique pattern of responses for any given protein. The electronic tongue may not be far away.

ACTUATORS

Generation of electrical stimuli (e.g., a change in potential) as a result of the sensing process can be used to initiate an appropriate response—actuation. Consideration of the processes discussed earlier indicates that substantial changes occur when conducting polymers are oxidized/reduced. These changes have been studied at the molecular level using a technique known as inverse chromatography, both in solution (66–68) and in the gas phase (69,70).

These studies revealed that at least when the dopant (A^-) is small and mobile, reduction of the polymer decreases the anion exchange capacity of the polymer and increases the hydrophobicity of the polymer backbone. These changes inevitably affect the way the polymer interacts with the immediate environment.

Molecular Actuators

The reduction of ICPs also results in exclusion of small dopant anions from the polymer backbone. The dopants can be chosen so that the release process has the desired effect on the chemical composition of the immediate environment. For example, Miller described the triggered release of glutamate (71) and salicylate (72) among other compounds. We have similarly demonstrated the ability to release quinones (73) and metal complexing agents, dithiocarbamates (74). Devices/structures based on this principle will have a reservoir capacity of active ingredients determined by the original doping level of the conducting polymer. If this reservoir of active ingredients is not sufficient, then controlled release devices that utilise the unique properties of conducting polymer membranes can be configured. It has been shown that the transport properties of ICPs are dependent on the oxidation state of the membrane. This has been demonstrated both in solution (75,76) for transport of dissolved ions or molecules and in the dry state (77,78) for transport of volatiles. Extraordinary selectivity factors have been reported for the separation of some volatiles, for example, selectivity factors of 3590 for H_2/N_2 , 30 for O_2/N_2 and 336 for CO_2/CH_4 (79). With membranes operating in solution, the controlled transport of simple ions (80), metal ions (81), small organic molecules (82), and even proteins (83) has been demonstrated.

One could further envisage structures containing packages of active materials (capsules, hollow fibres) wrapped in an ICP membrane, with the capacity determined by the internal volume rather than the dopant capacity of the ICP itself.

Mechanical Actuators

The transitions that occur within the conducting polymers result in dramatic changes in physical properties. For example, upon reduction, the resistance increases markedly (84,85) and the materials became more transparent (86,87).

These incorporation/exclusion events at the molecular level result in changes in the mechanical properties of the bulk material. For example, both tensile strength (88,89) and Young's modulus (89) decrease dramatically as does the overall volume (dimensions) of the polymer change (90). It was these volume changes that led Baughman and colleagues to the concept of electromechanical actuators based on conducting polymers (90). By producing simple laminated structures containing the ICP, they were able to generate a force upon the oxidation/reduction of the active polymers, causing movement. A number of other studies into the effects of polymer composition, supporting electrolyte, and rate of stimulation on the forces generated have been carried out (91–97).

Since the process of force generation depends on the ability of ions to diffuse into/out of the polymer, systems with improved transport properties will give enhanced performances. This has led Hutchison et al. to employ polypyrrole-coated fiber bundles in actuator devices to increase the active surface area and, hence, the rate of diffusion of ions (98). This approach not only substantially increases the surface area exposed to the ion source/sink, it more than doubles the proportion of the actual component in the device. This has led to an increase in force density from 1.25 N/mm² for the laminated device to 5.1 N/mm² for a fiber bundle device (98).

Smela and co-workers (99,100) have demonstrated that elegant performance can be obtained from polymer devices of three dimensions as long as they are small—the folding boxes video is a technological treat (101). Others have demonstrated microcantilevers based on conducting polymers fabricated on silicon substrates (102).

Other Triggers

All of the above-mentioned responses (actuators) are initiated by creating an appropriate electrical potential that causes the polymer to change form. For demonstration purposes this is usually achieved by the imposition of a potential from an external source. However, this potential may be generated by configuring the active electrode as one part of a galvanic cell that is charged/discharged directly. Alternatively, the system/device could be configured so that the ICP sensor acts as a switch, gating the actuation mechanism. Changes in the conductivity or patterns of conductivity can be used to complete circuits and activate responses.

INFORMATION PROCESSING

We are familiar with the use of inorganic, silicon-based materials in the development of complex circuitry that is capable of processing vast amounts of information. Following on from this, the concept of molecular electronics has attracted considerable interest in recent years (103). Within this field ICPs have attracted attention for use as components in polymer-based diodes (104,105), transistors (106,107), and even amplifiers (108).

It is conceivable that eventually more complex information processing, storage, and transport based on polymeric devices will be incorporated into intelligent polymer

Table 1. Summary of Photovoltaic Performance of Some Conducting Polymers

Polymer System	Device	Voc (V)	Isc (mA/cm ²)	FF	Y (%)
Polyacetylene (PA)	n-Si/p-PA	0.53	18.18	0.32	4.3
Polymethylthiophene	Al/PMT/Au	0.23	0.16 ($\times 10^{-3}$)	0.30	—
Polypyrrole (PP)	PP/n-Si	0.29	9.0	0.46	1.2
Poly (N-vinyl carbazole) (PVK)	Al/PVK/Au	1.0	0.18 ($\times 10^{-3}$)	0.23	0.028
Polyaniline (PAn) (9)	Al/PAn/ITO	0.43	—	0.70	0.8 ^a
Polythiophene (3)	Photoelectrochemical cell	0.41	0.35 ($\times 10^{-3}$)	—	0.6 ^b
Polyparavethylene (PPV) (4,5)		1.00	4 ($\times 10^{-3}$)	0.60	6.0 ^c

^cQuantum efficiency

systems. This will require the development of innovative approaches to polymer processing and device fabrication.

ENERGY CONVERSION/STORAGE

The functions/performance required of intelligent polymer systems, namely sensing, information processing, and actuation, will most likely expend energy. Consequently, the intelligent polymer system should preferably be capable of converting energy from a natural source, such as sunlight, and storing it until required. Fortunately, inherently conducting polymers appear to be capable of these functions also.

It has been demonstrated that ICPs are capable of functioning as the active layer in photovoltaic devices (109,110). Since p-n junctions are readily created using conducting polymers, a number of photovoltaic cell designs are possible. Initially, poly(p-phenylene vinylene)-based polymers were used (111,112). More recently, polyaniline (32) and polythiophene (113)-based polymers have been employed. Although these polymers are currently low in efficiency (Table 1), the attachment of light-harvesting molecules or moieties that enhance charge separation and transport within the polymer structure should improve this (114). The fact that they can be fabricated in different forms means that the efficiencies attainable in \$ per square meter would be achievable.

Inherently conducting polymers have also been used in polymer battery fabrication, and an all-polymer battery structure has been developed (115). A specific charge capacity of 22 mA hg⁻¹ and a cell potential of 0.4 V were obtained. The cells showed no loss in capacity when cycled 100 times. Others have utilized conducting polymers as just one of the electrodes in a battery setup (116).

In addition, ICPs have been used in the development of so-called "super capacitors" (117-119).

POLYMER PROCESSING

The above-mentioned applications of ICPs have significant commercial potential. However, in most cases, this has not been exploited because of the lack of convenient polymer processing and device fabrication protocols. For example, while polypyrroles exhibit the desirable properties

mentioned above, polymerization usually results in the formation of an insoluble, infusible material not amenable to subsequent fabrication. Conducting polyaniline and polythiophene salts are similarly intractable. Several approaches have recently been employed to overcome this problem of intractability.

Use of Ring-Substituted ICPs

Solubility has been induced in polypyrroles by attaching alkyl (120,121) or alkyl sulfonate (122) groups to the pyrrole monomer prior to polymerization. This results in markedly enhanced solubility in organic or aqueous media, respectively. For example, we have shown that the electrochemical method (123) can be used to produce alkylated polypyrroles with high (400 g/L) solubility in organic solvents and reasonable (1-30 S cm⁻¹) conductivity.

Both electrochemical and chemical oxidation have been used to produce 3-substituted alkylsulfonated pyrroles (124). Electrochemical polymerisation was achieved using acetonitrile as solvent to form a solid deposit on the electrode. Alternatively, FeCl₃ was used as oxidant. Conductivities in the range 0.001 to 0.500 s cm⁻¹ were obtained, with lower conductivity products obtained from chemical polymerisation. Others (125,126) have prepared homopolymers and copolymers of polypyrroles with alkyl sulfonate groups attached via the N-group. This N-group substitution decreases the polymers' inherent conductivity.

Polythiophenes can also be rendered either organic solvent soluble (127) or water soluble (128) using these derivitization approaches. Similarly, the incorporation of ionizable sulfonic acid groups onto the aniline rings or the aniline nitrogen atom, either pre- or postpolymerization, has provided routes to self-doped, water-soluble polyanilines (129-131). Water-soluble sulfonated polyanilines have been recently synthesized under high pressure to obtain products with higher molecular weight (132). The polymerization of aniline monomers containing alkyl or alkoxy ring substituents leads to polymers with improved solubility in organic solvents (133,134).

Formation of Colloidal ICPs

The improvements in solubility achieved via ring substitution generally result in significant loss in electrical

conductivity of the final polymer. Consequently, formation of colloidal dispersions is an attractive alternative route to solution processing in water, as this allows for postsynthesis handling while retaining reasonable conductivity.

Conducting polymer colloids can be produced by chemical (135,136) or electrochemical (128,137,138) oxidation of monomer in the presence of a steric stabilizer. Colloids produced electrochemically are formed by interrupting the polymer deposition on the electrode surface utilizing hydrodynamic control. This is facilitated by the presence of a steric stabilizer in solution that coats the insoluble polymer upon formation, preventing deposition. The electrochemical approach is advantageous in that the polymer properties can be altered by accurate control of the oxidation potential during polymerisation. This technique also allows a wide range of dopants to be incorporated into the polymer to give different properties. For example, proteins can be incorporated into conducting polymers while retaining their biological integrity (138).

Armes et al. (139–142) have shown that polypyrrole and polyaniline colloids can be successfully prepared via chemical oxidation using fine colloidal silica as a dispersant. The colloids have a low percentage of conducting polymer but still have reasonable conductivity. Zeta potential measurements (139) suggest that stabilization is actually provided by formation of “raspberry” morphologies with the inorganic oxide on the outer layer. The colloids obtained have significant microporosity (140,143). Silica nanocomposites containing polyanilines had particle sizes in the range 300 to 600 nm and typical conductivities of about $6 \times 10^{-2} \text{ s cm}^{-1}$. We have generated similar silica-stabilized colloidal polyanilines via the electrohydrodynamic route, including optically active PAn.(+)-HCSA/silica (144).

Use of Surfactant-like Dopant Anions

For organic solvent solubility, an alternative approach to solubilizing polyanilines and polypyrroles, without sacrificing high electrical conductivity, is the use of surfactant-like dopant anions. With polypyrrole this has recently been achieved via oxidation of the pyrrole monomer with ammonium persulfate in the presence of dodecylbenzene

sulfonate (145,146). Similarly, the conducting emeraldine salt form of PAn.HA can be readily solubilized in a range of organic solvents via the use of camphorsulfonic acid or dodecylbenzenesulfonic acid as the dopant, HA (147,148).

DEVICE FABRICATION

For the fabrication of a practical device, the functional properties of ICPs must be integrated within a host structure that provides the mechanical/physical properties required.

Components with improved mechanical properties can be produced by mixing the above-noted processable polymers with other polymers. For example, conducting polymer colloids have been mixed with water-based latex paints to form conductive, electroactive paints with excellent adhesion to a range of metals (149). Interestingly, the paint-metal adhesion was actually increased by addition of the conducting polymer colloid.

ICPs have also been assembled inside a number of host polymers including polyacrylonitrile (150) and polyvinyl alcohol (151). The inert (insulating) host matrix is first cast onto a suitable electrode. After imbibing the monomer into the host polymer and supporting electrolyte (to provide the dopant), electropolymerization to form a conducting polymer network is initiated. ICPs have also been assembled inside hydrogels retaining both the electronic properties of ICPs and the water adsorption properties of gels (152,153). The growth of conducting polymers inside these host structures provides an opportunity to make all polymer devices since the host may function as a polymer electrolyte.

Composites have been prepared using emulsion polymerization approaches (154,155) or by co-precipitation (156). Others have coated polymethyl methacrylate (PMMA) spheres (157) with conducting polymers. The resultant particles can then be pressed to form films. A similar approach was used by DSM Pty. Ltd. (158) to produce water-borne polyurethane dispersions that could be simply cast as films. The solubility of polyanilines containing selected dopants facilitates their use in formation of polymer blends (159).

Figure 6. Schematic representation of approaches used to coat fabrics.

*TBA = Tributylammonium

Figure 7. Structure of PBHE.

Conducting polymers have been prepared as coatings on both natural and synthetic fibres and fabrics. For example, silk, wool (160,161), and nylon (162) have been successfully coated with thin, uniform, adherent coatings. The Milliken Corporation developed the first commercial process for producing conducting polymer-coated fabrics (163) by an in situ chemical polymerization method that utilizes dopants that promote adhesion to the fabric. Detailed studies in our laboratories have shown that the properties of the ICP coating are intimately related to the surface chemistry of the textile substrate used as well as the polymerization condition. A vapor phase polymerization method (Fig. 6) has also been used to coat a range of fabrics.

The physical properties of ICPs can be manipulated by incorporating polyelectrolytes (PEs) as dopants. For example, sulfated poly(β -hydroxy) ethers (PBHE) shown in Fig. 7 have been incorporated with dramatic effects on the mechanical properties—increasing the elongation to break to greater than 200% (117,164).

Recently (165), this polyelectrolyte has been incorporated into polythiophene using bithiophene as the monomer. Again, remarkable physical properties (tensile strength = 120 MPa) were obtained.

Others (166) have shown that polyanilines can be rendered “water soluble” by incorporation of appropriate polyelectrolytes such as polystyrenesulfonate. Electrically conducting gels (materials with high water content/good conductivity) are also formed by incorporation of polyelectrolytes as dopants (167,168).

A number of functions require creation of p–n junctions. To date this is usually achieved with an ICP-metal, the metal being predeposited on a suitable substrate or sputter coated onto the polymer. Thin metal layers may also be necessary for highly conducting interconnects. More recently, p–n junctions have been created using the same polymer with different dopants (169).

The ability to provide more processable inherently conducting polymers, as described previously, enables new approaches to device fabrication, including ink jet printing (170) and screen printing (171). Both approaches utilize well-proven technologies to produce patterns on surfaces. As conducting polymer formulations are refined for these purposes, the production of polymer circuits on a wide range of surfaces will be realized. Photolithography has also been used to produce ICP patterns (172–174), while spin coating has been used to produce thin, even films (175).

CONCLUSIONS

The discovery of inherently conducting polymers just over 20 years ago provided materials that could be utilized as an organic alternative in areas previously limited to the use of inorganic materials. The use of inherently conducting polymers in areas such as sensors, electrochemical actuators, photovoltaic materials, electronic components, and light-emitting coatings has subsequently been pursued. In many instances, the polymers were coupled with the new processing and fabrication approaches and attained great performance.

The discovery of inherently conducting polymers has provided a class of materials that will feed the imagination of scientists and engineers in pursuit of intelligent material systems and structures. No other class of materials possesses the inherent properties necessary to function as sensors, information processors and actuators, as well as the possibility of providing an energy conversion and storage system.

CURE AND HEALTH MONITORING

TAKEHITO FUKUDA
TATSURO KOSAKA
Osaka City University
Sumiyoshi-ku, Osaka, Japan

SMART MONITORING SYSTEM

The smart monitoring system has evolved due to advances in sensors, sensing methods, and communication technologies, as shown in Fig. 1. The sensing function involves sensors, signal sources, and signal detectors. Measured data are analyzed by a signal processor using an appropriate analytical approach. The analyzed results are reported to operators or observers. In the old days, human beings performed these functions (Fig. 1a). Today, they are replaced by sensor devices, computers, and communication networks (Fig. 1b). For example, a fire alarm system consists of a temperature sensor, a microcomputer, and an alarm. Furthermore, the recent development in sensors and computers make these devices so small and light that they can be integrated into structures. An integrated monitoring system makes the materials and structures "smart", and then it can be called a "smart" monitoring system (Fig. 1c).

Figure 1. Concepts of monitoring systems in the past, present, and in the future.

The smart monitoring system was an imaginary technology several decades ago. You may see or read a science fiction story of a spacecraft that has a function for monitoring the state of all elements. Such a structure is still a potential, but it is becoming a real structure as the smart monitoring system advances. The elements of a smart monitoring system are integrated sensors, integrated microprocessors, analytical software, and a network. Small, lightweight sensors that are embedded in or attached to structures add the function of self-inspection to the host structures. Powerful microprocessors and analytical software make it possible to analyze data more precisely for identification or prediction in real time. An integrated network function enables remote monitoring everywhere in the world. The integrated monitoring system has much merit. The material and structure, where the monitoring system is integrated, can know and estimate the condition by itself, in other words, can feel the condition. Therefore, the maintenance cost of materials and structures can be reduced. The total weight of the monitoring systems can also be reduced because the sensors used in smart monitoring systems are smaller and lighter than traditional sensors. In addition, a new business service may develop to monitor structures in the future and ensure the safety and performance after construction. These advantages have motivated studies of smart monitoring techniques that increase from year to year.

The smart monitoring system has mainly two practical, commercial targets. One is "manufacturing process monitoring" and another is "health monitoring." The former is a technique for monitoring the state of materials in the manufacturing process. Monitoring of the molding process for thermosetting polymers, called "cure monitoring," has been especially focused on polymer matrix composites (PMCs). In manufacturing process monitoring, the chemical and physical state of materials and the integrity of products are monitored. The collected data can also be used for optimal control of the forming process to improve efficiency. Monitoring the integrity of the product makes it unnecessary to inspect after manufacture. Then, the manufacturing cost can be reduced by introducing this technique. Health monitoring, on the other hand is a technique for monitoring the condition of materials and structures in operation. In the last decade, health monitoring has become a hot issue especially in aerospace and civil structures. These structures suffer from mechanical and thermal fatigue, long exposure time, and natural disasters such as earthquakes and typhoons. Thus, periodic inspections are required to maintain the safety of these structures adequately. However, the inspection cost of large structures is very high, and operation must be interrupted during the inspection. Therefore, real-time health monitoring promises to reduce maintenance costs and to improve reliability. By combining these two monitoring techniques, it is possible to monitor the state of materials and structures from their beginnings to their ends. This means that the quality of products can be ensured continuously at low cost. Therefore, the idea is a very attractive solution for reducing the total cost of ownership, including the price, maintenance, and operating cost.

As described before, the smart monitoring technique consists of three technologies, a sensing technology, an analytical technology, and a network technology. In this

article, the sensing technology is particularly emphasized because integrated sensors make materials and structures smart. Small size, lightweight, durable sensors are desired for the smart monitoring technique. Suitable sensors are fiber-optic sensors, piezoelectric sensors, electrostrictive sensors, magnetostrictive sensors, and dielectric sensors. Some applications require special properties. For example, the sensors for a space structure must be insensitive to an electromagnetic field and temperature. Civil structures require long-term survivability of integrated sensors. Traditional sensors such as strain gauges and thermocouples are used only for compensation in laboratory studies. Some types of sensors, such as fiber-optic strain sensors, dielectric sensors, and piezoelectric sensors, can be used for both cure monitoring and health monitoring; such sensors can be employed to monitor materials from their beginning to their end. Measurement of material properties such as stiffness, density, damping, and conductivity is also available for health monitoring. The advantage of measuring the variation of material properties makes embedded sensors unnecessary. More details of these topics are given in the following subsections.

CURE MONITORING

Today, engineering plastics and polymer matrix composites (PMCs) are widely used in consumer and leisure products such as golf clubs, fishing rods, skis, and tennis rackets. Fiber-reinforced plastics (FRPs), particularly, are the most promising composite materials for airplanes, space structures, and military ships. Thermosetting and thermoplastic polymers are common materials used in FRPs. In the molding process for polymers, a liquid resin becomes solid. As for thermosetting polymers, a monomeric liquid resin becomes a cross-linked rigid solid and a tightly bound three-dimensional network is produced. This process is called "cure." Thermoplastics do not need to be cured because they are not cross-linked. In these advanced engineering materials, the integrity of the product is very important for certifying the performance. The quality of a product strongly depends on the profiles of the control parameters such as the temperature and pressure in the molding process. Therefore, many researchers have developed techniques for optimizing the molding process. The monitoring technique is essential for the optimal control system of the molding process. The cure monitoring technique, especially has been an important focus because the cure reaction of a thermosetting FRP is too complicated to predict. Techniques for monitoring the molding process of thermosetting FRPs are not discussed. However, it should be remembered that some of the techniques that monitor the mechanical, optical, and electrical properties, can also be applied to monitor the state of solidification in the process of molding thermoplastic polymers.

There are many molding processes for manufacturing PMCs. As shown in Fig. 2, they can be classified by the intermediate stage or the forming stage (1). In the intermediate stage, the manufacturing processes are divided into the manufacturing of molding compounds, the impregnation of resin, and the manufacturing of preforms. The molding methods in forming the final products are

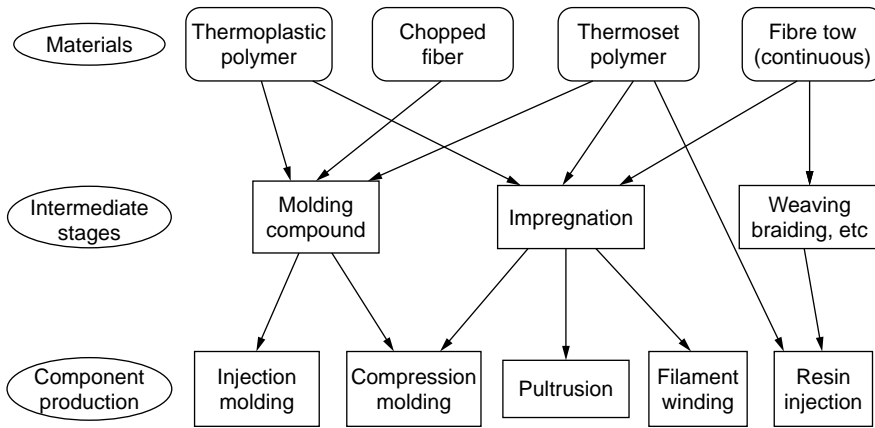

Figure 2. Schematic overview of the approaches employed in fabricating polymer matrix composites (1).

autoclave molding, hot-press molding, liquid molding, injection molding, pultrusion molding, and filament winding (FW) molding. Sheet molding compounds (SMCs) and bulk molding compounds (BMCs) are intermediate molding compounds that contain thermosetting resin, hardeners, thickening agents, and chopped fibers. SMCs are formed into sheets and used for hot-press molding. BMCs have no shape and are used for hot-press molding, injection molding, etc. Hand lay-up (HLU) or spray lay-up (SLU) methods are commonly used for manufacturing of large composite structures. The HLU is a forming method, in which prepregs are stacked up in a die. A prepreg is an intermediate product, which is formed into a tape or a sheet of continuous fibers impregnated by resin. In the SLU method, a liquid resin that contains chopped fibers is sprayed into the die. The resin that covers the die is cured at room or high temperature. The laminate FRPs reinforced by using continuous fibers are molded by applying the proper temperature and pressure to the stacked prepregs in autoclave molding or hot-press molding. Liquid molding methods such as resin transfer molding (RTM), vacuum assisted resin infusion (VARI), and resin infusion molding (RIM) are used to form complex-shaped FRPs. In liquid molding, a reinforcement preform is placed in the mold, and liquid resin is poured into it. FW molding is used to form a pipe or a tank. In FW molding, a mandrel is wound with reinforcement fiber strands that are impregnated by resin. Pultrusion molding is a method for manufacturing long FRPs. In pultrusion molding, continuous fibers impregnated by resin are forced through a die, in which the composites are cured by heat. In most cases, traditional noncontact monitoring cannot be applied to monitoring the cure of FRPs because the surfaces of composites are covered by mold release sheets. Therefore, *in situ* monitoring is essential to monitor the cure state of FRPs.

By the way, remember that cure monitoring is part of manufacturing process monitoring for thermosetting polymers and PMCs. The technology, including monitoring and optimal control of the manufacturing process, can be called “smart” manufacturing technology (Fig. 3). In this article, the manufacturing process includes setup, molding, and inspection. The setup is important for molding complex-shaped products. For example, in liquid molding, monitoring and optimal control of resin flow are desired to certify the integrity of the resin impregnation before curing. In the

curing process, *in situ* sensors monitor changes in chemical constitution, viscosity, elasticity, and conductivity to determine the cure state of the resin. The *in situ* temperature sensor is useful for controlling temperature more precisely by monitoring the temperature distribution in the material because thick or complex-shaped products have complicated temperature distributions during cure. Optimal control of the curing process minimizes processing time. In the cooling stage of the curing process, the residual stress and imperfections in products are monitored to ensure the quality of the final products because the residual stress affects their strength and durability. It is important to monitor residual strain distribution because unexpected residual strain causes defects and damage such as warping, matrix cracks, and delaminations. The smart manufacturing process does not need inspection after curing because the quality is already ensured by integrated sensors at the end of the curing process. Furthermore, product defects can be discovered in the early stages. These advantages have the potential for reducing manufacturing cost. Here, it is considered that the words “smart manufacturing” have another face, which is the manufacturing technique for smart composites. The manufacturing technique for smart composites has been developed to solve problems of interface and interphase between the sensor/actuator and the matrix and problems of connection between the sensor/actuator and the controller. Note that “smart manufacturing” means “smart” manufacturing technology in this article because the monitoring system is the main focus.

The best final product performance is achieved from optimum conditions of temperature and pressure in the curing process. However, these conditions have been obtained mainly by trial and error, and therefore, the curing process is inefficient. Furthermore, nondestructive inspection must be conducted for advanced composites such as carbon-fiber-reinforced plastics (CFRPs) because internal defects cannot be detected visually. The inefficiency, which is caused by the long processing time and nondestructive inspection, increases the manufacturing cost. Therefore, efficient (short time) and optimally controlled cure processing techniques are desired. The cure monitoring technology has an older history than that of smart materials and structures technology, which involves smart monitoring techniques. The traditional methods of cure monitoring

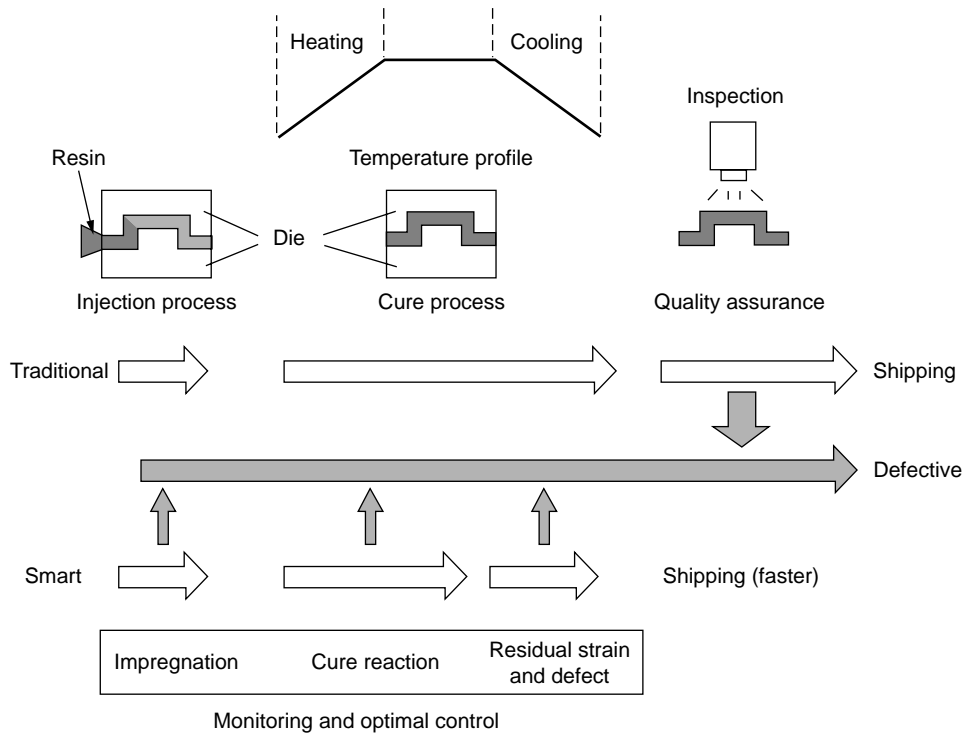

Figure 3. Comparison of the traditional manufacturing process and the smart manufacturing process.

are differential scanning calorimetry (DSC), dynamic mechanical analysis (DMA), infrared spectroscopy (IRS), and dielectric measurement. DSC and DMA cannot be used in molding of actual products. The DSC method measures the heat of calorific reaction in the curing process. The degree of cure (DOC) of the resin is generally defined as the ratio of the heat of initiation to the total heat of the curing reaction. The thermochemical requirements for predicting the DOC were presented by Loos and Springer (2). They also proposed a model to predict the behavior of resin flow in the curing process for FRP laminates. The DMA method measures the variation in the mechanical viscosity of the resin at various temperatures. IRS can be used to measure the variation in the chemical constitution of the resin. The changes in the electrical properties of the resin during cure can be measured by using a dielectric sensor.

The traditional techniques of cure monitoring are in a sense effective. However, *in situ* sensing, which is proposed in smart monitoring, is a more effective approach for

monitoring the cure state because local information is useful for identifying the DOC. Traditional monitoring techniques are employed to develop an analytical model and to supplement the data measured by *in situ* sensors. As shown in Table 1, fiber-optic sensors, dielectric sensors, piezoelectric sensors, and ultrasonic sensors have been investigated for monitoring the state in the manufacturing process. Some of them, such as IRS-based fiber-optic sensors, dielectric sensors, and ultrasonic sensors are based on traditional monitoring techniques. The recent monitoring techniques have come from smart materials and structures technology. Among these sensors, fiber-optic sensors are best for embedding, and they can be used to monitor the chemical, mechanical, and optical properties of the resin in the curing process. However, their cost is high because commercial optical devices are expensive. Dielectric sensors are used for measuring the electrical properties mainly in monitoring cure. The main purpose for using piezoelectric wafers for monitoring cure is their

Table 1. *In Situ* Sensors for Cure Monitoring

	Configuration	Monitored Value	Cost	Use in Operation
Fiber-optic sensors	Embed	Chemical constitution, refractive index, strain, temperature	High	Good

application to vibrational control and health monitoring of structures in operation. Ultrasonic sensors do not need to be embedded because the materials propagate ultrasonic waves. In this article, sensing techniques are described from the viewpoint of sensor technology.

Fiber-Optic Sensors for Cure Monitoring

To apply a traditional optical technique such as IRS, the exposed face of the FRPs must be visible in the molding setup. The use of an optical fiber is the best solution for *in situ* optical monitoring because an optical fiber has the advantages of small size and high temperature resistance, and can be embedded. In addition, an embedded fiber-optic sensor can be used for health monitoring in operation after the product is manufactured. This technique has been developed in the last decade due to the advances in fiber-optic sensors. Most of the traditional optical cure-monitoring techniques can be applied to *in situ* monitoring by using an optical fiber guide. As shown in Table 2, three types of traditional optical sensing methods, near-infrared spectroscopy (NIRS), fluorimetry, and refractive index methods, are commonly used for monitoring cure by using optical fibers today. Nontraditional fiber-optic sensors, which are *in situ* strain and temperature sensors, can be employed to monitor strain and temperature in PMCs during cure. The NIRS fiber-optic sensor and the fluorimetry fiber-optic sensor can monitor the chemical constitution of the resin and the curing agent. The refractive index fiber-optic sensor is the cheapest solution for monitoring cure. Strain/temperature fiber-optic sensors provide information about internal status, and they can be used after manufacture. In this subsection, these four types of fiber-optic sensors for monitoring cure are described.

The NIRS-based sensing is a technique whereby light transmitting through a sample is absorbed at some

Figure 4. Schematic of the NIRS-based fiber-optic sensor system for monitoring cure.

wavelength in the range of the NIR due to the resonant vibration with the molecules of resin. In the process of curing polymers, some molecule groups appear or disappear, so the absorbance at the characteristic wavelength (or frequency) changes. Therefore, the NIRS-based sensor can measure the chemical constitution of the resin directly in the curing process. The NIRS-based fiber-optic sensor is an application of the technique that uses an optical fiber guide. The system has a white light source, a modified optical fiber, and a device for measuring an optical spectrum (Fig. 4). The wavelength used for NIRS-based cure monitoring is in the wavelength range of 1300–2300 nm (the range of NIR light). Note that optical fibers have peculiar transmission properties in the wavelength domain, as shown in Fig. 5 (3). Silica fibers are very cheap and have good transmission properties only in the range from visible light to NIR light. Sapphire and fluoride fibers have better transmission properties than silica fibers. Chalcogenide, AgCl, and AgBr fibers cover the mid-infrared region, but have lower transmission properties. Because optical fibers except silica fiber are much more expensive, silica fibers have been widely employed for monitoring cure. A spectral range of an FT-IR (Fourier Transform Infrared Spectroscopy) is in the near-infrared and that of a general grating-based optical spectrum analyzer is from visible to 1600 nm. Then, an FT-IR is preferred for NIRS-based sensing. Because the targeted wavelengths for monitoring cure depend on the kind of polymer, it is important

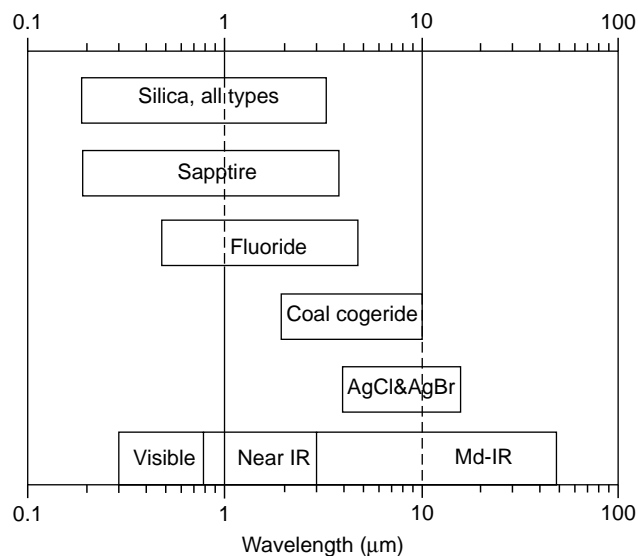

Figure 5. Transmission properties of optical fibers (3).

Figure 6. Constructions of sensing parts of NIRS-based, fluorimetry-based, and index-based fiber-optic sensors (a) transmission type; (b) evanescent type; (c) distal end type.

to determine the properties of the polymer's optical absorption to select a proper measuring instrument. For instance, monitoring the cure of the epoxy-amine resin system requires the 1500 to 1700-nm range, which includes the absorption bands of epoxy, amine, C-H, and O-H groups (4,5).

The sensing part of the optical fiber is fabricated so that the light propagates through the polymer. Two configurations of fiber-optic sensors are suggested (4–8). One is a transmission-type sensor, and the other is an evanescent-type sensor. The transmission-type sensor has a simple structure, in which the sensor has a gap, as shown in Fig. 6a. A configuration that uses a bore metal capillary is proposed to fix the input and output fibers (6). When the sensor placed in liquid polymer, the gap is filled by it. Then, light propagates through the polymer in the gap. The evanescent-type sensor consists of a fiber, which has a stripped cladding region, as shown in Fig. 6b. An evanescent wave is light transmitted in the cladding of the fiber. In the stripped region of the evanescent-type sensor, the evanescent wave transmits in the polymer instead of in the silica cladding of the fiber. The refractive index of the fiber core must be larger than that of the resin to propagate light in the stripped region (4). An example of the application of an NIRS-based sensor is shown in Fig. 7. The figure shows that the absorption peak of epoxy decreases due to a decrease in epoxy molecules from cross-linking in the epoxy-amine resin system in the curing process. Note that the behavior of absorption peaks is sometimes complex due to the overlaps of peaks related to different molecules. The use of neural network analysis has been proposed to improve the difficult quantitative analysis of spectra (9).

Fluorimetry is an optical spectroscopic technique that measures the molecular or atomic composition of a liquid, gas or solid by using ultraviolet (UV) light or X rays. This

technique is based on the photoluminescent phenomenon that incident light irradiates fluorescent materials. The fluorimetry-based fiber-optic sensor uses this phenomenon for monitoring the cure of the resin (7,8,10). When UV light is incident on a liquid resin mixed with a fluorescent curing agent, the curing agent absorbs the UV light and emits short-wavelength visible light (400–600 nm). The fluorimetry-based sensing system has UV light source and two wavelength-scanning filters for the excitatory light and the emission light, and a photo detector (Fig. 8). The emission spectra are scanned by fixing the excitatory wavelength at the absorption wavelength of the fluorescent material, and the excitation spectra have a fixed emission wavelength, which has maximum emission intensity. In the curing process, the peak position and the intensity of

Figure 7. Overlaid optical fiber evanescent wave spectra obtained during the cure of Epikote 828 and hexanediamine at 40°C (6).

Figure 8. Schematic of fluorimetry-based fiber-optic sensor system for monitoring cure.

the spectrum are changed due to changes in the chemical structure of the fluorescent curing agent. The peak shifts of the spectra provide a quantitative measurement of the cure state. Fluorimetry-based sensors have an evanescent-type sensor and a distal end-type sensor as shown in Fig. 6 b,c (7,8,10). The construction of an evanescent-type sensor is similar to that of the NIRS-based sensor. A distal end-type sensor has a flat end where the light leaks out. An example of cure monitoring by using a fluorimetry-based fiber-optic sensor is shown in Fig. 9 (8). The figure shows the peak of excitatory spectra shifts in the curing process. The use of a sapphire optical fiber for the evanescent-type sensor has also been reported (7).

A refractive-index-based fiber-optic sensor measures changes in the refractive index of a polymer from the intensity of light. There are two types of construction for the sensor, a transmission-type sensor and a reflection-type sensor, as shown in Fig. 6b,c (5). The transmission-type sensor used in the index-based sensor is similar to the evanescent-type sensor used in the NIRS-based sensor and the fluorimetry-based sensor (4,5). The transmission-type sensor that uses a polymer core fiber has also been proposed since the late 1980s (11). A light propagates in the

fiber core by reflecting at the boundary between the fiber core and the resin in the stripped region. The reflection-type sensor uses Fresnel reflection at the cut end of the fiber, which contacts the polymer (5,12,13). The changes in the intensity of light result from changes in the reflection rate at the boundary between the fiber core and the resin. The reflection-type sensor requires a simple, low-cost optical system that uses a silica fiber for communication, so the cost is much lower than that of spectroscopic monitoring methods. However, note that the long-term stability of optical devices that include a light source and a detector is essential for stable and low S/N measurement during cure. Figure 10 shows the experimental measurements of the two types of refractive-index-based sensors during cure (6). The figure shows that the curve of the reflection-type sensor is inversely proportional to that of the transmission-type sensor.

Because most fiber-optic strain sensors are sensitive to temperature, they can also be used for measuring temperature. Several kinds of fiber-optic strain/temperature sensors are discussed later. An extrinsic Fabry–Perot interferometer (EFPI) sensor, a fiber Bragg grating (FBG) sensor, and an interferometric sensor are commonly used for *in situ* monitoring. These sensors were developed originally for health monitoring, and therefore, they can be used after the manufacture of products. An EFPI sensor is constructed from two optical fibers that are fixed in a capillary tube and have half-mirrors at the ends of the fibers (Fig. 11). The two mirrors comprise a multiple ray interferometer in the capillary tube, which is called a Fabry–Perot interferometer. There are two measurement systems for EFPI sensors. One uses a narrowband light source, and the other uses a broadband light source. The former is cheaper and is used for high-speed measurement but is strongly affected by the optical power loss in the fiber-optic guide. The loss is a problem for cure monitoring because high pressure is applied to PMCs in the manufacturing process. The latter is independent of the optical power loss due to the capability for absolute measurement of the cavity length in the wavelength domain (14). Therefore, the latter system is more suited to monitoring in the manufacturing process. Most of the commercial EFPI strain sensors have low thermal sensitivity because the gauge length is about 20 times as long as the cavity length. Then, the thermal effect on EFPI strain sensors is sometimes negligible for strain measurement. There are several applications for monitoring strain or temperature in the curing process. The residual strains in a pultruded composite rod in the

Figure 9. Excitatory spectra of DGEBA-DDS epoxy obtained *in situ* at 180°C as a function of cure time (spectra plotted without regard to intensity) (8).

Figure 10. Cure data obtained from single-wavelength back-reflection (reflection-type) and stripped cladding (transmission-type) optical fiber sensors during the cure of Epikote 828 and hexanediamine at 45°C (6).

pultrusion molding process were evaluated in (14). It appeared that the strain measured in FRPs by using EFPI sensors could be used for cure monitoring in an autoclave molding and an FW molding (15,16). The thermal sensitivity of the sensor for temperature measurement can be maximized by bonding the capillary tube to a high CTE (coefficient of thermal expansion) material such as aluminum (17). An FBG sensor has a longitudinal periodic variation in its refractive index in the core of a single-mode fiber (Fig. 12a). The wavelength shift of the reflected light from the Bragg grating is proportional to the strain variation. This absolute measurement technique is affected by strain and temperature change. The effect of temperature on strain measurement by an FBG sensor cannot be negligible during cure at high temperature. It was reported that FBG sensors embedded in CFRP and GFRP composites can detect the onset of vitrification of the resin during cure (18). An FBG sensor for temperature measurement can be manufactured, so that it is sensitive only to temperature, by making a sensing part free from strains, as shown in Fig. 12b (19,20). Simultaneous measurement of temperature and strain by FBG sensors are of major interest, and the studies are described in the section on health monitoring.

Dielectric Sensors for Cure Monitoring

Most polymers are nonconductive but have a little conductivity in the liquid state. Therefore, the electric properties of polymers provide useful information about the cure state. Dielectric measurement techniques for polymers have been investigated since the 1960s. The application to monitoring cure started in the 1980s, and microdielectric sensors have been developed especially for *in situ* cure monitoring. This measurement technique is based on the method for measuring the complex dielectric constant of conductive materials. The real part ϵ' and the imaginary part ϵ'' are called relative permittivity and loss factor, respectively. The basic components of dielectric sensing are a voltage source and two electrodes. A micro dielectric sensor has an electrode pattern printed on a small, thin base plate, as shown in Fig. 13 (21). When the sensor is covered by resin, it can be assumed that the sensor and the resin comprise an equivalent RC electric circuit. Consequently, when a sinusoidal voltage is applied to the circuit, the sinusoidal current generates with a lag of phase angle δ . Then, the resin capacitance C , the resin resistance R , and $\tan \delta$ can be obtained simply from the current output. The complex dielectric constant is represented by the

Figure 11. Schematic of an EFPI fiber-optic sensor.

Figure 12. Schematic of an FBG fiber-optic sensor (19,20).

following simple form: $\epsilon' = C/C_0$, and $\epsilon'' = 1/R\omega C_0$, where C_0 is the capacitance of a free space capacitor and ω is the angular frequency of the voltage source. The previous relationship indicates that the loss factor depends on the frequency. The loss factor consists of both a dipole orientation and a free charge migration. Hence, the loss factor is expressed as a linear combination of the contribution of dipole polarization $(\epsilon_r - \epsilon_u)(\epsilon\tau)/(1 + \omega^2\tau^2)$ and the contribution of free charge migration $\sigma/\omega\epsilon_0$. Here, ϵ_r is the relaxed permittivity, ϵ_u is the unrelaxed permittivity, ϵ_0 is the permittivity in vacuum, τ is the relaxation time, and σ is the ionic conductivity defined as $\sigma = \epsilon_0 G/C_0$. The contribution of dipole polarization is negligible when $\omega\tau \ll 1$ at low frequency which is generally less than 1 kHz (22), and then the ionic conductivity can be calculated from the equation $\sigma = \omega\epsilon_0\epsilon''$. The ionic conductivity is convenient for estimating the cure state because it has a strong relationship to the mobility of ions in polymers. The resistance $1/\sigma$ is called the ion viscosity, and the logarithmic value is used also for the estimate. The behavior of the ion viscosity is similar to that of the viscosity before the gel point. Figure 14 shows that the behavior of the log ion viscosity of a graphite/epoxy composite is qualitatively similar

to that of the mechanical viscosity up to the gel point, but the difference increases after the point (23). A comparison of the DOC data from DSC and the dielectric measurement of an epoxy resin is shown in Fig. 15. It is evident that the DOC from the dielectric measurement does not have a linear relationship to that obtained by DSC measurement. The dielectric measurement of polymers is described in detail in the paper by Mijovic et al. (23).

Several new systems, new sensors, and new applications have been proposed in recent years for *in situ* cure monitoring by dielectric sensors. A comparative study of three types of commercial dielectric sensors was conducted (24). It was demonstrated that the dielectric sensors used for monitoring the cure of a polymer coating can monitor the degradation of performance properties during use in acid, at high temperature, and in water (25). This implies the feasibility of using embedded dielectric sensors in both cure and use. The dielectric parameters were measured at a high-frequency range (kHz–MHz) to monitor dipole rotational mobility (25,26). The new parameter was introduced to estimate the DOC from the measured dielectric parameters; the experimental data agreed well with simulation from using an analytical model and

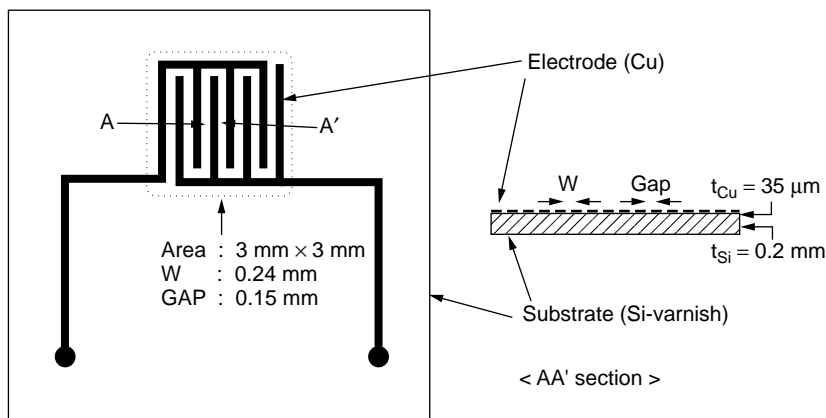

Figure 13. Schematic of a micro dielectric interdigital sensor (21).

Figure 14. Measured resistivity and viscosity as a function of time during the cure of a graphite/epoxy composite (23).

DSC data from the various temperature profiles (21). The Dielectric sensing technique was applied to process monitoring in the SMC/BMC industry and involved cure monitoring and quality assurance/quality control (27). As for the impregnation process in liquid molding, it was shown that the dielectric sensors can be applied to monitoring the impregnation in resin infusion molding (28) and in RTM molding (22,29). The prediction method for the DOC using finite-element analysis from the results of dielectric measurement was also studied (30). Control of a curing process that had a dielectric sensing system was tried by using artificial intelligence (31).

Piezoelectric Sensors for Cure Monitoring

Piezoelectric ceramics wafers have been employed as sensors/actuators for monitoring and controlling structural vibration. Cure monitoring using a piezoelectric wafer actuator/sensor started in 1997. This cure monitoring technique uses the phenomenon that the piezoelectric wafer becomes

constrained by resin in the solidification during cure. Two types of measurement concepts were proposed. One is the measurement of viscosity using a PZT (lead zirconate titanate) laminate that sandwiches two PZT thin films in three insulating tapes (32). Another is the impedance measurement of an equivalent electromechanical circuit composed of a piezoelectric wafer and resin (33). The former has individual PZT sensor and PZT actuator parts, whereas the latter uses a piezoelectric wafer as both sensor and actuator. The former PZT sensor was applied to monitoring the cure of GFRP laminates in autoclave molding (32). The experimental results show that the output curve of the PZT sensor reflects the viscosity qualitatively and that gelation can be monitored.

For impedance measurement, the system composed of a piezoelectric wafer and resin can be modeled by a series of mass–spring–damper systems that comprise equivalent electric circuits (Fig. 16). In the process of curing the resin, changes in the shear modulus (spring) and viscosity (damper) affect the electric response of the piezoelectric wafer. The measurement of electric response in the resonant frequency region is carried out to monitor changes in electric admittance at the resonant frequency and the antiresonant frequency. The increase in the modulus and viscosity of the resin reduces the amplitude of the transfer function, which is the peak-to-peak value. An example of transfer functions of an epoxy resin measured at different curing times is shown in Fig. 17 (34). The temperature influences the capacitance of piezoelectric wafers and consequently, the magnitude of the transfer function. However, the peak-to-peak amplitude of the transfer function is more sensitive to changes in the mechanical properties of

Figure 15. A comparison of the degree of cure from DSC and from dielectric measurements (normalized log resistivity) as a function of time during the cure of an epoxy resin at 200°C (23).

Figure 16. A simplified model of a piezoelectric wafer in a viscous liquid (34).

Figure 17. Transfer functions of a piezoelectric wafer embedded in epoxy taken at different curing times (34).

a liquid-state resin (35). Therefore, the measurement before the gelation of the resin is available. It is found that the resonance peak amplitudes of the transfer function of a piezoelectric wafer have a good relationship to the viscosity of the resin before gelation, whereas the resonant response is suppressed after gelation of the resin. Therefore, this sensor can be used only as an internal temperature sensor after gelation. This technique has the advantage that embedded piezoelectric ceramics can be used in operation as well as in cure. Because the peak-to-peak amplitude of the transfer function changes with respect to the contact area with liquid, it can be used for controlling the impregnation process in liquid molding such as RTM (35).

Ultrasonic Measurement for Cure Monitoring

The monitoring technique using an ultrasonic wave propagating in a material is a traditional nondestructive technique for measuring modulus, density, and viscosity. This technique is also widely used for nondestructive testing of products in inspection. The ultrasonic monitoring technique has been applied to *in situ* cure monitoring of polymers since the late 1980s. This cure monitoring technique is based on measuring the velocity and attenuation of an ultrasonic wave propagating in a viscoelastic and anisotropic material (36). Elastic wave propagation is affected by changes in the modulus, density, and viscosity of a resin in the curing process. In most cases, the size of the reinforcement of a composite is smaller than the wavelength of propagating elastic waves, so that the composite can be treated as homogeneous materials. There are two methods for generating ultrasonic waves in composites during the molding process. One locates ultrasonic transmitters and receivers in or on the mold, and therefore, this configuration has the advantage that internal sensors are not needed (37). Another method uses an acoustic waveguide that propagates an ultrasonic elastic wave (38). The wave velocity, the attenuation, and the reflection factor can be used to estimate the DOC. Sound velocity increases as the elastic modulus of a resin increases from liquid to solid in the curing process, whereas the attenuation decreases by the viscoelastic relaxation and the scattering factor. Sound velocity is convenient for evaluating the DOC because the influence of molding pressure on sound velocity is small.

Figure 18. Longitudinal sound velocity and relative attenuation as a function of processing time of a phenolic-formaldehyde molding compound PF31 (37).

Figure 18 shows an example of measurements of longitudinal sound velocity and relative attenuation in the cure of a thermoset resin (37).

HEALTH MONITORING

Like the human body, structures deteriorate or are damaged in long-term use. The damages are generated by the initial defects, overload, and impacts. Structural performance such as modulus, strength, and damping is degraded by moisture, acid, and high temperature. The damage and the deterioration of structures are significant problems because they often cause catastrophic accidents. However, unlike the human body, the health of structures cannot be recovered automatically. Therefore, periodic inspection is essential to ensure the safe operation of structures. The most common inspection method is visual inspection by human eyes. It involves specimen inspection by microscopy and easier visible inspection techniques such as inspection by using a fluorescent dyestuff. However, damages generated in opaque materials cannot be found by visual inspection techniques. In addition, undetected small damages trigger accidents due to the rapid development of damages that result from their interaction. Nondestructive evaluation (NDE) techniques have been developed to detect internal or invisible damage. Traditional NDE techniques are ultrasonic scan, an eddy current method, X radiography, an acoustic emission method, and passive thermography. These NDE techniques are effective in detecting damages in materials and structures, but it is difficult to use them in operation due to the size and weight of the devices. This means that traditional NDE techniques require field operators and transporters for heavy, large testing machines. Then, the operation must be interrupted during traditional NDE testing. Because these facts increase operating cost, speedy and simple inspection techniques are desired.

Health monitoring is an attractive approach to solving the problems that occur in aged and degraded structures. The damage and performance degradation are checked for maintaining the health of materials and structures. The mechanical, thermal, and chemical states in and around structures provide useful information for predicting the

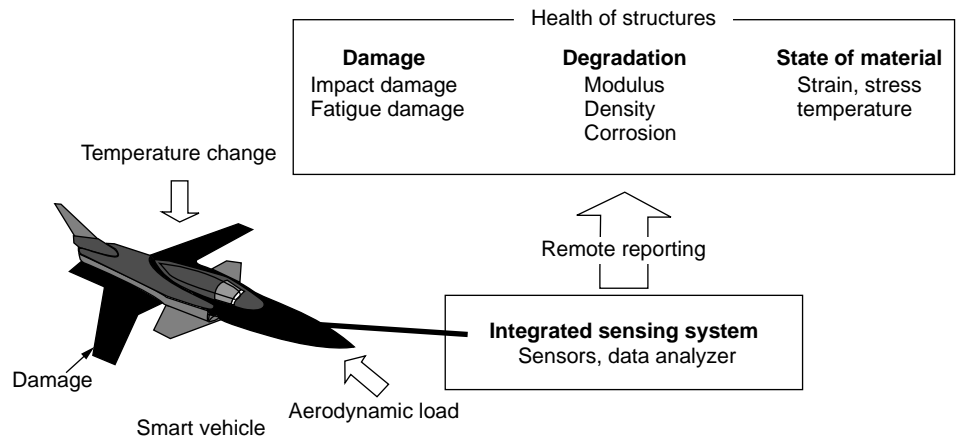

Figure 19. Concept of a smart vehicle that has a health monitoring system.

service life. These values are remotely monitored by a health monitoring automated system in real time. The need for health monitoring has been growing in the fields of aircraft, space structures, and civil structures since the 1980s. The accidents and the growth of maintenance costs of aging structures motivate the need for research into health monitoring systems. The structures located in space or in the deep sea especially require real-time and remote monitoring systems to improving safety and reliability because on-site maintenance sometimes costs more than manufacturing and installing new ones.

Here, we emphasize that the research area of health monitoring in smart materials and structures partially overlaps that of NDE. However, unlike NDE, a health monitoring system is naturally integrated into materials and structures by using small sensors and a powerful data analyzer. Remote monitoring is sometimes essential for practical applications. Figure 19 shows a schematic view of a vehicle that has a health monitoring system. The development of the health monitoring technique has been accelerated by advances in sensor technologies. Advanced computer technology is so powerful for analyzing monitored data in real-time and so small that it can be in a structure. The rapid development of the computer network, "Internet," enables remote monitoring on the www (World Wide Web) using software written in a network-friendly language like JAVA. These advanced technologies comprise an automated health monitoring system that can perform a self-inspection, a self-assurance of safety, and a self-report for the future. Nondestructive damage

detection techniques are employed for self-inspection. Safety assurance can be achieved by monitoring whether the measured values such as strain, load, or temperature go over the safety limit.

In recent years, many sensors and sensing techniques have been developed for health monitoring. Representative sensing techniques are shown in Table 3. They are fiber-optic sensors, piezoelectric sensors, a magnetostrictive tagging technique, and an electrical resistance technique. Fiber-optic sensors and piezoelectric sensors are so small that they are embedded in materials. Fiber-optic sensors are most suited for internal measurement by embedded sensors due to their size, weight, high flexibility and long-term durability. The magnetostrictive tagging technique and the electrical resistance technique do not need any embedded sensors for *in situ* monitoring because the material itself acts as a sensor. These four types of sensing techniques are available for detecting internal damages. Some types of fiber-optic sensors can detect internal damage directly without computational identification. To detect damage, piezoelectric sensors use diagnostic signals, which are generated by impact or actuators. The changes in magnetic and electrical properties of conductive materials such as carbon-reinforced composites reflect the presence and progress of damage. Note that detectable damage modes depend on the kind of sensors, sensing methods, and integrating configurations. Therefore, to select sensors and a sensing technique, it is important to understand the behavior of damage initiation and growth in materials and structures. Piezoelectric sensors can be used for

Table 3. *In Situ* Sensing Techniques for Health Monitoring

	Configuration	Monitored Value	Sensing Area	Cost	Sensor Networking
Fiber-optic sensors	Embed, Attach	Break, strain, vibration, temperature	Around fiber	High	Normal (depends on method)
Piezoelectric sensors	Embed, Attach	Dynamic strain, impedance	Middle-large	Middle	Easy

Table 4. Requirement and Purpose of Health Monitoring System in Engineering Fields

	Requirement	Purpose
Aircraft	Light weight, reliability	To maintain safe operation To reduce maintenance cost
Space structure	Light weight, reliability, insensitivity to electromagnetic field, temperature resistance, radiation resistance	To maintain performance
Civil structure	Long-term durability, chemical resistance, moisture resistance	To reduce maintenance cost

dynamic strain measurement, and magnetostrictive tagging and electrical resistance techniques for static strain measurement. Fiber-optic sensors can be used to measure both static and dynamic strain. Internal temperature can be measured by using fiber-optic sensors. Here, the sensing area of the sensing techniques should be considered. Magnetostrictive tagging and electrical resistance techniques provide large sensing areas. Size of popular piezoelectric sensors for health monitoring is several centimeters. Fiber-optic sensors have various gauge lengths according to the kind of sensor, but the sensing area is limited to the neighborhood of the optical fiber.

Applied studies of health monitoring techniques concentrate on aircraft, space structures, and civil structures. These fields have individual purposes for health monitoring systems, as shown in Table 4. The increase of aging aircraft motivates the development of health monitoring systems for aircraft to maintain safety and provide quick, low-cost maintenance. In the field of civil engineering, a health monitoring system is expected to reduce maintenance cost, which grows as large civil structures increase. The health monitoring of spacecraft is an approach to compensate for performance when the craft is damaged. As shown in Table 4, the requirements of the sensing techniques are different for each of the applied fields. Aircraft and space structures require lightweight sensors and measurement systems because of the additional weight introducing by the sensing system, which increases operating cost. A health monitoring system for aircraft and space

structures must be reliable because these engineering fields are conservative. The sensing techniques used for space structures must be insensitive to electromagnetic fields, temperature, and radiation. For civil structures, long-term durability, chemical resistance, and moisture resistance are required because of the long lifetimes of the structures.

In this section on health monitoring, four types of sensing techniques are described from the viewpoint of sensor technology. In additions, the application of health monitoring techniques to aircraft, space structures, and civil structures are also described.

Fiber-Optic Sensors for Health Monitoring

Fiber-optic sensors are the sensors most promising for monitoring the internal state of materials. Early studies of health monitoring of composites by using optical fibers can be seen in papers published in the 1980s (39–42). The simple sensing method in these studies was based on an optical power loss by a break in an optical fiber. The quantitative monitoring of internal strain and temperature using embedded fiber-optic sensors started in the early 1990s. There are many kinds of fiber-optic sensors for *in situ* health monitoring, including intensity-based sensors, interferometric sensors, polarimetric sensors, EFPI sensors, FBG sensors, long-period grating based (LPG) sensors, Raman scattering sensors, and Brillouin scattering sensors, as shown in Table 5. The sensors, except for Raman scattering

Table 5. Fiber-Optic Sensors for *In Situ* Health Monitoring

	Monitored Value	Multiplexing/ Distributing	Gauge Length	Sensor Cost	System Cost

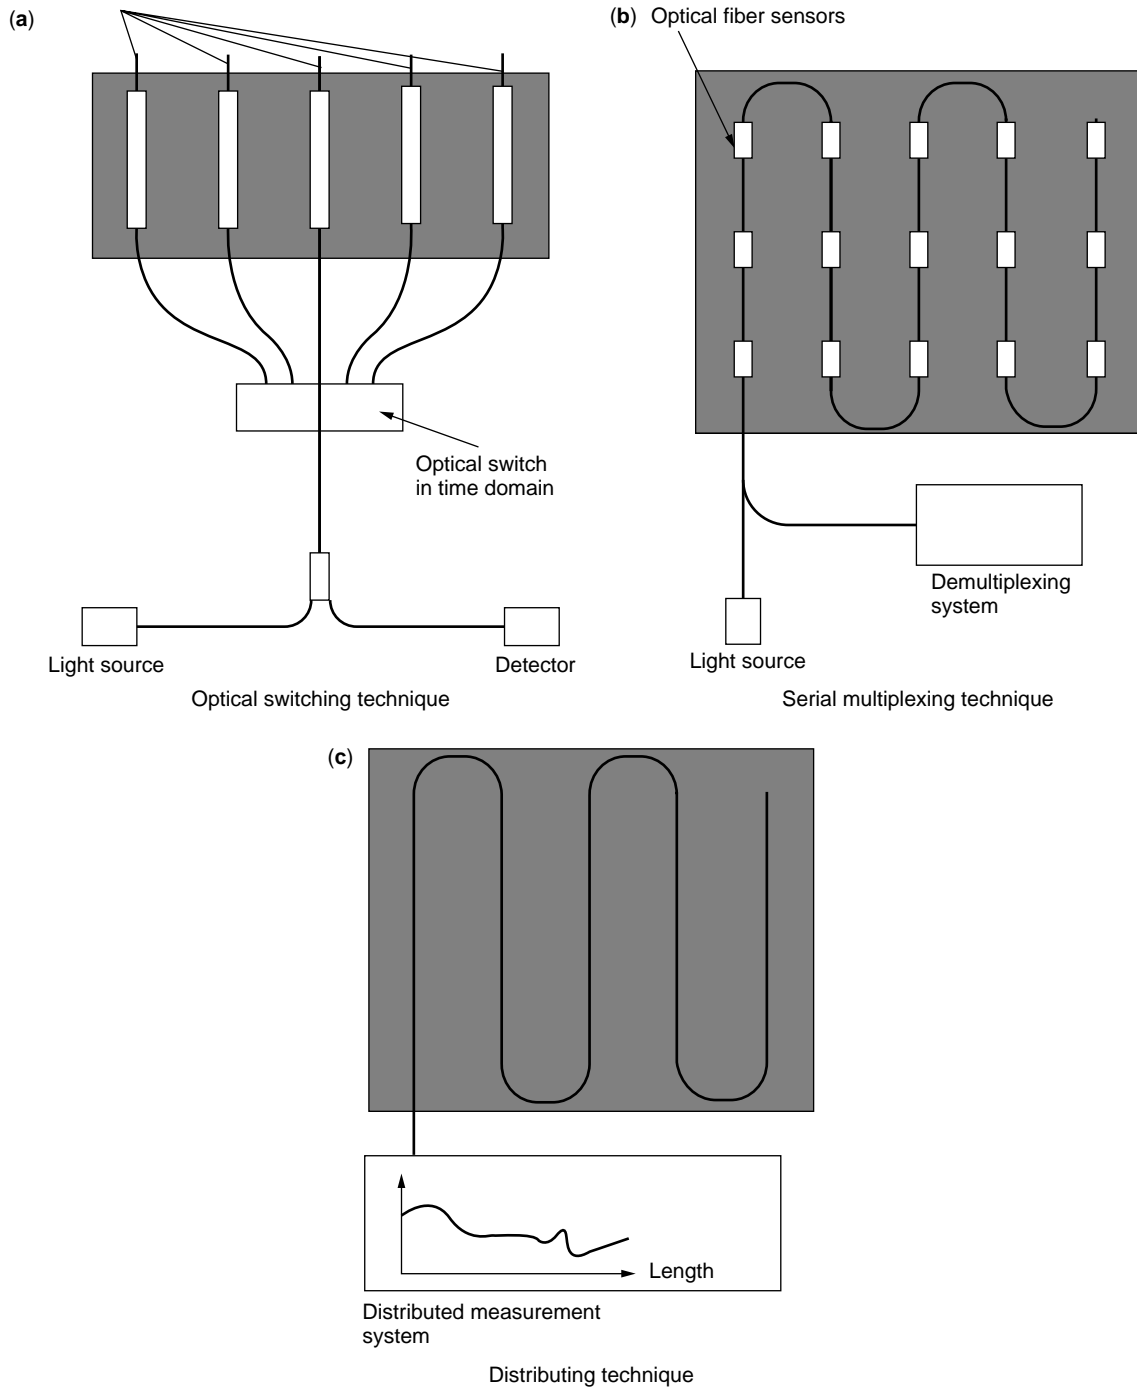

Figure 20. Configurations of distributing and multiplexing techniques.

sensors, can measure the static strain. It is difficult to apply sensing systems in the frequency domain such as absolute EFPI sensors, FBG sensors, LPG sensors, and Brillouin scattering sensors to measuring high-speed vibration. Most of the sensors can also measure temperature because the reflective index is sensitive to temperature. The distributing or multiplexing techniques for fiber-optic sensors are key techniques in making a health monitoring system practical. Three configurations, optical switching (parallel multiplexing), serial multiplexing, and

distributing, are available, as shown in Fig. 20. The optical switching system is the common method of measurement that uses multiple fiber-optic sensors, but the system is not ideal due to the low switching speed, (Fig. 20a). The serial multiplexing technique is ideal for short-gauge sensors such as intensity-based strain sensors, EFPI sensors, and FBG sensors (Fig. 20b). The total weight and cost of a serial multiplexed fiber-optic sensor system can be reduced compared to that of a system using optical switching devices due to the simple configuration and the short length

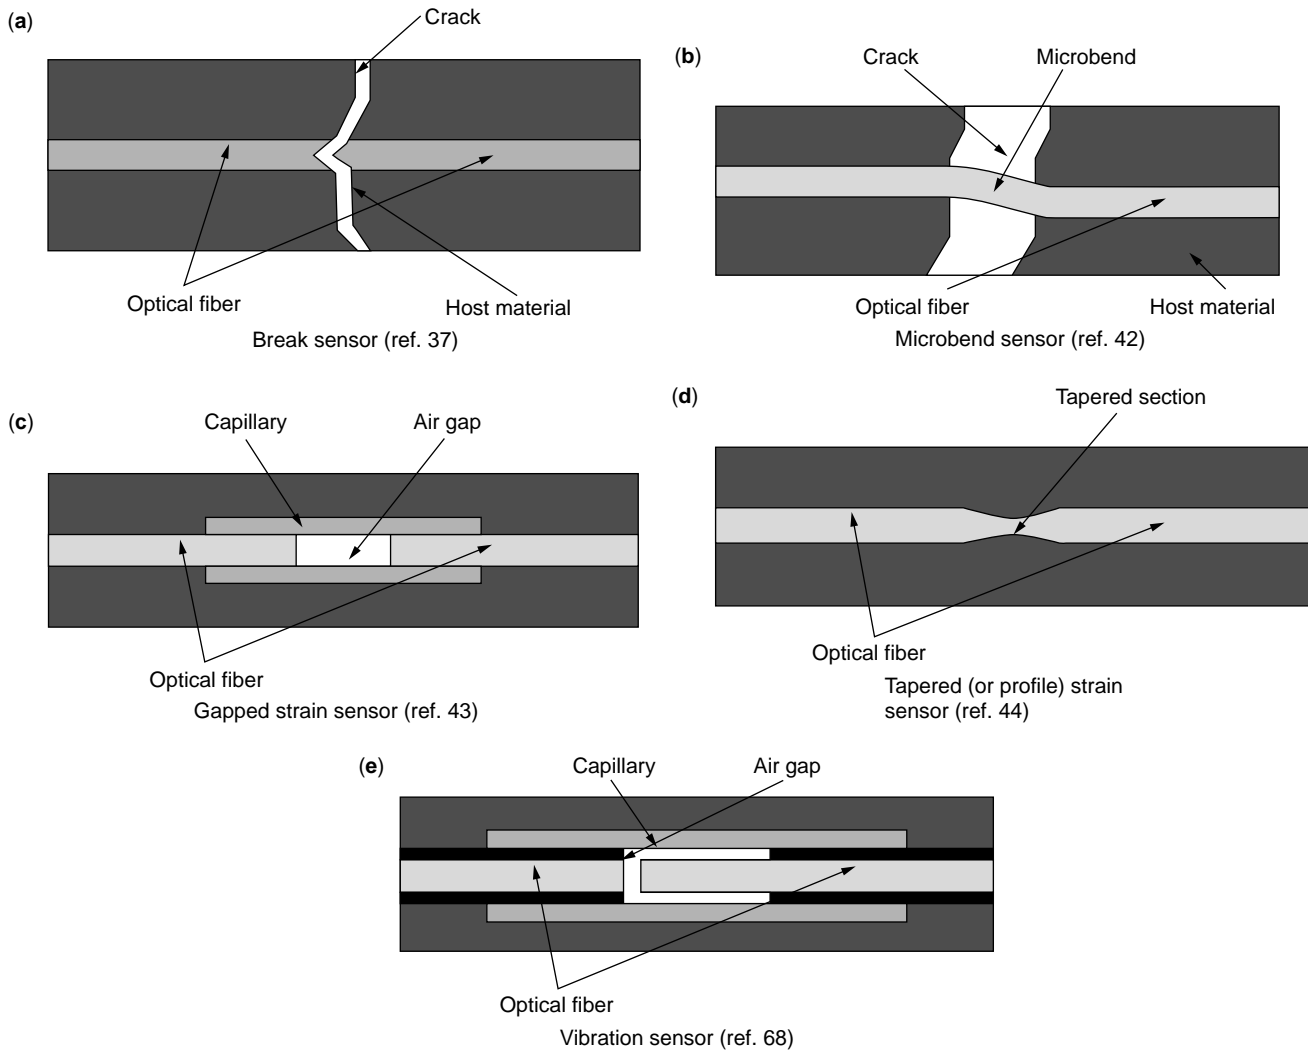

Figure 21. Configurations of intensity-based fiber-optic sensors.

of the optical fibers. EFPI sensors that measure the change in the cavity length in the frequency domain by using a broadband light source can be multiplexed in a single optical fiber (43). FBG sensors can also be easily multiplexed in a single fiber due to the frequency domain measurement. The number of FBG sensors in a single fiber is limited by the strain range and the dynamic range of the wavelength-scanning device. Intensity-based sensors can be multiplexed by an optical time domain reflectometer (OTDR). OTDR is a popular distribution sensing technique along a single fiber, as shown in Fig. 20c; it consists of a short-pulse laser and a high-speed detector. It scans the location of the reflection through a single fiber in the time domain. Because the OTDR is a reflectometer, any kind of reflected or back-scattered light can be detected. However, note that the resolution of OTDR depends on the pulse width that is from several hundred millimeters to several meters. Raman scattering sensors and Brillouin scattering sensors are generally used with an OTDR. Interferometric fiber-optic sensors and polarimetric fiber-optic sensors can be multiplexed by optical switching devices. Brief explanations of these sensors and sensing systems follow.

Intensity-based sensors are based on measuring the optical intensity of reflected or transmitted light. The sensing system is very simple and cheap due to the low cost of the fibers and devices; however, it becomes unstable when the guide section of the optical fiber is subject to an excessive bend. It consists of a cheap laser-emitting diode (LED) source, a cheap photodetector (PD), and a silica or plastic optical fiber used in communication. Intensity-based fiber-optic sensors have several configurations for measuring values, as shown in Fig. 21. Intensity-based break sensors and microbend sensors have no special sensing section, they are based on measuring optical power loss (39–42). The break sensor can detect damages that cut the optical fiber (Fig. 21a). They were investigated for detecting cracks in composites early in the development of health monitoring techniques that used optical fibers. Figure 22 shows that the transmission power rapidly drops when the optical fiber is fractured by impact (42). The local deformation of the optical fiber can be monitored by microbend sensors (Fig. 21b). Figure 23 shows that the optical power loss increases when the fiber is subject to a microbend by the crack opening (44). Intensity-based strain sensors have

Figure 22. Transmission drop of optical fibers embedded in Kevlar/epoxy following impacts of various energies (42).

two configurations; gapped-type (Fig. 21c) and tapered-type (Fig. 21d). The gapped-type sensor is based on the optical power loss in air using broadband light sources (45).

The tapered-type sensor has a tapered-shape in the sensing part, from which some light leaks (46,47). Figure 24 shows that the output of the tapered-type sensor has a linear relationship to the strains (46). Interferometric fiber-optic sensors and polarimetric fiber-optic sensors are fundamental sensing methods that use optical fibers. In most cases, these sensors are not suitable for distributed measurement of internal values due to the long gauge length and the difficulty of multiplexing. Some applications that use interferometric and polarimetric fiber-optic sensors have been reported (48–50). The sensing methods that use EFPI and FBG sensors are described in the previous section on cure monitoring. The EFPI sensor is one of the interferometric fiber-optic sensors, but the most important difference is that it has a short sensing section in a single fiber. The FBG sensor is most promising for *in situ* strain and temperature measurement due to its strength, flexibility, and easy multiplexing. A number of demodulation systems for multiplexed FBG sensor systems are shown in the review paper by Rao (51). There are many applications of FBG sensors to concrete structures (52,53) and composite structures (54–56). Like an FBG sensor, a LPG sensor

Figure 23. Signal loss vs. crack opening obtained from the crack simulator specimen (44).

Figure 24. Relative output optical power vs. microstrains measured by resistive gauge for two different tapers of 52 and 22 μm waist diameters (46).

has a grating in the fiber core, but its period is much longer than that of an FBG sensor. As a forward-propagating mode in core is combined with several cladding modes in a LPG, the several valleys can be measured in the spectrum of transmitted broadband light, as shown in Fig. 25 (52). Because the wavelength shifts of the valleys have respective sensitivities to strain and temperature, the strain and temperature can be separated by selecting proper valleys (57). The LPG sensor can be used as a chemical sensor for corrosion monitoring because it is sensitive to changes in the refractive index of the fiber cladding (58). A Raman scattering OTDR (ROTDR) can measure temperature distribution from the frequency peak shift of the Raman back-scattered light (59). Like a ROTDR, a Brillouin scattering OTDR (BOTDR) uses the frequency peak shift of the back-scattered light, whereas the BOTDR can measure both

Figure 25. Transmission spectrum of a LPG whose period is 198 μm (52).

Figure 26. BOTDR waveforms along a fiber (60).

strain and temperature (60,61). Figure 26 shows waveforms measured by a BOTDR along a fiber (60). Strain was measured using a BOTDR that had a spatial resolution of 400 mm and a strain precision of 50 microstrains (61).

As described in the section on cure monitoring, fiber-optic strain sensors are sensitive to temperature. Therefore, temperature compensation is necessary to retain the precision of strain measurements if they are used in an environment that has large temperature variation such as space. The strain measured by an EFPI sensor is stable in a normal environment of small temperature variation due to its low temperature sensitivity. The LPG sensor can simultaneously sense strain and temperature (57). For other types of sensors, the simultaneous sensing technique is required if they are used in normal environments. The FBG sensor and the BOTDR sensor are sensitive to both strain and temperature like the EFPI sensor, but their temperature sensitivities are much larger than that of the EFPI sensor. Therefore, the simultaneous measuring strain and temperature is a major topic for the FBG sensor and the BOTDR sensor. One idea for simultaneous measurement uses several wavelengths reflected from a single sensor. Dual FBGs in a polarization maintaining (PM) fiber can simultaneously measure three-axis strains and temperature from four Bragg wavelengths (62). The FBG sensor using the first and the second diffractions can also be used for simultaneous measuring of strain and temperature from two Bragg wavelengths (63). The simultaneous measurement of strain and temperature by a BOTDR using a PM fiber has been demonstrated (64). Another idea is based on a combination of more than two types of strain/temperature sensors. The strain and temperature in composites were simultaneously measured by a combination of an EFPI sensor and an intrinsic rare-earth doped fiber (65). The FBG/EFPI combined sensor has been proposed for simultaneously monitoring strain and temperature (56). The idea of a combination sensor can be applied to the development of a multifunctional fiber-optic sensor. A multi-functional sensor that combines an FBG temperature sensor and an NIRS-based sensor for simultaneously monitoring both temperature and chemical cure was proposed (20).

Damage detection is one of the main purposes of health monitoring. The damage area and location can be

estimated analytically from the strain distribution measured by strain sensors. However, some types of fiber-optic sensors have the potential for directly detecting damages, which means that changes in signals directly indicate damage initiation and development without an analytical identification. These sensors must be placed near the damaged region because the sensing area of the fiber-optic sensors is limited to the neighborhood. Intensity-based break and microbend sensors can directly detect damage. The disadvantage of the break sensor is the difficulty of quantitatively measuring the damage mode, area, and location. Furthermore, the break sensor can detect only a few initial cracks (42,66). However, this concept is effective on irreparable parts such as composite parts of aircraft, and the sensing function of the fiber break is a final function of all types of fiber-optic sensors. The microbend sensor can detect cracks, which deform locally but do not break the fiber (44). Break or microbend sensors are available as distributed sensors combined with an OTDR technique to monitor the locations of damages (67,68). The FBG sensor can directly detect cracks by monitoring the optical spectral shape of reflected light, which is affected by the strain concentration at the crack tip. The spectral shape of reflected light is distorted when a nonuniform strain distribution occurs in the FBG sensing part. Studies of qualitative monitoring of strain concentration at a crack tip in a notched specimen (69) and at transverse cracks in a cross-ply laminate (54) were reported.

The location, size, and energy of impact damage applied to materials can be detected by fiber-optic vibrational sensors. Because high-speed measurement in the kilohertz to megahertz range is required for vibrational sensing, intensity-based sensors or interferometric sensors can be used for the purpose. Structural vibrational behavior measured by distributed fiber-optic vibrational sensors can be used to monitor the damages or the degradation of performance from changes in frequency responses. Ultrasonic waves from an impact can be caught by vibrational sensors to identify the location and energy of the impact. There are two concepts for vibrational sensors. One is based on dynamic strain measurement, and the other on the frequency property without a strain conversion. The latter is specialized for measuring the frequency property, as shown in Fig. 21e. An intensity-based vibrational sensor was proposed for detecting impact (6,70). For examples of dynamic strain measurement, impact damage detection in filament wound (FW) tubes using embedded intensity-based strain sensors was reported (47). An analytical model of wave propagation in a composite material was used to identify the damage from the responses of intensity-based fiber-optic vibrational sensors by neural network methods (70).

Piezoelectric Sensors for Health Monitoring

The use of piezoelectric elements in smart materials and structures has been studied since the 1980s. The research at this early stage was focused on the application to adaptive structures, which can control their properties of vibration, damping, and modal frequency. In these cases, the piezoelectric elements were used principally as actuators

Figure 27. Configurations of piezoelectric elements for health monitoring.

and sensors in the control system. The application of piezoelectric elements to health monitoring started in the early 1990s. It is well known that the piezoelectric elements have a wider dynamic range than resistive strain gauges. Therefore, they are applied to health monitoring that uses the high-frequency range. It is a great advantage that a piezoelectric element can act as an actuator because the health monitoring technique using piezoelectric actuators and sensors can be used to detect tensile or fatigue damage as well as impact damage. Piezoelectric thin films such as polyvinylidene fluoride (PVDF) and PZT can be integrated in materials and structures due to their small size. PZT has better transmission efficiency and higher sensitivity than PVDF, but a PVDF thin film can be formed into any desired shape to be attached to the surface of complex structures due to its low stiffness and high flexibility (71). In most cases, piezoelectric sensors are distributed to monitor the overall region of materials and structures. Health monitoring by piezoelectric elements can be classified into structural vibrational monitoring, impact

damage monitoring, internal damage detection by diagnostic signals, structural impedance monitoring, and internal damage monitoring by Lamb wave, as shown in Fig. 27. The use of PVDF thin film for crack growth monitoring at low frequency was reported as an other interesting monitoring technique using piezoelectric elements (72).

Information on mode shapes and modal frequencies obtained from structural vibration properties can be used to evaluate structural health such as damage and performance degradation in structural vibrational monitoring, (Fig. 27a). A huge number of analytical models for evaluation from dynamic responses have been proposed. In passive health monitoring using modal analysis, piezoelectric elements are employed as a dynamic strain sensor substituting for a resistive strain gauge (71). This technique is aimed mainly at monitoring the health of large structures. Active health monitoring using actuators is more attractive for damage detection in materials because it is available without external vibration. Techniques for detecting

Figure 28. Piezosignals of elastic and injurious impacts (75).

delamination in composite materials using active health monitoring have been proposed (73,74).

For impact monitoring, impact damage, location, and energy can be evaluated by distributed piezoelectric elements, which catch the impacting signals transmitted in a material (Fig. 27b) (75–78). High-speed measurement by fiber-optic sensors is also available for impact monitoring. Figure 28 shows impacting, which is caught by a piezoelectric transducer bonded to a specimen. The signal from injurious impact involves a high-frequency signal generated by delamination (75). The identification of impact damage, location, and energy from the outputs of the distributed sensors is complicated because the process is a nonlinear and inverse problem. Therefore, a numerical identification technique is essential. A numerical code was developed and demonstrated for impact detection on a plate using piezoelectric sensors (79). Recently, an active sensing method, which uses a piezoelectric transducer as a transmitter and receiver, was proposed for internal damage detection (Fig. 27c) (79). The sensor configuration of the method is almost the same as that of the passive sensing method. The active sensing method has the advantage that it can detect damage without impact signals, that is, it is feasible to monitor the integrity generated by overload or fatigue as well as impact damage at any time. It was shown that the extent of impact damage could be predicted from the phase delay in transmitted diagnostic waves (Fig. 29; 79).

The impedance-based monitoring method using a piezoelectric transducer is based on measuring the coupled electromechanical impedance of a piezoelectric patch (80). The piezoelectric transducer and a host structure comprise an equivalent electric circuit (Fig. 27d). Therefore,

degradation of the structural performance is reflected in the impedance of the circuit. The admittance curves of a damaged experimental bridge joint were measured by an attached PZT, and the results represented the feasibility of qualitatively monitoring the damages in the range of the structural interactive frequency (80).

Some types of piezoelectric actuators/sensors are designed to generate and detect Lamb waves propagating through thin plates (Fig. 27e; 81–84). The Lamb wave has the capability of long-distance propagation and detecting internal damages such as delaminations of composite laminates. This technique is based on ultrasonic measurement, which is one of the traditional NDE techniques.

Figure 29. The relationship between impact damage size and phase delay in transmitted diagnostic waves measured by a piezosensor (79).

Figure 30. Measured signals from Lamb waves in the pulse-echo mode on an aluminum plate. (a) no defect; (b) defect; (c) defect position (83).

Miniaturized bonded PZT transducers were developed to produce Lamb waves (81,84). Interdigital PVDF transducers attached to a thin plate were investigated for generating Lamb waves (83). An embeddable PZT transducer was proposed for exciting Lamb waves in a composite plate (82). The experimental results for burst mode measurement of Lamb waves transmitted in a damaged composite laminate showed that attenuation changes in the damaged region (81). The pulse-echo mode of measurement, it was demonstrated, detects the reflection in the damaged region (Fig. 30; 83).

Magnetostrictive/Ferromagnetic Tagged Composites

Figure 31 illustrates a tagging technique that places functional material tags into the matrix of composites (85). The tag is small (mostly less than a micrometer) and has the shape of a particle or whisker. Mechanical properties of tagged composites are almost same as those of host materials due to their low volume fraction (mostly less than 10%). Magnetostrictive or ferromagnetic tagging techniques add a magnetic function to nonmagnetic composites. Magnetostrictive or ferromagnetic composites that have a high percentage have been developed since the early

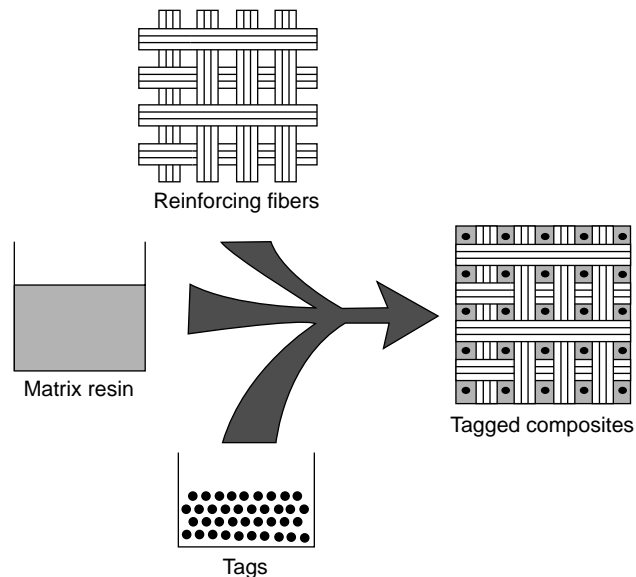

Figure 31. Concept of tagged composites (85).

1990s as actuators to improve the performance of magnetostrictive materials or to add an actuator function to polymers (86,87). This tagging technique has been used for monitoring the strain and internal damage in PMCs since the middle 1990s. Tagged composites have self-monitoring functions, so that embedded sensors in the materials are not necessary for *in situ* health monitoring.

A Terfenol-D magnetostrictive alloy particle (3–5 μm) is a representative magnetostrictive tag (87,88). The monitoring technique is based on the magnetostrictive effect, and therefore, the magnetic flux produced by the loaded material is measured to monitor the load or damage. The magnetic flux can be measured by magnetic probes such as a gauss meter probe or a Hall effect device (88). The transverse flux density produced is much larger than the axial flux density. It was reported that the magnetic flux has a nonlinear but monotonic relationship to the applied stress and the loading and unloading curves have a hysteretic loop (85). Figure 32 shows that the stress concentration around a hole affects the magnetic flux density.

Ferromagnetic elements such as nickel oxide (NiO), zinc oxide (ZnO), and ferrite (Fe_2O_3) are often employed in powder form (submicron–20 μm) (89). Health monitoring of ferromagnetic tagged composites is based on eddy current testing or the ferromagnetic effect. Eddy current testing is a traditional nondestructive technique for conductive materials. Therefore, carbon-reinforced composites do not need the tags for the test due to the electric conductivity of the carbon. Nonconductive PMCs such as glass-fiber-reinforced plastics (GFRPs) become conductive materials by tagging with ferromagnetic particles (or other conductive elements such as ferroelectric particles). It has been reported that eddy current testing was not so effective for monitoring internal damages (89). The ferromagnetic effect is a phenomenon whereby strain is generated in a ferromagnetic material when a magnetic field is applied. The ferromagnetic tagged composite vibrates in a periodic

Figure 32. Axial magnetic flux readings for a through-hole specimen loaded in tension (85).

magnetic field. This means that the ferromagnetic tagged composite is used as the actuator itself to monitor damages from changes in the vibrational properties. It was reported that the frequency response is sensitive to cracks in/on the materials (89).

Electrical Resistance Measurement in Carbon-Reinforced Composites

The technique for health monitoring by measuring electrical resistance has become attractive since the late 1980s for carbon-reinforced composites (90). This technique measures changes in electrical resistance when strains or damages are applied to the composites. Like the tagging technique, the advantage of this technique is that there is no need for embedded sensors for *in situ* monitoring. In addition, the mechanical properties of the composites are not affected by using this monitoring technique because the carbon reinforcements work as sensors. Recently, applications have focused on three types of composites; carbon-fiber-reinforced concrete, carbon-fiber-reinforced polymers (CFRPs), and carbon fiber-carbon matrix (C/C) composites (91). The self-monitoring functions of carbon-reinforced composites are aimed at strain and damage monitoring. These functions result from changes in the electrical paths and in the conductivity of carbons. Figure 33 shows the electrical paths of these three types of composites. Short carbon-fiber-reinforced concrete consists of low conductive concrete and carbon fibers at a low volume fraction. In continuous carbon-reinforced polymers, the electrical paths

Figure 33. Electrical paths of current flowing through carbon-reinforced composites.

are composed of the carbon fibers due to the nonconductivity of polymers. A current flows overall in the C/C composite because it has conductivity in the fiber and matrix. The electrical paths in the composites are changed by damages such as fiber breaks, delaminations, matrix cracks, and debonding between the fiber and matrix. The mechanism of the variation of electrical resistance differs among these composites due to their different electrical paths.

The short carbon-fiber-reinforced concrete, which has high strength, high ductility, and low drying shrinkage, was developed for civil structures (91). Because the concrete matrix has low conductivity, contact between adjacent fibers is not essential in forming an electrical path (Fig. 33a). This means that composites that have a low volume fraction of carbon (less than 0.2 vol.%) have enough conductivity to monitor electric resistance (91). The effect can be seen in cement and mortar as well as in concrete. The electric resistance is reversibly proportional to the strain of the material, as shown in Fig. 34. This reversible and linear effect of the strain is driven by the variation in contact electrical resistivity between the fiber and the matrix (92). The figure shows the difference of the behavior in the first loading cycle due to matrix cracks and debonding between the fiber and matrix. After the first loading cycle, the fiber pull-out during loading and fiber push-in during unloading change the electrical resistance reversibly. The damage also affects the electric resistance, but the sensitivity to damage is less than that to strain sensing (92).

In unidirectional CFRPs, the carbon fibers comprise a complicated electrical network because neighboring fibers contact each other and the polymer matrix has no conductivity, as shown in Fig. 33b (93–96). The current flows along the fiber reinforcements in the longitudinal direction, and in the transverse direction through the contact area of the fibers. Therefore, unidirectional CFRPs have orthotropic electric conductivity. CFRPs without damages have the capability of reversible strain sensing due to variation of the conductivity of carbon fibers, and the residual strain that results from the alignment of carbon fibers can be observed in the first loading cycle. The electric paths change when damages such as fiber breaks, matrix cracks, and delamination occur under mechanical loading, as shown in Fig. 35 (93–95). Therefore, the electric resistance of CFRP laminates is sensitive to damages as well as strains. The breakage of carbon fiber is a principal damage mode that strongly affects the electric resistance of CFRP laminates. Figure 36 shows that the electrical resistance increases as fiber breakage grows (96). The residual resistance after unloading can be seen in the figure. This means that the history of damages can be recorded in the electrical resistance of CFRPs (97). This fact is very important for monitoring fatigue damage because fiber breakage occurs in a large number of loading cycles in the range of operational strain. Delamination in non-unidirectional CFRP laminates can be also detected by measuring the electrical resistivity due to the change in the electrical path in the transverse direction (95). Figure 37 shows that the delamination extent strongly affects the electrical resistance of CFRP cross-ply laminates.

Figure 34. Changes in resistance, strain and stress during cyclic tensile loading of cement paste with ozone treated carbon fibers (91).

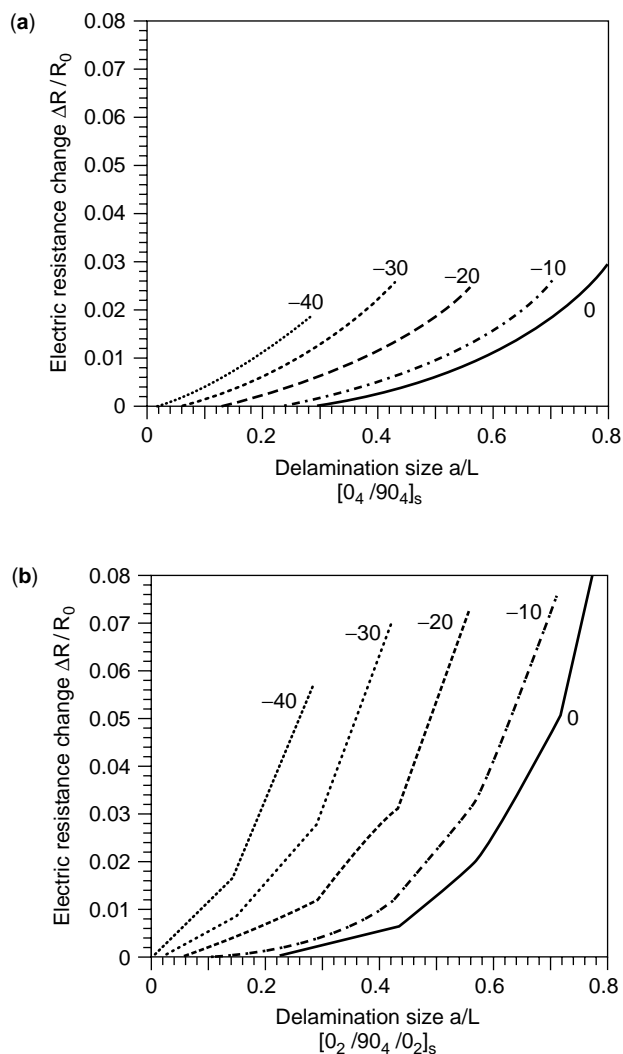

Figure 37. Relation between delamination extent and electric resistance of CFRP laminate. Numbers in the figures indicate the positions of delamination (95).

C/C composites are used for aerospace structures that operate at high temperature due to the high-temperature resistance of carbon. C/C composites are brittle and porous, and thus matrix cracks are easily generated under tension. Conventionally, monitoring the damage of C/C composites has been tried by using an acoustic emission technique. However, the wave propagation behavior in a C/C composite is very complicated, and attenuation of high-frequency waves is largely due to the porous matrix. Therefore, the electric resistance measurement is an effective technique for monitoring damages in C/C composites. Because they consist of continuous carbon fibers and a carbon matrix, a current flows overall through the composites (Fig. 33c). C/C composites have self-monitoring functions for strains and damages like CFRPs. The principal damage mode of C/C composites is a matrix crack, which affects the electrical resistance due to the conductivity of the carbon matrix. The electrical resistance of C/C composites is more sensitive to fatigue damage than that of CFRP laminates. Figure 38 shows that the electric resistance of a C/C woven composite increases nonlinearly under small strains due to generation of matrix cracks during a static tensile test (91).

Health Monitoring of Aircraft and Space Structures

On 28 April 1988, Aloha Airlines Boeing 737-200 cruising at 24,000 ft. over Hawaii suddenly lost an entire upper fuselage section. This accident resulted from fatigue damage, and then the health of aging aircraft that have undergone a high number of takeoff and landing cycles has been focused (98–100). A large number of flights degrades the structural performance of aircraft by mechanical and thermal fatigue and corrosion. Increases in aging aircraft in recent years and accidents caused by fatigue damage have become a serious problem of aircraft service (101). Two concepts have been applied to aircraft design to prevent accidents from fatigue damage. One is a fail-safe design, and the other is a damage tolerance design. The Fail-safe concept certifies the safe operation of an undamaged aircraft

Figure 39. Concept of smart airplanes that have sensors (99).

under a limit load, and the damage tolerance concept aims at the survivability of a damaged aircraft under a limit load until the next inspection. In the latter concept, damages must be detected until they grow to a dangerous size at inspection. Multiple small damages, which are difficult to detect in periodic inspections, sometimes rapidly develop to large size damages because they combine, or they degrade damage tolerance due to their interaction (101,102). Therefore, structural inspection (overhaul) of aircraft must be performed to maintain the safety and reliability of aircraft. NDE techniques have been developed and employed to detect invisible damages during structural inspection. However, the cost of these inspections and repairs is very high because the overhaul require the airplane to be out of service. Such a time-consuming inspection is especially a problem for military aircraft. From this background, a new concept in the design of aircraft, called health monitoring aircraft, has emerged from the technology of smart materials and structures (99). Figure 39 shows the concept of smart airplanes that have sensors. Under the concept of health monitoring aircraft, an aircraft has a self-monitoring function provided by an integrated sensing system in the airframe and engines.

Recently, *in situ* sensor technologies for composites have been instituted by researchers in aerospace engineering because composite members used in aircraft are increasing due to the need for lightweight aircraft. Many types of composites, glass-fiber-reinforced polymers (GFRPs), CFRPs, and ceramic matrix composites (CMCs) are being considered as composite members of aircraft. CFRPs are promising as structural materials such as the frames and skins of the body or wings of the next generation because CFRPs have high specific stiffness, high specific strength, and high durability. However, the CFRP structural members that have invisible damages can cause tragic accidents due to their brittle behaviors of failure. Therefore, many demonstrations, in which health monitoring techniques are applied to composite aircraft frames, panels or wings,

have been conducted. Some applications of intensity-based fiber-optic sensor arrays, which were embedded in CFRP airframe skins, were proposed in the late 1980s (39–41). Recently, multiplexed or distributed fiber optic sensors have been applied to airframe components in laboratory studies. These sensors embedded in CFRP components can be used for monitoring strain, temperature, delaminations, transverse cracks, and impact (43,45,51,54,69,70). Piezoelectric sensors have been also employed for monitoring the health of CFRP components of aircraft, especially to detect impact damages such as delamination (73,74,77–79). For example, damage to an F/A-18 horizontal stabilizer was monitored by measuring the vibrational response using piezoelectric sensors, as shown in Fig. 40 (71). The impact damage in a large CFRP panel was detected by using embedded piezoelectric sensors (79). Electric resistance measurement of CFRP is a cost-effective approach to monitoring internal damages. However, these techniques are actually applied to small specimens. The health monitoring

Figure 40. Damage monitoring of an F/A-18 horizontal stabilizer using a piezoelectric sensor (71).

Figure 41. Concept of a smart bridge that has a health monitoring system.

techniques, which are proposed using smart materials and structures, have not yet been employed in actual aircraft, but experimental field tests are currently ongoing.

For space structures, degraded structures present different problems versus aircraft. The performance of space structures can be degraded by mechanical and thermal fatigue and damage by space debris. To compensate for errors in performance such as observation, monitoring, and communication, measurements of strain, deformation, temperature, and vibration are desired (103). Damage monitoring of orbital spacecraft will be required to monitor damage type, location, and size and to specify a repair method when a low-cost launch is realized in the future. The sensors for spacecraft require light weight; long-term durability to mechanical, thermal and radioactive fatigue; and immunity to electromagnetic interference. Therefore, the most suitable sensor is a fiber-optic sensor. Most of the fiber-optic sensing techniques for CFRP components can be applied to space structures, but smaller, lighter sensing devices are desired. The measurement of strain distribution in a composite plate element of a satellite and its antenna reflectors was demonstrated by using a multiplexed FBG sensor system (103).

Health Monitoring of Civil Structures

Civil structures such as bridges, highways, roads, large buildings, tunnels, and dams need periodic inspections because they deteriorate from fatigue, corrosion, and natural disasters such as earthquakes and typhoons. The number of civil structures is increasing, and therefore, the maintenance cost of civil structures, including inspection, repair, and renewal is increasing (104). The traditional inspection methods are visual and acoustic inspections by human operators, which are obviously inefficient methods for large structures. Therefore, low-cost, highly reliable inspection methods are desired in the field of civil engineering. Based on this background, health monitoring technology becomes an attractive approach for civil structures.

In Japan, the Kobe earthquake in 1995 accelerated the development of practical applications of health monitoring to civil structures (59). The key technologies for health monitoring of civil structures are long-lived distributed sensors, analytical modeling of structural behavior, and a remote monitoring system through a worldwide network, as shown in Fig. 41. Long-term survivability and distributed sensing are essential in civil structures due to their long-term continuous operation. In addition, it is important that the sensor system can be handled easily by workers or operators in construction areas. The structural materials of civil structures are steel, concrete, cement, mortar, and carbon-fiber-reinforced composites. Recently, CFRP composites were employed as structural members and wires. CFRP repair sheets were the most promising solution for repair of damaged concrete shoring and walls. Therefore, some of the health monitoring techniques used for CFRP composites can also be available for CFRP structures in civil structures.

A major monitoring technique, which is employed in health monitoring of civil structure, is a structural dynamic-based system. The structural dynamic-based system is an analytical approach to monitoring the damage and performance degradation of large structures by measuring the dynamic response. In this method, distributed sensor patches attached to the members of structures provide vibrational response such as mode shapes and modal frequency. Piezoelectric patches and fiber-optic vibrational sensors can be used for measuring the dynamic response. Optimizing the location of the sensors is important for the system to be cost-effective because the operating cost of health monitoring depends on the number of sensors (105). There are various techniques for damage identification for a structural dynamic-based system. They use a modal analysis technique that has a structural model or finite-element analysis (104), a neural network technique (106), etc.

Fiber-optic sensor-based health monitoring is an attractive idea for civil engineering because of its high durability, high strength, high sensitivity, nonperturbation by

electromagnetic interference, and ability to be embedded internally (49). However, because an optical fiber is fragile, easy installation of the fiber is required in construction areas. Furthermore, embedded fiber-optic sensors require modification to protect them from cracks that propagate in concrete or composites because the members of civil structures are difficult to replace when the sensor is broken. Some applied examples of the health monitoring of concrete and composite structures that use fiber-optic sensors are described following. Distributed or multiplexed fiber-optic sensors such as BOTDR, ROTDR, a multiplexed FBG sensor system, and a long-gauge fiber-optic sensor system (intensiometric and interferometric) have been employed for monitoring strain distribution and detecting damages in civil structures. It was proposed that ROTDR could be used for permanent monitoring of the soil temperature of an in-ground tank (59). FBG strain sensors, polarimetric extension sensors, and OTDR crack sensors were employed to monitor local strain change, 2.5 m long-gauge displacement, and crack generation and location in a full-scale destructive bridge test (107). The strain on a CFRP cable of a stay cable bridge in Winterthur, Switzerland, was monitored by using multiple FBG sensors (108). Intensity-based fiber-optic sensors were used to monitor the failure of concrete in the Stafford Medical Building in Vermont, U.S.A. (109). Structural monitoring of a concrete member was conducted by curvature analysis using an interferometric sensor (48). The health of a building at the University of Colorado was monitored using multiplexed FBG sensors and a remote sensing system through the Internet (53). Electric resistance measurement can be applied to the health monitoring of carbon- or steel-reinforced concrete or CFRP repair sheet. Electric resistance measurement of carbon or steel composite structures provides information about the matrix and the reinforcement condition such as breakage or corrosion. There are many laboratory studies of the resistance measurement technique (90–97).

A remote monitoring technique through a worldwide network has become practical because of the advance of the Internet in the late 1990s. This idea is very attractive to construction corporations because it produces a new business of low-cost maintenance service. This technique involves high-speed communication devices, wireless communication devices, and web-based technologies. Remote health monitoring on the Web has been proposed by Web-based software written in a network-friendly language (53). The advantage of Web-based remote monitoring is that special software installed in a local computer is not necessary. Wireless devices make it possible to collect data from integrated sensors without an on-line cable (110).

DRUG DELIVERY SYSTEMS

JOSEPH KOST

SMADAR A. LAPIDOT

Ben-Gurion University of the Negev

Beer Sheva, Israel

INTRODUCTION

The rapid advancement of biomedical research has led to many creative applications for biocompatible polymers. As modern medicine discerns more mechanisms of both physiology and pathophysiology, the approach to healing is to mimic, or if possible, to recreate the physiology of healthy functioning. Thus, the area of responsive drug delivery has evolved. Also called “smart” polymers, for drug delivery, the developments fall in two categories: externally regulated or pulsatile systems (also known as “open-loop” systems) and self-regulated systems (also called “closed-loop”). This article outlines the fundamentals of this research area and gives a detailed account of the most recent advances in both pulsatile and self-regulated drug delivery systems.

DEVELOPMENT OF CONTROLLED DRUG DELIVERY

Control of Drug Concentration Levels Over Time

The overall goal in developing controlled release devices is maintaining the drug in the therapeutic range (zero-order release kinetics) and targeting delivery to specific tissues (lowering systemic exposure and side effects). Polymers have been used in developing all four types of devices, classified by release mechanism: (1) diffusion controlled, both reservoir and monolithic; (2) chemically controlled release, that is, bioerodible carriers; (3) solvent controlled release, where swelling of the matrix is the mechanism that enables the entrapped drug to come out; and (4) externally controlled release (1).

Although newer and more powerful drugs continue to be developed, increasing attention is being given to the methods of administering these active substances. In conventional drug delivery, the drug concentration in the blood rises when the drug is taken, then peaks, and declines. Maintaining drug in the desired therapeutic range by using just a single dose or targeting the drug at a specific area (lowering the systemic drug level) are goals that have been successfully attained by using commercially available controlled release devices (2). However, there are many clinical situations where the approach of a constant drug delivery rate is insufficient, such as the delivery of insulin for patients who have diabetes mellitus, antiarrhythmics for patients who have heart rhythm disorders, gastric acid inhibitors for ulcer control, nitrates for patients who have angina pectoris, as well as selective β -blockade, birth

control, general hormone replacement, immunization, and cancer chemotherapy. Furthermore, studies in the field of chronopharmacology indicate that the onsets of certain diseases exhibit strong circadian temporal dependence. Thus, treatment of these diseases could be optimized by using responsive delivery systems (3), which are, in essence, man-made imitations of healthy function.

Biocompatibility

When designing a controlled delivery device, the effects of the drug must be taken into account and also the potential effects of the device itself on the biological system (4). In other words, both the effects of the implant on the host tissues and the effects of the host on the implant must be considered. These are some of the important potential effects: inflammation and the “foreign body reaction,” immunologic responses, systemic toxicity, blood–surface interactions, thrombosis, device-related infection, and tumorigenesis (4). Many of these effects actually comprise the body’s defense mechanism against injury; placement of a drug delivery device in the body causes injury and therefore, elicits these reactions. However, the degree of perturbation is strongly impacted by the biomaterial that comprises the device.

The first response to be triggered is inflammation. The cellular and molecular mechanisms have been well described, but avoiding them has not yet been achieved. Many of the inflammatory responses are local to the site of implantation and dissipate relatively quickly. Some of the most potent chemical mediators, such as lysosomal proteases and oxygen-derived free radicals also play an important role in the degradation and wear of biomaterials (1).

The products of degradation and wear can cause immune responses and/or nonimmune systemic toxicity. Thus, when testing a delivery device, both the intact device and its degradation products must be thoroughly examined *in vitro* before implantation *in vivo*. An additional phenomenon that can hamper the device’s function is fibrous encapsulation of the biomaterial. These reactions can be very specific to the host, and *in vivo* experiments are not always indicative of the human response. There is a wealth of literature regarding biocompatibility mechanisms and testing into which the interested reader is encouraged to delve (4).

Classification of “Smart” Polymers

“Intelligent” controlled release devices can be classified as open- or closed-loop systems, as shown in Fig. 1. Open-loop control systems (Fig. 1a) are those where information about the controlled variable is not automatically used to adjust the system inputs to compensate for the change in process variables. In the controlled drug delivery field, open-loop systems are known as pulsatile or externally regulated.

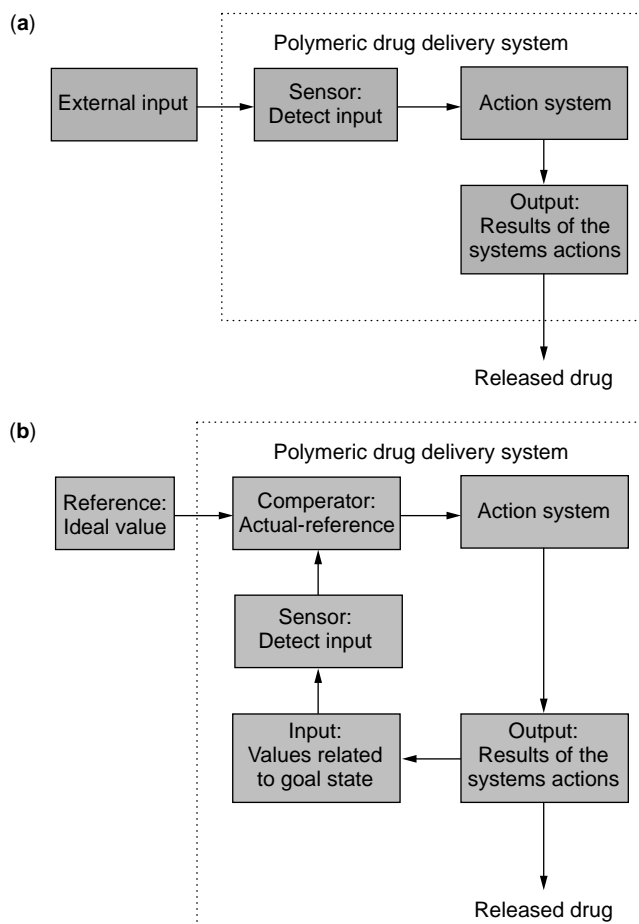

Figure 1. Schematic representation of drug delivery systems and their control mechanisms: (a) open-loop system; (b) closed-loop system.

Externally controlled devices apply external triggers such as magnetic, ultrasonic, thermal, or electric irradiation for pulsatile delivery.

Closed-loop control systems, on the other hand, are defined as systems where the controlled variable is detected, and as a result the system output is adjusted accordingly. Closed-loop systems are known in the controlled drug delivery field as self-regulated. The release rate in self-regulated devices is controlled by feedback information without any external intervention, as shown in Fig. 1b. Self-regulated systems use several approaches for rate control mechanisms (5,6) such as pH-sensitive polymers, enzyme–substrate reactions, pH-sensitive drug solubility, competitive binding, antibody interactions, and metal concentration-dependent hydrolysis.

Many approaches for mimicking the physiological healthy state are undergoing research. The focus of this article is on “smart” polymers; therefore, other important areas, such as using pumps for controlled drug delivery, microencapsulation of living cells, or gene therapy, are not covered. An additional area of significant research that is not covered in this article is site-directed or targeted drug delivery, where the release is constant (as in chemotherapy

for cancer treatment). Here, the fundamental principles and recent advances of *responsive* drug delivery for both pulsatile and self-regulated systems are reviewed.

PULSATILE SYSTEMS

Magnetically Stimulated Systems

Feasibility. Drug molecules and magnetic beads are uniformly distributed within a solid polymeric matrix in magnetically triggered systems. Although drug is released by diffusion when the device is exposed to fluids, a much higher release rate is obtained in the presence of an external oscillating magnetic field. The magnetic system was characterized *in vitro* (7–9). Subsequent *in vivo* (10) studies showed that when polymeric matrices made of ethylenevinyl acetate copolymer (EVAc) that contain insulin and magnetic beads are placed subcutaneously in diabetic rats for two months, glucose levels can be repeatedly and reproducibly decreased on demand by applying an oscillating magnetic field.

Mechanisms. The two principal parameters that control the release rates in these systems are the magnetic field characteristics and the mechanical properties of the polymer matrix. It was found that when the frequency of the applied field was increased from 5 to 11 Hz, the release rate of bovine serum albumin (BSA) from EVAc copolymer matrices rose linearly (7). Saslavski et al. (11) investigated the effect of magnetic field frequency and repeated field application on insulin release from alginate matrices and found that using repeated applications, inverse effects can occur: high frequencies gave a significant release enhancement for the second magnetic field application. Subsequent stimulation resulted in decreased enhancement due to faster depletion at high frequencies.

The mechanical properties of the polymeric matrix also affect the extent of magnetic enhancement (7). For example, the modulus of elasticity of the EVAc copolymer can easily be altered by changing the vinyl acetate content of the copolymer. The release rate enhancement induced by the magnetic field increases as the modulus of elasticity of EVAc decreases. A similar phenomenon was observed for cross-linked alginate matrices: higher release rate enhancement for less rigid matrices (11). Edelman et al. (12) also showed that enhanced release rates observed in response to an electromagnetic field (50 G, 60 Hz) applied for 4 minutes were independent of the duration of the interval between repeated pulses.

Ultrasonically Stimulated Systems

Feasibility. Release rates of substances can be repeatedly modulated at will from a position external to the delivery system by ultrasonic irradiation (13). Both bioerodible and nonerodible polymers were used as drug carrier matrices.

The bioerodible polymers evaluated were polyglycolide, polylactide, poly(bis(*p*-carboxyphenoxy) alkane

anhydrides and their copolymers with sebacic acid. Both the polymer erosion and drug release rates were enhanced when the bioerodible samples were exposed to ultrasound. The system's response to ultrasonic triggering was rapid (within 2 minutes) and reversible. The releasing agents, *p*-nitroaniline, *p*-aminohippurate, bovine serum albumin, and insulin, were tested for integrity following exposure to ultrasonic energy and were found intact.

The enhanced release was also observed in nonerodible systems exposed to ultrasound where the release is diffusion-dependent. Release rates of zinc bovine insulin from EVAc copolymer matrices were 15 times higher when exposed to ultrasound compared to the unexposed periods.

In vivo studies (13) have suggested the feasibility of ultrasound-mediated drug release enhancement. Implants composed of polyanhydride polymers loaded with 10% *p*-aminohippuric acid (PAH) were implanted subcutaneously in the backs of catheterized rats. When exposed to ultrasound, a significant increase in the PAH concentration in urine was detected (400%). Rat's skin histopathology of the ultrasound-treated area after an exposure of 1 hour at 5 W/cm² did not reveal any differences between treated and untreated skin.

Similar phenomena were observed by Miyazaki et al. (14) who evaluated the effect of ultrasound (1 MHz) on the release rates of insulin from ethylene vinyl alcohol copolymer matrices and reservoir type drug delivery systems. When diabetic rats that received implants containing insulin were exposed to ultrasound (1 W/cm² for 30 min), a sharp drop in blood glucose levels was observed after the irradiation, indicating a rapid rate of release of insulin at the implanted site.

During the past 40 years, numerous clinical reports have been published concerning phonophoresis (15), the technique of using ultrasonic irradiation to enhance transdermal drug delivery. Ultrasound nearly completely eliminated the usual lag time for transdermal delivery of drugs. Ultrasound irradiation (1.5 W/cm² continuous wave or 3 W/cm² pulsed wave) for 3–5 minutes increased the transdermal permeation of insulin and mannitol in rats by 5–20-fold within 1–2 hours after ultrasound application.

Miyazaki et al. (16) performed similar studies that evaluated the effect of ultrasound (1 MHz) on indomethacin permeation in rats. Pronounced effects of ultrasound on transdermal absorption for all three ranges of intensities (0.25, 0.5, and 0.75 W/cm²) were observed. Bommannan et al. (17) examined the effects of ultrasound on the transdermal permeation of the electron-dense tracer, lanthanum nitrate, and demonstrated that exposure of the skin to ultrasound can induce considerable and rapid tracer transport through an intercellular route. Prolonged exposure of the skin to high-frequency ultrasound (20 min, 16 MHz), however, resulted in structural alterations of epidermal morphology. Tachibana et al. (18–20) reported using low-frequency ultrasound (48 KHz) to enhance transdermal transport of lidocaine and insulin through hairless mice skin. Low-frequency ultrasound was also used by Mitragotri et al. (21,22) to enhance transport of various low molecular weight drugs, including salicylic

acid and corticosterone, as well as high molecular weight proteins, including insulin, γ -interferon, and erythropoietin, through human skin *in vitro* and *in vivo*.

Mechanisms. It was proposed (13) that cavitation and acoustic streaming are responsible for the augmented degradation and release of bioerodible polymers. In experiments conducted in a degassed buffer where cavitation was minimized, the observed enhancement in degradation and release rates was much smaller. It was also considered that several other parameters (temperature and mixing effects) might be responsible for the augmented release due to ultrasound. However, experiments were conducted which suggested that these parameters were not significant. It has also been demonstrated that the extent of release rate enhancement can be regulated by the intensity, frequency, or duty cycle of the ultrasound.

Miyazaki et al. (14) speculate that the ultrasound caused increased temperatures in their delivery system, which may facilitate diffusion. The increased temperature caused by ultrasound or other forms of irradiation can be used as a trigger to cause collapsing of a hybrid hydrogel that has protein domains, as described by Wang et al. (23). Additional thermostimulated polymers are discussed later in the temperature-sensitive section of self-regulated systems.

Mitragotri et al. (24) evaluated the role played by various ultrasound-related phenomena, including cavitation, thermal effects, generation of convective velocities, and mechanical effects during phonophoresis. The authors' experimental findings suggest that among all the ultrasound-related phenomena evaluated, cavitation plays the dominant role in sonophoresis using therapeutic ultrasound (frequency: 1–3 MHz; intensity; 0–2 W/cm²). Confocal microscopy results indicate that cavitation occurs in the keratinocytes of the stratum corneum upon ultrasound exposure. The authors hypothesized that oscillations of the cavitation bubbles induce disorder in the stratum corneum lipid bilayers, thereby enhancing transdermal transport. The theoretical model developed to describe the effect of ultrasound on transdermal transport predicts that sonophoretic enhancement depends most directly on the passive permeant diffusion coefficient in water, not on the permeant diffusion coefficient through the skin.

Electrically Stimulated Systems

Feasibility. Electrically controlled systems provide drug release by the action of an applied electric field on a rate-limiting membrane and/or directly on the solute and thus control its transport across the membrane. The electrophoretic migration of a charged macromolecule within a hydrated membrane results from the combined response to the electrical forces on the solute and its associated counterions in the adjacent electrolyte solution (25).

Electrically controlled membrane permeability has also been of interest in the field of electrically controlled or enhanced transdermal drug delivery (e.g., iontophoresis, electroporation) (26,27).

Anionic gels as vehicles for electrically modulated drug delivery were studied by Hsu and Block (28). Agarose and

combinations of agarose and anionic polymers (polyacrylic acid, xanthan gum) were evaluated. The authors conclude that the use of carbomer (polyacrylic acid) in conjunction with agarose enables the formulator to achieve zero-order release by electrical field application. Increased anisotropy of a gel system due to the application of electrical current could alter the effectiveness of the drug delivery system.

D'Emanuele and Staniforth (29) proposed a drug delivery device that consists of a polymer reservoir that has a pair of electrodes placed across the rate-limiting membrane. By altering the magnitude of the electric field between the electrodes, the authors proposed to modulate the drug release rates in a controlled and predictable manner. A linear relationship was found between current and propranolol HCL permeability through poly(2-hydroxyethyl methacrylate) (PHEMA) membranes cross-linked with ethylene glycol dimethacrylate (1%v/v). It was found that buffer ionic strength, drug reservoir concentration, and electrode polarity have significant effects on drug permeability (30).

Labhassetwar et al. (31) propose a similar approach for modulating cardiac drug delivery. The authors studied a cardiac drug implant in dogs that can modulate electric current. A cation-exchange membrane was used as an electrically sensitive rate-limiting barrier on the cardiac-contacting surface of the implant. The cardiac implant demonstrated *in vitro* drug release rates that were responsive to current modulation. *In vivo* results in dogs confirmed that electrical modulation resulted in regional coronary enhancement of drug levels and a current-responsive increase in drug concentration.

A different approach for electrochemical controlled release is based on polymers that bind and release bioactive compounds in response to an electric signal (32). The polymer has two redox states, only one of which is suitable for ion binding. Drug ions are bound in one redox state and released from the other. The attached electrodes switch the redox states, and the amount of current passed can control the amount of ions released. Hepel and Fijalek (33) propose to use this method of electrochemical pulse stimulation on a novel composite polypyrrole film for delivering cationic drugs directly to the central nervous system (CNS).

By encapsulating drugs in multicomponent hydrogel microspheres, Kiser et al. (34) propose a synthetic mimic of the secretory granule that can be triggered to release the bioactive agent by various forms of external stimulation. In the report, the external protective lipid membrane was porated by electrical stimulation. Following electroporation, the hydrogel microsphere quickly swells to dissipate the pH gradient. The swelling leads to a burst of drug release. Thus, an off/on irreversible mechanism is described that can be triggered in a controlled fashion.

Mechanisms. Grimshaw (35) reported four different mechanisms for the transport of proteins and neutral solutes across hydrogel membranes: (1) electrically and chemically induced swelling of a membrane to alter the effective pore size and permeability, (2) electrophoretic augmentation of solute flux within a membrane, (3)

electrosmotic augmentation of solute flux within a membrane, and (4) electrostatic partitioning of charged solutes into charged membranes.

Kwon et al. (36) studied the effect of electric current on solute release from cross-linked poly(2-acrylamido-2-methylpropane sulfonic acid-*co-n*-butylmethacrylate). Edrophonium chloride, a positively charged solute, was released in an on-off pattern from a matrix (monolithic) device by an electric field. The mechanism was explained as an ion exchange between a positive solute and the hydroxonium ion, followed by fast release of the charged solute from the hydrogel. The fast release was attributed to electrostatic force, a squeezing effect, and electro-osmosis of the gel. However, the release of neutral solute was controlled by diffusion effected by swelling and deswelling of the gel.

Photostimulated Systems

Feasibility. Photoinduced phase transition of gels was reported by Mamada et al. (37). Copolymer gels of *N*-isopropylacrylamide and the photosensitive molecule bis(4-dimethylamino)phenyl(4-vinylphenyl)methyl leucocyanide showed a discontinuous volume phase transition upon ultraviolet irradiation that was caused by osmotic pressure of cyanide ions created by the ultraviolet irradiation.

Yui et al. (38) proposed photoresponsive degradation of heterogeneous hydrogels comprised of cross-linked hyaluronic acid and lipid microspheres for temporal drug delivery. Visible light induced degradation of cross-linked hyaluronic acid gels by photochemical oxidation using methylene blue as the photosensitizer. [The authors also proposed that hyaluronic acid gels are inflammation-responsive (39)].

By combining technologies developed for targeted drug delivery and external photostimulation of the active agent released, Taillefer et al. (40) propose using polymeric micelles to deliver water-insoluble, photosensitizing anticancer drugs.

Mechanisms. Photoresponsive gels reversibly change their physical or chemical properties upon photoradiation. A photoresponsive polymer consists of a photoreceptor, usually a photochromic chromophore, and a functional part. The optical signal is captured by the photochromic molecules, and then isomerization of the chromophores in the photoreceptor converts it to a chemical signal.

Suzuki and Tanaka (41) reported a phase transition in polymer gels induced by visible light, where the transition mechanism is due only to the direct heating of the network polymer by light.

SELF-REGULATED SYSTEMS

Environmentally Responsive Systems

Polymers that alter their characteristics in response to changes in their environment have been of great recent interest. Several research groups have been developing drug delivery systems based on these responsive polymers

that more closely resemble the normal physiological process. Drug delivery in these devices is regulated by an interaction with the surrounding environment (feedback information) without any external intervention. The most commonly studied polymers that have environmental sensitivity are either pH- or temperature-sensitive. There are also inflammation-sensitive systems and systems that use specific binding interactions, which are discussed in the next section.

Temperature-Sensitive Systems. Temperature-sensitive polymers can be classified into two groups based on the origin of the thermosensitivity in aqueous media. The first is based on polymer–water interactions, especially, specific hydrophobic/hydrophilic balancing effects and the configuration of side groups. The other is based on polymer–polymer interactions in addition to polymer–water interactions. When polymer networks swell in a solvent, there is usually a negligible or small positive enthalpy of mixing or dilution. Although a positive enthalpy change opposes the process, the large gain in entropy drives it. The opposite is often observed in aqueous polymer solutions. This unusual behavior is associated with a phenomenon of polymer phase separation as the temperature is raised to a critical value that is known as the lower critical solution temperature (LCST). *N*-Alkyl acrylamide homopolymers and their copolymers, including acidic or basic comonomers, show this LCST (42,43). Polymers characterized by LCST usually shrink as the temperature is increased through the LCST. Lowering the temperature below the LCST results in swelling of the polymer. Bioactive agents such as drugs, enzymes, and antibodies may be immobilized on or within temperature-sensitive polymers; examples of such uses are discussed below. Responsive drug release patterns regulated by external temperature changes have been recently demonstrated by several groups (42,44–57).

pH-Sensitive Systems. The pH range of fluids in various segments of the gastrointestinal tract may provide environmental stimuli for responsive drug release. Several research groups (58–72) studied polymers that contain weakly acidic or basic groups in the polymeric backbone. The charge density of the polymers depends on the pH and ionic composition of the outer solution (the solution to which the polymer is exposed). Altering the pH of the solution causes swelling or deswelling of the polymer. Thus, drug release from devices made from these polymers display release rates that are pH-dependent. Polyacidic polymers are unswollen at low pH because the acidic groups are protonated and hence un-ionized. Polyacid polymers swell as the pH increases. The opposite holds for polybasic polymers because ionization of the basic groups increases as the pH decreases. Siegel et al. (73) found that the swelling properties of polybasic gels are also influenced by buffer composition (concentration and pKa). A practical consequence proposed is that these gels may not reliably mediate pH-sensitive, swelling-controlled release in oral applications because the levels of buffer acids in the stomach (where swelling and release are expected) generally cannot be controlled. However, the gels may be

useful as mediators of pH-triggered release when precise rate control is of secondary importance.

Annaka and Tanaka (59) reported that more than two phases (swollen and collapsed) are found in gels that consist of copolymers of randomly distributed positively and negatively charged groups. Polymer segments in these gels interact with each other through attractive or repulsive electrostatic interactions and through hydrogen bonding. The combination of these forces seems to result in the existence of several phases, each characterized by a distinct degree of swelling, and abrupt jumps occur between them. The existence of these phases presumably reflects the ability of macromolecular systems to adopt different stable conformations in response to changes in environmental conditions. The largest number of phases was seven in copolymer gels prepared from acrylic acid (the anionic constituent) and methacryl-amido-propyl-trimethyl ammonium chloride (460 mmol/240 mmol). A similar approach was proposed by Bell and Peppas (69); membranes made from grafted poly (methacrylic acid-glycol) copolymer showed pH sensitivity due to complex formation and dissociation. Uncomplexed equilibrium swelling ratios were 40 to 90 times higher than those of complexed states and varied according to copolymer composition and polyethylene glycol graft length.

Giannos et al. (74) proposed temporally controlled drug delivery systems that couple pH oscillators and membrane diffusion properties. By changing the pH of a solution relative to the pKa, a drug may be rendered charged or uncharged. Because only the uncharged form of a drug can permeate across lipophilic membranes, a temporally modulated delivery profile may be obtained by using a pH oscillator in the donor solution.

Heller and Trescony (75) were the first to propose using pH-sensitive bioerodible polymers. In their approach, described in the section on systems that utilize enzymes, an enzyme–substrate reaction produces a pH change that is used to modulate the erosion of a pH-sensitive polymer that contains a dispersed therapeutic agent.

Bioerodible hydrogels that contain azoaromatic moieties were synthesized by Ghandehari et al. (76). Hydrogels that have lower cross-linking density underwent a surface erosion process and degraded at a faster rate. Hydrogels that have higher cross-linking densities degraded at a slower rate by a process in which the degradation front moved inward to the center of the polymer.

Recently, recombinant DNA methods were used to create artificial proteins that undergo reversible gelation in response to changes in pH or temperature (77). The proteins consist of terminal leucine zipper domains that flank a central, flexible, water-soluble polyelectrolyte segment. Formation of coiled-coil aggregates of the terminal domains in near-neutral aqueous solutions triggers formation of a three-dimensional polymer network, where the polyelectrolyte segment retains solvent and prevents precipitation of the chain. Dissociation of the coiled-coil aggregates by elevating pH or temperature causes dissolution of the gel and a return to the viscous behavior that is characteristic of polymer solutions. The authors suggest that these hydrogels have potential in bioengineering

applications that require encapsulation or controlled release of molecules and cellular species.

Inflammation-Responsive Systems. Yui et al. (39) proposed an inflammation-responsive drug delivery system based on biodegradable hydrogels of cross-linked hyaluronic acid. Hyaluronic acid is specifically degraded by hydroxyl radicals that are produced locally at inflammatory sites by phagocytic cells such as leukocytes and macrophages. In their approach, drug-loaded lipid microspheres were dispersed into degradable matrices of cross-linked hyaluronic acid.

Brown et al. (78) developed a biodegradable, biocompatible, inflammation-responsive microsphere system. The gelatin microspheres were synthesized by complex coacervation, a low temperature method that does not denature the encapsulated active agent. Gelatinase and stromelysin are activated in the synovial fluid of an inflamed joint. These enzymes degrade the gelatin microspheres and thus cause release of the bioactive protein, making this delivery system potentially useful for treating osteoarthritis.

An infection-responsive delivery system was developed by Tanihara et al. (79). As in an inflammatory response, inflection responses are characterized by the secretion of specific proteins. By responding to thrombin-like activity in infected wound fluid, the novel system released gentimycin as needed, thus avoiding problematic overexposure to antibiotics.

Systems Using Specific Binding Interactions

All of the following drug delivery systems use a specific binding interaction to manipulate the microenvironment of the device and thus modulate the rate of drug release from the polymer. The basic principles of binding and competitive binding are the underlying mechanism of the function of these systems. Due to the vast amount of literature on the subject of glucose-responsive insulin delivery systems, they are discussed in a separate section.

Systems Using Antibody Interactions. Pitt et al. (80) proposed utilizing hapten-antibody interactions to suppress the enzymatic degradation and permeability of polymeric reservoirs or matrix drug delivery systems. The delivery device consists of naltrexone contained in a polymeric reservoir or dispersed in a polymeric matrix configuration. The device is coated by covalently grafting morphine to the surface. Exposure of the grafted surface to antibodies to morphine results in coating of the surface by the antibodies, a process that can be reversed by exposure to exogenous morphine. Antibodies on the surface or in the pores of the delivery device block or impede the permeability of naltrexone in a reservoir configuration or enzyme-catalyzed surface degradation and the concomitant release of the drug from a matrix device. A similar approach was proposed for responsive release of a contraceptive agent. The β subunit of human chorionic gonadotropin (HCG) is grafted to the surface of a polymer, which is then exposed to antibodies to β -HCG. The appearance of HCG in the circulatory system (indication of pregnancy) causes release of a contraceptive drug. (HCG competes for the polymer-bound

antibodies to HCG and initiates release of the contraceptive drug.)

Pitt et al. (80,81) also proposed a hypothetical reversible antibody system for controlled release of ethinyl estradiol (EE). EE stimulates biosynthesis of sex-hormone-binding globulin (SHBG). High serum levels of EE stimulate the production of SHBG, which increases the concentration of SHBG bound to the polymer surface and reduces the EE release rate. When the EE serum level falls, the SHBG level falls, as does binding of the SHBG to the polymer surface, which produces an automatic increase in the EE release rate.

The reversible binding of antigen to antibody that is the basis for swelling of a hydrogel that could lead to release of a bioactive agent was recently reported (82). Miyata et al. describe the grafting of both antigen and antibody in the polymer network that causes the formation of reversible cross-linking. In the presence of free antigen that competes with the immobilized antigen, swelling ensues (82) and creates an antigen-responsive hydrogel.

Systems Using Chelation. Self-regulated delivery of drugs that function by chelation was also suggested (83). These include certain antibiotics and drugs for treating arthritis, as well as chelators used for treating metal poisoning. The concept is based on the ability of metals to accelerate the hydrolysis of carboxylate or phosphate esters and amides by several orders of magnitude. Attachment of the chelator to a polymer chain by a covalent ester or amide link prevents premature loss by excretion and reduces its toxicity. In the presence of the specific ion, a complex with the bound chelating agent forms, followed by metal-accelerated hydrolysis and subsequent elimination of the chelated metal. Measurement of the rates of hydrolysis of polyvinyl alcohol coupled with quinaldic acid chelator (PVA-QA) in the presence of Co(II), Zn(II), Cu(II), and Ni(II) confirmed that it is possible to retain the susceptibility of the esters to metal-promoted hydrolysis in a polymer environment.

Recently, Goldbart and Kost (84) reported developing a calcium-responsive drug delivery system. Calcium in external media reactivates α -amylase that was immobilized after being reversibly inactivated in a starch matrix. The activated enzyme causes degradation of the matrix, thus releasing an entrapped active agent. These investigators also developed a compartmental mathematical model that describes the release and degradation mechanisms involved (85).

Systems Using Enzymes

In this approach, the mechanism is based on an enzymatic reaction. One possible approach studied is an enzymatic reaction that results in a pH change and a polymer system that can respond to that change.

Urea-Responsive Delivery. Heller et al. (75) were the first to attempt using immobilized enzymes to alter local pH and thus cause changes in polymer erosion rates. The proposed system is based on converting urea to NH_4HCO_3 and NH_4OH by the action of urease. Because this reaction

causes a pH increase, a polymer that is subjected to increased erosion at high pH is required.

The authors suggested a partially esterified copolymer of methyl vinyl ether and maleic anhydride. This polymer displays release rates that are pH-dependent. The polymer dissolves by ionizing the carboxylic acid group. The pH-sensitive polymer that contains dispersed hydrocortisone is surrounded by urease immobilized in a hydrogel that is prepared by cross-linking a mixture of urease and BSA with glutaraldehyde. When urea diffuses into the hydrogel, its interaction with the enzyme leads to a pH increase, therefore, resulting in enhanced erosion of the pH-sensitive polymer and concomitant increases in the release rate of hydrocortisone.

Ishihara et al. (86,87) suggested a nonerodible system based on a similar idea. The system is comprised of a pH-sensitive membrane, produced by copolymerizing 4-carboxy acrylanilide with methacrylate, sandwiched within a membrane that contains urease immobilized in free radically cross-linked *N,N*-methylenebisacrylamide. The permeation of a model substance, (1,4-bis(2-hydroxyethoxy) benzene, varied with the urea concentration in the external solution.

Morphine Triggered Naltrexone Delivery System. Heller and co-workers (88–95) have been developing a naltrexone drug delivery system that would be passive until drug release is initiated by the appearance of morphine external to the device. Naltrexone is a long acting opiate antagonist that blocks opiate-induced euphoria, and thus the intended use of this device is to treat heroin addiction. Activation is based on the reversible inactivation of enzymes achieved by the covalent attachment of hapten close to the active site of the enzyme–hapten conjugate with the hapten antibody. Because the antibodies are large molecules, access of the substrate to the enzyme's active site is sterically inhibited and thus effectively renders the enzyme inactive. Triggering of drug release is initiated by the appearance of morphine (hapten) in the tissue and dissociation of the enzyme–hapten–antibody complex that renders the enzyme active. This approach is being developed by incorporating the naltrexone in a bioerodible polymer. The polymer matrix is then covered by a lipid layer that prevents water entry, and this prevents its degradation and therefore also the release of naltrexone. The system is placed in a dialysis bag. The bag contains lipase (enzyme) that is covalently attached to morphine and reversibly inactivated by antimorphine complexation. Thus, when morphine is present in the tissues that surround the device, morphine diffuses into the dialysis bag, displaces the lipase-morphine conjugate from the antibody, and allows the now activated enzyme to degrade the protective lipid layer. This in turn permits degradation of the polymeric core and subsequent release into the body of the narcotic antagonist, naltrexone.

A key component of this morphine-responsive device is the ability to inactivate an enzyme reversibly and completely and to disassociate the complex rapidly using concentrations as low as 10^{-8} to 10^{-9} M. To achieve this sensitivity, lipase was conjugated with several morphine analogs and complexed with polyclonal antimorphine

antibodies purified by affinity chromatography. *In vivo* studies (91) suggest that the concentration of morphine in a device implanted in a typical heroin-addicted patient is estimated at about 10^{-7} to 10^{-8} M. Recent studies have shown that reaching such sensitivity is possible (89).

Many of the glucose-responsive systems discussed in the next section also use enzymes.

Glucose-Responsive Insulin Delivery

The development of glucose-sensitive insulin-delivery systems has used several approaches, including immobilized glucose oxidase in pH-sensitive polymers, competitive binding, and a polymer–complex system. None of the present modes of treatment, including insulin pumps, fully mimics the physiology of insulin secretion. Therefore the development of a “smart” insulin-delivery system could significantly help patients who have diabetes to control their blood glucose level and thus avoid the various severe complications including eye disease, gangrene of the extremities, cardiovascular disease, and renal failure (96).

Polymer–Complex System. Kitano et al. (97) proposed a glucose-sensitive insulin release system based on a sol–gel transition. A phenylboronic acid (PBA) moiety was incorporated in poly(*N*-vinyl-2-pyrrolidone) by the radical copolymerization of *N*-vinyl-2-pyrrolidone with *m*-acrylamidophenylboronic acid [poly(NVP-*co*-PBA)]. Insulin was incorporated into a polymer gel formed by a complex of poly(vinyl alcohol) with poly(NVP-*co*-PBA). PBA can form reversible covalent complexes with molecules that have diol units, such as glucose or PVA. By adding glucose, PVA in the PVA–boronate complex is replaced by glucose. This leads to a transformation of the system from the gel to the sol state that facilitates the release of insulin from the polymeric complex. The same group (98) modified the approach and suggested glucose-responsive gels based on complexation between polymers that have phenylboronic acid groups and PVA. The introduction of an amino group into phenylborate polymers was effective in increasing the complexation ability and the glucose responsivity at physiological pH.

Shiino et al. (99) attached gluconic acids to insulin. The modified insulin that contains two gluconic acid units per insulin (G-Ins) was bound into a PBA gel column, and the G-Ins release profile in response to varying concentrations of glucose was studied. Concentration of released G-Ins from PBA gel responded to concentration changes of the eluting glucose. These polymeric complexes have been applied as interpenetrating polymer networks to achieve pulsatile insulin release in response to changes in glucose concentration.

Competitive Binding. The basic principle of competitive binding and its application to controlled drug delivery was first presented by Brownlee and Cerami (100) who suggested the preparation of glycosylated insulins that are complementary to the major combining site of carbohydrate binding proteins such as Concanavalin A (Con A). Con A is immobilized on Sepharose™ beads. The glycosylated insulin, which is biologically active, is displaced from the Con A by glucose in response to, and proportional to, the

amount of glucose present that competes for the same binding sites. Kim et al. (101–108) found that the release rate of insulin also depends on the binding affinity of an insulin derivative to Con A and can be influenced by the choice of the saccharide group in glycosylated insulin. By encapsulating the glycosylated insulin-bound Con A by using a suitable polymer that is permeable to both glucose and insulin, the glucose influx and insulin efflux would be controlled by the encapsulation membrane.

It was found (102) that glycosylated insulins are more stable to aggregation than commercial insulin and are also biologically active. The functionality of the intraperitoneally implanted device was tested in pancreatectomized dogs by an intravenous glucose tolerance test (IVGTT). The effect of an administered 500 mg/kg dextrose bolus on blood glucose level was compared with normal and pancreatectomized dogs without an implant. The results of this study indicated that the diabetic dogs that had the implant had normal glucose levels (107). In addition, the blood glucose profile for a period of 2 days demonstrated that a diabetic dog, implanted with the self-regulating insulin delivery system, could maintain acceptable glucose levels (50–180 mg/dL) for the majority of the experiment (40 hours) (104–106). Makino et al. (101) proposed a modification based on hydrophilic nylon microcapsules that contained Con A and succinyl-amidophenyl-glucopyranoside insulin. The thin wall of these microcapsules and large surface area resulted in rapid diffusion of glucose and glycosylated insulin and therefore, a much shorter lag time.

To limit the leakage of Con A (which is toxic) and allow preparation of porous microspheres, Pai et al. (109) cross-linked the Con A by first blocking the sugar binding sites and then reacted it with glutaraldehyde. The porous microspheres demonstrated rapid exchange between succinyl-amidophenyl-glucopyranoside insulin and glucose, and had a short response time.

Kokufata et al. (110) reported a gel system that swells and shrinks in response to specific saccharides. The gel consists of a covalently cross-linked polymer network of *N*-isopropylacrylamide in which the lectin, Con A, is immobilized. Con A displays selective binding affinities for certain saccharides. For example, when the saccharide dextran sulphate is added to the gel, it swells to a volume up to fivefold the original volume. Replacing dextran sulphate with nonionic saccharide α -methyl-D-mannopyranoside brings about collapse of the gel, almost to its native volume. The process is reversible and repeatable.

Taylor et al. (111) proposed a similar approach for delivering insulin. It was shown that a self-regulating delivery device, responsive to glucose, operates *in vitro*. The device comprises a reservoir of insulin and a gel membrane that determines the delivery rates of insulin. The gel consists of a synthetic polysucrose and the lec, Con A. The mechanism is one of displacing the branched polysaccharide from the lec receptors by incoming glucose. The gel loses its high viscosity as a result but reforms upon removal of glucose and thus provides the rate-controlling barrier to the diffusion of insulin or any other antihyperglycemic drugs.

A similar approach was presented by Park et al. (112–114) who synthesized glucose-sensitive membranes based on the interaction between polymer-bound glucose and Con A.

Immobilized Glucose Oxidase in pH-Sensitive Polymers.

Responsive drug delivery systems based on pH-sensitive polymers have been developed along three different approaches: pH-dependent swelling, degradation, and solubility.

pH-Dependent Solubility. Glucose-dependent insulin release was proposed by Langer and co-workers (115–117) based on the fact that insulin solubility is pH-dependent. Insulin was incorporated into ethylene vinyl acetate (EVAc) copolymer matrices in solid form. Thus, the release was governed by its dissolution and diffusion rates. Glucose oxidase was immobilized to Sepharose™ beads which were incorporated along with insulin into EVAc matrices. When glucose entered the matrix, the gluconic acid produced caused a rise in insulin solubility and consequently enhanced release. To establish this mechanism at the physiological pH of 7.4, the insulin was modified by three additional lysine groups so that the resultant isoelectric point was 7.4. *In vitro* and *in vivo* studies demonstrated the response of the system to changes in glucose concentration. In the *in vivo* experiments, a catheter was inserted into the left jugular vein, and polymer matrices that contained insulin and immobilized enzyme were implanted subcutaneously in the lower back of diabetic rats. Serum insulin concentrations were measured for different insulin matrix implants. A 2 M glucose solution was infused, 15 minutes into the experiments, through the catheter. Rats that received trilycine insulin/glucose oxidase matrices showed a 180% rise in serum insulin concentration which peaked at 45 minutes into the experiment. Control rats that received matrices that contained no insulin, or insulin but no glucose oxidase, or diabetic rats without implants showed no change in serum insulin.

pH-Dependent Degradation. Heller et al. (88,89,118) suggested a system in which insulin is immobilized in a pH-sensitive bioerodible polymer prepared from 3,9-bis-(ethylidene 2,4,8,10-tetraoxaspiro(5,5)undecane and *N*-methyl-diethanolamine), which is surrounded by a hydrogel that contains immobilized glucose oxidase. When glucose diffuses into the hydrogel and is oxidized to gluconic acid, the resultant lowered pH triggers enhanced polymer degradation and release of insulin from the polymer in proportion to the concentration of glucose. The response of the pH-sensitive polymers that contained insulin to pH pulses was rapid. Insulin was rapidly released when the pH decreased from 7.4 to 5.0. Insulin release was shut off when the pH increased. The amount of insulin released showed dependence on pH change. However, when the *in vitro* studies were repeated in a physiological buffer, the response of the device was only minimal, even at very low pH pulses. The authors found that the synthesized amine-containing polymer undergoes general acid catalysis and the catalyzing species is not the hydronium ion but rather the specific buffer molecules used. Therefore, further development of this system will require developing a bioerodible polymer that has adequate pH sensitivity and also undergoes specific ion catalysis.

pH-Dependent Swelling. Systems based on pH-sensitive polymers consist of immobilized glucose oxidase in a pH-responsive hydrogel that encloses a saturated insulin solution or is incorporated with insulin (119–129). As glucose diffuses into the hydrogel, glucose oxidase catalyzes its conversion to gluconic acid, thereby lowers the pH in the microenvironment of the hydrogel, and causes swelling. Because insulin should permeate the swelled hydrogel more rapidly, faster delivery of insulin in the presence of glucose is anticipated. As the glucose concentration decreases in response to the released insulin, the hydrogel should contract and decrease the rate of insulin delivery.

Horbett and co-workers (119–126) immobilized glucose oxidase in a cross-linked hydrogel made from *N,N*-dimethylaminoethyl methacrylate (DMA), hydroxyethyl methacrylate (HEMA), and tetraethylene glycol dimethacrylate (TEGDMA). It was previously shown that membranes prepared at -70°C by radiation polymerization retain enzymatic activity (130). To obtain sufficient insulin permeability through the gels, porous HEMA/DMA gels were prepared by polymerization under conditions which induce a separation into two phases during polymerization: one phase is rich in polymer, and the other is rich in solvent plus unreacted monomer. When gelation occurs after phase separation, the areas where the solvent/monomer phase existed become fixed in place as pores in the polymer matrix. The authors used a dilute monomer solution to obtain a porous gel, whose pores were typically 1–10 μm in diameter (106).

The rate of insulin permeation through the membranes was measured in the absence of glucose in a standard transport cell; then glucose was added to one side of the cell to a concentration of 400 mg/dL, and the permeation measurement was continued. The results indicated that the insulin transport rate is enhanced significantly by the addition of glucose. The average permeability after addition of 400 mg/dL glucose was 2.4 to 5.5 times higher than before glucose was added. When insulin permeabilities through the porous gels were measured in a flowing system, where permeabilities were measured as fluid flowed continuously past one side of the membrane, no effect of glucose concentration on insulin permeabilities could be detected. The authors propose that inappropriate design of the membranes used in the experiments is the explanation for their lack of response to glucose concentration (105).

A mathematical model that describes these glucose-responsive hydrogels demonstrates two important points (119,120): (1) Progressive response to glucose concentration over a range of glucose concentrations can be achieved only by using a sufficiently low glucose oxidase loading; otherwise, depletion of oxygen makes the system insensitive to glucose. (2) A significant pH decrease in the membrane and resultant swelling can be achieved only if the amine concentration is sufficiently low that pH changes are not prevented by the buffering of the amines.

The great advantage of reservoir systems is the ease by which they can be designed to produce constant release rate kinetics, but their main disadvantage is leaks that are dangerous because all of the incorporated drug could be released rapidly. To overcome this problem, Goldraich and Traitel (127,128) proposed incorporating the drug (insulin) and the enzyme (glucose oxidase) into the pH-responsive

polymeric matrices. Furthermore, Traitel et al. (129) developed a compartmental math model that describes the pH-responsive swelling of the matrix and can be used to optimize the system further.

Ishihara et al. (86,87,131–134) investigated two approaches to glucose-responsive insulin delivery systems: One approach is similar to that investigated by Horbett et al. (125). The polymers were prepared from 2-hydroxyethyl acrylate (HEA)-*N,N*-dimethylaminoethyl methacrylate (DMA), 4-trimethylsilylstyrene (TMS), by radical polymerization of the corresponding monomers in dimethylformamide (DMF). The mole fractions of HEA, DMA, and TMS in the copolymer were 0.6, 0.2, and 0.2, respectively. Membranes were prepared by solvent casting. Capsules that contained insulin and glucose oxidase were prepared by interfacial precipitation using gelatin as an emulsion stabilizer. The average diameter of the polymer capsules obtained was 1.5 mm (131,134). The water content of HEA–DMA–TMS copolymer membranes increased as the pH of the medium decreased. An especially drastic change was observed in the pH range of 6.15 to 6.3. The permeation of insulin through the copolymer membrane increases in response to pH decreases. The permeation rate of insulin at pH 6.1 was greater than that at pH 6.4 by about 42 times. The permeation of insulin through the copolymer membranes was very low in buffer solution without glucose. Adding 0.2 M glucose to the upstream compartment induced an increase in the permeation rate of insulin. When glucose was removed, the permeation rates of insulin gradually returned to their original levels (131).

Podual et al. recently reported a glucose-sensitive system that works on the same principle but utilizes a different polymer (135). The authors found that poly(diethyl aminoethyl methacrylate-*g*-ethylene glycol) that contained glucose oxidase and catalase resulted in matrices that were reproducibly and reversibly glucose-sensitive.

The other approach proposed by Ishihara et al. (133) is based on a glucose oxidase immobilized membrane and a redox polymer that has a nicotinamide moiety. The device consists of two membranes. One membrane that contains the immobilized glucose oxidase acts as a sensor for glucose and forms hydrogen peroxide by an enzymatic reaction; the other membrane is a redox polymer that has a nicotinamide moiety that controls the permeation of insulin by an oxidation reaction with the hydrogen peroxide formed. The oxidation of the nicotinamide group increases hydrophilicity and therefore should enhance the permeability to water-soluble molecules such as insulin. The results showed relatively small increases in insulin permeability.

Iwata et al. (136,137) pretreated porous poly(vinylidene fluoride) membranes (average pore size of 0.22 μm) by air plasma, and subsequently, acrylamide was graft polymerized on the treated surface. The polyacrylamide was then hydrolyzed to poly(acrylic acid). In the pH range of 5–7, grafted poly(acrylic acid) chains are solvated and dissolved but cannot diffuse into the solution phase because they are grafted to the porous membrane. Thus, they effectively close the membrane pores. In the pH range of 1 to 5, the chains collapse, and the permeability increases. To achieve sensitivity of the system to glucose, glucose oxidase was immobilized onto a poly(2-hydroxyethyl methacrylate) gel.

Ito et al. (138) adopted the approach proposed by Iwata et al. (137) using a porous cellulose membrane that had surface-grafted poly(acrylic acid) as a pH-sensitive membrane. By immobilizing glucose oxidase onto the poly(acrylic acid)-grafted cellulose membrane, it became responsive to glucose concentrations. The permeation coefficient after glucose addition was about 1.7 times that before the addition of glucose. The authors suggest improving the proposed system (sensitivity of insulin permeability to glucose concentrations) by modifying the graft chain density, length, and size, or density of pores.

Siegel and co-workers (139,140) proposed an implantable "mechanochemical" pump that functions by converting changes in blood glucose activity into a mechanical force, generated by the swelling polymer that pumps insulin out of the device.

More recently, Siegel (141) proposed self-regulating oscillatory drug delivery based on a polymeric membrane whose permeability to the substrate of an enzyme-catalyzed reaction is inhibited by the product of that reaction. This negative feedback system can, under certain conditions, lead to oscillations in membrane permeability and in the levels of substrate and product in the device. Any one of these oscillating variables can then be used to drive a cyclic delivery process. The product concentration in the chamber inhibitorily affects the permeability of the membrane to the substrate. That is, increasing product concentration causes decreasing flux of substrate into the device. Siegel proposed several means of controlled drug delivery based on this idea. Drug solubility could be affected by substrate or product concentration, which oscillates. Alternatively, the drug permeability of the membrane can oscillate with time along with the substrate permeability.

CONCLUDING REMARKS

During the last three decades, polymeric controlled drug delivery has become an important area of research and development. In this short time, a number of systems that display constant or decreasing release rates have progressed from the laboratory to the clinic and clinical products. Although these polymeric controlled delivery systems are advantageous compared to the conventional methods of drug administration, they are insensitive to a changing metabolic state. Responsive mechanisms must be provided to control the physiological requirements of specific drugs more closely. The approaches discussed represent attempts conducted during the past two decades to achieve pulsatile release. These drug delivery systems are still in the developmental stage, and much research will have to be conducted for such systems to become practical clinical alternatives. Critical considerations are the biocompatibility and toxicology of these multicomponent polymer-based systems, the response times of these systems to stimuli, the ability to provide practical levels of the desired drug, and addressing necessary formulation issues in dosage or design (e.g., shelf life, sterilization, reproducibility). A key issue in the practical use of pulsatile, externally triggered systems (i.e., magnetic, ultrasound, electrically regulated, and photoresponsive) will be the design of small portable trigger units that the patient can use easily. Ideally, such

systems could be worn by patients, wristwatch-like. They could either be preprogrammed to go on and off at specific times or patients could turn them on when needed. A critical issue in the development of responsive, self-regulated systems such as those that contain enzymes or antibodies are the stability and/or potential leakage and possible immunogenicity of these bioactive agents. The successful development of responsive polymer delivery systems is a significant challenge. Nevertheless, the considerable pharmacological benefit that these systems could provide, particularly in view of ongoing research in biotechnology, pharmacology, and medicine that may provide new insights into the desirability and requirements for pulsatile release, should make this an important and fruitful area for future research.

ELECTRICALLY CONDUCTIVE ADHESIVES FOR ELECTRONIC APPLICATIONS

DAOQIANG LU
C.P. WONG
Institute of Technology
Atlanta, GA

INTRODUCTION

Soldering processes using tin/lead solders (Sn/Pb) are standard interconnection technologies for electronic components on printed circuit boards (PCBs). The most common reflow soldering process for surface mounted technology (SMT) uses tin/lead solder pastes (1–4). The pressure to reduce the industrial use of lead is growing, particularly in Europe (5–7). Lead is a well-known hazard to human health. Even small quantities can damage the brain, nervous system, liver, and kidneys when ingested. When Sn/Pb solders are disposed of in landfills, lead can leach into soils and pollute ground water. As such, the pressure to remove or minimize the use of lead is steadily building. Most European communities, in fact, have proposed a ban on the landfill disposal of electronic products containing leaded printed circuit boards, as well as on the sale of products containing the metal. In United States, consumer electronics were identified as the second largest source of lead (30%) in the municipal solid waste stream after lead-acid batteries (65%), which were already being separated from trash before disposal (5). Thus, usage of tin/lead solder paste in the SMT process is considered environmentally harmful and must be reduced or eliminated. Lead-free and environmentally sound interconnect bonding processes are urgently needed. Among the possibilities are electrically conductive adhesives (ECAs) and lead-free solders (8). Compared to soldering technology, ECA technology can offer numerous advantages such as fewer processing steps which reduces processing cost, lowers the processing temperature which makes the use of heat-sensitive and low cost substrates possible, and fine pitch capability (8).

ELECTRICALLY CONDUCTIVE ADHESIVES (ECAs)

There are two main types of conductive adhesives, anisotropic conductive adhesives (ACAs) and isotropic conductive adhesives (ICAs) (9–15). All electrically conductive adhesives consist of a polymer binder and a conductive filler. ACAs provide unidirectional electrical conductivity in the vertical or Z axis. This directional conductivity is achieved by using a relatively low-volume loading of the conductive filler. The low-volume loading is insufficient for interparticle contact and prevents conductivity in the X, Y plane of the adhesive. The ACA in film or paste form is interposed between the surfaces to be connected. Heat and pressure are simultaneously applied to this

stack-up until the particles bridge the two conductor surfaces on the two adherends. Once electrical continuity is produced, the polymer binder is hardened by a thermally initiated chemical reaction (for thermosets) or by cooling (for thermoplastics). The advantage of this approach is that the material conducts only in the direction in which the force was applied (12). A major disadvantage, however, is that pressure and heat must be simultaneously applied while the polymeric matrix is hardened, otherwise the conductive pathway is lost. ACAs are now being used to connect flat panel displays, tape-automated bonding (TAB), flip chips and fine pitch surface-mounted devices (SMDs). A cross section of an ACA junction is shown in Fig. 1.

The discussion in the following sections is focused mainly on isotropic conductive adhesives (ICAs). ICAs consist of metallic particles (normally in flake form) in a polymer binder. Typical filler loadings are 25–30 volume %. At these loadings, the materials have achieved the percolation threshold and are electrically conductive in all directions after they are cured. The most common ICAs are silver-flake-filled thermosetting epoxies which are typically provided as one-part thixotropic pastes (13–15). They can provide both electrical and mechanical interconnections between components after they are cured (Fig. 2) (12–15). Because the mechanical strength of the joint is provided by the polymer binder, the challenge in a formulation is to use the maximum metal filler loading without sacrificing the required strength. ICAs are often called “polymer solders” (15). ICAs have been used in the electronic packaging industry, primarily as die attach adhesives (16–18). Recently, ICAs have been proposed as an alternative to tin/lead solders in surface-mounted technology (SMT) applications. The benefits and drawbacks of ICAs compared to Sn/Pb solders have been thoroughly discussed in literatures. Briefly, the advantages of ICAs include environmental friendliness (lead-free and no flux), low processing temperature, low thermomechanical fatigue, compatibility with a wide range of surfaces (includes nonsolderable substrates), finer pitch interconnect capability, simple processing, and low cost (9,18–21).

However, conductive adhesive technology is still in its infancy, and concerns and limitations do exist. The main limitations of current commercial ICAs include lower conductivity, unstable contact resistance with nonnoble metal finished components, and poor impact performance. The electrical conductivity of an ICA is lower than that of Sn/Pb solders. Although this conductivity is adequate for most electronics applications, the electrical conductivity of ICAs must still be improved. Contact resistance between an ICA and nonnoble metal (such as Sn/Pb, Sn, and Ni) finished components increases dramatically especially under elevated temperature and humidity aging conditions (18,20–23). In addition, printed circuit board assemblies are subject to significant shocks during assembly, handling, and throughout product life. The packages cannot survive

Figure 1. A cross section of an anisotropic conductive adhesive junction.

Figure 2. A cross section of an ICA joint.

without desirable impact performance. Most of the current commercial ICAs have poor impact performance. Components assembled using ICAs tend to fall from the substrate when the package experiences a sudden shock (14,21). For conductive adhesive technology to find universal appeal as a solder replacement, new conductive adhesives with desirable overall properties must be developed (22). In the past few years, there has been a great deal of effort to improve the properties of ICAs and to make them smarter materials. Recent smart material designs and formulations have resulted in improved electrical conductivity, contact resistance stability, and impact performance of ICAs. These will be reviewed in the following sections.

IMPROVEMENT OF ELECTRICAL CONDUCTIVITY OF ICAs

The electrical conductivity of ICAs is inferior to that of solders (24). Even though the conductivity of ICAs is adequate for most applications, higher electrical conductivity is still needed. To develop a novel ICA for modern electronic interconnect application, a thorough understanding of the materials is needed.

An ICA is generally composed of a polymer binder and Ag flakes. There is a thin layer of organic lubricant on the Ag flake surface. This lubricant layer plays an important role in the performance of ICAs, including the dispersion of the Ag flakes in the adhesives and the rheology of the adhesive formulations (24–27). This organic layer is a Ag salt formed between the Ag surface and the lubricant which typically is a fatty acid such as stearic acid (27,28). This lubricant layer affects the conductivity of an ICA because it is electrically insulating (27,28). To improve the conductivity, the organic lubricant layer

must be partially or fully removed. Some chemical substances can be used to dissolve the organic lubricant layer (27–29). However, the viscosity of an ICA paste might increase if the lubricant layer is removed. An ideal chemical substance (or lubricant remover) should be latent (does not remove the lubricant layer) at room temperature but be active (capable of removing the lubricant layer) at a temperature slightly below the cure temperature of the polymer. The lubricant remover can be a solid, short-chain acid, a high boiling point ether such as diethylene glycol monobutyl ether or diethylene glycol monoethyl ether acetate, or a low molecular weight polyethylene glycol (27–29). These chemical substances can improve the electrical conductivity of ICAs by removing the lubricant layer on the Ag flake surfaces and providing intimate flake–flake contact (27,28).

In general, an ICA paste has low conductivity before cure, but the conductivity increases dramatically after the ICA is cured. The ICA achieves conductivity during cure, mainly through more intimate contact between Ag flakes caused by cure shrinkage of the polymer binder (30). Cure shrinkage of the polymer binder affects the electrical conductivity of an ICA. An ICA that has higher cure shrinkage generally shows better conductivity (30). Therefore, increasing cure shrinkage of the polymer binder is another method for improving electrical conductivity. For ICAs based on epoxy resins, a small amount of a multifunctional epoxy resin can be added into an ICA formulation to increase cross-linking density, shrinkage, and thus increase conductivity (30).

Electrical conductivity of ICAs can be improved by applying an electrical field before or while curing them. An applied electrical field could improve electrical conductivity significantly. However, the exact reasons for this improvement are not yet clear (31).

Another approach to improving conductivity is to incorporate transient liquid-phase sintering metallic fillers in ICA formulations. The filler used is a mixture of a high melting point metal powder and a low melting point alloy powder. The electrical conduction is established through a plurality of metallurgical connections formed *in situ* from these two powders in a polymer binder. When heated at a specific high temperature, the low melting point alloy powders melt and diffuse rapidly into the high melting point filler and eventually solidify at that temperature. The polymer binder fluxes both the metal powders and the metals to be joined and facilitates transient liquid bonding of the powders to form a stable metallurgical network for electrical conduction and also forms an interpenetrating polymer network that provides adhesion (Fig. 3). High electrical conductivity can be achieved by using this method (32–34). One critical limitation of this technology is that the number of combinations of lower melting point filler and high melting point filler are limited. Only certain combinations of two metallic fillers can dissolve each other and form metallurgical interconnections.

IMPROVEMENT OF CONTACT RESISTANCE STABILITY

Contact resistance between an ICA (generally a Ag-flake-filled epoxy) and nonnoble metal finished components

Figure 3. Diagram of transient liquid-phase sintering conductive adhesives.

increases dramatically during elevated temperature and humidity aging, especially at 85°C/85% relative humidity. The National Center of Manufacturing and Science (NCMS) set a criterion for solder replacement conductive adhesives. The criterion is that if the contact resistance shift after a 500-hour 85/85 aging is less than 20%, then the contact resistance is defined as “stable” (21).

Two main mechanisms, simple oxidation and corrosion of the nonnoble metal surfaces, have been proposed in the literature. Simple oxidation of the nonnoble metal surfaces was claimed as the main reason for the increased resistance in most of the literature. Corrosion was claimed as the possible mechanism for resistance shift in only a few papers (18,20,35–37). A recent study strongly indicated that galvanic corrosion rather than simple oxidation of the nonnoble metal at the interface between an ICA and the nonnoble metal was the main mechanism for the shift in contact resistance of ICAs (Fig. 4) (38,39). The nonnoble metal acts as an anode, is reduced by losing electrons, and turns into metal ion ($M - ne^- = M^{n+}$). The noble metal acts as a cathode, and its reaction generally is $2H_2O + O_2 + 4e^- = 4OH^-$. Then M^{n+} combines with OH^- to form a metal hydroxide or metal oxide. After corrosion, a layer of metal hydroxide or metal oxide is formed at the interface. Because this layer is electrically insulating, the contact resistance increases dramatically (38,39). A galvanic corrosion process has several characteristics: (1) happens only under wet conditions, (2) an electrolyte must be present, and (3) oxygen generally accelerates the process. Based on this finding, several methods can be employed to stabilize the shift in contact resistance.

Galvanic corrosion happens only in wet conditions. An electrolyte solution must be formed at the interface before galvanic corrosion can happen. Therefore, one way to prevent galvanic corrosion at the interface between an ICA and a nonnoble metal surface is to lower the moisture pickup of the ICA. ICAs that have low moisture absorption generally showed more stable contact resistance on nonnoble surfaces (40,41). Without electrolyte, the rate of galvanic corrosion is very low. The electrolyte in this case is mainly from the impurities in the polymer binder (generally epoxy resins). Therefore, ICAs formulated with resins of high purity should show better performance.

Figure 4. Metal hydroxide or oxide formation after galvanic corrosion.

The second method of preventing galvanic corrosion is to introduce some organic corrosion inhibitors into ICA formulations (39,41). In general, organic corrosion inhibitors act as a barrier layer between the metal and environment by being adsorbed as a film over the metal surfaces (43–46). Some chelating compounds are especially effective in preventing metal corrosion (45). Most organic corrosion inhibitors can react with epoxy resins at certain temperatures. Therefore, if an ICA is epoxy-based, the corrosion inhibitors must not react with the epoxy resin when the epoxy resin is cured. Otherwise, the corrosion inhibitors are consumed by reacting with the epoxy resin and lose their effect. Organic corrosion inhibitors are thoroughly summarized in the literature (44,46). As an example, Fig. 5

Figure 5. Effect of a corrosion inhibitor on the contact resistance between an ICA and a Sn/Pb surface (aging conditions: 85°C/85% relative humidity) (38).

Figure 6. A joint connected with an ICA that contains oxide-penetrating particles and silver powders.

shows the effect of a chelating corrosion inhibitor on contact resistance between an ICA and Sn/Pb surface. It can be seen that this corrosion inhibitor is very effective in stabilizing the contact resistance.

Oxygen can accelerate galvanic corrosion. Therefore, another way to slow down the corrosion process is to incorporate some oxygen scavengers into ICA formulations (43). When an oxygen molecule diffuses through the polymer binder, it reacts with the oxygen scavenger and is consumed. However, when the oxygen scavenger is depleted completely, then oxygen can still diffuse into the interface and accelerate the corrosion process. Therefore, oxygen scavengers can delay galvanic corrosion process only for some time. Similarly, the oxygen scavengers used must not react with the epoxy resin at its cure temperature. Common oxygen scavengers include hydrazine, carbonylhydrazide, hydroquinone, gallic acid, propyl gallate, hydroxylamines and related compounds, dihydroxyacetone, 1,2-dihydro-1,2,4,5-tetrazines, erythorbic acid, and oximes (43,47–50).

It is claimed that transient liquid-phase sintering conductive adhesives mentioned in the previous section have stable contact resistance during elevated temperature and humidity aging (32). The joints formed include metallurgical alloying to the junctions as well as within the adhesive itself. This provides a stable electrical connection during aging.

Another approach for improving contact resistance stability during aging is to incorporate some electrically conductive particles, which have sharp edges, into the ICA formulations. The particle is called an oxide-penetrating filler. Force must be provided to drive the oxide-penetrating particles through the oxide layer and hold them against the adherend materials. This can be accomplished by employing polymer binders that show high shrinkage when cured (Fig. 6) (51). This concept is used in Poly-Solder which has good contact resistance stability with standard surface-mounted devices (SMDs) on both solder-coated and bare circuit boards.

IMPROVEMENT OF IMPACT PERFORMANCE

Impact performance is a critical property of solder replacement ICAs. Effort has been continued in developing ICAs that have better impact strength and will pass the drop test, a standard test used to evaluate the impact strength of ICAs.

Nanosized metal particles were used in ICAs to improve electrical conduction and mechanical strength. Using nanosized particles, agglomerates are formed due to surface tension (52). Another approach is simply to decrease the filler loading to improve impact strength (53). However, such a process reduces the electrical properties of the conductive adhesives. A recent development was reported where conductive adhesives were developed using resins of low modulus, so that this class of conductive adhesives could absorb the impact energy developed during the drop (54). However, the electrical properties of these materials were not mentioned in the paper. Conformal coating of the surface-mounted devices was also used to improve mechanical strength. It was demonstrated that conformal coating could improve the impact strength of conductive adhesives joints (13,55).

More recently, a new class of conductive adhesives which is based on an epoxide-terminated polyurethane (ETPU) has been developed (56,57). This class of conductive adhesives has the properties of polyurethane materials, such as high toughness and good adhesion. The modulus and glass transition temperature of the ICAs can be adjusted by incorporating some epoxy resins such as bisphenol-F epoxy resins. Conductive adhesives based on ETPU showed a broad loss factor ($\tan \delta$) peak with temperature and a high $\tan \delta$ value at room temperature. The $\tan \delta$ value of a material is a good indication of the damping property and impact performance of the material. In general, the higher the $\tan \delta$ value, the better the damping property (impact strength) of the material. As an example, changes in $\tan \delta$ and modulus of an ETPU-based ICA with temperature are shown in Fig. 7. ICAs based on ETPU resins also showed a much higher loss factor in a wide frequency range than ICAs based on bisphenol-F epoxy resins (Fig. 8). This indicated that the ICAs based on ETPU resins should exhibit good damping properties and improved impact performance in different electronic packages. This class of conductive adhesives showed superior impact performance and substantial stable contact resistance with non-noble metal surfaces such as Sn/Pb, Sn, and Cu (56,57).

Again, transient liquid-phase sintering conductive adhesives showed good impact strength due to the

Figure 7. Changes in $\tan \delta$ and modulus with temperature of an ETPU-based conductive adhesive measured by a dynamic mechanical analyzer (DMA) (56).

Figure 8. Loss factor versus frequency of two ICA materials.

metallurgical interconnection between the conductive adhesive and the components (32).

HIGH-PERFORMANCE CONDUCTIVE ADHESIVES

A solder replacement conductive adhesive should have the following main properties (22):

1. Bulk resistivity lower than 1 milliohm-cm ($m\Omega\text{-cm}$);
2. Shift of contact resistance (after 500-hour $85^\circ\text{C}/85\%\text{RH}$ aging) less than 20%; and
3. Passes six drops from a 60-inch height.

Based on the review in the previous sections, a high-performance conductive adhesive can be formulated mainly by two approaches which are described as follows.

Conductive Adhesives Based on an Epoxide-Terminated Polyurethane (ETPU)

A hardener (usually a liquid anhydride), which can provide the ICA with the lowest moisture pickup, should be selected first. A conductive adhesive formulation should consist of the following components: the epoxide-terminated polyurethane, an epoxy resin (optional), the hardener, an adhesion promoter, a conductivity promoter, Ag flakes (mixture of large and small particles), and some other additives, for example, corrosion inhibitors and oxygen scavengers. Conductive adhesives based on this formulation showed desirable conductivity, superior impact performance, and substantial contact resistance on nonnoble metal surfaces such as Cu, Sn, and Sn/Pb (56,57). These materials are being tested in surface-mounted applications.

Transient Liquid-Phase Sintering Conductive Adhesives

A conductive adhesive from this category should include a high melting point metal filler, a low melting point metal filler, a polymer binder, and other (optional) additives. The low melting point metal filler must alloy with the high melting point metal filler and the metal surface to be joined at a specific acceptable temperature. The alloy formed should not liquify at the processing or usage temperature of the ICA. Otherwise, the contact resistance and adhesion might be diminished. For the low melting point alloy to wet

the high melting point filler and for the metal surfaces to be joined, the polymer binder must also contain a flux or have a fluxing function to remove the oxide on the high melting point metal filler and the metal surfaces to be joined. Due to the metallurgical connection at the junctions and inside the conductive adhesive, the junction showed stable contact resistance during elevated temperature and humidity aging and desirable impact strength.

ELECTROCERAMICS

HARRY TULLER

Massachusetts Institute of Technology
Cambridge, MA

INTRODUCTION

Ceramics have traditionally been admired for their mechanical, chemical, and thermal stability; however, their unique electrical, optical, and magnetic properties have become of increasing importance in many key technologies including communications, energy conversion and storage, electronics, and automation. Such materials are now classified as *electroceramics* as distinguished from other functional ceramics such as advanced structural ceramics. It is the combination of the traditional ruggedness of conventional ceramics and the exceptional functionality of select electroceramic materials that make electroceramics particularly attractive as *smart materials* and as components of *smart systems*.

ELECTROCERAMICS AND SMART SYSTEMS

The term *smart* suggests emulation of living systems that sense their environments, evaluate these inputs in relation to knowledge stored in memory, and respond accordingly, thereby operating by using a built-in *feedback* mechanism. A very general schematic of the feedback loop is shown in Fig. 1.

From a technological standpoint, the feedback system's functions are commonly subdivided into the categories of (1) sensor, (2) microprocessor and memory, and (3) actuator. The *brain* of the feedback network operates nearly exclusively in the electrical domain, so the sensor normally functions as a transducer that converts various physical and chemical inputs or stimuli into electrical outputs, and the actuators convert electrical inputs from the microprocessor into the appropriate physical and chemical outputs. These feedback system features are illustrated in Fig. 2. Both sensor and actuator often require auxiliary inputs to enable them to operate properly. This will become obvious

Figure 1. Smart structures: Incorporation of sensing and actuating functions in a control system. A feedback loop can go through a control circuit or directly between sensor and actuator.

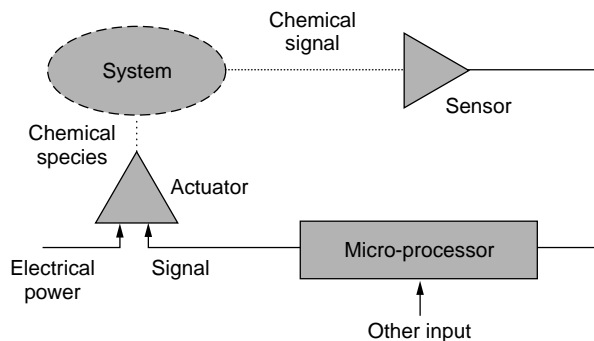

Figure 2. A schematic of a feedback system including sensor, microprocessor, and actuator that monitors and controls the chemical state of the system. Both sensor and actuator may require auxiliary inputs to enable them to operate properly.

as specific examples of sensors and actuators are discussed. Pursuing biological counterparts further, we are aware that some stimuli bypass the brain. Some responses are triggered automatically, for example, when one pulls one's hand away from a hot object. Corresponding automatic responses occur in materials systems. Newnham subdivides smart materials into two categories (1). *Passively smart materials* are defined as those that respond automatically to external change without assistance, whereas *actively smart materials* use a feedback loop that enables them to recognize the change and initiate an appropriate response through an actuator, as illustrated in Fig. 1. Obviously, *passively smart materials* potentially provide much simpler and thereby less costly alternatives, whereas *actively smart materials*, though more complex, via programming provide considerably more flexibility in their response. Examples of both types of smart materials are described in following sections.

Based on this definition of *smart*, any feedback system, independent of size, complexity, power requirements, cost, etc., would qualify. However, as additional constraints of speed, size, power, harsh environmental operation, and cost are imposed on such systems, then the types of materials, their modes of fabrication, transduction efficiency, and stability begin to play important roles. *Electroc ceramic* materials excel for many of these reasons.

Enormous strides have been made in microprocessor speed and memory density during the past few decades, but comparable developments in sensors and actuators have, in many cases, lagged considerably. Many such devices remain bulky, consume substantial power, do not readily interface with electronics, and respond sluggishly. The effective integration of functional *electroc ceramic* materials into microelectronic and microelectromechanical (MEMS) technologies remains a key challenge for this field. The ability to harvest the benefits of miniaturization, low power, integration, and the ability to fabricate large arrays, will, however, pay major dividends in performance, versatility, speed, and reduced costs.

To appreciate the versatility of *electroc ceramics* and their potential use in smart systems, we summarize some of the key properties most commonly associated with sensing and actuating functions. For example, piezoelectrics such as $\text{Pb}(\text{Zr}_{1-x}\text{Ti}_x)\text{O}_3$ (PZT) are used to detect mechanical

Table 1. Energy Transduction Types, Materials, and Applications

Energy Transduction	Materials	Applications
Electrical \Rightarrow mechanical	Pb(Zr _{1-x} Ti _x)O ₃ (PZT)	Positioner, optical tuner
Mechanical \Rightarrow electrical		Igniter
Electrical \Rightarrow chemical	Zr _{1-x} Y _x O _{2-x/2} (YSZ),	Oxygen pump
Chemical \Rightarrow electrical	SnO ₂	Gas sensor
Electrical \Rightarrow optical	LiNbO ₃	Electro-optic modulator
Optical \Rightarrow electrical	GaN	Light detector
Electrical \Rightarrow magnetic	AB ₂ O ₄ spinel: A,B = Mn, Zn	Write head
Magnetic \Rightarrow electrical	La _{1-x} Ca _x MnO ₃	Read head
Electrical \Rightarrow thermal	SiC	Resistive heater
Thermal \Rightarrow electrical	AB ₂ O ₄ spinel: A,B = Mn, Ni, Fe, Co, Cu	NTCR thermistor
	BaTiO ₃ perovskite	PTCR thermistor

displacement electrically and inversely to induce mechanical displacements by applying electric fields. Solid electrolytes, such as Zr_{1-x}Y_xO_{2-x/2} (YSZ), are used potentiometrically to monitor the chemical state (oxygen activity) of an environment or to modify that state by electrochemically pumping oxygen into that environment. These and other examples that relate to transduction between electrical, optical, magnetic, and thermal forms of energy are summarized in Table 1. Typical materials and applications are included in this table.

The performance of *electroc ceramic* materials and devices depends on the complex interplay among processing, chemistry, and structure at many levels. Because *electroc ceramics* are commonly polycrystalline, their microstructure (grain size and distribution, porosity, phase distribution) and their crystal and defect structures often play crucial roles in determining their properties. Likewise, domain structures dominate the properties of ferroelectric and ferromagnetic *electroc ceramic* materials. These factors are discussed when addressing some of the specific applications of these materials relevant to the design and development of smart materials.

Articles in the professional literature deal with the processing, characterization, structure, properties, modeling, and performance of *electroc ceramics*. Recent advances in these areas are described in the *Journal of Electroceramics* and other general or more specialized journals such as the *Journal of Applied Physics*, *Journal of the American Ceramic Society*, *Ferroelectrics*, and *Solid State Ionics*.

The numbers and types of applications for smart materials and systems are limited only by the imagination, so we selected five that (1) are representative from the standpoint of dealing, in one form or another, with each of the six major energy types (electrical, optical, magnetic, chemical, mechanical, and thermal); (2) illustrate popular applications; and (3) illustrate the use of passively and actively smart materials. For each of these examples, we summarize the underlying physical principles, discuss figures of merit, and consider materials of choice. When appropriate, we also list opportunities for further development.

ELECTROMECHANICAL ACTUATORS

Applications

Vibrational Damping. There are many applications where vibrational reduction and/or control is required. The

military has an interest in reducing acoustic emissions from submarines, commercial airlines are concerned with the vibrations in passenger cabins, and automobile manufacturers, deal with the vibrations experienced by passengers riding over rough terrain. Two recent examples where such concepts have been applied to the world of sports are examined: the ski/snowboard, and the bicycle shock absorber. Figure 3 shows the piezoelectric stack used in ski and snowboard vibrational control. The heart of the vibrational damper is a piezoelectric element connected to an electric circuit that is tuned to dissipate energy at frequencies deemed undesirable, as illustrated in Fig. 3.

A more sophisticated design is the smart shock absorber or suspension system. Smart suspensions are already installed in many cars. For simplicity, we examine a shock absorber designed for bicycles (Fig. 4). The magnetic GMR sensor sends data relating to the rate of motion to the control electronics that in turn instructs the piezoelectric actuator to manipulate a valve in the hydraulic shock absorber that controls damping.

Precision Positioning. In the microelectronics industry, piezoelectric motors or stacks enable mask positioning in

Figure 3. Vibrational damper in skis and snowboards. An electrical circuit is tuned to damp out vibrations in the undesired frequency band (ACX designs).

Figure 4. Design for a smart shock absorber. The rate of motion is monitored by the magnetic GMR sensor, and the piezoelectric actuator manipulates a valve that controls damping (Design by K2 SmartShock™).

the submicron range. Similar positioning systems are used in electron microscopy and atomic force microscopy (AFM) to control stage movements of 10–100 nm. In AFM, for example, the position of the microcantilever beam relative to the substrate is detected optically by reflecting a laser beam off the microcantilever beam and measuring its movement by using position-sensitive photodetectors. Thus, the feedback loop involves an optical sensor, computer, and piezoelectric actuator.

Camera Components. Consumer applications include camera lens controllers and video camera stabilizers. Auto-focus camera lenses now contain built-in piezoelectric ultrasonic motors. These motors operate in a feedback mode and reposition the optical components in the lens to achieve fast and accurate autofocusing (for more details see section on smart optical systems).

Some manufacturers use piezoelectric sensors to sense video camera vibrations. Two piezoelectric velocity sensors respond to the camera's movement along its vertical and horizontal axes. The sensors control motors that realign a

Figure 5. Piezoelectrics sense camera movement and adjust the prism to stabilize the image in a video camera.

prism that bends the light to compensate for vibrations. The operation of this system is illustrated in Fig. 5.

ACTUATOR MATERIALS

General

Mechanical actuators are encountered in many forms and sizes. Although electromagnetic motors and hydraulic jacks serve many applications, there are limitations to their use in smaller scale applications. A comparison of conventional and piezoelectric actuation methods is shown in Table 2. Piezoelectrics excel in bandwidth and power density.

The development of precision electromechanical actuators (EMA) has grown in recent years. The world market for medical ultrasonic probes alone stands at \$250 million/year (2). The major advantages of these actuators are high precision (on the order of 10 nm), rapid response time (10 μ s), and high generative force with low driving power (see Table 2). These properties make EMAs attractive for optical systems, precision machinery, and small, high-power motors (3).

Another category of piezoelectric applications uses resonant strain obtained by an applied ac field. Ultrasonic motors, pumps and surgical knives are just a few examples of high-frequency, high-accuracy applications that use resonating piezoelectric materials. A list of some general types of applications that use piezoelectric and electrostrictive actuators is given in Table 3. The table also lists some of the major research institutes that are developing those applications.

BASIC RELATIONSHIPS AND PHENOMENA

The Piezoelectric Family of Materials

The piezoelectric effect relates electric polarization to applied stress. Polarization requires a nonsymmetrical structure; therefore all crystallographic point groups that have a center of symmetry cannot support piezoelectricity. Furthermore, although the cubic class 432 lacks a center of symmetry, it cannot accommodate piezoelectricity. Therefore, only 20 of the 32 crystallographic point groups exhibit piezoelectricity. Of these groups, 10

Table 2. Comparison of Conventional and Piezoelectric Actuation

Actuation Method		Stress (Mpa)	Strain (%)	Efficiency (%)	Bandwidth (Hz)	Work (J/cm ²)	Power (W/cm ³)
Conventional	Electromagnetic	0.02	50	90	20	0.005	0.1
	Hydraulic	20	50	80	4	5	20
	Pneumatic	0.7	50	90	20	0.175	3.5
Piezoelectric	Polycrystal	35	0.2	50	5000	0.035	175
	Shape-memory	200	1.0	3	3	10	30
	Single-crystal	300	1.7	90	5800	2.55	15000

have a unique crystallographic axis and therefore, can have an electric dipole even at zero applied field (electrical and mechanical). These materials are defined as pyroelectric and show a change of polarization when temperature changes.

Pyroelectric materials include a subclass of materials in which an applied external field can change the direction of polarization. These materials are referred to as ferroelectric. In some cases, although a polar unit cell exists in the material, the overall behavior is nonpolar. Materials that have polar subcells organized so that adjacent subcells have opposite polarization are called antiferroelectric. The relationships between the different symmetry groups and polarization properties are shown in Fig. 6.

The Piezoelectric Effect

The piezoelectric modulus d is a third-rank tensor that relates the polarization P_i to the applied stress σ_{jk} :

$$P_i = d_{ijk} \sigma_{jk}. \quad (1)$$

The units of the piezoelectric modulus are [C/N] or [m/V].

The converse piezoelectric effect relates changes in crystal shape and size to an applied electric field. It can be shown that the coefficient that relates strain ε_{ij} to an applied electric field E_k is identical to the direct piezoelectric

modulus, so that

$$\varepsilon_{jk} = d_{ijk} E_i. \quad (2)$$

For a detailed discussion of the tensor behavior of the piezoelectric coefficient and a proof of the equality of the direct and converse effects see (5, Chaps. VII and X).

Piezoelectric Figures of Merit

The piezoelectric coefficient is a very important parameter of piezoelectric actuators. There are, however, other important parameters of these materials to consider.

Polarization is not an easy property to measure. In many sensors, the measured value is the voltage, or the electric field E , that is induced by an applied stress σ . The relationship between the field and the stress is given by the piezoelectric voltage constant g :

$$E_i = g_{ijk} \sigma_{jk}. \quad (3)$$

Taking into account the relationship between the electric field and polarization, one can easily show that the two piezoelectric constants are related by

$$g = d/\varepsilon \cdot \varepsilon_0. \quad (4)$$

This is a simplified form of the tensor relationship that holds for homogeneous materials or along a principal axis.

^aRef. 4.

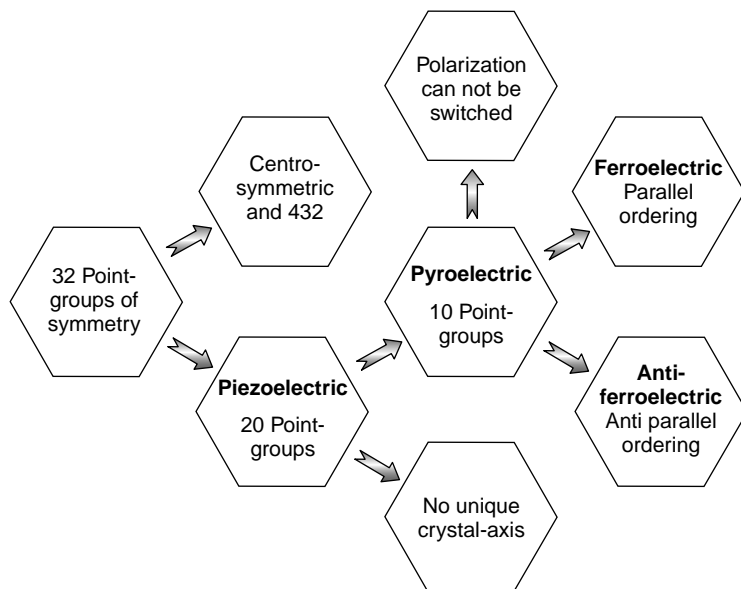

Figure 6. Crystallographic symmetry groups and their relationship to polarized materials.

Both the strain and the voltage piezoelectric constants give the magnitude of the effect; however, they do not tell us how efficient the system is. Three parameters describe the transfer between electrical and mechanical energies:

1. Efficiency: $\eta = (\text{output energy})/(\text{consumed energy})$
2. Energy transmission coefficient: $\lambda_{\max} = [(\text{output energy})/(\text{input energy})]_{\max}$
3. Electromechanical coupling factor: $k^2 = (\text{stored energy})/(\text{input energy})$

Although the differences between these parameters are small, they are important. They are not, however, independent. It can be shown that the electromechanical coupling coefficient is related to the stiffness c or the compliance s and to the piezoelectric and dielectric constants (6):

$$k^2 = d^2 c / \varepsilon \cdot \varepsilon_0 = d^2 / s \cdot \varepsilon \cdot \varepsilon_0 \quad (5)$$

From this, the relationship between the coupling coefficient and the energy transmission coefficient can be calculated as

$$\lambda_{\max} = \left[\left(\frac{1}{k} \right) - \sqrt{\left(\frac{1}{k^2} \right) - 1} \right]^2 \quad (6)$$

By taking the consumed energy as the difference between input and output energies, the relationship between the

efficiency and the energy transmission can be written as

$$\eta = \frac{\lambda_{\max}}{1 - \lambda_{\max}} \quad (7)$$

Piezoelectric materials have a characteristic electromechanical resonant frequency. The material response close to that frequency is highly nonlinear, and the parameters described before are insufficient. The resonance behavior is very important for applications such as sensors and ultrasonic motors. The frequency width $\Delta\omega$ of the resonance is used to describe the quality of the resonance in the material around the resonant frequency ω_0 :

$$Q_m = \omega_0 / 2\Delta\omega \quad (8)$$

A full description of resonators and acoustic wave sensors is beyond the scope of this article. Comprehensive coverage of the topic can be found in (7). Table 4 summarizes the figures of merit.

Ferroelectric Hysteresis

Ferroelectric materials have a remanent polarization at a zero applied field. The energy needed to rotate domains and to move domain walls creates a hysteric loop, as shown in Fig. 7. Similar behavior is seen in the strain-field curve. This results in a permanent strain after removing the electric field that can be used for shape-memory

Table 4. Figures of Merit for Piezoelectric Materials^a

Figure of merit	Parameter (units)	Important Relationships
Piezoelectric strain constant	d (C/N)	$\varepsilon_{jk} = d_{ijk} E_i$; $P_i = d_{ijk} \sigma_{jk}$
Piezoelectric voltage constant	g (V · m/N)	$E_i = g_{ijk} \sigma_{jk}$; $g = d / \varepsilon \cdot \varepsilon_0$
Electromechanical coupling coefficient	k^2 (-)	$k^2 = d^2 c / \varepsilon \cdot \varepsilon_0 = d^2 / s \cdot \varepsilon_0$
Mechanical quality factor	Q_m (-)	$Q_m = \omega_0 / 2\Delta$

^aSymbol definitions can be found in the text.

Figure 7. [i] Polarization curve and [ii] strain curve, in a ferroelectric material. The domain images on the right side are schematic representations of the polarization state in the material at different points along the curves (Based on 8,9).

applications. The drawback of these systems is the relatively high loss due to hysteresis. In high-frequency applications, this leads to heating, and special care must be taken to limit temperature excursions to less than the Curie temperature.

Two important parameters are related to the hysteretic loop; the remanent polarization and the coercive field. The remanent polarization is the polarization level in the absence of an external electric field (P_R in Fig. 7). This is the effective amount of charge that the material can hold after the electric field is removed and therefore, is the amount of “memory” that the material can have. The remanent polarization is accompanied by a remanent strain. This is important in actuators because it can effectively latch a strained state without the need to keep a constant voltage on it and therefore can save energy. The coercive field (E_C in Fig. 7) is the field required to remove the remanent polarization. The higher that field, the more stable the latching effect. This can be important for preventing spontaneous depoling; however, a high coercive field requires a higher operating voltage and is more limited in high-frequency applications.

Actuation by Phase Transition

At times, electric fields can be used to induce phase transitions in ferroelectric materials. Application of an appropriate field to the rhombohedral phase causes rotation of the polarization vector toward the direction of the applied field. Under sufficient rotation, the induced structural change induces a phase transition illustrated in Fig. 8.

At times, the new phase is metastable so that it remains after the electric field is removed (see Fig. 8). In such cases, a latching, or memory effect is observed, and the material remains strained with respect to its initial state. An electric field in the opposite direction must be applied to return it to the unstrained state. This is similar to the memory effect described in the previous section, although the remanent field and strain are usually much higher.

ELECTROSTRICTIVE BEHAVIOR IN MATERIALS

Electrostriction is a second-order effect of an electromechanical interaction. This is not to say that it is always

Figure 8. Field-induced phase transition from the rhombohedral to the tetragonal phase. Data is for PLZHT (10).

negligible compared to first-order piezoelectricity. When looking at a simplified rigid sphere model, the piezoelectric effect is the result of the difference in the spring constants of the different ions. The electrostrictive effect is represented by divergence from a perfect harmonic oscillator (4), as illustrated in Fig. 9. Because it is a second-order effect, the electrostriction is not limited to systems that have no center of symmetry. Furthermore, electrostriction is not limited to specific crystallographic systems.

The combined electrostrictive and piezoelectric converse effect is given by

$$\varepsilon_{jk} = d_{ijk} E_i + q_{iljk} E_i E_l. \quad (9)$$

Figure 9. Rigid ion model and the corresponding strain-field behavior of (a) a non centrosymmetric, piezoelectric material, and (b) a centrosymmetric, electrostrictive crystal (8).

Figure 10. A unit cell of the perovskite structure. The B ion is octahedrally coordinated by the oxygen ions.

It is important to note that, even if one begins with a centrosymmetric structure, the application of an electric field can result in breaking that symmetry and consequently the appearance of a piezoelectric element (5).

MATERIALS SYSTEMS

Perovskite Structure

Most oxygen-octahedral structures that have ferroelectric properties and high Curie temperatures are based on corner linking of the oxygen octahedra (11). Of these, the simplest and most common structure is the perovskite family shown in Fig. 10. The figure describes the high symmetry cubic prototype ($m\bar{3}m$) for this family. At lower temperatures, phase transitions to ferroelectric / antiferroelectric phases occur due to lattice distortion and oxygen octahedral tilting. This results in a loss of symmetry, as shown in Fig. 11.

PZT-Based Materials

Lead zirconate titanate ($\text{PbZr}_x\text{Ti}_{1-x}\text{O}_3$) solid solutions are some of the most commonly used piezoelectric materials. A morphotropic phase boundary between a tetragonal and a rhombohedral structure occurs around $x = 0.52$. Materials whose compositions are close to that boundary exhibit a high piezoelectric coefficient and higher coupling coefficient. A second morphotropic phase boundary exists between ferroelectric and antiferroelectric phases around $x = 0.92$. This region is particularly useful for shape-memory actuators.

Barium-Titanate-Based Materials

Barium Titanate (BaTiO_3) is another very common ferroelectric material. For many years, the main interest in this materials system was for its excellent dielectric properties. BaTiO_3 has a low piezoelectric coefficient at room temperature; however, by using a solid solution of BaTiO_3 that contains other materials, such as BaZrO_3 , the rhombohedral phase can be stabilized, and a much higher piezoelectric response can be achieved (12).

Figure 11. The four key structural types exhibited by compounds that have perovskite structures. Note the orientations of the polarization vector in the tetragonal, orthorhombic, and rhombohedral distortions of the cubic structure.

Single-Crystal Materials

The most widely used single-crystal piezoelectric materials are quartz, lithium niobate (LiNbO_3), and lithium tantalate (LiTaO_3). Although the piezoelectric coefficients of these materials are much smaller than that of PZT, they hold an important position in resonance applications. The quality factor of single crystalline materials can be three orders of magnitude higher than that of polycrystals. This increases their response close to the resonant frequency.

Quartz oscillators are used for clock source and frequency stabilizers in many household appliances. LiNbO_3 and LiTaO_3 have very high electromechanical coupling coefficients for surface acoustic waves (SAW) and are often used in SAW devices.

Relaxor-Based Ferroelectric Single Crystals

In recent years, a new family of ferroelectrics has received great attention for use in electromechanical actuation. Relaxor-based ferroelectrics have shown great promise as actuator materials due to their high strain. Strain levels up to 1.7% have been reported for PZN-PT (13) compared to 0.15% for PZT.

Table 5 summarizes the key properties of the piezoelectric materials discussed before.

THERMAL SYSTEMS

Applications

The most pervasive form of energy that has traditionally interested humankind in measuring and controlling is thermal. Presently, this ranges from monitoring and controlling the temperatures of our homes, offices, and automobiles, the foods that we prepare, and various key industrial processes (chemical and drug syntheses, semiconductor fabrication, metal forming, etc.) on which we depend.

Self-Regulating Heaters. Electroceramics offer passively smart systems that regulate temperature without temperature controllers. Certain types of electroceramic materials, fabricated as honeycombs, are used as heating elements that have built-in self-regulation of temperature. Heat is obtained by forcing air through hundreds of holes in each element (see Fig. 12). The elements, largely based on barium titanate, have a positive temperature coefficient (PTC) of electrical resistance. As the temperature of the ceramic increases, its resistance increases rapidly, thereby reducing the current flow through it. Therefore, the temperature of the PTC heater is self-regulating and does not exceed a given *set* temperature that is fixed by the composition of the ceramic. Some typical applications include portable fan heaters, clothes dryers, and fuel evaporators.

PTC ceramics are also used for overcurrent and overtemperature protection of devices such as motors, transformers, and electronic circuits. When a fault occurs, the element heats up and the resulting increase in resistance prevents damage to the device by limiting the current. In this manner, the *thermistor* acts like a smart fuse;

Table 5. Properties of Piezoelectric Materials^a

Material	T_c ($^{\circ}\text{C}$)	ϵ_r	k_{33}	d_{33} (pC/N)	Q_m
PZT 4 (hard)	325	1200	0.70	285	500
PZT 5H (soft)	195	2800	0.75	593	65

BaTiO_3 (modified)	80	1500	—	480	—
PZN-8%PT	175	5000	0.94	2500	70

^aBased on (6,14,15).

Figure 12. A self-regulated heater element fabricated as a honeycomb. This provides a convenient means for heating air forced through the structure (16).

once the circuit fault is corrected, it returns to its normal protective function.

Miniaturized Flow Sensor. Miniaturization provides the means to integrate multiple functions into a single package that enables designing and fabricating smarter sensors. An example that uses elements both for generating thermal energy and detecting its flow and direction is the micromachined airflow sensor illustrated in Fig. 13 (17). The mass airflow sensor consists of thermally isolated silicon nitride microbridges suspended over a cavity etched into a silicon wafer. Thin film sensing elements (thermally sensitive resistors) are positioned on both sides of centrally located heating elements that maintain the bridge at a well-defined temperature above ambient ($\sim 150^\circ\text{C}$). The thermal isolation limits the temperature rise on the surrounding chip to less than 1°C . Airflow directed laterally across the chip cools the upstream resistor and heats the downstream resistor. The output of a Wheatstone bridge then becomes proportional to the airflow, and the polarity of the voltage depends on the direction of flow. One such device, manufactured by Honeywell (18), is illustrated in Fig. 14. The sensitivity depends, in part, on the temperature coefficient of resistivity of the resistors and the thermal mass of the elements. These devices provide sensitivity to low flows (0.1 sccm), consume little power (30 mW), and have rapid response times. Typical applications include medical respirators, leak detection, gas metering and analysis, process control, and air conditioning systems.

Figure 13. A schematic of a micromachined flow sensor (17).

Figure 14. A micromachined flow sensor manufactured by Honeywell similar in design to this schematic in Fig. 13 (18).

Operating Principles

Resistive. All matter exhibits temperature-dependent resistivity, but the nature and magnitude of this sensitivity varies widely among different materials. The resistivity of metals increases as temperature increases and thus the designation *positive temperature coefficient of resistance* (PTCR). This relatively weak variation with temperature results from thermally induced scattering of carriers and is reflected in a nearly linear increase of resistivity with temperature. On the other hand, the resistivity of semiconductors and insulators, in general, decreases with temperature and thus the designation *negative coefficient of resistance* (NTCR). The decrease in resistivity is exponential and is most commonly tied to the thermal activation of charge carriers across an energy gap. However, among *electroceramic* materials, many are characterized by mobilities (small polaron) that themselves are thermally activated. This becomes relevant in our subsequent discussions of NTCR thermistors.

A limited number of materials exhibit phase change induced anomalous and strong temperature-dependent changes in resistivity across relatively narrow temperature limits. Examples of the various types of temperature-dependent resistivities are illustrated in Fig. 15, and the

Figure 15. Characteristic resistance-temperature dependencies for various sensor materials (20).

Table 6. Sensitivity, Stability, and Operating Range of Sensor Materials^a

Sensor Material	Resistance Change (1/R)dR/dT (%/°C)	Stability	Temperature Range (°C)
Metals	+0.1–0.5	Fair to good	100–1000
Silicon	+0.1	Fair to good	150
BaTiO ₃ (PTC)	+10 to 100	Good at T_C	200+
NTC	–6.0 to –1.0	Good to excellent	300

^aRef. 20.

relative sensitivity, stability, and temperature range of usage are summarized in Table 6.

Devices designed to detect temperature changes by monitoring corresponding changes in resistance are called *thermistors*. The resistivity ρ of NTCR thermistor materials takes the form

$$\rho = \rho_0 \exp(E/kT), \quad (10)$$

where E is the effective activation energy that takes into account both carrier generation and mobility contributions. This is conventionally rewritten in terms of resistance R as

$$R = A \exp(B/T), \quad (11)$$

where the material constant B , or beta factor, is simply E/k and A is a constant related to the device dimensions and materials resistivity. Typical values of B fall around 3500 K, which corresponds to an activation energy of ~ 0.3 eV. The temperature coefficient of resistance (TCR) is often designated by the symbol $\sigma = (1/R) (dR/dT)$ and is related to B by $\alpha = -B/T^2$.

PTCR thermistors, in contrast to the majority of NTCR thermistors, which are grain controlled devices, depend instead on the resistance of the boundaries between the grains. N-type barium titanate BaTiO₃, prepared using appropriate additives and annealed in oxidizing atmospheres, develops grain boundary regions depleted in electrons. This results in creating space charge barriers (see Fig. 16) that block the flow of electrons between grains and a corresponding increase in the overall resistance of the material. For a small bias, the resistance is given by (21)

$$R \approx (A/T) \exp(\phi_B/kT). \quad (12)$$

The barrier height ϕ_B is related to N_D the donor density, d the space charge width, and ϵ the dielectric constant by

$$\phi_B = qN_D d^2 / 2\epsilon. \quad (13)$$

For materials such as BaTiO₃, which become ferroelectric at reduced temperatures and comply with the Curie–Weiss law,

$$\epsilon = C/T - T_C. \quad (14)$$

Combining Eqs. (12)–(14), one obtains the following dependence of R on T :

$$R \approx (A/T) \exp\{(qN_D d^2 / 2Ck)[(T - T_C)/T]\}. \quad (15)$$

As the temperature approaches the Curie temperature T_C from above, the dielectric constant increases and leads to a rapid drop in resistance. This correlation between R (or equivalently the resistivity ρ) and ϵ is clearly illustrated in Fig. 17 which shows that the resistivity decreases by nearly eight orders of magnitude as the effective dielectric constant increases from ~ 2000 to $\sim 30,000$. This resultant strong PTCR effect in the vicinity of the Curie temperature is used in a number of applications for temperature measurement and control.

Materials Systems

NTCR thermistors are traditionally fabricated from complex oxide spinels of the general formula AB₂O₄. The A and B sites are, respectively, tetrahedrally and octahedrally coordinated by oxygen. Transport reportedly occurs largely between neighboring B-site cations of different valence. The temperature dependence of resistivity is largely tied to the thermally activated mobility of the carriers, given that these systems already possess high carrier densities. Because the spinel structure accommodates large variations in composition, these allow great flexibility in tailoring both the magnitude of resistivity and its temperature coefficient of resistance (TCR), as illustrated in Fig. 18. Furthermore, thermistors fabricated from this family of materials can be reproduced with high precision and reproducibility (20).

Figure 16. Schematic of the energy band diagram of the interfacial region between two n-type semiconducting grains. Interfacial traps induce depletion of electrons and band bending in the adjacent grains. Depletion widths are given by d , grain boundary width $w \ll d$, ϕ_{B0} the barrier height, and $\xi = E_C - E_{FB}$, the energy difference between the conduction band edge and the Fermi energy in the bulk (21).

Figure 17. Temperature dependence of resistivity and dielectric constant of a PTCR thermistor (22).

PTCR thermistors are largely based on the perovskite barium titanate (see earlier section for more details). As discussed before, a key parameter is the Curie temperature which defines the onset temperature of the PTCR effect. This corresponds to the cubic to tetragonal phase transition

Figure 18. Relationship between room temperature resistivity and beta value for selected NTCR thermistor materials classes: (A) Li-doped $(\text{Mn},\text{Ni},\text{Co})\text{O}$; (B) complex spinels AB_2O_4 : $(\text{Ni},\text{Mn})_3\text{O}_4$, $(\text{Ni},\text{Mn},\text{Fe},\text{Co})_3\text{O}_4$; (C) hematite $(\text{Fe},\text{Ti})_2\text{O}_3$ (19).

that can be controlled by many hundreds of degrees Celsius by forming solid solutions using Pb (raises T_C) or Sr (lowers T_C), as illustrated in Fig. 19. Other additives are added to control the level of resistivity of the grains, the height of the space charge barrier, and to aid in densifying the ceramic body. These are summarized in Table 7.

SMART CHEMICAL SYSTEMS

Applications

Auto Exhaust Sensor. Smart chemical systems are of growing importance, given society's increasing sensitivity to and concern for changes in the environment. Sensors are needed to detect and monitor an increasing number of chemical species. Gases such as NO_x , SO_2 , and CO_2 , which contribute to smog, acid rain, and the greenhouse effect, are of particular concern. An important example of such a smart system is represented by the auto exhaust sensor that, in conjunction with the fuel injector, maintains the air-to-fuel (A/F) ratio within narrow limits. The sensor, based on the oxygen ion conductor calcia or yttria stabilized zirconia, is designed to measure the oxygen partial pressure of the exhaust gas across more than fifteen orders of magnitude that represent conditions ranging from fuel-rich to fuel-lean operation. By maintaining A/F close to the so-called stoichiometric ratio, the *three-way catalyst*, placed in the exhaust stream, can simultaneously reduce NO_x , CO, and hydrocarbon emissions with high efficiency. Figure 20 illustrates the position of the zirconia sensor within the auto exhaust manifold, the feedback loop to the electronic control unit (ECU), and the fuel injector.

Table 7. Chemistry Considerations for PTC Sensor Manufacture: Additions Impacting Barium Titanate Semiconductor Properties^a

Addition Type	Addition Function	Typical Substitution Level for Ba or Ti	Addition Elements Used
Isovalent	Solid-solution substitution for Ba or Ti in the titanate	0–0.20	Sr, Pb, Ca, Sn
Altrivalent	Semiconduction or resistivity control	0–0.008	Y, La, Sb, Ce, Nb
Boundary Sintering	Barrier layer control	0–0.002	Mn, Fe, V, Cu
Poisons	Liquid-phase sintering	0.005–0.020	Si, Ti, Ge
	Impurities that degrade PTC quality	0.0002–0.0050	Na, K, Al, P, Mg, transition metals

Smart Gas Sensors Demonstrating Selectivity. The performance materials depend on their chemical makeup. In the semiconductors, such as silicon (Si), even a parts per million (ppm) variation in its chemical makeup has a marked impact on properties. Traditionally, in chemicals production, samples extracted from the process line are chemically analyzed off-line. This procedure is slow, awkward, and often costly. Increasingly, manufacturers are looking for sensors that can operate *in situ* and provide continuous feedback regarding the chemical state of the process. A smart system also provides means for modifying the

Figure 20. The feedback loop between the oxygen exhaust sensor, electronic control unit, and fuel injector used to maintain the air-to-fuel ratio within prescribed limits (22).

process to maintain it within prescribed limits. For example, this might be achieved by controlling the flow rate of certain gases or liquids into the system via an electromechanical flow valve or in principle via an electrochemical pump (24). Similar schemes are under development for drug delivery to patients in which the blood chemistry is continuously monitored and drugs administered appropriately. Gases may also represent health or safety hazards. In contrast to the auto exhaust sensor, which is designed to monitor only oxygen, gas sensors for many of the applications discussed earlier require additional levels of intelligence to monitor a number of gases simultaneously and distinguish among potentially interfering gases.

As in the flow sensor, integration of electroceramics into microelectromechanical systems (MEMS) provides important advantages. Figure 21 shows an image of a 2×2 array of NIST developed microhotplate-based sensors (25,26). Each microhotplate consists of a low thermal mass, resistively heated membrane thermally isolated from the remainder of the silicon wafer by thin tethers. A cross section of the device (Fig. 22) illustrates its multilayer nature that includes a polysilicon heater, a metal thermometer/heat distribution plate, and

Figure 21. A 2×2 array of microhotplate gas sensor platforms developed at NIST (25).

Figure 22. A cross section of the microhotplate sensor in Fig. 21 that show heater, thermometer, contact pads, and sensing film (26).

sensing film electrical contacts separated by insulating SiO_2 layers. Electroceramic films such as SnO_2 or ZnO are deposited onto the top of each device, and gases are sensed by monitoring the change in the resistance of these films. Key features of the device include low power consumption (50 mW for continuous 500°C operation), short turn-off and turn-on times ($\sim\text{ms}$), and wide operating temperature range (typically $20\text{--}500^\circ\text{C}$). The short heating and cooling times enable programmed temperature cycling that leads to improved gas selectivity, as illustrated in Figure 23. These results represent the response of a number of gases, including acetone, formaldehyde, ethanol, and methanol, to a program that consists of ten 100 ms pulses at each of eight temperatures ranging from $20\text{--}370^\circ\text{C}$ in 50°C increments. These gases are normally difficult to distinguish by using conductometric sensors such as SnO_2 when operated at a fixed temperature. By cycling the temperature, characteristic thermal fingerprints

Figure 23. Conductance-time plots showing the response of SnO_2 films to period changes in sensor temperature. Note that each gas exhibits a distinctive thermal “fingerprint” (25).

of the different gases are obtained that are more easily distinguished. By using arrays of sensors, each optimized for different gases, the types of gases and their relative concentrations can be determined much more accurately (28). Because these hotplates are fabricated onto silicon wafers, the option exists to integrate the necessary electronics directly onto the same chip. Similar microhotplate-based sensors are now being micromachined from the more refractory SiC enabling such sensors to operate *in situ* at high temperature and/or in chemically corrosive environments (29,30).

Operating Principles

Electrolytic. Solids that have largely ionic bonding and large band gaps exhibit predominantly ionic conductivity. When these solids are highly defective and the crystalline structure provides high diffusivity pathways between equivalent sites, they may exhibit ionic conductivities comparable to those of liquids (31). Such solids are typically called *solid electrolytes* or *fast ion conductors*. When a concentration gradient of a chemical species contained in the electrolyte is imposed across it, a voltage, known as the Nernst emf is induced across it. For an oxygen ion conducting electrolyte such as stabilized zirconia mentioned before, the voltage takes the form

$$E_N = (kT/4q) \ln(P\text{O}_2''/P\text{O}_2'), \quad (16)$$

where $P\text{O}_2''$ and $P\text{O}_2'$ are the oxygen partial pressures on the two sides of the electrolyte. Examining a schematic of an oxygen sensor used in automotive exhaust systems (see Fig. 24), if $P\text{O}_2'$ is set to a reference gas such as air, then the oxygen partial pressure in the exhaust gas $P\text{O}_2''$ can be determined from the induced output voltage (E in the figure) and the sensor temperature T . Such sensors are called *potentiometric* sensors (32).

By applying a voltage across an electrolyte, it is possible to pump chemical species electrochemically from one chamber to the other thereby modifying its chemical

Figure 24. Schematic of a zirconia-based potentiometric auto-exhaust sensor. The sensor is shown inserted into the wall of the exhaust manifold.

Figure 25. (a) Illustration of semiconductor grains in contact with oxygen ions adsorbed at the surfaces of the grains thereby forming depleted regions near the surfaces. (b) An energy band diagram, as in Fig. 16 that shows barriers of energy qVS between grains (34).

composition. Such *amperometric* devices may be used as sensors or as actuators (24,33).

Conductometric. Compound semiconductors exposed to different gases often exhibit changes in their resistance or equivalently their conductance. At lower temperatures, this effect is limited to gas molecules adsorbing and desorbing from the surface of the semiconductor. Such molecules may form energy states at the surface of the semiconductor and trap free carriers thereby forming depletion layers and space charge barriers at the interface (34), as illustrated in Fig. 25. In the most common electroceramic gas sensor materials, such as SnO₂, these barriers block the flow of charge carriers between adjacent grains in porous polycrystalline ceramics. Adsorbed oxygen increases the barrier height, and reducing gases decrease it. Such sensors exhibit high sensitivity, but this detection mechanism does

not readily distinguish between different reducing gases. Improved selectivity is achieved by adding catalysts or incorporation into arrays of the type discussed earlier.

At sufficiently high temperatures, the bulk of the semiconductor is reduced or oxidized, depending both on temperature and gas composition. The defects formed during the redox process act as donors or acceptors and thereby modify the conductance of the semiconductor. In general, the conductivity σ follows a well-defined power law dependence on the gas partial pressure (20):

$$\log \sigma = \log (ne\mu) = \frac{1}{r} \log P_{O_2} + C(T), \quad (17)$$

where the factor r depends on the defect regime (negative for electrons, positive for holes) and $C(T)$ is a temperature-dependent constant. Sensors of this type require means for compensating for cross sensitivity to temperature [the $C(T)$ term] and for achieving reduced response times (20).

Materials Systems

Solid Electrolytes. In the most common form of potentiometric sensor, the chemical species to be sensed is also the mobile ion in the solid electrolyte. For example, the oxygen ion conductor, yttria stabilized ZrO₂, may be used to monitor oxygen partial pressure. Likewise, one would use a sodium ion conductor, such as sodium beta alumina, to monitor the sodium concentration (or activity) in a solution or melt that contains sodium. In Table 8, we list a number of popular solid electrolytes and their properties.

A number of factors need be considered in selecting a particular solid electrolyte for sensor and/or actuator application. Considering the materials listed in Table 7, phase stability is an obvious criterion. A number of the materials go through phase transitions from relatively insulating to conductive states. One must consider the operating range required before selecting a candidate electrolyte. For potentiometric (open circuit) measurements, the magnitude of conductivity is not as critical as it is in amperometric applications where a given current must flow through the

Table 8. Mobile Ions and Electrical Properties of Solid Electrolytes

Material	Mobile Ion	Properties	Remarks
Zr _{0.85} Y _{0.15} O _{2-x} (35)	O ²⁻	$\sigma(1000^\circ\text{C}) = 0.12 \text{ S/cm}$ $E = 0.8 \text{ eV}$	Material of choice in auto exhaust sensors

SnO ₂ + Pd	C ₂ H ₅ OH	380–450

device. In general, higher conductivities are advantageous even for potentiometric devices because they enable the use of low input impedance voltmeters. Secondly, the electronic conductivity must typically be less than about one part per thousand. Electronic conductivity provides short circuiting pathways for the atoms through the electrolyte, even under open circuit conditions. Such permeation may result in polarizing the electrodes and generating overpotentials that disturb the Nernst potential. Because electronic carriers are typically created under sufficiently oxidizing or reducing conditions, a key criterion is the “electrolytic domain width” that specifies the range of chemical activities for which the electrolyte remains predominantly ionic. These and related issues are discussed in (42).

Semiconductors. Many semiconducting oxides have been examined for their response to various gases, but the greatest emphasis by far has been on several of the binary oxides, including SnO₂, ZnO, and TiO₂.

It is likely that fabricating them is typically much simpler and more reproducible than the more complex oxides. Furthermore, a large band gap is desirable (≥ 3 eV) to insure minimal electron–hole generation even at operating temperatures of 250–450°C. Finally, outside of its surface adsorption/desorption characteristics, the material should remain inert to minimize aging effects. For this reason, SnO₂ has been the material of choice for surface controlled semiconducting gas sensors. Its versatility is illustrated in Table 9 (34).

These results demonstrate that selectivity to specific gases can be enhanced by the adding various dopants and/or catalysts.

**Figure 26.** An example of a Canon EOS SLR camera focusing system that shows the use of photovoltaic and pyroelectric materials.

For high temperature measurements, bulk conductive properties are impacted. Here, materials that equilibrate rapidly with the atmosphere (i.e., have high oxygen diffusivities) and exhibit well-defined dependence on the atmosphere are desired. These and other key figures of merit are summarized in Table 10.

Materials under investigation for such purposes include SrTiO₃, TiO₂, Nb₂O₅, and CeO₂ (20,34,43).

OPTICAL MATERIALS

Applications

Light sensors are used in many applications: pyroelectric materials in automatic door openers and automatic light switches, photovoltaic and photoconductive materials in cameras, and electrochromic materials for smart windows.

Camera Focusing System. A good example of integrating smart materials and systems is the EOS camera focusing system by Canon. The system contains three major components; two sensors and one actuator. The first sensor is an IR sensor array that follows the eye movement and analyzes the direction in which the user is looking. The second sensor is a CMOS sensor array to measure distance to the object. The data from these two sensors controls a piezoelectric motor that moves the optical lenses and changes the focal length according to the object the user is looking at. Figure 26 shows a schematic diagram of the system. Another smart component in the system is the dichromic window. It allows the passage of visible

Table 10. Materials Requirements for Resistive Exhaust Gas Oxygen Sensors

1. High electronic conductivity strongly dependent on oxygen partial pressure
2. Small temperature coefficient of resistance
3. High mobility of oxygen-related lattice defects (e.g., oxygen vacancies)
4. High porosity and small particle size (for ceramics)
5. High catalytic activity and good oxygen-transfer characteristics
6. Wide oxygen partial pressure and temperature range of stability

Figure 27. Pyroelectric motion detector and intruder alarm. A simpler design can be used to open doors automatically.

light but reflects IR. This allows it to minimize the number of optical components in the system and simplify the design.

Pyroelectric Motion Detector. Pyroelectric motion detectors are very common in intruder alarm systems (Fig. 27) and in automatic door openers and light dimmers. These devices are designed to sense the blackbody radiation emitted from the human body ($T \approx 300$ K, $\lambda \approx 10$ μm). A short wavelength filter that has a cutoff of about 5 μm is used to prevent the device from responding to changes in background lighting levels (14).

Figure 28. Cross section of a smart electrochromic window illustrating the five-layer structure (46).

Electrochromic Windows

Smart electrochromic windows are used to conserve energy by manipulating their optical reflectivity in response to changes in the ambient illumination. Thus, on a hot summer day, the reflectivity edge is shifted to longer wavelengths to reduce the amount of visible light allowed into the building. Alternatively, in the evening, the reflectivity edge is shifted to short wavelengths to allow the heat from the building to radiate outward. The system is based on the ability to insert and reversibly remove protons and alkali ions such as Li, electrochemically, from certain oxides such as WO_3 . For example, when Li atoms are inserted into WO_3 , the ions enter the lattice interstitially, and the electrons enter directly into the conduction band. An increasing free electron density increases the plasma energy E_P ($\propto n^{1/2}$) and thus shifts the reflectivity edge to shorter wavelengths (44). The electrical conductivity can be shifted in this manner from as little as 10^{-6} to as much as 5×10^4 S/cm (45).

The cross section of such a window is shown in Fig. 28. Aside from the outer transparent conducting electrodes, the key layers include the solid electrolyte middle layer (see earlier section), the electrochromic electrode (e.g., WO_3), and the counterelectrode that itself may be electrochromic (e.g., LiCoO_2) but of a complementary nature (i.e., it is transparent when loaded with Li and becomes more reflective as Li is removed). In reality, this structure represents a thin film battery whose optical properties depend on its state of charge. The overall smart system requires an optical sensor to monitor the light intensity, a microprocessor to evaluate this data in the light of other data, for example,

the time of day, the date, and temperature, and the actuator that is an electrochemical pump whose state of charge determines its reflectivity. Figures of merit include rate of reflectivity shift, ratio of maximum-to-minimum reflectivity, number of reproducible cycles, life, and cost. Another key application would be a smart automobile rear view mirror whose reflectance is conditioned on the amount of glare that reaches the mirror from other traffic.

Basic Relationships and Phenomena

Index of Refraction, Birefringence, and the Electro-optic Effect. The index of refraction n is defined as the ratio between the speed of light in vacuum and that in a given material. The index of refraction is related to the electric and magnetic permittivities by

$$n = \frac{c_0}{c} \Leftrightarrow n = \sqrt{\frac{\varepsilon}{\varepsilon_0} \cdot \frac{\mu_0}{\mu}} \approx \sqrt{\frac{\varepsilon}{\varepsilon_0}}. \quad (18)$$

The last approximation is justified for nonmagnetic materials and for the range of visible light where the magnetic permittivity is nearly constant.

In nonisotropic materials, these values differ in different crystallographic directions, and one has to look at the dielectric tensor. It is convenient to work in the major electro-optic axis (where the dielectric constant is diagonalized), as shown in Fig. 29. Materials that have two polarization vectors of light propagating at different speeds are called birefringent.

The dielectric constant (and therefore the index of refraction) is related to polarization in the material by the Clausius–Mossotti equation (47):

$$(\varepsilon - 1)(\varepsilon + 2)^{-1} = \frac{4\pi}{3V}\alpha, \quad (19)$$

where V is the unit-cell volume and α is the polarizability. This implies that changing the polarization can change the index of refraction. Therefore, piezoelectric materials

Figure 29. The index ellipsoid for n_{11} , n_{22} , and n_{33} as major axis indexes. For light propagating in the S direction, the field can be considered one that has two polarizations—one has index n_1 , and the other has index n_2 . The ellipse perpendicular to S defines the polarization plane.

usually also show electro-optic behavior, a change in the optical index of refraction due to an applied electric field. From the Clausius–Mossotti equation, one can derive the change in index as a function of strain and polarization (48):

$$\frac{\Delta n_i}{n_i} = \frac{(n_i^2 - 1)(n_i^2 + 2)}{6n_i^2} \left(-\frac{\Delta V}{V} + \frac{\Delta \alpha_i}{\alpha_i} \right). \quad (20)$$

In our previous discussion of electromechanical actuation, we described three types of a ctuation: piezoelectric, electrostrictive, and phase transition. The equivalent electro-optic behaviors in piezoelectric materials are (1) quadratic birefringence (Kerr effect), (2) linear birefringence (Pockels effect), and (3) memory scattering. The different behaviors for these effects and a typical setup to generate them are shown in Fig. 30.

Photoconductive and Photovoltaic Materials. The electron–hole pair production rate R in semiconductors depends on the flux of light ϕ , the absorption efficiency η , and the illuminated volume (limited by either the thickness or the characteristic absorption depth) (50):

$$R = \frac{\eta\phi}{V}. \quad (21)$$

These excess charge carriers are free to move in the material until they recombine and therefore contribute to a change in conductivity:

$$\Delta\sigma = e(\mu_e + \mu_h)\Delta n = \frac{e(\mu_e + \mu_h)\eta\tau}{V}\phi, \quad (22)$$

where μ is the mobility for holes and electrons and τ is the excess-carrier recombination lifetime.

The rate of photogeneration G under optical intensity I can be written as

$$G = s(N_D - N_D^+)I, \quad (23)$$

where s is the photoionization cross section, N_D is the density of dopants (donors or acceptors), and the $+$ superscript represents ionized dopants. The recombination rate R is

$$R = \gamma_R n N_D^+ \quad (24)$$

where γ_R is the recombination constant that is inversely proportional to the recombination lifetime. And by comparing Eqs. (15) and (16) at equilibrium, one can calculate the density of carriers n :

$$n = \frac{s}{\gamma_R} \frac{N_D - N_D^+}{N_D^+} I. \quad (25)$$

The photovoltaic current density \mathcal{J}^{ph} is given by (51):

$$j_i^{\text{ph}} = \beta_{ijk} E_j E_k^*, \quad (26)$$

where E_i is the electric field component of the light wave.

Figure 30. Operational configurations and typical light output response for (a) quadratic birefringence, (b) linear birefringence, and (c) memory scattering (49).

Pyroelectric Materials. Pyroelectric materials are a subgroup of piezoelectric materials (see Fig. 6). Pyroelectric materials experience a change in polarization due to a change in temperature, which makes them excellent candidates for IR detectors. Photoconductivity in pyroelectric crystals can be accompanied by current flow without an external field due to the anisotropy, as shown in Fig. 31.

The pyroelectric coefficient is defined as the change in spontaneous polarization P_s as a function of temperature T :

$$p = -\frac{\partial P_s}{\partial T}. \tag{27}$$

In general, polarization increases as temperature decreases, resulting in a positive pyroelectric coefficient.

The responsivity r_i of the material is defined as the current density per unit power of the radiating light. For a

sample of area A and radiation power W ,

$$r_i = \frac{1}{WA} \frac{\partial q}{\partial t} \propto \frac{p}{\rho \cdot c_p}. \tag{28}$$

In this equation, ρ is the density and c_p the heat capacity. Materials that have a high heat capacity take longer to change their temperature and are therefore slower sensors. Because response time is important, the ratio between the pyroelectric coefficient and the heat capacity is used as a figure of merit. A list of modified figures of merit for different applications is given in Table 11.

Pyroelectric materials are used mainly for detecting infrared radiation. The pyroelectric effect requires a change in temperature to produce a change in polarization. This means that only changes in incident radiation can be measured. When response from a stationary object is required, a radiation chopper is used. Such choppers can be rotating

Figure 31. Pyroelectric effect. (a) The change in polarization due to heating of the surface causes current to flow in the circuit. (b) Example of a commercial pyroelectric sensor (442-3 IR-EYE™ by Acroname Inc.).

^aBased on (6,14,54).

discs, although new piezoelectric bimorphs have been developed (53).

Another important design consideration derives from the fact that pyroelectric materials are a subgroup of piezoelectric materials. Any external stress or electric field can cause an electric signal that will interfere with the measured response. Furthermore, any small changes in environment temperature will further compromise the measurements. To compensate for these effects, a second pyroelectric element, identical to the measurement unit, is set up with a light-blocking layer (see Fig. 31). Any environmental changes create the same voltage on both elements, and therefore any voltage difference between them is due to the incident light.

Materials Systems

Some key pyroelectric materials and their properties are listed in Table 12. The temperature change in the sample is larger the smaller the specific heat under constant heating, and the voltage generated by a given induced charge is larger for a smaller dielectric constant. Other factors to consider include materials stability, reproducibility, and ease of fabrication. TGS has a high figure of merit, but it is a fragile and water-soluble crystal. Lithium tantalate is readily grown as a single crystal, is insensitive to moisture, and stable in vacuum to temperatures required to enable outgassing (14).

CONCLUSIONS

Electroceraamics, as has been shown, exhibit a wide range of properties that make them ideally suited to serve as transducers in the form of sensors and/or actuators. In some cases, as in the PTCR self-regulated heater, the device is inherently smart and requires no microprocessor

to respond appropriately to a stimulus. In the vast majority of cases, a microprocessor is needed for the appropriate feedback. Here, the start of a trend toward integrating electroceramics into microelectronic and microelectromechanical systems (MEMS) will hasten the development of self-contained miniaturized smart systems. The microhotplate gas sensor array represents a graphic example. Last, we have emphasized transduction to and from electrical forms of energy because this is what most signal handling systems need to operate. This is beginning to change, particularly as all optical systems develop. Here again, given the electro-optic, piezo-optic, thermo-optic, magneto-optic effects that are exhibited by electroceramics, this group of materials should make important contributions to smart optical systems.

ELECTROCHROMIC SOL-GEL COATINGS

L.C. KLEIN
Rutgers—The State University of New Jersey
Piscataway, NJ

DEFINITION OF ELECTROCHROMISM

Certain inorganic compounds, especially oxides of polyvalent metals, exhibit coloration that depends on the oxidation state of their cations. This property leads to electrochromism, which is a reversible and visible change in transmittance and/or reflectance. The oxidation–reduction reactions are electrochemically induced, using low voltages of the order of ± 1 V dc.

An electrochromic (EC) device is a multilayer construction in which one of the layers shows electrochromic properties (Fig. 1) (1–5). An EC device operates on the principle of a galvanic cell. The best known electrochromic material is tungsten trioxide (WO_3), which forms deep blue alkali and hydrogen tungsten bronzes (M_xWO_3) on reduction. The reaction is expressed by the following

Figure 1. Schematic of an electrochromic (EC) device, substrate (indium–tin oxide coated commercial float glass), electrode (tungsten oxide), solid electrolyte (lithium-containing inorganic gel), counterelectrode (vanadium oxide), and substrate.

equation:

where M is hydrogen or an alkali and $0 < x < 1$. Typically, a low-voltage EC device that has an electrochromic cathode is colored in the charged state and bleached in the discharged state.

A major application of electrochromic devices is so-called “smart windows.” These electronically controlled windows, which can lighten or darken depending on charge insertion/extraction, are designed to adjust to the amount of sunlight, the time of the day, or the season of the year. Control of transmittance through windows is a factor in energy usage in a building, as well as the creation of a pleasant environment in interior spaces. Using them on buildings reduces the heat lost through architectural windows, if they are colored on bright, summer days and bleached on cloudy, winter days.

EC windows that fulfill these expectations have been demonstrated using thin film technologies other than sol-gel processing (6,7). Substitution of a sol-gel layer for any one of the layers—the EC electrode, the counterelectrode or the electrolyte—is a breakthrough in making affordable EC windows (8–10).

Principle of the Galvanic Cell

Recall for a moment, the basic galvanic cell. The cell consists of an anode, a cathode, and an electrolyte. In an EC device, the layers are referred to as electrode, counterelectrode, and electrolyte.

Requirements for the Electrodes. The performance of an EC device is shown schematically in Fig. 2. Assuming that the EC device is operating with a lithium ion ($\text{M} = \text{Li}^+$), when charging, the Li is oxidized at the cathode (electrode)

Figure 2. Schematic operation of an EC device, comparing the colored state (charged) and bleached state (discharged).

and reduced at the anode (counterelectrode)

In all cases, the cathode is an intercalation compound that has a layered or framework structure (11). In a reversible cell, which is rechargeable, both the anode and cathode are intercalation compounds (12,13). In addition to tungsten oxides, other common electrode materials are vanadium oxides, niobium oxides, and titania-doped cerium oxides (14–16).

The requirements for the electrodes are

- high coloration efficiency
- fast switching between colored and bleached states
- high diffusivity for lithium; high capacity for lithium
- compatibility with electrolyte

Requirements for Solid Electrolytes. The electrolyte, which has to transport ions back and forth between the cathode and anode, is a critical feature in the galvanic cell. (Because we have worked on solid electrolytes for about 15 years, the electrolyte receives more attention in this chapter.) The electrolyte has to have

- a wide electrochemical potential window
- stability during charge/overcharge and discharge/overdischarge.

Most commercial electrolytes are polymers and “gel” electrolytes (17,18). Some problems with commercial electrolytes are that aqueous electrolytes may generate H_2 and nonaqueous electrolytes have conductivities that are too low.

Solid electrolytes are attractive because there are effectively no moving parts, meaning no mobile protons. While a solid electrolyte is functioning as a separator and membrane, it is mechanically rigid and holds the components of

the electrochromic device fixed. But most solid electrolytes do not have high enough ionic conductivity at ambient temperature (19). One way around this problem is thin-film technology (20), which is, in part, the motivation for using sol-gel processing.

Sol-Gel Processing

A gel is a material that has solid-like properties, which means that a gel has a fixed shape. On the one hand, organic “gels”, which are frequently used in batteries, are rigid, but only in the sense that they “set” when shear stress is absent. Inorganic gels, on the other hand, that result from the sol-gel process are irreversible gels [see Brinker and Scherer (21) for general background]. These gels are based on an oxide network. These gels are rigid structures, and they are also inert in contact with organics and solvents.

A natural advantage of the sol-gel process is the fact that a film of oxide can be placed on a substrate directly from solution (22–24). Other methods of depositing films of oxides are sputtering or chemical vapor deposition (CVD). These methods may succeed in some cases, but the sol-gel process is simpler than either one.

Dipping and spinning are common processes for preparing sol-gel thin films. Among the available techniques, dip coating is more widely used. Its advantages include the following:

- deposits uniform thin films on large areas
- allows coating any size or shape
- allows control of film microstructure
- delivers multicomponent films without changing the deposition equipment
- provides flexibility in manufacturing.

Another important consequence of the sol-gel process is the fact that the film is less than a micron thick. The film is rigid, but it is thin enough to resist cracking, so that dimensional changes in the electrodes can be accommodated even when the electrolyte is in place.

Sol-Gel Processing of the Electrochromic Layer. Sol-gel thin films used in EC devices have exceptional requirements:

- significant spectral switching over the visible and infrared regions of the solar spectrum
- acceptable chemical and physical durability during a long exposure time [~ 30 year lifetime of architectural windows (25)].

There are three basic approaches to preparing transition-metal oxides (26–31). One of the routes is to prepare a solution using alkoxides, metal organic compounds with alkoxy groups. The available alkoxides are only slightly soluble in common organic solvents and tend to be very reactive with water. The second route is to use salts such as oxychlorides as the network-forming oxide precursor. The third route is to use colloidal sols (32).

A sol is a colloidal suspension of small particles (1–500 nm) in a liquid. Oxide sols are obtained after hydrolysis–condensation reactions of the precursors. Hydrolysis occurs when metal cations (M) are solvated by water molecules. Condensation occurs as soon as hydroxyl groups are present in the coordination sphere of M. These reactions lead to M–O–M bonds. When the number of links is high enough, the sol becomes a gel. The gel point occurs when the solid phase becomes continuous. After this point, the gel continues to age, primarily causing changes in structure. This is followed by drying, when evaporation of the liquid can further shrink the gel structure.

Tungsten Oxide Gels. There are several ways to obtain WO_3 thin films (14), and the least expensive precursor is tungstic acid. The reasons for choosing tungstic acid sols are

- their low cost
- their aqueous nature
- their ability to be recycled
- the presence of W–O–W bonds in the sols
- their amorphous nature and nondirectional morphology.

A drawback of tungstic acid sols is that they gel in 30 minutes.

A solution of aqueous sodium tungstate, $\text{Na}_2\text{WO}_4 \cdot 2\text{H}_2\text{O}$, is made by mixing tungstic acid powder, sodium hydroxide, and water. The solution is poured through a proton exchange resin, which is conditioned before use by washing with 2N HCl. Excess acid is removed from the column by washing with distilled water.

The sol is collected in a beaker that contains a defined amount of solvent. The sol, which is clear yellow, contains polymeric species. The mechanism of polymerization is approximately

Solvents can be used to delay gelling of the sols, but they must be easy to remove during drying and low temperature curing. A general trend is that more homogeneous films are obtained by using solvents that have higher surface tension. Wetting is also better for sols that contain aprotic solvents, rather than protic solvents. For a given solvent, less solvent results in better wetting. In addition, the higher the boiling point of the solvent, the more slowly the solvent evaporates, so drying is slower. Slow drying (hours vs. minutes) can be useful in preventing cracking of the films, although cracking is not a major issue for film thicknesses from 200–400 nm. The net result in one study was that more uniform films were obtained by using acetone at a slow dipping/withdrawal speed (~ 2.5 cm/min) (32).

As-prepared WO_3 films that are poorly crystallized have higher coloring efficiency than crystallized WO_3 (27,33). Crystallization of WO_3 thin films occurs after heating at

Figure 3. Percent light transmittance across the visible range (350–800 nm) for WO_3 films deposited on glass substrates with an ITO coating, measured by using a Perkin-Elmer Lambda 9 Spectrometer. The spectra were collected before and after 10 cycles.

400°C, so films should not crystallize when heat treated for one hour at only 90°C.

Comparisons between uncoated glass and coated glass showed that the transmittance in the visible range is lower by about 10–15% for coated samples. Nevertheless, the transmittance of the coated glass is acceptable for most applications. A typical transmittance curve before and after 10 lithiation cycles is shown in Fig. 3. The WO_3 sol was deposited on commercial float glass that was coated with indium tin oxide (ITO).

Vanadium Oxide Gels. Again, there are several ways to obtain V_2O_5 thin films (34–39). These include nitric acid dissolution of vanadate salts, proton exchange, hydrolysis of vanadium alkoxides, and hydration of amorphous vanadia. The least expensive precursor is vanadia powder that is melted at 1000°C ($T_{\text{melt}} = 690^\circ\text{C}$) and quenched in water to produce amorphous vanadia. This glassy material is soluble in water and yields a golden brown, colloidal sol that is suitable for dip coating. In many respects, the behavior of vanadia sols parallels that of the tungstic acid sols, so that thin, transparent coatings can be produced.

Sol-Gel Processing of the Solid Electrolyte. Sol-gel processing has been used for more than 15 years to prepare solutions that contain oxide components desirable as fast ion conductors (FIC) (19). The sol-gel process has been used to duplicate conventional crystalline fast ion conductors, as well as fast ion conducting gels and glasses. Glasses are desirable because they

- are isotropic
- have few restrictions on composition
- have more channels for fast ion conduction than crystalline compounds.

Ionic transport in solids is an activated process. In most fast ion conductors, the activation energy is indicative of the energy of motion rather than the energy to form charge

carriers. The desired features in a fast ion conductor are

- large number of mobile ions
- large number of sites for the ions
- relatively low activation energy
- wide compositional range
- ease of fabrication in complex shapes and thin films.

Classically, high ionic conductivity requires high alkali concentration. The system originally investigated for the solid electrolyte was lithium silicates (40). In the $\text{Li}_2\text{O}-\text{SiO}_2$ gels, the second component was introduced typically as lithium nitrate. The nitrate salt dissolves in water and then crystallizes in the dried gel as nitrate nanocrystals (41). Alternatively, lithium hydroxide was used to create very high pH conditions, increasing the chance of a reaction between LiOH and the silica network to give $\text{Si}-\text{O}-\text{Li}$ bonds (42). The alkoxide-based gels, or so-called polymerized gels, showed values of ionic conductivity that are stable and in the range needed for operating a lithium battery at around 250°C. Lithium nitrate gels had a characteristic behavior described by a composite mechanism (43,44).

Thermodynamic calculations were performed to find out which oxide could improve the stability of the gel. Using the standard heats of formation, it is easy to see that no oxide addition makes lithium silicates stable compared to lithium metal. At best, the addition improves the kinetic stability at low temperatures. Alumina is one candidate for increasing the kinetic stability of lithium silicate gels.

In the past, small alumina substitutions were made in lithium silicate gels to suppress crystallization (45). When the $\text{Al}_2\text{O}_3/\text{SiO}_2$ ratio was varied for a constant $(\text{LiCl})_2$ mole%, the role of Al_2O_3 was identified in charge compensation for nonbridging oxygens. The ionic conductivity increased as the LiCl content and the $\text{Al}_2\text{O}_3/\text{SiO}_2$ ratio increased (46). Consequently, silicate gels were prepared using different amounts of alumina.

Lithium aluminosilicate gels were prepared by using an alkoxide and salts (46). Tetraethylorthosilicate (TEOS, $\text{SiO}(\text{CH}_2\text{CH}_3)_4$) was used as the precursor for the network-forming oxide, silica. TEOS was added to ethanol/water mixtures that contained lithium nitrate and aluminum nitrate hydrate. For most samples studied, the Li_2O content was 15 mol%, which corresponds to a reasonable concentration for ionic conductivity.

Conductivity can be measured under dc or ac conditions, but dc conductivity measurements provide little information about these materials other than discriminating long-range ion migration from localized motions. ac conductivity measurements, on the other hand, provide information about possible conduction mechanisms (47). They allow discriminating electrode capacitance, grain boundary capacitance, and electronic contributions.

Ionic conductivity measurements were carried out by the ac complex impedance method using a Solartron 1250 frequency response analyzer and 1186 electrochemical interface, which were programmed by a Hewlett-Packard 9816 desktop computer for data collection and analysis. Experiments were performed on pressed pellets that had

Figure 4. Ionic conductivity of alumina-containing lithium silicate bulk gels, plotted as an Arrhenius plot of log (conductivity) vs. reciprocal temperature.

both sides coated by a layer of platinum paste to provide contacts with platinum electrodes.

Thermal analysis shows that weight loss occurs at 160°C for adsorbed species and at 210°C for organics. Heat treatment of the gels to 250°C for 1 hour removes volatiles. Ionic conductivity was measured on gels heated from 100°C to around 360°C at a heating rate of 10°C/min in the frequency range of 10 Hz to 65 kHz. Measurements were repeated and reproduced to eliminate any concern about a contribution to the measurements from protons. A summary of measured conductivities is shown in Fig. 4. Ideally, the solid electrolyte has only mobile lithium ions as charge carriers (48). As seen in Fig. 4, in bulk materials, the conductivities are too low at room temperature for use in an electrochromic device.

For measurements on thin films, the surface of a microelectrode (Microsensor Systems SAW 302), that consisted of an interdigitated array of gold electrodes deposited on a quartz crystal substrate, was coated with the solution (49). A sample containing 10 mol% Al₂O₃ was selected because measurements on the bulk showed good ionic conductivity for this composition. The values of ionic conductivity measured on thin films matched those for bulk ionic conductivity.

In lithium aluminosilicate compositions, conductivity is due to the conventional hopping mechanism, taking two interdependent factors into account. First, when alkali ions are incorporated into the network, the excess oxygen is accommodated by the network by breaking bridging oxygens to create nonbridging oxygens (NBO). According to the

following relationship:

the Li⁺ ion is available to charge compensate for the nonbridging Si-O bond. Secondly, borrowing from results found for (LiCl)₂-SiO₂-Al₂O₃ in ⁷Li, ²⁷Al, and ²⁹Si NMR experiments (46), the silicon ions and most of the aluminum ions are four coordinated with oxygen ions, and there is some octahedrally coordinated aluminum. Because one oxygen ion shares its two charges with two tetrahedra, oxygen ions can not compensate for the charge deficit provided by Al³⁺. The additional charge needed is provided by one lithium ion located near the tetrahedron. In a sense, there are two types of lithium ions associated with the network: the first category compensates for [AlO₄] units, and the second compensates for NBO in the silica network.

Assuming that the only species that can move is the lithium ion, the changes in conductivity are related to changes in mobility. Further, it is observed that the conductivity increases when the Al₂O₃ content increases, indicating a link between mobility and Al₂O₃ content. The higher the Al₂O₃ mol% in the gels, the more [AlO₄] units should replace SiO₄ units, and the more Li ions compensate for these [AlO₄] units. This means that the mobility of Li⁺ ions compensating for [AlO₄] units is different from that of Li⁺ compensating for NBO of [SiO₄]⁻. This difference is undoubtedly due to differences in electrostatic interactions between oxygen and lithium ions. When a lithium ion acts as a charge compensator in the silica network, the lithium ion is very close to the oxygen ion, and the electrostatic interaction is very strong. When Li plays the part of compensating for [AlO₄] units, the interaction is weaker, and Li⁺ is more able to move under a current flow, meaning a lower activation energy.

Stable and reproducible conductivities have been demonstrated in thin films, but the conductivity values are still too low. Further advances in electrochromic devices depend on finding a solution to the electrolyte problem. Some recent studies of organically modified electrolytes are leading in the right direction (50,51).

CONCLUSIONS

In further pursuing the development of completely sol-gel EC devices, physical properties need to be considered, in addition to the ionic conductivity. Of course, the electrolyte has to have

- high electronic resistivity,
- high ionic conductivity
- no defects.

In addition, all of the layers require

- a film thickness less than about 1000 nm (generally less than 500 nm)
- high transparency across the visible range

- good adhesion between adjacent layers
- thermodynamic stability between adjacent layers across a wide electrochemical window.

Overall, an EC device should operate under the approximate conditions of +2.5 volts (100 s)/-1.5 volts (100 s) for more than 10,000 cycles at 15 mC/cm².

For practical EC windows, there has been significant recent progress using a variety of technologies (52,53). Sol-gel processing, of course, is only one route under investigation. Interest continues in sol-gel processing because precursors for all of the layers that lead to the appropriate oxide gels are readily available. The resulting gels are inorganic and rigid. In particular, the sol-gel electrolyte operates while playing the role of a mechanical divider between the electrodes. In addition, sol-gel processing is a logical batch process for large area coatings. Several studies show that sol-gel coatings have the required transmittance across the visible light range. Finally, the layers have "no moving parts."

ELECTORRHEOLOGICAL FLUIDS

TIAN HAO

Rutgers—The State University of New Jersey
Piscataway, NJ

INTRODUCTION

An electrorheological (ER) fluid is a colloidal system in which one kind of particulate material is dispersed in a nonconductive liquid base. When an electric field of several kilovolts per millimeter is applied, ER fluids reversibly change from a liquid state to a solid crystallized state within a millisecond. What the working mechanism of the ER effect is and how to design a high-performance ER fluid for industrial uses have been studied for many years; however, there is no clear answer yet. Because the ER effect is induced by an external electric field, it is believed that polarization of both the liquid medium and the solid particles plays an important role. The dielectric tool is thus widely used to characterize the ER fluids, and many efforts have been spent on revealing how the dielectric properties of the ER fluids correlate physically with the ER effect. The purpose of this article is to draw a logical relationship between the dielectric properties of the materials used for making an ER fluid and the ER mechanism. To achieve this goal, the dielectric investigation that was done to characterize an ER fluid and the related ER models that were developed to describe ER phenomena are reviewed following. Attention is paid to the ER models proposed on the basis of the dielectric studies; other ER models are only briefly described.

The ER phenomenon was first reported in 1947 by Winslow (1) in an insulating oil that contained starch or flour particulate material. The first example of using a dielectric tool to investigate the ER phenomena was carried

out by Klass (2) in 1967. It was found that the dielectric constant of the ER suspension increases linearly with the particle volume fraction, and an electric-double-layer (EDL) mechanism was proposed to explain the observed experimental results. The interaction among the EDLs, as well as the interaction between the EDL and the particles, becomes much stronger once an electric field is applied. The EDLs can be polarized and then distorted; thus the electrostatic force between particles can dramatically increase, generating the observed ER effect. A deeper dielectric investigation of the way the dielectric constant of the whole suspension changes as the water content in the suspension and the particle volume fraction change was carried out by Ujima (3). At that time, it was believed that the "water" (4) and the EDL (2) are crucial to the ER effect because all ER fluids were active only if the dispersed particles adsorb a trace amount of water or surfactants.

After the innovation of anhydrous ER fluids (5,6) in 1985, the mechanism of the ER effect was substantially modified because neither the "water" nor the EDL mechanism can explain the considerably strong ER effect in ER fluids without any amount of water. The dielectric properties of polymer-based water-free ER fluids were studied by Block (7), who proposed a flow modified polarization (FMP) theory to explain the ER effect. According to the FMP theory, there should be resonance between the applied electric field and the applied shear field. It was found that the dielectric constants and losses of the ER suspensions peak when the shear rate is 4π times the frequency of the electric field. An extra surface charge is generated once a particle is polarized in an electric field, which in turn drives the particles to rearrange in the suspensions. It was thought that this is a possible reason that the ER suspensions can be fibrillated to form a bridge spanning between two electrodes. However, the physical picture of the way the dielectric properties of the particulate material can change ER performance is not clear in Block's theory.

The influence of the conductivities and dielectric constants of both the liquid medium and particulate material on the ER effect was addressed by Anderson (8) and Carino et al. (9). It was found that the ER effect becomes stronger once the dielectric constant ratio of the particle-to-liquid increases. This issue was further addressed theoretically by Davis (10–12), and he found that the ER effect is controlled by the conductivity ratio of the particle-to-liquid in a low-frequency electric field and by the dielectric constant ratio in a high-frequency field, which is the well-known polarization model. It was believed that the dielectric constant mismatch between the suspended particles and the medium is essential. However, the ER effect of a barium titanate suspension (the dielectric constant of BaTiO_3 is around 2000, depending on its crystallization state), inactive in a dc field (13) and active after adsorbing a small amount of water (14) or being stimulated by an ac field (9), suggests that the polarization model does not adequately reveal the physical essence of the ER effect. The polarization model has much room for improvement.

Because of the obvious shortcomings of the polarization model, another model called the conduction model was introduced by Atten (15,16) and was well developed by other researchers (17–21). Good agreement between the

theoretically predicted parameters (the current density, the yield stress, etc.) of the conduction model and the experimentally measured values determined either by them or by Inoue (22) was achieved. However, as stated in Khusid's paper (23), the conduction model can be used only when the suspension microstructure has been fully formed. A major shortcoming of the conduction model is that it cannot explain the response time of ER fluids that vary from 0.1 ms to 1 s because only particle interaction is considered in the conduction model regardless of the microstructural change before and after an electric field is applied. The dynamic process that occurs in ER fluids in an electric field is not taken into account. A contrary experimental result was obtained in the magnesium hydroxide/poly (methylphenylsiloxane) system (24): A negative ER effect was observed in this system in a dc field, although a positive ER effect was expected according to the conduction model, strongly suggesting that the conduction model too, does not reflect the physical essentials of ER effect. The limitations of both the polarization and the conduction models stem, we think, from the fact that both are static and do not involve dynamic processes that occur in ER fluids.

Besides the polarization and conduction models, many other models were also proposed to unveil the ER mechanism. An excellent theory was proposed by Khusid (23): Both the electric-field-induced particles aggregative process and the interfacial polarization process were considered. Almost all of the currently observed ER phenomena can be explained, especially those that cannot be understood by the polarization and the conduction models. However, some discrepancies in the experimental results still exist, which arise from the assumptions on which the theory is based. Two presumptions were used to derive the theory: The dispersed particles and the suspending medium have no intrinsic dielectric dispersion, and the variation of the applied electric field is very slow compared with the rate of polarization; these are not always valid in ER fluids. A so-called layered model proposed by See and Saito (25) gives derivations similar to those from the conduction model. The first-principle method was used for calculating how ER properties (the yield stress and the modules) change as the frequency and water content change under the assumption that the Debye relaxation process is dominant (26,27). It was found that the theoretical predictions and the experimental results agree very well. However, because only few solid materials exhibit Debye-type relaxation behavior, good agreement between the theoretical predictions and the experimental results on the transient ER response was also achieved by Tang and Conrad (18) without using the Debye-type relaxation assumption. Whether the Debye-type relaxation process is important in ER fluids thus remains a question.

The dielectric studies of anhydrous ER fluids provide deep insight into the ER mechanism. The intrinsic properties of dispersed particles, it was thought, contribute to the ER effect of anhydrous ER fluids (6,28–30); mobile charges (ions or electrons) on the surfaces of particles that can move freely on the surfaces but cannot move off are essential. The ER effect should somewhat correlate with the dielectric dispersion in a low-frequency field; however, the ER effect does not correlate directly with charge concentration. The

polarization rate, as well as its magnitude, was stressed (7): Too high a rate of polarization and too low a rate of polarization were experimentally found unfavorable to a strong ER effect. An ER fluid might deliver a strong ER effect if it meets the following empirical requirements: Its dielectric relaxation frequency should be between 100 and 10^5 Hz, and the difference between the dielectric constants below and above the relaxation frequency must be large (31–33). Those experimental results, we think, imply that the ER effect may correlate with particle dielectric loss because charges moving within the particles in an electric field would be one of origins of dielectric loss. The influence of the polarization rate on the ER effect was theoretically addressed (34), and good agreement with experimental results was obtained. However, why the polarization rate is important is not clear. The explanation rests on interfacial polarization, but there is no clear physical picture of the ER mechanism from employing the interfacial polarization framework.

This article attempts to provide a clear physical picture of the ER response mechanism through dielectric analysis of ER phenomena. We begin with a general description of the dielectric properties of heterogeneous systems such as colloidal suspension systems, which is introduced in the following section. In the subsequent section, experimental evidence of the way dielectric parameters change the ER effect are discussed, and an empirical dielectric criterion for designing high-performance ER fluids is proposed. A theoretical treatment on the dielectric criterion is described in the following section IV, and an ER mechanism is proposed in the section thereafter. A yield stress equation based on the ER mechanism is theoretically derived in the next section, and comparisons with currently available experimental results are also made. Final conclusions of this article are discussed in the last Section.

DIELECTRIC PROPERTIES OF HETEROGENEOUS SYSTEMS

Four kinds of polarization are generated in a heterogeneous system under an electric field: the electronic, atomic, Debye, and interfacial polarizations. They are schematically illustrated in Fig. 1 on the basis of the relative relaxation times (35). The former three polarizations occur in a homogeneous phase, whereas interfacial polarization occurs only in heterogeneous systems. Electronic and atomic polarization are induced by the displacement of an electron and atom, separately; Debye polarization is due to dipole orientation, and interfacial polarization is due to heterogeneous interfaces. Debye polarization usually takes place in liquids and in a few solids because dipole orientation becomes possible only if the dipole is not firmly fixed in bulk materials. Electronic and atomic polarizations appear in a high-frequency field; usually they are regarded as fast polarizations. Debye and interfacial polarizations are rather slow processes compared with the electronic and the atomic polarizations, and are usually called slow polarizations. Another type of polarization is ionic displacement polarization that takes place only if the particulate material is ionic. If the ER effect is controlled by polarization, then the kind of polarization that is responsible for the ER

Figure 1. Dielectric constant and dielectric dispersion of a heterogeneous system vs. frequency [reproduced from (49)].

effect would be important in understanding the ER effect. This article attempts to clarify this issue and addresses it in the next section.

Debye polarization can be described by the Debye equation, and interfacial polarization can be described by the Wagner–Maxwell equation. If the particle conductivity σ_p is much larger than that of the medium, a simplified Maxwell–Wagner equation can be expressed by (36)

$$\varepsilon = \varepsilon_\infty \left[1 + \frac{K}{(1 + \omega^2 t^2)} \right]; \quad (1)$$

in this equation,

$$\varepsilon_\infty = \varepsilon_{sm} \left[1 + \frac{3\Phi(\varepsilon_{sp} - \varepsilon_{sm})}{2\varepsilon_{sm} + \varepsilon_{sp}} \right], \quad (2)$$

$$K = \frac{9\Phi\varepsilon_{sm}}{2\varepsilon_{sm} + \varepsilon_{sp}}, \quad (3)$$

$$t = \frac{\varepsilon_0(2\varepsilon_{sm} + \varepsilon_{sp})}{\sigma_p}, \quad (4)$$

where ε_0 , ε_{sm} , and ε_{sp} are the static dielectric constants of the vacuum, the medium, and the particles; Φ is the particle volume fraction, ω is the frequency of the alternating electric field, ε_∞ is the infinite frequency dielectric constant of the suspension, and t is the relaxation time of polarization. The dielectric loss tangent is given by

$$\tan \delta = K\omega t / (1 + K + \omega^2 t^2) \quad (5)$$

The Wagner theory may not hold for concentrated dispersions because it was derived for diluted systems whose particle volume fraction is less than 10%. Hanai et al. (37)

proposed a new theory applicable to concentrated dispersions and derived an equation similar to Bruggeman's (37,38). There is no obvious difference between Bruggeman's and Wagner's equations until the volume fraction of dispersed particles exceeds 40% (37,38). So, applying the Wagner equation for concentrated ER suspensions whose particle volume fraction is as high as 40% is acceptable.

EXPERIMENTAL FACTS

The experimental facts presented here demonstrate (1) the kind of polarization that is responsible for the ER effect, (2) whether the Wagner–Maxwell equation describes the dielectric properties of ER fluids, and (3) whether the dielectric loss is also important in the ER effect. A criterion is extracted from these experimental facts for designing high-performance ER fluids. We will follow this sequence to show the experimental evidence.

As indicated in the introduction, it is most likely that the ER effect is controlled by slow polarization (Debye and interfacial polarization) rather than fast polarization (electronic and atomic polarization) because the response time of the ER effect occurs on a millisecond scale. Dielectric dispersions in many good ER fluids are usually observed in low-frequency fields (31–33), further confirming that the ER effect may have something to do with slow polarization. As an example, the dielectric loss tangents of two kinds of ER suspensions consisting of aluminosilicate powder dispersed in polydimethylsiloxane (PDMS) oil (powder treated at 550 and 750°C for 8 hours and named AS1 and AS2, respectively) are plotted against frequency in Fig. 2. These two ER suspensions give a very strong ER effect, and the dielectric dispersions appear in low-frequency fields of less than 10^3 Hz, indicating that dielectric dispersions arise from slow polarization, which in turn contributes to the ER effect. Experimental results obtained by Filisko (29,40) also suggested

Figure 2. Dielectric loss tangents of the AS1 and AS2 suspensions vs. frequency [reproduced from (49)].

Figure 3. dc current passing through AS2 vs. time [reproduced from (49)].

that the ER effect might result from low-field dielectric dispersion. Other stronger evidence is that the dc currents that pass through ER fluids are not stable, exponentially decrease with time, and then level off; this was found both in a polymeric ER fluid (oxidized polyacrylonitrile/PDMS) and an inorganic ER fluid (aluminosilicate/PDMS) (39). A typical example of dc current passing through the AS2 suspension in an electric field (1.5 kV/mm) versus time is shown in Fig. 3. This is the so-called dielectric adsorption phenomenon that arises from heterogeneity and slow polarization, further indicating that slow polarization rather than fast polarization is very distinct in the ER system. All of these experimental facts demonstrate that slow polarization in ER systems is likely to be the most important process.

If slow polarization is responsible for the ER effect, another question arises: which slow polarization, Debye or interfacial polarization, controls the ER effect or jointly control the ER effect? As we know, Debye polarization is generated due to dipole orientation in an electric field. The dipole of most solid materials is almost unable to reorient because solidification usually fixes the molecule with such rigidity in the solid lattice that there is little or no orientation of dipoles, even in an extremely strong electric field. If the ER effect stems from polarization of solid particulate material, Debye polarization can almost be ruled out. This can be further confirmed by measuring the ER response time that should be determined by the relaxation time of polarization that controls the ER effect. The relaxation times of Debye and interfacial polarization are governed by different factors; Debye polarization is governed by the potential barrier between two equilibrium positions between which the dipole would orient (41), and interfacial polarization is governed by the dielectric constants and conductivities of the two components (35,36). The relaxation time of the Debye t_d , can be expressed as (41)

$$t_d = (\pi/2\omega_a) A e^{H/kT}, \quad (6)$$

where $\pi/2\omega_a$ is the average time required by an excited molecule to turn from one equilibrium direction to the

Figure 4. The shear stresses of AS1 and AS2 suspensions vs. frequency (0.3 kV/mm) [reproduced from (49)].

other, A is a factor that varies only slowly with temperature T , H is the energy barrier that separates the two equilibrium positions, and k is the Boltzmann constant. The relaxation time t_i for interfacial polarization in one system where σ_p (conductivity of the particle) $\gg \sigma_m$ (conductivity of the medium) can be expressed as (35,36)

$$t_i = \varepsilon_0(2\varepsilon_m + \varepsilon_p)/\sigma_p. \quad (7)$$

Clearly, t_d depends on the material state (liquid or solid), the molecular interaction and the environment, whereas t_i depends on the dielectric properties of the two components, especially on particle conductivity. The response times of AS1 and AS2 were determined by measuring the shear stress dependence on field frequency (see Fig. 4). The response times of these two suspensions are very different. The response time of the suspension whose particle conductivity is 6.0×10^{-7} S/m (AS1) is 0.6 ms, and that of the suspension whose particle conductivity is 8.4×10^{-10} S/m (AS2) is 0.22 s. If Debye polarization controls the ER effect, these two ER fluids should give, almost the same response time. According to Eq. (6), because the solid particulate material in these two suspensions is almost same, and the energy barrier H should not be very different. The quite different response times can be reasonably understood only from Eq. (7), which indicates that interfacial polarization probably governs the ER effect.

The publications previously cited, support this conclusion. The data presented in (42) showed that the experimentally measured response time is inversely proportional to the particle conductivity and agrees well with Eq. (7) Also, Wen et al. (27) and Conrad and Chemn (43) found that even the same particulate material displays different response time after adsorbing different amounts of water; the larger amount of water leads to a shorter response time. These are also consistent with Eq (7). Because oil is hydrophobic, the added water can adsorb just on the particle surface and enhance particle conductivity considerably. Whittle et al. (44) also found the same inversely proportional relationship between particle conductivity and ER response time.

The dielectric could provide a direct way to distinguish Debye and interfacial polarization in ER fluids. Differentiating Eq. (5) with respect to frequency ω , one can easily obtain the value of $tg\delta_{\max}$,

$$tg\delta_{\max} = \frac{K}{2\sqrt{1+K}} = \frac{9\phi\epsilon_{sm}}{2\sqrt{(9\phi\epsilon_{sm} + 2\epsilon_{sm} + \epsilon_{sp})(2\epsilon_{sm} + \epsilon_{sp})}} \quad (8)$$

Assuming that both ϵ_{sm} and ϵ_{sp} depend on temperature T and differentiating Eq (8) with respect to T ,

$$\begin{aligned} \frac{dtg\delta_{\max}}{dT} &= \frac{(2+K)\frac{dK}{dT}}{4(1+K)^{3/2}} = \frac{(2+K)}{4(1+K)^{3/2}} \\ &\times \frac{9\phi\left(\epsilon_{sp}\frac{d\epsilon_{sm}}{dT} - \epsilon_{sm}\frac{d\epsilon_{sp}}{dT}\right)}{(2\epsilon_{sm} + \epsilon_{sp})^2} \end{aligned} \quad (9)$$

The sign of $(dtg\delta_{\max}/dT)$ obviously depends on the sign of $(\epsilon_{sp}\frac{d\epsilon_{sm}}{dT} - \epsilon_{sm}\frac{d\epsilon_{sp}}{dT})$ because the rest of the equation is always positive. According to Frohlich’s theory (41), the static dielectric constant of a polar liquid decreases as temperature increases. Usually, the most commonly used dispersing medium for ER fluids is PDMS oil, a polar liquid; thus $d\epsilon_{sm}/dT$ would be less than zero. If $d\epsilon_{sp}/dT > 0$, then, the term $(\epsilon_{sp}\frac{d\epsilon_{sm}}{dT} - \epsilon_{sm}\frac{d\epsilon_{sp}}{dT})$ would be less than zero, and thus, $dtg\delta_{\max}/dT < 0$. If $\frac{d\epsilon_{sp}}{dT} < 0$, the situation is somewhat complicated, and one needs to know all of the parameters involved in the term $(\epsilon_{sp}\frac{d\epsilon_{sm}}{dT} - \epsilon_{sm}\frac{d\epsilon_{sp}}{dT})$. These feature the dielectric characteristics of an ER suspension in dominant Maxwell–Wagner polarization.

It is well known that the maximum value of the dielectric loss tangent, $tg\delta_{d\max}$ of Debye polarization can be

expressed as (41)

$$tg\delta_{d\max} = \frac{\epsilon_{sp} - \epsilon_{\infty p}}{2\sqrt{\epsilon_{sp}\epsilon_{\infty p}}} \quad (10)$$

where $\epsilon_{\infty p}$ is the dielectric constant at very high frequency. Differentiating Eq. (10) with respect to T and assuming that only ϵ_{sp} is temperature dependent,

$$\frac{dtg\delta_{d\max}}{dT} = \frac{\left(1 + \frac{\epsilon_{\infty p}}{\epsilon_{sp}}\right)\frac{d\epsilon_{sp}}{dT}}{4\sqrt{\epsilon_{\infty p}\epsilon_{sp}}} \quad (11)$$

Comparing Eqs. (9) and (11), if $d\epsilon_{sp}/dT > 0$, the observed $(dtg\delta_{\max}/dT)$ determined by Maxwell–Wagner polarization gives a sign opposite to that determined by Debye polarization. Then, it would be easier to distinguish the polarization type. If $d\epsilon_{sp}/dT < 0$, one has to know the exact value of $d\epsilon_{sp}/dT$.

A suspension consisting of Molecular Sieve 3A (MS3A) powder dispersed in PDMS oil was used to address this issue by direct dielectric means. The dielectric properties of the PDMS oil were measured at different temperatures, as shown in Fig. 5. Because PDMS oil is a good insulator, it almost does not have any dielectric loss (the dielectric loss in the measurement frequency range is almost zero). Its dielectric constant remains unchanged in the measured frequency range, and thus, its low-frequency dielectric constant can be regarded as a static dielectric constant. Figure 6 gives the temperature dependence of the dielectric constant of PDMS oil at 20 Hz. The dielectric constant obviously decreases as temperature decreases, and the slope of the linear regression line is $-2.4 \times 10^{-3}(1/^{\circ}\text{C})$, which can be reasonably regarded as the value of $d\epsilon_{sm}/dT$ in Eq. (9). The dielectric constant and the dielectric loss of pure MS3A

Figure 5. Dielectric constant of poly(dimethylsiloxane) oil vs. frequency at temperatures from (20–120°C).

Figure 6. Static dielectric constant of poly(dimethylsiloxane) oil vs. temperature.

versus frequency measured at 20°C are shown in Fig. 7. The static dielectric constant of pure MS3A was calculated by using the Cole–Cole plot and is shown in Fig. 8. The static dielectric constant of pure MS3A increases as temperature increases, that is, $(d\varepsilon_{sp}/dT) = 0.40 > 0$. Thus, the term $(\varepsilon_{sp} \frac{d\varepsilon_{sm}}{dT} - \varepsilon_{sm} \frac{d\varepsilon_{sp}}{dT})$ in Eq. (9) can be determined and is equal to -1.21 , which means that $(dtg\delta_{max}/dT)$ is less than zero. According to the criteria given before, it would be easier to distinguish the polarization type in the MS3A suspension— $(dtg\delta_{max}/dT)$ would be less than zero in dominant Maxwell–Wagner polarization, and it would be larger than zero in dominant Debye polarization. This result indicates that Maxwell–Wagner polarization is dominant in the particle-type MS3A ER suspension. The direct dielectric measurement of the MS3A suspension further confirms the conclusion. Figure 9 shows the dielectric loss tangent of the MS3A suspension as a function of frequency obtained at temperatures from 20 to 120°C. The maxima of the dielectric loss tangent obviously decrease as temperature increases, in accordance with the theoretical prediction.

If mainly interfacial polarization occurs in ER fluids, the Wagner–Maxwell equation should be able to describe the dielectric properties of ER fluids. Filisko (40) and

Figure 7. The dielectric constant and the dielectric loss of pure MS3A vs. frequency at 20°C.

Figure 8. The static dielectric constant of pure MS3A vs. temperature.

Weiss and Carlson (45) measured the dielectric constants and dielectric losses of their ER fluids and found that the Wagner–Maxwell equation is a suitable model for describing the dielectric properties. The Wagner–Maxwell equation should also be able to explain the frequency dependence of the yield stress of an ER fluid. The yield stress of the oxidized polyacrylonitrile (OP) /PDMS

Figure 9. The dielectric loss tangent of the MS3A suspension as a function of frequency obtained at temperatures from 20–120°C.

Figure 10. The frequency dependence of the yield stress of the OP suspension obtained at 300 V/mm. The solid line is the Wagner model's prediction [reproduced from (56)].

oil suspension versus frequency is shown in Fig. 10. The yield stress was obtained at an oscillatory field strength of 300 V/mm and a frequency range from 10^{-1} to 10^4 Hz, and the dielectric constant data were calculated by using the Wagner–Maxwell equation. The frequency dependences of the yield stress and the dielectric constant coincided, indicating that the Wagner–Maxwell polarization controls the dielectric properties of ER suspensions and then the ER effect.

As the experimental facts indicated, the importance of the Wagner–Maxwell polarization in ER fluids is obvious. However, it is still not clear how interfacial polarization controls the ER effect or how the material dielectric constant and dielectric loss correlate with the ER effect. From the Wagner–Maxwell Eq. (4), one can see that interfacial polarization depends greatly on the conductivity of the solid particulate material. A material, whose conductivity can be changed easily and thus whose ER performance would be different due to the different interfacial polarization contribution, would be very useful for evaluating whether the dielectric constant or the dielectric loss are important in the ER effect. Oxidized polyacrylonitrile (OP) and aluminosilicate (AS) were selected as candidates for this purpose because the conductivity of OP can be easily varied by changing the carbonating temperature and that of the AS can also be easily controlled by changing the

Figure 11. The shear stress of OP and AS suspensions versus the dispersed particle constant [reproduced from (52)].

Figure 12. The shear stress of OP and AS suspensions versus the dispersed particle dielectric loss tangent [reproduced from (52)].

heat treatment temperature. The heat processing is controlled merely to change the material's conductivity rather than the material itself. The shear stresses versus the particulate dielectric constants and dielectric loss tangents of both of these materials are shown in Figs. 11, 12. The shear stresses do not change monotonically with the dielectric constant or dielectric loss tangent even for the same series of samples. From these two figures, one can see that the material that has a larger dielectric constant and a large dielectric loss would give a stronger ER effect. The ER effect would be weak if the material has only a large dielectric constant but a small dielectric loss. This means that the dielectric loss is also very important. By analyzing the experimental results presented in Figs. 11 and 12, one can conclude that the dielectric loss tangent of the solid particulate material should be around 0.10 at 1000 Hz, which is the precondition for the ER effect. Furthermore, the larger the dielectric constant, then the stronger the ER effect. These results are little surprising because one cannot imagine what the function of the dielectric loss in the ER effect is. However, taking a look at the dielectric loss tangent data of solid materials that it is already found, present a good ER effect (see Table 1), one has to come to the same conclusion, indicating that the empirical criterion proposed before is reasonable.

Table 1. Dielectric Constant ϵ and Dielectric Loss Tangent ($tg\delta$) of Currently Used ER Solid Materials at 20°C

Material	ϵ	$tg\delta$	Frequency (Hz)
Silica glass	9.7	0.24	1000
Sandy soil	3.42	0.08	1000
Titanium dioxide	200	0.35	1000
Phenol-formaldehyde	7	0.11	1000
Cellulose nitrate	8.4	0.1	100
Methyl cellulose	7.6	0.128	100
Polyvinyl alcohol acetate

(85°C)	100	1.3	1000
Polyethyl methacrylate			
(25°C)	2.75	0.042	1000
(80°C)	3.36	0.11	1000
Oxidized polyacrylonitrile	5.5	0.085	1000

THEORETICAL TREATMENT

What is the physical basis of the empirical criterion described before? This section will deal with this issue theoretically. One typical feature of ER fluids is that ER particulates can form a fibrillated structure in an electric field, whereas non-ER particulates cannot. Because the order in ER fluids increases dramatically after an electric field is applied, the entropy changes in the ER systems should obviously be less than zero.

Consider a general ER system. Assuming that the volume of the ER fluid is always constant and that the temperature T is the only parameter besides the electric field E that varies, the increase dU of internal energy U per unit volume of ER suspension, after an electric field is applied, can be expressed as follows, according to the first thermodynamic law and electromagnetic theory (41):

$$dU = dQ + \frac{E}{4\pi}dD, \quad (12)$$

where dQ is the influx of heat per unit volume, D is the electric displacement, and $\frac{E}{4\pi}dD$ represents the influx of energy into the ER fluid. For ER fluids, it is already known that, both theoretically and experimentally, there is a critical electric field at which the liquid–solid (disorder–order) transition takes place (23). The critical electric field is usually less than 200 V/mm, and a typical value is around 45 V/mm for many ER systems. When the applied electric field is slightly larger than the critical field, one may assume that the static dielectric constant ε_s of an ER suspension is independent of E because the applied electric field is not very strong. Even in a very strong field, the static dielectric constant of many materials would not substantially change (46). Then $D = \varepsilon_s E$; thus,

$$dD = d(\varepsilon_s E) = \varepsilon_s dE + E d\varepsilon_s = \varepsilon_s dE + E \frac{\partial \varepsilon_s}{\partial T} dT, \quad (13)$$

because ε_s depends just on T . It will be useful to take T and E^2 as independent variables. Thus Eq. (12) can be rewritten as

$$dU = dQ + \frac{\varepsilon_s}{8\pi}d(E^2) + \frac{E^2}{4\pi} \frac{\partial \varepsilon_s}{\partial T} dT = \frac{\partial U}{\partial(E^2)}d(E^2) + \frac{\partial U}{\partial T}dT. \quad (14)$$

One also can think that entropy S is a function of T and E^2 , as $dS = dQ/T$, the second thermodynamic law for a reversible process, so that

$$dS = \frac{\partial S}{\partial T}dT + \frac{\partial S}{\partial(E^2)}d(E^2). \quad (15)$$

Inserting dQ from Eqs. (14) and (15),

$$dS = \frac{1}{T} \left(\frac{\partial U}{\partial T} - \frac{E^2}{4\pi} \frac{\partial \varepsilon_s}{\partial T} \right) dT + \frac{1}{T} \left(\frac{\partial U}{\partial(E^2)} - \frac{\varepsilon_s}{8\pi} \right) d(E^2). \quad (16)$$

The condition that dS is a total differential requires that

$$\frac{\partial}{\partial(E^2)} \left[\frac{1}{T} \left(\frac{\partial U}{\partial T} - \frac{E^2}{4\pi} \frac{\partial \varepsilon_s}{\partial T} \right) \right] = \frac{\partial}{\partial T} \left[\frac{1}{T} \left(\frac{\partial U}{\partial(E^2)} - \frac{\varepsilon_s}{8\pi} \right) \right]. \quad (17)$$

Carrying out the differentiation,

$$\frac{\partial U}{\partial(E^2)} = \frac{1}{8\pi} \left(\varepsilon_s + T \frac{\partial \varepsilon_s}{\partial T} \right). \quad (18)$$

Comparing Eqs. (14) and (15) and inserting $\partial U/\partial(E^2)$ from Eq. (18),

$$\frac{\partial S}{\partial(E^2)} = \frac{1}{8\pi} \frac{\partial \varepsilon_s}{\partial T}. \quad (19)$$

Integrating,

$$S = S_0(T) + \frac{\partial \varepsilon_s}{\partial T} \frac{E^2}{8\pi}, \quad (20)$$

where $S_0(T)$ is the entropy in the absence of a field. Thus

$$\Delta S = \frac{\partial \varepsilon_s}{\partial T} \frac{E^2}{8\pi}. \quad (21)$$

For an ER fluid, $\Delta S < 0$; this obviously requires that $\partial \varepsilon_s/\partial T < 0$. The static dielectric constant ε_s of an ER fluid is the dielectric constant at $\omega = 0$. Thus, it can be expressed from Eq. (1) as

$$\varepsilon_s = \varepsilon_\infty(1 + K). \quad (22)$$

Assuming that both ε_{sm} and ε_{sp} are functions of T ,

$$\begin{aligned} \frac{d\varepsilon_s}{dT} = & \left[1 + 3\Phi + \frac{54\Phi^2\varepsilon_{sm}(\varepsilon_{sp}^2 - 1.5\varepsilon_{sm}\varepsilon_{sp} - \varepsilon_{sm}^2)}{(2\varepsilon_{sm} + \varepsilon_{sp})^3} \right] \frac{d\varepsilon_{sm}}{dT} \\ & - \frac{27\varepsilon_{sm}^2\Phi^2(\varepsilon_{sp} - 4\varepsilon_{sm})}{(2\varepsilon_{sm} + \varepsilon_{sp})^3} \frac{d\varepsilon_{sp}}{dT}. \end{aligned} \quad (23)$$

For polar liquids, $d\varepsilon_{sm}/dT$ is always less than zero. So, if $\varepsilon_{sp} > 4\varepsilon_{sm}$ and $d\varepsilon_{sp}/dT > 0$, $d\varepsilon_s/dT$ would be less than zero under any conditions; if $\varepsilon_{sp} > 4\varepsilon_{sm}$, $d\varepsilon_{sp}/dT < 0$, the situation becomes complicated, and the ER effect is still theoretically possible if

$$\begin{aligned} & \left(\frac{d\varepsilon_{sp}}{dT} \right) / \left(\frac{d\varepsilon_{sm}}{dT} \right) \\ & < \frac{(1 + 3\Phi)(2\varepsilon_{sm} + \varepsilon_{sp})^3 + 54\Phi^2\varepsilon_{sm}(\varepsilon_{sp}^2 - 1.5\varepsilon_{sm}\varepsilon_{sp} - \varepsilon_{sm}^2)}{27\Phi^2\varepsilon_{sm}^2(\varepsilon_{sp} - 4\varepsilon_{sm})}. \end{aligned}$$

However, the possibility is low because the entropy decrease is not so large (the particles contribute positively) and the ER solidification process would need a much larger decrease in entropy to form a body-centered tetragonal crystalline structure. So, only the weak ER effect or even

no ER effect would be generated. If the value of $(\frac{d\varepsilon_{sp}}{dT})/(\frac{d\varepsilon_{sm}}{dT})$ is larger than the value of

$$\frac{(1 + 3\Phi)(2\varepsilon_{sm} + \varepsilon_{sp})^3 + 54\Phi^2\varepsilon_m(\varepsilon_{sp}^2 - 1.5\varepsilon_{sm}\varepsilon_{sp} - \varepsilon_{sm}^2)}{27\Phi^2\varepsilon_{sm}^2(\varepsilon_{sp} - 4\varepsilon_{sm})},$$

$\frac{d\varepsilon_s}{dT}$ would be larger than zero, a negative ER effect, i.e., a decrease in the viscosity of the fluid as the applied electric field increases, would be observed. If $\varepsilon_{sp} < 4\varepsilon_{sm}$, $d\varepsilon_{sp}/dT$ is unlikely to be less than zero because a small dielectric constant is generally due to polar group orientation, as well as electronic and atomic polarization. For a polar material that has a comparatively small dielectric constant, its $d\varepsilon_{sp}/dT$, likely of the same order as $d\varepsilon_{sm}/dT$, would be larger than zero (41). So the ER effect might also be generated but would still be very weak. Here, we just concentrate on the positive ER situation, $d\varepsilon_{sp}/dT > 0$.

According to the Clausius–Mossotti formula, the static dielectric constant ε of a pure material can be expressed as (47)

$$\frac{\varepsilon - 1}{\varepsilon + 2} = \frac{4}{3}\pi N(\alpha_e + \alpha_a + \alpha_i + \alpha_d), \quad (24)$$

where α_e , α_a , α_i , and α_d are the polarizabilities of the electron, atom, ion displacement, and dipole rotation; and N is the number of molecules per unit volume. For a solid material, dipole polarization is negligible because solidification usually fixes the molecule with such rigidity in the lattice that little or no orientation of the dipole occurs in an electric field (41). Thus for ER particles,

$$\frac{\varepsilon_{sp} - 1}{\varepsilon_{sp} + 2} = \frac{4}{3}\pi N(\alpha_e + \alpha_a + \alpha_i). \quad (25)$$

In a very high frequency region, Eq. (25) leads to

$$\frac{\varepsilon_{\infty p} - 1}{\varepsilon_{\infty p} + 2} = \frac{4}{3}\pi N(\alpha_e + \alpha_a). \quad (26)$$

Differentiating Eq. (25) with respect to T ,

$$\frac{3}{(\varepsilon_{sp} + 2)^2} \frac{d\varepsilon_{sp}}{dT} = \frac{4}{3}\pi(\alpha_e + \alpha_a + \alpha_i) \frac{dN}{dT} + \frac{4}{3}\pi N \frac{d\alpha_i}{dT}. \quad (27)$$

Because $\frac{1}{N} \frac{dN}{dT} = -3\beta$, where β is the material's linear coefficient of expansion, Eq. (27) can be rewritten as

$$\frac{d\varepsilon_{sp}}{dT} = \left[-3 \frac{\varepsilon_{sp} - 1}{\varepsilon_{sp} + 2} \beta + \frac{4\pi N}{3} \frac{d\alpha_i}{dT} \right] \frac{(\varepsilon_{sp} + 2)^2}{3}, \quad (28)$$

where $\alpha_i = \frac{2q^2}{k}$, $k = \frac{2M(n-1)q^2r_0^{n-1}}{3r^{n+2}}$ [see (47)], q is the ion charge, k is the elastic bonding coefficient between two ions of opposite sign of charge, M and n are constants, and r_0 and r are the equilibrium distance and the distance between the two ions. Assuming that the α_i and k are function of temperature due to the fact that r would change

with temperature,

$$\frac{d\alpha_i}{dT} = -\frac{\alpha_i}{k} \frac{dk}{dT}, \quad (29)$$

$$\frac{dk}{dT} = -(n+2)k \frac{1}{r} \frac{dr}{dT}. \quad (30)$$

By definition, $\frac{1}{r} \frac{dr}{dT} = \beta$. From Eq. (26),

$$\frac{d\alpha_i}{dT} = \alpha_i(n+2)\beta = \frac{3}{4\pi N} \left(\frac{\varepsilon_{sp} - 1}{\varepsilon_{sp} + 2} - \frac{\varepsilon_{\infty p} - 1}{\varepsilon_{\infty p} + 2} \right) (n+2)\beta. \quad (31)$$

Inserting Eq. (31) into Eq. (28) and assuming $\frac{\varepsilon_{sp} - 1}{\varepsilon_{sp} + 2} = p_s$ and $\frac{\varepsilon_{\infty p} - 1}{\varepsilon_{\infty p} + 2} = p_\infty$,

$$\frac{d\varepsilon_{sp}}{dT} = [(n-1)p_s - (n+2)p_\infty] \frac{(\varepsilon_{sp} + 2)^2 \beta}{3}. \quad (32)$$

Only when $\frac{p_s}{p_\infty} > \frac{n+2}{n-1}$, would $d\varepsilon_{sp}/dT$ be larger than zero. This requirement leads to

$$\frac{\varepsilon_{sp} - \varepsilon_{\infty p}}{\varepsilon_{sp}\varepsilon_{\infty p}} > \frac{1}{n} \approx 0.1 \quad (33)$$

because for most materials, $n \approx 10$ [see (47)]. Equation (33) is the dielectric requirement for an ER particulate material.

The conductivities of most ER particulate materials are comparatively low, and one would assume that the particle dielectric loss results just from ion displacement polarization. The dielectric loss due to ion displacement polarization can be calculated from the absorption current. Assuming that the initial conductivity of an ER particle material is σ_0 the absorption current can be expressed as $\sigma_0 e^{-t/\theta}$, t is time, θ is a time constant, $\theta = \frac{\varepsilon_{sp} + 2}{\varepsilon_{\infty p} + 2} \tau$, τ is the relaxation time, thus under an oscillatory electric field $E = E_0 e^{i\omega t}$, the induced current density d_i due to ion displacement polarization can be expressed as (47)

$$\begin{aligned} d_i &= \sigma_0 \int_{-\infty}^{t_1} \frac{dE}{dt} e^{-\frac{t-t}{\theta}} dt = i\bar{\omega} \sigma_0 E_0 \int_{-\infty}^{t_1} e^{i\bar{\omega}t - \frac{t-t}{\theta}} dt \\ &= \frac{i\bar{\omega} \theta \sigma_0}{1 + i\bar{\omega} \theta} E_0 e^{-\frac{t_1}{\theta}} e^{\frac{1+i\bar{\omega}\theta}{\theta}}, \\ &= \frac{\bar{\omega}^2 \theta^2 \sigma_0}{1 + \bar{\omega}^2 \theta^2} E_0 e^{i\bar{\omega}t_1} + i \frac{\bar{\omega} \theta \sigma_0}{1 + \bar{\omega}^2 \theta^2} E_0 e^{i\bar{\omega}t_1}, \end{aligned} \quad (34)$$

where t_1 is a constant. The first term of this equation has the same phase as the applied electric field, can be called the ohmic component d_{io} , and would contribute to the dielectric loss; the second term has a $(\pi/2)$ phase difference from the electric field, can be called the capacitive component d_{ic} , and contributes just to polarization. Because atomic and electronic polarizations also contribute to the capacitive current density and the general relationship between the induced current density d and the dielectric

constant ε is $d = \frac{\bar{\omega}\varepsilon E_0}{4\pi}$, the current density due to these two kinds of polarization d_{ae} can be expressed as $d_{ae} = \frac{\bar{\omega}\varepsilon_{\infty p} E_0}{4\pi}$. Then, the total capacitive current density d_c can be written as

$$d_c = d_{ic} + d_{ae} = \bar{\omega} \left(\frac{\varepsilon_{\infty p}}{4\pi} + \frac{\theta\sigma_0}{1 + \bar{\omega}^2\theta^2} \right) E_0. \quad (35)$$

According to the definition, the dielectric loss tangent $tg\delta$ is given by

$$tg\delta = \frac{d_{io}}{d_c} = \frac{\bar{\omega} \theta^2 \sigma_0}{\frac{\varepsilon_{\infty p}}{4\pi} (1 + \bar{\omega}^2 \theta^2) + \theta \sigma_0}. \quad (36)$$

The total dielectric constant ε is given by

$$\varepsilon = \frac{d_c}{\bar{\omega} E_0} 4\pi = \varepsilon_{\infty p} + \frac{4\pi\theta\sigma_0}{1 + \bar{\omega}^2\theta^2}. \quad (37)$$

In a dc field ($\omega = 0$),

$$\varepsilon_{sp} = \varepsilon_{\infty p} + 4\pi\theta\sigma_0. \quad (38)$$

Inserting Eq. (38) into Eq. (36),

$$tg\delta = \frac{\bar{\omega} \theta (\varepsilon_{sp} - \varepsilon_{\infty p})}{\varepsilon_{sp} + \varepsilon_{\infty p} \bar{\omega}^2 \theta^2}. \quad (39)$$

Equation (39) is a general expression for a solid material of very low conductivity and marked ionic displacement polarization. Differentiating Eq. (39) with respect to ω , $tg\delta$ has a maximum value,

$$tg\delta_{\max} = \frac{\varepsilon_{sp} - \varepsilon_{\infty p}}{2\sqrt{\varepsilon_{sp}\varepsilon_{\infty p}}}. \quad (40)$$

Comparing this with Eq. (33),

$$tg\delta_{\max} > \frac{\varepsilon_{sp} - \varepsilon_{\infty p}}{\varepsilon_{sp}\varepsilon_{\infty p}} > 0.1. \quad (41)$$

For many ER particle materials, $\sqrt{\varepsilon_{sp}\varepsilon_{\infty p}}$ is always larger than 2. Equation (34) indicates that the suspended particles can become ordered in an electric field only when the maximum value of the dielectric loss tangent is larger than 0.1, which matches exactly the empirical criterion obtained experimentally.

In conclusion, from the basic fact that the entropy of an ER fluid is greatly reduced after an electric field is applied, one may theoretically find that the maximum value of the dielectric loss tangent of the dispersed particles should be larger than 0.1, which agrees well with experimental results. The negative ER effect becomes possible only if $d\varepsilon_{sp}/dT < 0$.

THE MECHANISM OF THE ER EFFECT

It is found experimentally and theoretically that both the large dielectric loss and the large dielectric constant of dispersed particles are very important for the ER effect.

Interfacial polarization is also crucial. What is the relationship between interfacial polarization and the dielectric constant and loss of dispersed particles? Why can ER particulates form a fibrillated structure?

As shown in Fig.1, the total polarization P of a heterogeneous material can be expressed as

$$P = P_i + P_d + P_a + P_e. \quad (42)$$

Correspondingly, the total dielectric constant ε can be expressed as

$$\begin{aligned} \varepsilon &= \varepsilon_s + \varepsilon_i + \varepsilon_d + \varepsilon_a + \varepsilon_e, \\ &= \varepsilon_s + \varepsilon_i + \varepsilon_d + \varepsilon_{\infty}, \end{aligned} \quad (43)$$

where ε_i , ε_d , ε_a , and ε_p are artificially regarded as the dielectric constant induced by the interfacial, Debye, atomic, and electronic polarizations, respectively; ε_s is the static dielectric constant; and $\varepsilon_{\infty} = \varepsilon_a + \varepsilon_e$, is the high-frequency dielectric constant. As stated before, the dipole orientation contribution of solid particulate materials can be negligible; thus, Eq. (43) can be written as

$$\varepsilon = \varepsilon_s + \varepsilon_i + \varepsilon_{\infty}. \quad (44)$$

The dielectric constant and the dielectric loss are not independent, and the dielectric loss originally results from slow polarization, interfacial polarization in this case. A large dielectric loss tangent for an ER suspension would mean that the ratio of ε_i to ε is large. Obviously, the large dielectric loss of dispersed particles would result in a large dielectric loss for the whole suspension and then high interfacial polarization. So, interfacial polarization stems from the dielectric loss of dispersed particles. No obvious interfacial polarization is expected if the particulate material does not have a marked dielectric loss.

One typical feature of ER fluids is that ER particles can fibrillate between two electrodes; however, non-ER particles cannot do so. In the primary stage, ER and non-ER particles have almost same microstructures—the particles randomly distribute in the medium or stochastically form some clusters. After they are exposed to an external electric field, why do they behave quite differently? A major difference between ER and non-ER particles is that the dielectric loss tangents of many ER particulate materials are comparatively higher, around 0.10 at 1000 Hz., that is, ER suspensions usually have large interfacial polarizations. Why does the large interfacial polarization produce a difference between ER and non-ER particles? Because the interfacial polarization is originally associated with bounded surface charges, one has to presume that large amount of surface charge can make ER particles turn in the direction of an external electric field. The non-ER particles, however, cannot turn due to the lack of surface charge. Although they still can be polarized, the total interparticle force would be canceled out owing to the diversity of particle dipole vectors (see Fig. 13).

Generally, surface charge is associated with the material's dielectric loss and can be produced by the following mechanisms (46,48): (1) Debye polarization from dipole

Figure 13. Schematic illustration of ER and non-ER particle behavior before and after an external electric field is applied. (a) ER particle; (b) non-ER particle [reproduced from (49)].

orientation; (2) interfacial polarization (Maxwell–Wagner polarization) from the displacement of charge carriers across a microscopic distance; and (3) leakage conduction from the formation of space charges. The two former effects do not involve any transfer of charge carriers between the dielectric and the electrodes and would contribute to the dielectric absorption; the latter would scale the space charge movement between the dielectric and the electrodes. So the net surface charge of a dielectric would be determined by the former two mechanisms. Because Debye orientation can be overlooked in ER systems, the net surface charge can be produced only by interfacial polarization and can be calculated from dc absorption current measurement. Hao and Xu (40) experimentally proved that even in a very weak electric field $E_{cr} = 12\text{V/mm}$, a particle can turn to align in the direction of the applied electric field if large interfacial polarization can be generated. ER particles turning in an electric field were also detected by using X-ray diffraction (50).

Obviously, after ER particles turn in the direction of an electric field, the interparticle force would be determined mainly by how much the particles are polarized, that is the value of particle dielectric constant. So, the mechanism of the ER effect contains two steps: first, the particles turn in the direction of the applied electric field; second, the particles bind together due to polarization. The first step is controlled by the dielectric loss of the dispersed particles, and the second step is controlled by the dielectric constant.

THE YIELD STRESS EQUATION

According to the ER mechanism proposed, the entropy change in an ER system obviously includes two parts: the particle configurational entropy, which represents the entropy change from the randomly distributed particle state to the body-centered tetragonal (bct) crystalline state; the other is the entropy change from the very weak interparticle force state to the exceptionally strong interparticle force state. The former would contribute to the particle arrangement, whereas the latter would contribute to the ER effect and is originally induced by interfacial polarization. In the first part, interfacial polarization could be presumed thought not to take place, and the interparticle

Figure 14. Schematic of the hypothesized two-step process during the solidification transition of an ER suspension in an external electric field [reproduced from (55)].

force could be negligible because it is extremely weak in this state; in the second part, interfacial polarization takes place, making the already well-arranged particles become strongly correlated. This hypothesized process is schematically illustrated in Fig. 14. To determine the yield stress of an ER suspension, one has to know the internal energy and entropy changes of the second step, ΔS_2 and ΔU_2 , respectively. Obviously,

$$\Delta S_2 = \Delta S - \Delta S_1, \quad (45)$$

$$\Delta U_2 = \Delta U - \Delta U_1. \quad (46)$$

Integrating Eq. (18),

$$U = U_0(T) + \frac{E^2}{8\pi} \left(\varepsilon_s + T \frac{\partial \varepsilon_s}{\partial T} \right), \quad (47)$$

where $U_0(T)$ represents the internal energy of an ER suspension in the absence of an electric field. Thus, the internal energy change ΔU due to the applied electric field is

$$\Delta U = \frac{E^2}{8\pi} \left(\varepsilon_s + T \frac{\partial \varepsilon_s}{\partial T} \right). \quad (48)$$

Substituting Eqs. (22), (23) into Eq. (48),

$$\begin{aligned} U = U_0 + \frac{E^2}{8\pi} & \left[(1 + 3\Phi) \left(\varepsilon_{sm} + T \frac{d\varepsilon_{sm}}{dT} \right) \right. \\ & + \frac{27\Phi^2 \varepsilon_{sm}^2 (\varepsilon_{sp} - \varepsilon_{sm})}{(2\varepsilon_{sm} + \varepsilon_{sp})^2} \\ & + \frac{54\Phi^2 \varepsilon_{sm} T (\varepsilon_{sp}^2 - 1.5\varepsilon_{sm}\varepsilon_{sp} - \varepsilon_{sm}^2)}{(2\varepsilon_{sm} + \varepsilon_{sp})^3} \frac{d\varepsilon_{sm}}{dT} \\ & \left. - \frac{27\Phi^2 \varepsilon_{sm}^2 T (\varepsilon_{sp} - 4\varepsilon_{sm})}{(2\varepsilon_{sm} + \varepsilon_{sp})^3} \frac{d\varepsilon_{sp}}{dT} \right]. \quad (49) \end{aligned}$$

For step 1, we assumed that interfacial polarization does not take place, which is likely only under the condition $\varepsilon_{sm} = \varepsilon_{sp}$. Then, the static dielectric constant of this assumed system, according to Eq. (22), is $\varepsilon_{sm}(1 + 3\Phi)$. Thus, the influx of electric energy into the assumed system for

arraying disordered particles to form the very loose bct. lattice can be expressed, analogous to Eq. (47), by

$$\Delta U_1 = (1 + 3\Phi) \left(\varepsilon_{sm} + T \frac{d\varepsilon_{sm}}{dT} \right) \frac{E^2}{8\pi}, \quad (50)$$

and the entropy change

$$\Delta S_1 = (1 + 3\Phi) \frac{E^2}{8\pi} \frac{\partial \varepsilon_{sm}}{\partial T}. \quad (51)$$

Therefore, according to Eqs. (45) and (46),

$$\begin{aligned} \Delta U_2 = & \frac{E^2}{8\pi} \left[\frac{27\Phi^2 \varepsilon_{sm}^2 (\varepsilon_{sp} - \varepsilon_{sm})}{(2\varepsilon_{sm} + \varepsilon_{sp})^2} \right. \\ & + \frac{54\Phi^2 \varepsilon_{sm} T (\varepsilon_{sp}^2 - 1.5\varepsilon_{sm}\varepsilon_{sp} - \varepsilon_{sm}^2)}{(2\varepsilon_{sm} + \varepsilon_{sp})^3} \frac{d\varepsilon_{sm}}{dT} \\ & \left. - \frac{27\Phi^2 \varepsilon_{sm}^2 T (\varepsilon_{sp} - 4\varepsilon_{sm})}{(2\varepsilon_{sm} + \varepsilon_{sp})^3} \frac{d\varepsilon_{sp}}{dT} \right], \quad (52) \end{aligned}$$

$$\begin{aligned} \Delta S_2 = & \frac{E^2}{8\pi} \left[\frac{54\Phi^2 \varepsilon_{sm} T (\varepsilon_{sp}^2 - 1.5\varepsilon_{sm}\varepsilon_{sp} - \varepsilon_{sm}^2)}{(2\varepsilon_{sm} + \varepsilon_{sp})^3} \frac{d\varepsilon_{sm}}{dT} \right. \\ & \left. - \frac{27\Phi^2 \varepsilon_{sm}^2 T (\varepsilon_{sp} - 4\varepsilon_{sm})}{(2\varepsilon_{sm} + \varepsilon_{sp})^3} \frac{d\varepsilon_{sp}}{dT} \right]. \quad (53) \end{aligned}$$

ΔU_2 should be less than zero because the interparticle force in the ER crystalline lattice is attractive. Thus, Eq. (52) should be expressed as

$$\begin{aligned} \Delta U_2 = & -\frac{E^2}{8\pi} \left[-\frac{27\Phi^2 \varepsilon_{sm}^2 (\varepsilon_{sp} - \varepsilon_{sm})}{(2\varepsilon_{sm} + \varepsilon_{sp})^2} \right. \\ & - \frac{54\Phi^2 \varepsilon_{sm} T (\varepsilon_{sp}^2 - 1.5\varepsilon_{sm}\varepsilon_{sp} - \varepsilon_{sm}^2)}{(2\varepsilon_{sm} + \varepsilon_{sp})^3} \frac{d\varepsilon_{sm}}{dT} \\ & \left. + \frac{27\Phi^2 \varepsilon_{sm}^2 T (\varepsilon_{sp} - 4\varepsilon_{sm})}{(2\varepsilon_{sm} + \varepsilon_{sp})^3} \frac{d\varepsilon_{sp}}{dT} \right]. \quad (54) \end{aligned}$$

ΔS_2 should also be less than zero; as in step 2, entropy obviously decreases substantially and requires $\varepsilon_{sp} > 4\varepsilon_{sm}$ when $\frac{d\varepsilon_{sp}}{dT} > 0$ and $\varepsilon_{sp} < 4\varepsilon_{sm}$ when $\frac{d\varepsilon_{sp}}{dT} < 0$. These are the preconditions of Eq. (54).

Equation (54) gives the internal energy change per unit volume of the whole suspension. For an ER suspension of volume V , particle volume fraction ϕ , and particle diameter r , the number of particles N in this volume is

$$N = \frac{V\phi}{\frac{4}{3}\pi r^3} = \frac{3V\phi}{4\pi r^3}. \quad (55)$$

Then, the interparticle energy U_{ip} is

$$U_{ip} = \frac{\Delta U_2 V}{N/2} = \frac{8\pi r^3 \Delta U_2}{3\phi}. \quad (56)$$

Figure 15. Schematic of the unit cell of a bct lattice formed by ER particles in an electric field. The radius of the particle is r [reproduced from (55)].

The free volume per particle V_{fp} in an off-state electric field is

$$V_{fp} = \frac{V - V\phi}{N} = \frac{4\pi r^3(1 - \phi)}{3\phi}. \quad (57)$$

It is known that ER particles in an electric field form fibrillation chains of a bct. lattice. The unit cell of a bct. lattice is schematically illustrated in Fig. 15. One center particle, which belongs to a different chain class, would have eight nearest neighbor particles at the interparticle distance $2r$; besides, one center particle, which belongs to the same chain class, also has another six nearest neighbor center particles also at the interparticle distance $2r$. So, the total energy U_{it} for one particle in the unit cell

$$U_{it} = (8 + 6) \times U_{ip} = \frac{112\pi r^3 \Delta U_2}{3\phi}. \quad (58)$$

Because a particle cannot freely leave the cell of the lattice, the free volume per particle in an electric field, V_{fE} , would become

$$V_{fE} = V_{fp} - \left(\frac{2r \times \sqrt{6}r \times \sqrt{6}r}{2} \right) = \frac{4\pi r^3(1 - \Phi) - 18\Phi r^3}{3\Phi}. \quad (59)$$

Note that there are two equivalent particles in one unit cell. Assuming that the yield stress τ_y is the force that can drive one particle to move within the free volume per particle (51),

$$\begin{aligned} \tau_y = & \frac{|U_{it}|}{V_{fE}} = \frac{112\pi}{4\pi(1 - \Phi) - 18\Phi} |\Delta U_2| \\ = & \frac{14E^2}{4\pi(1 - \Phi) - 18\Phi} \left[-\frac{27\Phi^2 \varepsilon_{sm}^2 (\varepsilon_{sp} - \varepsilon_{sm})}{(2\varepsilon_{sm} + \varepsilon_{sp})^2} \right. \\ & \left. - \frac{54\Phi^2 \varepsilon_{sm} T (\varepsilon_{sp}^2 - 1.5\varepsilon_{sm}\varepsilon_{sp} - \varepsilon_{sm}^2)}{(2\varepsilon_{sm} + \varepsilon_{sp})^3} \frac{d\varepsilon_{sm}}{dT} \right. \\ & \left. + \frac{27\Phi^2 \varepsilon_{sm}^2 T (\varepsilon_{sp} - 4\varepsilon_{sm})}{(2\varepsilon_{sm} + \varepsilon_{sp})^3} \frac{d\varepsilon_{sp}}{dT} \right] \end{aligned}$$

$$+ \frac{27\Phi^2 \varepsilon_{sm}^2 T(\varepsilon_{sp} - 4\varepsilon_{sm})}{(2\varepsilon_{sm} + \varepsilon_{sp})^3} \frac{d\varepsilon_{sp}}{dT} \Big]. \quad (60)$$

Equation (60) presents a correlation between the yield stress of an ER suspension and the physical parameters of the suspension materials. One can easily obtain the yield stress value if all of the parameters are already known. Equation (60) can be further developed to a more meaningful form. According to the Clausius–Mossotti equation, the liquid media used in ER fluids are usually nonpolar, and then,

$$\frac{d\varepsilon_{sm}}{dT} = -\frac{(\varepsilon_{sm} - 1)(\varepsilon_{sm} + 2)}{3} \beta_m, \quad (61)$$

where β_m is the linear expansion coefficient of the liquid. Assuming $\xi = \varepsilon_{sp}/\varepsilon_{sm}$ and substituting Eqs. (32) and (61) in Eq. (60),

$$\begin{aligned} \tau_y = & \frac{126\Phi^2 E^2}{4\pi(1-\Phi) - 18\Phi} - \left[\frac{3\varepsilon_{sm}(\xi^2 + \xi - 2)}{(2+\xi)^3} \right. \\ & + \frac{2\beta_m T(\xi^2 - 1.5\xi - 1)(\varepsilon_{sm}^2 + \varepsilon_{sm} - 2)}{(2+\xi)^3} \\ & \left. + \frac{T\beta_p p(\xi - 4)(\varepsilon_{sm}\xi + 2)^2}{(2+\xi)^3} \right]. \quad (62) \end{aligned}$$

where $p = [(n-1)p_s - (n+2)p_\infty]$. Once the parameters are known, Eq. (62) gives the yield stress value of the ER fluid. First, let us take a look at how the particle-to-oil dielectric constant ratio ξ changes the yield stress of an ER fluid on the basis of Eq. (62). Assuming that $d\varepsilon_{sp}/dT$ is 0.40 and $\beta_p p = 3.82 \times 10^{-4}$ (both are typical values for ER systems based on the experimental data), one can get the numerical relationship between the yield stress and the particle-to-oil dielectric constant ratio of the silicone oil ER system, which is shown in Fig. 16. Figure 16 clearly shows that the yield stress dramatically increases as ξ increases at a low particle-to-oil dielectric constant ratio; however, the yield stress gradually levels off after ξ is higher than 60. The sharp increase in yield stress takes place in the range of $\xi < 50$, indicating that materials whose static dielectric constant is around 150 would potentially display the best ER effect and materials that have a larger static dielectric constant would not always display a good ER effect if other properties are not beneficial to the ER effect.

Note that this conclusion is derived under the assumption that the parameter p has a positive value. If p is negative, the larger particle-to-oil dielectric constant ratio would not generate a larger yield stress. According to the definition and assuming that $\varepsilon_{sp} - \varepsilon_{\infty p} = A$,

$$p = \frac{3(n - \varepsilon_{\infty p})A - 3\varepsilon_{\infty p}(\varepsilon_{\infty p} + 1) + 6}{(\varepsilon_{\infty p} + 2)^2 + (\varepsilon_{\infty p} + 2)A}. \quad (63)$$

If $\varepsilon_{\infty p}$ is not so large (less than 10 for most small dielectric constant materials), $3(n - \varepsilon_{\infty p})$ is always larger than $(\varepsilon_{\infty p} + 2)$, and thus p would increase as A increases, that is, the ER effect would increase approximately with the difference between the dielectric constants below and above

the relaxation frequency; this was already found experimentally by Ikazaki and Kawai (31,32). For a solid material whose leak conductivity is σ , initial conductivity is σ_0 , and relaxation time related constant is θ , it is known that (47)

$$\varepsilon_{sp} - \varepsilon_{\infty p} = 4\pi\theta\sigma_0 \quad (64)$$

and

$$tg\delta = \frac{\sigma(1 + \bar{\omega}^2\theta^2) + \bar{\omega}^2\theta^2\sigma_0}{\frac{\varepsilon_{\infty p}\bar{\omega}}{4\pi}(1 + \bar{\omega}^2\theta^2) + \bar{\omega}\theta\sigma_0}. \quad (65)$$

Thus,

$$A = 4\pi\theta\sigma_0 = \frac{4\pi(1 + \bar{\omega}^2\theta^2) \left(\frac{\varepsilon_{\infty p}\bar{\omega} tg\delta}{4\pi} - \sigma \right)}{\bar{\omega}^2\theta - \bar{\omega} tg\delta}, \quad (66)$$

where $\bar{\omega}$ is the field frequency and $tg\delta$ is the dielectric loss tangent of the solid material. Equation (66) indicates that A obviously increases as $tg\delta$ increases, provided that $\bar{\omega}\theta > tg\delta$ (this always holds because A should have a positive value). Differentiating Eq. (66) with respect to σ , one would find a maximum value for A at

$$\sigma = \frac{\left(\frac{\varepsilon_{\infty p}\bar{\omega}}{4\pi} \frac{dtg\delta}{d\sigma} - 1 \right) \bar{\omega}^2\theta + \bar{\omega} tg\delta}{\bar{\omega} \frac{dtg\delta}{d\sigma}}, \quad (67)$$

because the second derivative of A with respect to σ , $\frac{d^2 A}{d\sigma^2}$, is negative. Considering that $\bar{\omega}\theta > tg\delta$ and $\frac{\varepsilon_{\infty p}\bar{\omega}}{4\pi} \frac{dtg\delta}{d\sigma} \gg 1$, $\sigma \approx \frac{\varepsilon_{\infty p}\bar{\omega}^2\theta}{4\pi}$. For solid materials, one would assume that Debye polarization cannot occur and the dielectric adsorption phenomenon stems just from ion polarization; at $\bar{\omega} = \frac{1}{\theta} \sqrt{\frac{\varepsilon_{sp}}{\varepsilon_{\infty p}}}$, ion polarization-induced $tg\delta$ would reach at a maximum value (47). Then, parameter A also

Figure 16. The numerical relationship between the normalized yield stress, $\tau_y[4\pi(1-\Phi) - 18\Phi]/\Phi^2 E^2$, and the particle-to-oil dielectric constant ratio ξ at room temperature for the silicon oil ER system based on Eq. (62) [reproduced from (55)].

reaches a maximum value. Thus, $\sigma \approx \frac{\epsilon_{sp}}{4\pi\theta}$, which indicates that the yield stress for different dispersed solids would peak at different particle conductivities. In the poly(acenequinones)/silicone oil system, the yield stress, it was found, peaks at a particle conductivity around 10^{-5} S/m (7). However, in the oxidized polyacrylonitrile/silicone oil system, the maximum value of the yield stress occurs near 10^{-7} S/m (52). According to the dielectric data presented in each paper, the optimal conductivity ($\sigma \approx \frac{\epsilon_{sp}}{4\pi\theta}$) is crudely estimated at 0.22×10^{-5} S/m for the former system and 0.88×10^{-7} S/m for the latter system, in good agreement with experimental results.

The temperature dependence of the yield stress can also be qualitatively analyzed using Eq. (62). Because σ and $tg\delta$ are more sensitive to temperature than the dielectric constant, one would still center on the temperature dependence of the parameter p . The conductivity of most solid dielectric materials would exponentially increase with temperature. Thus, the conductivity, rather than other parameters, would be a main variable and surely makes a big contribution to the yield stress as temperature varies [see Eq. (62)]. The yield stress would also go through a maximum value at the temperature where the conductivity reaches its optimal value. It was found experimentally that the yield stress first increases and then decreases with temperature (53,54). Accordingly, the yield stress would decrease with temperature if the conductivity of the solid particles were already larger than the optimal value, and the yield stress would increase with temperature if the conductivity were lower than the optimal value; this was also experimentally found before (54).

The relaxation time constant θ would also influence parameter A , and finally p substantially. From either Eqs. (64) or (66), one would find that p increases as θ increases, that is, the ER effect would be stronger if dielectric relaxation is slower. However, too slow a relaxation time (then slow response time) would make the ER fluids become useless. Generally, a ER response time around 1 millisecond is favorable, thus requiring that the relaxation time is of the same timescale, that is, a dielectric relaxation frequency around 10^3 Hz. Block thought that the polarization rate would be important in the ER response process and that polarization too fast or too slow is not good for an ER effect (7). Ikazaki and Kawai found experimentally that the ER fluids whose relaxation frequencies are within the range of 100 – 10^5 Hz would exhibit a large ER effect (31,32), supporting our derivation.

CONCLUSION

The dielectric properties of ER fluids are thoroughly addressed in this article. Among the polarizations (electronic, atomic, Debye, and interfacial) that occur in ER fluids in an electric field, it is found experimentally that interfacial polarization contributes to the ER effect and that the Wagner–Maxwell equation, which deals with interfacial polarization in heterogeneous systems can describe the dielectric phenomena observed in ER fluids. The dielectric loss of a dispersed particulate material, it is found, plays an important role in ER systems, and the dielectric constant

becomes dominant only when the dielectric loss tangent is larger than 0.10 at 1000 Hz. This empirical criterion for selecting an ER solid has a firm physical basis—it is the precondition for the entropy decrease commonly observed in ER systems. Theoretically, one also can come to the same conclusion if we assume that the entropies of the ER systems would greatly decrease, as ER fluids change from a randomly distributed suspension state to a body-centered-tetragonal crystal state after an external electric field is applied. The mechanism of the ER effect consists of two steps. The first is the particle turning process, which is controlled by the particle dielectric loss; the second is the particle's strong interaction, which is controlled by the dielectric constant. The entropy change in ER systems obviously includes two parts: One is the particle configurational entropy, which represents the entropy change from the randomly distributed particle state to the bct. lattice state; the other is the entropy change from the very weak interparticle force state to the exceptionally strong interparticle force state. The former contributes to particle rearrangement, and the latter contributes to the ER effect, which, it is thought, is originally induced by interfacial polarization. On the basis of this physical picture of the ER mechanism, a general form of a yield stress equation is derived from the internal energy and entropy changes of an ER fluid in an external static electric field. The yield stress equation can give very good predictions in accordance with the previous results obtained so far.

The yield stress equation involves a very important parameter p , which gives an appropriate expression for the dielectric loss tangent criterion put forward before and distinguishes our equation from others. When p is positive, the yield stress increases as the particle-to-medium dielectric ratio ξ increases; this is shown by the polarization model and other models. However, the yield stress gradually levels off when $\xi > 60$. The sharp increase in the yield stress takes place in the range of $\xi < 50$, indicating that materials that have a static dielectric constant around 150 would potentially display the best ER effect (in the PDMS oil system) and materials that have a larger static dielectric constant would not always display a good ER effect if other properties are not good for the ER effect. When p is negative, the suspension would give a weak or even no ER effect. To make the value of p as large as possible, very slow relaxation time and suitable particle conductivity are essential. To obtain a good ER fluid, from Eq. (62), one should use a liquid medium and a solid material that have high dielectric constants (a large dielectric constant ratio of the solid to the liquid). In addition, the solid must have a large dielectric loss tangent (a maximum value at least larger than 0.1) to keep the parameter p positive.

ELECTORRHEOLOGICAL MATERIALS

FRANK FILISKO
University of Michigan
Ann Arbor, MI

INTRODUCTION

Electrorheological (ER) materials are materials whose rheological properties, flow and deformation behavior in response to a stress, are strong functions of the electric field strength imposed upon them. The materials are typically fluids in the absence of an electric field (although they may be pastes, gels, or elastomers) but under constant shear stress at high enough fields, the materials can solidify into viscoelastic solids. In their solid state, various properties of the solid such as shear and tensile strengths and damping capacity, internal friction, and the ability to adsorb energy under impact are also strong functions of the electric field. Further, all physical and mechanical changes induced by the applied field are virtually instantaneously reversible upon removal of the field; such a material can almost instantaneously be solidified and liquefied by applying and removing the electric field. In the liquid state during flow, these materials exhibit resistivity to flow (or apparent viscosity) which can be increased by hundreds or thousands of times by applying an electric field. The materials can be compounded so that viscosities are near that of water under zero fields but approach infinity at very low shear rates under the

influence of fields of the order of a few thousand volts/mm. In the solid state, these materials can have shear strengths of the order of 5,000–10,000 Nt/m² (1–2 lb/in²) in fields around 5000 volts/mm. In brief, these are materials whose mechanical properties and physical state are determined at any instant by the electric field to which they are exposed.

ER materials are typically dispersions of fine hygroscopic particles in a hydrophobic nonelectrically conducting dispersion medium (1). Particle sizes in the range of 0.1–10 μm are common, although particles much larger have demonstrated ER effectiveness, and certain macromolecules in solution exhibit the effect. For example, materials that work well as the dispersed phase include such diverse materials as corn starch, various clays, silica gel, talcum powder, and various polymers. The fluid phase also may consist of a very wide range of liquids or greases which have the common properties of high electrical resistivity (so that high fields may be applied over the fluids without significant currents) and hydrophobicity. Liquids such as kerosene, mineral oil, toluene and silicone oil work well as do many other fluids. With few very significant exceptions, the vast majority of systems also require that significant amounts of water (10–30%) or other activators be adsorbed onto the particulate phase. This requirement severely limited the potential use of these materials. Dry particulate systems will be discussed later.

Although it is not necessary for an appropriate dispersion to demonstrate ER activity, various other types of additives, called activators, have been reported and are commonly incorporated into the mixtures, including various surfactants, to enhance the effect and to increase the stability of the dispersions. How they work is unclear, but as will be discussed later, they most certainly affect the particulate surface, the dispersing liquid, and the water on the particles.

BACKGROUND

The phenomenon which ultimately became known as electrorheology was first observed in the late 1800s by Duff (2) and others, but it was not until the work of Winslow (3,4) in the 1940s, 1950s, and 1960s that the engineering potential and application of these materials began being fully recognized. The most immediate and obvious applications included torque transmission and damping or vibration control. Upon attempting to use these materials, however, it was soon realized that a seemingly insurmountable obstacle prevented their widespread use; the dispersed phase required significant amounts of water to be adsorbed onto the particles (1,4). Work proceeded to resolve this problem by replacing the water with other substances such as glycerol (5) and silanol (6), but the ER effect was substantially reduced. In effect, it began to be accepted that adsorbed water was necessary. The problem was resolved in the late 1980s (1,7) resulting in a tremendous increase in activity within this field over the next decade and a considerable increase in understanding the physics and chemistry of ER suspensions.

Figure 1. Rheological data for titanium dioxide/paraffin oil (5 g/20 cm³) based ER fluids. The wet TiO₂ is as-received and the dried powder was maintained at 160°C for 5 hours under a liquid N₂ trapped vacuum.

One of the first models was proposed by Winslow (4) and follows from simple observations that particles in an ER fluid align between the electrodes under an electric field in static conditions. He hypothesized that under shear, these chains would become distorted and break but would reform again very rapidly. This could account for the increased stresses but does not address fundamental questions concerning the mechanism of interactions between particles, although a polarization mechanism is mentioned. Klass and Martinek (8) question this model because ER materials show activity in high-frequency ac fields and these chains could not re-form at such speeds. Brooks et al. (9) reported a timescale for fibrillation of around 20 s which is much greater than the submillisecond responses reported (8,10). Other notable discrepancies arise from the fact that chaining is a trivial consequence of polarization of the particles, and therefore it would seem straightforward to increase yield strengths by using particles of higher polarizabilities. However, as illustrated in Fig. 1, for an ERM that contains TiO₂ particulates and has a permittivity of 200, when dried, chaining still occurs, but the fluid loses its ER activity.

Another discrepancy arises from the fact that the strength of particle interactions due to polarization effects in chaining is related to the permittivity difference between the particles and liquid phase (11). This would suggest that metal particles (if appropriately insulated) would result in the strongest interactions between particles. Although this probably occurs, it is not reflected in stronger ER activity. Although there are some reports that metal particle systems are ER active, the strengths are quite low. This and other information suggest that mechanisms other than particle bulk polarizabilities must be involved in a major way in ER activity. An extension of this idea proposes that the particles that interact coulombically flow as clusters, but in static situations, will bridge the electrodes (12,13). Neither of these addresses the basis for particulate interactions on a molecular level.

The particles by themselves and/or in conjunction with the dispersing media must interact with the electric field for the particles to align, provide yield stress, and hold the clusters together. The particles and liquids can interact independently with the field by virtue of their inherent electrical and dielectric properties, and/or the components can act cooperatively by virtue of the electrical double layer (14,15) which develops around colloidal particles in a dispersing liquid, and/or by virtue of interfacial polarization which develops due to mobile charges at the interface of the two materials (16,17). The latter situations are most commonly considered related to ER activity, but it is not clear to what extent these two are interrelated or in fact may be part of the same mechanism. Part of the confusion comes from the fact that although the basis for interfacial polarization is fairly well understood, theories related to electrical double layers [which are well developed for suspensions in electrolytic fluids (18)], are poorly understood (19) for a nonconducting dispersing medium of which ER fluids are an example.

Klass and Martinek (8,10) were the first to involve electrical double layers in their explanation of ER activity. They proposed that the diffuse portion of the double layers would become polarized under the influence of the electric field and that the electrostatic interactions of these distorted double layers require additional energy during flow, especially in concentrated suspensions where the layers overlap. This energy is required due to repulsion of the double layers, so that the particles cannot simply move in a streamline but must have a transverse component that gives rise to the additional dissipation of energy. They do not explicitly discuss the function of the adsorbed water even though without it, there would be no ER effect in these systems; yet, double layers would still exist (19). An interesting observation, based upon the relative permittivities of the systems of particles they used and the relative ER effectiveness, is that the bulk dielectric properties of the dispersed particles does not play an important role. Interfacial and surface properties of the particles are much more important in ER activity. This finding is also supported by others (8,10,20).

Schul'man and Deinega (21) focus more on orientation of the particles and structures that may form in the electric field. They invoke electrical double layers and associate them with a surface-conducting layer on the particles (i.e., water) in a nonconducting fluid where ion exchange with the fluid is presumably negligible. In this case, the mobile charges responsible for the Maxwell-Wagner-Sillars interfacial polarization also involve this water layer. The charge carriers can move along this conductive film under the influence of the electric field and give rise to an MWS polarization. The moisture here serves an essential function. Ion extension into the surrounding medium, the dispersed double layer, may extend to various degrees, depending on among other factors, the degree of conductivity of this medium. In reality, we may speculate that both mechanisms are probably involved in the ER phenomenon. What is certain, however, is that if either of them are correct, then the surface charge conductivity introduced via the water certainly has a dramatic effect on the character of the double layer. This must actually

be the case because the bulk conductivities of the systems increase many orders of magnitude for wet versus dry particles (7), thereby suggesting significant ion transfer to the medium when water is present versus without it.

Uejima (20) presented dielectric measurements that provided the most direct support for these mechanisms. In these studies, he followed loss factor and dielectric constant versus frequency for ER materials composed of cellulose particles and various amounts of adsorbed water. Specifically, he was observing the MWS interfacial dispersion that shifts to higher frequencies as the amount of water on the particles is increased. This is reasonable for this type of polarization (16,22) but has a number of other implications. The first is that the charge carriers involved in this dispersion are characterized by a relaxational spectrum whose characteristic times, temperatures, and presumably distribution depend strongly on the amount and type of water present (23). Whether the MWS dispersion disappears as all the water is removed is an interesting mechanistic question because in these inherently heterogeneous systems, a MWS dispersion should still exist (16,21,23), but charge carriers may be of a different type.

Deneiga and Vinogradov (18) who also made dielectric and rheological measurements, characterized this water layer further by suggesting that upon increasing temperature and field, there is a corresponding rise in ER activity and in the permittivity of the dispersions. However, these quantities peak at some point, and beyond this peak, the bulk electrical conductivity of the system begins to increase dramatically. They suggest that a breakdown of the hydrate layer occurs from both temperature and field and results in lowering of the activation barrier for flow of carriers between particles. A very important point implied here is that the bulk conductivity may not be related to ER activity and the preferred situation is to contain charges on the particles by an infinite activation barrier between particles, if this is possible. This speculation is further supported by the work of Deinega and Vinogradov (18) on, the relationships among ER activity, adsorbed water, and bulk conductivity.

Using various modifications and extensions, virtually all investigations continued to refine the basic concepts of the electrical double layer extending into the liquid phase, a conductive surface layer of water (or other surfactant) on the particles that gives rise to lateral mobility of ions, which are responsible for the classical Maxwell-Wagner-Sillars interfacial polarization. All of them imply the presence of a conductive layer on the particles, most commonly ions in the water, but none explained why the ER effect disappears when the water is removed, even though the double layer and the MWS interfacial polarization still presumably remain.

A major advancement occurred based on reports of particulate systems that produce ER active materials without the need for adsorbed water or any water (7,24). This is critical in resolving the model because either the same mechanism is operating both with and without water or, less likely, that different mechanisms are operating. The implication here is very important because it suggests that the mechanism responsible for ER activity can be an intrinsic

Figure 2. Electrophoretic mobility for an ER material illustrating one that has a net negative EPM. The best ER fluids have curves whose maximum is around zero.

characteristic of the chemistry and physics of materials, not due solely to extrinsic factors such as water.

The models proposed for this activity are similar to those previously discussed but are modified in that the electrical double layer is probably less dominant and the mobile charge carriers are not a consequence of an adsorbed electrolyte. In an article by Block and Kelly (25), more emphasis is put on the particle polarization which is really identical to MWS interfacial polarization. Partially, support of this deemphasis away from the double layer is a consequence of electrophoretic mobility (EPM) measurements on the actual fluids, which indicate that the materials can be very active electrorheologically yet show no significant EPM.

Further, it appears that systems that show significant EPM are less active electrorheologically, (Fig. 2). A suggestion here is that those mechanisms responsible for EPM, fixed surface charges and a diffuse ion layer, are different from those responsible for ER activity and in fact oppose each other to some extent. Permanent fixed surface charges cause attraction or drift of the particles toward one electrode and create an oil or particle-free layer adjacent to the other electrode, thereby giving an apparent viscosity decrease. This also opposes formation of particle-mediated shear transfer between the electrodes which is necessary for ER activity. The mechanism responsible for ER activity, consistent with most others, is the presence of mobile charges (ions or electrons) associated with the particles that can move somewhat freely within the particles but cannot move off of them, that is, a low activation barrier for migration within a particle but an infinite barrier for motion away from the particle.

The explanation for the activity of these dry systems is based essentially on the presence of mobile charge carriers intrinsic to the molecular character or chemistry of the particles. This local mobility of the carriers on the particles is high, but mobility between particles should be very low. In the anhydrous materials of Block and Kelly (1,25), the carriers are presumably electrons because the particles

are semiconductors; in aluminosilicate systems, the charge carriers are ions that are intrinsic to the chemistry of the particles and are located on the surfaces (26). Surface here includes the walls of the extensive interparticulate network of channels and cavities inherent in the morphology of the particles, which can constitute more than 97% of the total surface area (27). An important distinction between the two systems is that the bulk currents in the semiconductor systems are very high (1,25), presumably because electrons can more easily jump or tunnel between the particles and all are available to the outside surface of the particles by standard conduction mechanisms. However, in the zeolite systems, ions on the outer surfaces have a much greater activation barrier to overcome to jump particles, but more important, most are contained within the internal structure of the particles and cannot migrate to the outside surface; yet, they are mobile within the internal labyrinth of channels and cavities afforded by the tremendous porosity inherent in the morphology of the materials. Apparent Maxwell-Wagner-Sillars interfacial dispersions are observed in all dried zeolite systems, as illustrated in Fig. 3. They all occur at very low temperatures.

Anhydrous polyelectrolyte systems are presumed to be ER active by virtue of locally mobile ions that can move within the environment of the chain coils or along a chain (28) but are not free to move easily between chains. It has been shown that ER activity is primarily a function of the pK of various polyelectrolytes (29).

MATERIALS

Although the number of materials that can produce ER active suspensions is almost infinite, it is well understood that for most, the phenomenon is a consequence of an extrinsic component, most commonly adsorbed water (or some other electrolyte) that contains various surfactants added, and has nothing or little to do with the chemistry of the particles. There are, of course properties of the materials that are beneficial in producing better ER materials such as particle porosity, high surface areas, and high affinity for water, but the ER mechanisms are not related to the particle chemistry. Such "wet" or extrinsic systems, most of which were summarized by Block and Kelly (1), were known for many years, and it was as well realized that the water severely limited the potential application of ER technology. Some of the reasons are listed here.

1. Thermal runaway currents, although small, but at the high voltages required cause i^2R heating which drives off some water, which, in turn, increases the current which increases i^2R heating which drives off more water which increases the current, etc., until virtually all the water is off, and the fluid no longer works.
2. Relatively high currents and therefore high powers needed.
3. Limited operating temperature range due to freezing and boiling of the water.
4. Electrolysis

Figure 3. Dielectric dispersion due presumably to MWS interfacial polarization for 4A zeolite.

5. Corrosion of devices containing fluids
6. Instability of fluids with time and operation
7. Irreproducibility of different batches
8. Solid mat formation upon settling due to interparticulate hydrate bond formation.

Other important considerations certainly exist, which will emerge as applications are developed, such as cost, environmental acceptability, raw material availability, settling in low shear applications, plating of particles on one or both electrodes, sealing, effect on pumps, breakdown of particles upon shear of polymeric particles, adsorption of water, and contamination. The items listed before, however, are those associated directly with the presence of adsorbed water.

Because of the discovery of water free or "intrinsic" systems, a number of immediate improvements were realized; many had to do specifically with the water. Some of these are listed here:

1. Thermal runaway eliminated, because no water or other adsorbent is required.
2. Low currents. Currents 10^3 to 10^6 lower as a result of dryness; currents are in the range of microamps/cm², or nanoamps/cm² instead of milliamps/cm² for aluminosilicate particulate systems. Drastic reductions in current do not occur in semiconductor systems.
3. Expanded temperature range. Zeolite-based fluids operate from -60 to 350°C when dispersed in silicone oil.
4. Electrolysis eliminated. Electrolysis does not occur because water is not present and is not needed.
5. Corrosion eliminated. Corrosion does not occur because water is not present.

6. Instability improved. A major cause of instability is loss of water due to operation or heating.
7. Irreproducibility substantially improved. Variability of water is a major source of difficulty in formulating water-based fluids.
8. Solid mat formation and settling substantially reduced.

An important additional consequence of these discoveries implies that mechanisms responsible for ER activity can be associated with the basic chemistry and physics of the particles. Thus, once these mechanisms are understood, materials can be synthesized specifically to optimize these mechanisms and improve ER properties in an intelligent manner.

It is realized that many continue to work on "wet" systems, mostly because it is relatively easy to improve properties to a limited extent. However, we consider that this is a very limited and interim approach because prior attempts to use this method to improve properties substantially in the 1950s and 1960s resulted in virtually complete failure. However it was also realized then that the water made the materials impractical for the most part.

Extrinsic ER (Wet) Systems

Extrinsic ER fluids are suspensions that require adding some substance other than the particles and matrix liquid to make the ER fluid function. This specifically refers to the particulate phase because most solids in suspension do not themselves result in ER active suspensions. Substances that are added to make a suspension ER active are sometimes called activators and may include many additives such as surfactants which are added to stabilize a suspension against settling. The most well known and effective is water, although many others have been reported (1).

Although virtually any particle can be made ER active by adsorbing sufficient water onto it, the actual function of the water is still not known. Theories proposed include that water bridges form that tie the particles together. Another proposes that the high dielectric constant (30) creates a stronger dipolar interaction between particles. Another suggests that water modifies the electrical double layer, and another that it increases the current. Whatever the reason for the effect of adsorbed water, it undoubtedly is the most effective activator. Yet, as explained previously, adsorbed water severely limits the commercial value of the phenomenon.

Intrinsic ER(Dry)Systems

Electrorheological fluids that operate without the need for adsorbed water on the particulate phase can be classified as follows:

1. ionic conductors
2. semiconductors
3. polyelectrolytes
4. solutions

Ionic Conductors. The main particulate systems in this category are alumino silicates, or zeolites. The particles are highly porous and contain numerous cavities and interconnecting channels such that around 97% of the total surface area of the particles is contained within the particles, that is, the walls of the cavities and channels (26). The dimensions of the cavities and channels can be varied by synthetic methods and by varying the aluminum/silicon ratio. Cationic charge carriers arise from the requirement for stoichiometry when some tetravalent Si atoms are replaced by trivalent Al without disrupting the crystal structure. Thus, an Al at the center of a tetrahedron that has oxygens at the vertices can bind to only three of these oxygens, leaving one unbonded and a net negative charge in the structure. This negative charge is balanced by introducing of cations into the system. These cations, however, cannot fit into the closely packed crystal structure and therefore must reside on the surfaces of the cavities and channels. Thus, the cations are present as a consequence of the chemistry of zeolites (not the presence of an electrolyte such as water), and they are mobile because they are on surfaces that are primarily internal and not confined within the crystal structure. Common uses of zeolites are as molecular sieves because they can synthetically control the channel dimensions, and as ion exchange materials due to the presence of unbonded cations that readily exchange with other cations in an aqueous suspension.

The intrinsic ER activity of these materials is associated with the presence of these cations which presumably can move locally under the influence of an electric field. Such materials are susceptible to modification partly by varying the Si/Al ratio, by incorporating atoms other than aluminum, and by varying the types of cations. These materials have been available commercially for years as molecular sieves.

Semiconductors. Most of the work in this area has been performed by Block and associates (24,25) using various polyacene quinone radicals (PAQR) and recently polyaniline. PAQRs are not available commercially but can be prepared by the method described by Pohl (12). The mechanism of activity for these materials is associated with the electronic charge carriers that can move locally under the influence of an electric field. A characteristic of these materials, associated with electron-mediated ER activity, is relatively high bulk current due to the relative ease with which electrons may jump or tunnel between particles.

Although there are many types of semiconductors that can be used to make ER materials, many are ineffective or only a few are effective when dried. The reasons for this may be related to the size of the energy band gaps, the charge mobility, and/or charge concentration, although I know of no studies reported in this regard.

Notable materials that fall into this category are the commercially available "carbonaceous" ER fluids of Bridgestone. The particulates in these fluids are presumably synthesized by the controlled pyrolysis of polymer(s). The most commonly used, although it is unknown what is used in the Bridgestone fluid, is polyacrylonitrile.

Photoconductors represent an interesting group of semiconductors that can be used to make ER materials. In this instance, many fluids that are inactive or weakly active can show much enhanced ER activity when exposed to the correct frequency of light (30,31). Phenothiazine demonstrates this rather dramatically, even when dried. Photoelectrorheological materials (PHERM) represent the clearest proof of the relationship between charge mobility and ER activity because exposing such materials to light produces a tremendous increase in the number of free electronic charge carriers.

Polyelectrolytes. Although many types of polyelectrolytes have been used in ER materials (poly lithium methacrylate is the most well documented), most require adsorbed water to function, presumably to dissociate the cations from the macroions. Treasurer (29) evaluated various polyelectrolytes that are commercially available as ion exchange resins and reported that many function with greatly reduced amounts of water. These were all dried at 120°C under vacuum for 4 days but retain between 0.1 and 2% water. No correlation was found between the ER activity and residual water; however, a strong correlation exists between the dissociation constant pK and ER activity. Another interesting observation was that some systems were ER active at 23°C and 100°C, some were inactive at both temperatures, and some were inactive or weak at 23°C but showed much enhanced activity at 100°C. Materials that have high and low pK s demonstrated activity at both temperatures. Materials that have intermediate pK s showed partial or no activity, and materials that were acidified, that is, contained no cations, showed activity at 100°C but not at 23°C. A common feature of these latter materials was that they all contained quaternary ammoniums, but no reason is given for the relationship to ER activity.

The mechanism for ER activity in these dried materials is presumably due to cations which, even in the absence of an electrolyte, can move locally within the confines of a chain coil in the presence of an electric field but cannot move outside the coil into the surrounding liquid (28). Direct evidence for this has not been obtained, but dielectric dispersions associated with interfacial polarization have been detected and are presumably due to these locally mobile ions.

Systems that contain polymers as the dispersed phase are very popular because the particles are soft and therefore reduce abrasion, because of the relatively low density which will aid the settling problem, and because of the vast body of knowledge on latex suspensions. Additionally, polymers represent an almost infinite range of systems that can be chemically customized for ER materials, once the basic chemical mechanisms for ER activity in "intrinsic" systems are better understood.

Two commercially available ER fluids fall into this category. One is from Nippon Shokubai Co., Ltd., which produces an ER fluid based on sulfonated polystyrene. The particles are prepared in a unique way, so that the sulfonation appears at the surface of the particles. Another commercially available material is made by Bayer-Silicone. This is not strictly a polyelectrolyte but is more correctly referred to as a polymeric electrolyte. The particles are block copolymers of a polyurethane and polyethylene oxide. Solid polyethylene oxide has an interesting capability of dissolving or ionizing small amounts of salts. Presumably, incorporating it into the polyurethane gives this material the capacity of producing ions which, as charge carriers, are considered important in ER activity. Because the material is a good ER fluid, it supports the charge mobility hypothesis.

Solutions. Two of the most common are solutions of poly- γ -benzyl-L-glutamate (PBLG) in various solvents (31) and poly(hexyl isocyanate) (PHIC) in various solvents (32). Difficulties encountered with the PBLG systems include achieving high concentrations before gelling occurs and the better solvents are polar thus resulting in high currents. Nonetheless, these solutions showed very significant increases in viscosity upon applying a field. Further, the effectiveness increased significantly with temperature, the limit is the boiling point of the solvent used.

PHIC systems, on the other hand, are soluble at much greater concentrations and in nonpolar solvents. The ER activities are also significantly higher.

The discovery of ER active solutions represents another very significant advance in the field of ER. One reason is that it would resolve the problem of settling which has remained a major concern in some device designs. These solutions, however, will have unique disadvantages such as the greater toxicity and aggressiveness of the solvents, limited upper operating temperatures due to solvents and thermal degradation of the polymers, and generally higher costs. What is most important, however, is that this discovery emphasizes the enormous versatility in the compositions of ER active materials, as well as the complexity in attempting to ascribe the behavior to a single mechanism.

One ER fluid that may be put into this category is not a suspension of solid particles but a mixture of a high and low viscosity liquid. Both phases are siloxane backbone polymers, but the high viscosity material contains liquid crystallizable side chains that are responsible for its ER activity. Similar to the PHICs in solution, the LC side chains are induced to form nematic structures by the electric field that is reportedly responsible for its ER activity (33–35).

MECHANICAL (RHEOLOGICAL) PROPERTIES OF ER MATERIALS

The rheological behavior of ER materials under the influence of an electric field is commonly characterized by observing their properties during steady-state flow (8,10,21,36). Under these conditions, the flow properties of ERM can be adequately described as Bingham bodies.

ER materials are usually fluids when subjected to unidirectional shearing and under zero field conditions. However, when shearing conditions are maintained constant, the shear stress increases with increasing applied electric field strength. It is commonly reported that the shear stress dependence is proportional to the field squared (4,8,10,21), but many other types of behavior are observed (25,37). According to idealized Bingham behavior (Fig. 4), ER materials are fluids under zero field but are solids under a nonzero field up to a certain critical shear stress (S_c) and liquids at shear stresses above S_c . Although adequate in steady-flow situations where transient or "start up" effects are neglected or unimportant, this model is not applicable when the transient behavior is important or under dynamic loading (i.e., rapid or impact stresses or in damping applications). In these situations, the Bingham model completely overlooks the properties of the materials at stresses less than S_c (38). A more complete description of the behavior of ER materials is illustrated by a plot of stress versus strain, as in Fig. 5.

Under these deformation conditions, ER materials can be described as viscoelastic solids below a certain critical yield stress or yield strain and as viscous liquids at stresses at or above S_c and strains greater than the yield strain. If characterized in this manner, ER materials can be described in terms of their overall rheology as viscoelastic perfectly plastic materials in which S_c and the yield

Figure 4. Bingham body illustration of rheological behavior of an ER material. (Oversimplified because nothing is in preyield).

Figure 5. Illustration of more correct rheological behavior of an ER fluid.

strain are strong functions of the electric field strength. The yield stress S_c is highly variable and depends strongly on numerous factors, including the ER material composition. Furthermore, the energy dissipation mechanisms in the preyield region are different from those mechanisms present in steady flow.

In the simplest case, the rheological behavior of ER materials in the preyield region can be characterized by a modulus and a yield stress (S_c), in contrast to the postyield region (i.e., liquid state) in which the material is characterized by an apparent viscosity (η_a). Furthermore, the behavior of the ER material is linear viscoelastic when deformation is restricted to the preyield state and the ER material is characterized by time constants and damping factors that are complex functions of the field strength.

ERM in Steady-State Flow (Postyield Behavior)

In steady-state flow at a shear rate of " $\dot{\gamma}$," ER materials are characterized by an apparent viscosity " η_a " which is defined as

$$\eta_a = [S_c(E) + S_o(\dot{\gamma})]/\dot{\gamma} \quad (1)$$

where S_c is a function of the electric field strength (E) and S_o is a function only of the shear rate and temperature and is material specific.

Two common criteria for evaluating ER materials in flow include (1) the magnitude to which the viscosity can be increased and (2) by what factor it can be increased. The second criterion is more important because it indicates how effective an electric field strength is on the rheology of the material. Regarding the latter point, we can define a fluid effectiveness factor K as

$$K = \eta_a(E)/\eta_o = [(S_o + S_c)/\dot{\gamma}]/(S_o/\dot{\gamma}) = 1 + S_c/S_o \quad (2)$$

where S_c is essentially a constant at a certain field strength but S_o increases continuously with increasing shear rate. Therefore, this suggests that K decreases toward one as the shear rate increases. This is an important first-order relationship for understanding the characteristics of ER materials under flow because it implies that to make a more

effective fluid requires making S_c as large as possible while keeping S_o as small as possible. The second parameter, S_o , is a function of the ER material composition and flow conditions. Thus, ER materials of low or high viscosity can be made by varying the solid concentration or the viscosity of the dispersing liquid. However, though the maximum shear stresses can be increased by making the zero-field materials thicker, the K factor can become small, so that the field-induced change in S_c becomes insignificant. Furthermore, it has been reported that S_o is a much stronger function of concentration than S_c (39), and it appears that S_c is a linear function of concentration (18).

ERM in Oscillatory Shearing (Three Rheological Regions)

The response of ER materials to dynamic loadings can be discussed in terms of three distinct rheological regions: preyield, yield, and postyield regions. In the previous section, discussion was limited to conditions of steady-state flow in which the transient effects of the preyield region were not considered. The preyield region can be effectively studied when oscillatory stresses are applied to the ER material such as may occur in vibration damping, as first reported in detail by Gamota and Filisko (40,41). Under these straining conditions, the amplitude of the shear stress response is a strong function of the applied field strength. However, a limiting shear stress value exists beyond which the shear stress response no longer follows the shape of the shear strain function, but becomes "cutoff" or truncated (40,42). The value of the shear stress at the onset of truncation is a function of the field strength and is also related to S_c . Rheologically, the appearance of the cutoff is an indication that the material is beginning to flow. During an oscillatory shear strain, the ER material may deform as a linear viscoelastic solid over part of the deformation cycle and as a liquid over the other part.

A representative series of stress responses for the ER material when subjected to a sinusoidal shear strain is presented in Fig. 6. Curve a is the applied sinusoidal shear strain of frequency 15 Hz and amplitude 0.25. Curve b is the shear stress response when the material is subjected to a zero-strength electric field. The shear stress response appears sinusoidal, and the phase angle between the applied shear strain and shear stress

Figure 6. Shear stress response to a constant strain amplitude at various electric fields. Curve a is the strain, b the shear stress where $E = 0$, c the shear stress where $E = 1$ kV/mm, d the shear stress where $E = 2.5$ kV/mm. (D is one-quarter scale.)

response is 90° , suggesting that the material is deforming as a viscous body. Subjecting the ER material to an electric field whose strength is 1.0 kV/mm yields Curve c; the shear stress response amplitude increases, and the phase angle decreases. Thus, when the ER material is subjected to a nonzero electric field, the material behaves as a viscoelastic material. If the strength of the electric field is increased to 2.5 kV/mm , the shear stress response deviates from sinusoidal behavior (Curve d). A nonsinusoidal response suggests that the material is behaving as a nonlinear viscoelastic material. In addition, as the material is subjected to a 2.5-kV/mm field, the fundamental harmonic of the shear stress response increases, and the phase angle between the fundamental harmonic of the shear stress response and the applied shear strain decreases. Thus, as the strength of the applied electric field is increased from 0.0 to 2.5 kV/mm , the ER material transforms from a viscous to a linear viscoelastic to a nonlinear viscoelastic body. Moreover, the energy storing and energy dissipating properties of the ER material are strong functions of the applied electric field strength.

The linear viscoelastic parameters, shear storage modulus (G') and shear loss modulus (G''), are strong functions of the applied electric field, strain amplitude, strain frequency, and material composition (9,18,41). In addition, it was shown (18,41) that the shear storage modulus is a stronger increasing function with increasing electric field strength compared to the shear loss modulus. Furthermore, it is of particular interest to note that ER materials become greater energy storing bodies as they simultaneously become greater energy dissipating bodies.

A second technique for observing the effect of the electric field under cyclic loadings is to observe shear stress—shear strain loops (hysteresis loops) for these materials at a constant strain frequency and amplitude, while varying the strength of the electric field. A sequence of hysteresis loops generated when the ER material is deforming as a linear viscoelastic body is shown in Fig. 7.

As the strength of the electric field increases, both the area within the hysteresis loops and the angle that the major axis of the hysteresis loop makes with the abscissa increase. The hysteresis loops are elliptical which is indicative of a linear viscoelastic response. The viscous component (energy dissipated) is determined by the area within the loop, and the elastic component (stored energy) is determined by the major axis inclination.

The existence of a deformation transition limits the applicability of linear viscoelastic mathematics for quantifying the energy storing and energy dissipating properties of an ER material. The amount of energy dissipated by the ER material during one deformation cycle, irrespective of a linear or nonlinear viscoelastic response, can be obtained by generating a hysteresis loop. The energy dissipated by an ER material is found by calculating the area within the loop. The recorded hysteresis loop for an ER material subjected to a strain of moderate frequency, moderate amplitude, and zero-strength electric field is elliptical, and the major axis of the hysteresis loop is parallel to the abscissa; this response is indicative of a viscous material (Fig. 8a). When the ER material is subjected to a field strength of 1.0 kV/mm , the area within

Figure 7. Hysteresis loops for an ER material when subjected to a strain of amplitude of 0.001 radian at 300 Hz . Loop 'a' is under a zero strength field, loop b: $E = 1.0 \text{ kV/mm}$, and loop c: $E = 2.0 \text{ kV/mm}$. 'a' is a hysteresis loop for viscous behavior; b and c represent hysteresis loops indicating viscoelastic behavior where the viscous component of $b < c$ and the elastic component of $b < c$.

the hysteresis loop increases, and the angle between the major axis of the hysteresis loop and the abscissa increases (Fig. 8b). The increased area within the hysteresis loop suggests that the ER material dissipates more energy and the increased angle is related to the energy storing properties of the ER material. Continuing to increase the strength of the electric field yields hysteresis loops that encompass greater areas, suggesting that the material dissipates more energy (Figs. 8c and 8d). However, the loops are no longer elliptical, and thus the ER

Figure 8. Actual hysteresis loops recorded for an ER material under various electric fields. a: $E = 0$, b: $E = 1 \text{ kV/mm}$, c: $E = 2 \text{ kV/mm}$, d: $E = 3 \text{ kV/mm}$.

material is behaving as a nonlinear viscoelastic material. Moreover, the energy storing properties of the ER material cannot be calculated when nonelliptical hysteresis loops are recorded. Thus, if the amplitude of the imposed impulse is large enough, nonelliptical hysteresis loops are recorded which indicates a nonlinear viscoelastic response. This occurrence suggests that the liquid or flow regime has been encountered.

MECHANICAL MODELS

Presently, the two most serious impediments to the intelligent and innovative design of various types of devices that employ ER materials are the lack of a good mechanical rheological model and corresponding mathematical equations that adequately simulate, at least qualitatively, the behavior of ER materials and the lack of quality engineering design data. The latter point is relative because, as mentioned previously, the composition of materials is virtually infinite and, they will ultimately be customized to optimize desirable and minimize undesirable properties for specific purposes. However, there is sufficient data in the literature to allow estimating reasonable levels of properties and inserting them into appropriate equations. However, an adequate rheological model is presently nonexistent.

In one case, a model by Bullough and Foxon (43) is proposed to simulate only damping and is then only linear viscoelastic so it can be treated mathematically. It is unrealistic in regard to three obvious deletions: first, it incorporates no flow element; second, it incorporates no coulombic damping term; and third, it is completely recoverable. It was not, however, intended to simulate the behavior of ER materials. The only other model by Shul'man (44) suffers from the same problems as that of Bullough and Foxon, but again it was intended only to simulate electric field control of damping.

A current model proposed by Gamota and Filisko (40) shown in Fig. 9 correlates qualitatively with the overall observed behavior of ER materials (i.e., preyield, yield, postyield regions) and has been tested quantitatively for experimentally observed preyield behavior (41).

Element "1" is a dashpot which is essentially field independent but governs the slope of the shear stress versus

shear rate data, that is, the slope of the lines in Fig. 4. Element "2" is a coulombic friction element which is strongly field dependent and controls the magnitude of the ER response under steady shear, that is, the yield stresses or S_c . Elements "3 and 4" combined in parallel form a Voigt element. Both elements are strongly field dependent and are responsible for the transient response and damping behavior under impact or vibration, that is, both the angle of inclination and the areas within the ellipses in Fig. 7. Under low amplitude, it may be only this portion of the model which is deforming. Element "5" is a spring which is strongly field dependent and governs the dynamic response in conjunction with the Voigt element.

Notice that under constant strain rate, elements "3,4, and 5" rapidly reach an equilibrium extension and contribute nothing in steady-state flow. Element "1" simply determines the slope of the stress – strain rate data which is essentially field independent, and element "2" which is field dependent determines the yield stress. However under dynamic loading, at low amplitudes, the block (friction element) may not move, and then only elements "3,4, and 5" determine the material characteristics. In more complex loading situations, all elements may contribute to various degrees to the rheological behavior of the electrorheological materials.

THEORIES OF ER

All current mathematical theories of ER evolve from the assumption that dielectric particles form bridges between electrodes that have a high potential between them. Particles in an electric field are induced by the field to become polarized, that is, become electrically positive on one side and negative on the opposite in perfect analogy to certain particles/objects that can be magnetized, either permanently or temporarily, when exposed to a magnetic field and as such acquire induced north and south magnetic poles. We are all aware that magnets stick together, north pole to south pole, etc., and many can easily be stuck together in progression to form a chain of magnets. In analogy, then, the induced electrical dipolar particles can stick together, positive to negative, etc., to form strings of particles, chain, or columns. Thus, the theories attempt to model mathematically the forces between these electrically induced dipolar particles (11,45).

An extension of this is that at high particle concentrations that are characteristic of ER fluids, typically in the range of 30% solids, particles in an electric field do not form just simple single file chains of particles but aggregates of many particles or columns that can be many hundreds of microns in cross section and therefore can have hundreds of particles across the width of a column (46). This is routinely observed and must be true due to free energy considerations. Simulations that involve monodisperse spheres conclude that the particles in these columns eventually organize into a body-centered tetragonal symmetry which, it is stated, may be the ground state for particle packing (46). This, however, is more of an academic exercise because particles in real ER fluids are neither spheres nor monodisperse and therefore cannot pack in any regular way.

Figure 9. Mechanical model simulating behavior of an ER material.

The third part of the calculations involve determining the force or more specifically the increase in shear stresses due to the electric-field-enhanced interactions between the particles in these columns. It is at this point that some assumptions must be made that are not necessarily rigorous or straightforward. All mathematical theories assume that the increases in shear stresses are due to the columns that break or fail in shear. This has apparently been observed many times but only for very low concentrations of particles where the chains or bridges are essentially composed of single file or a few widths of particles. Until recently, it had not been observed for the very thick columns involved in dispersions of normal concentration. The second assumption implicit in the first is that the columns of particles adhere to the electrodes without failure. Neither of these assumptions has been observed for real ER fluids under flow, but all mathematical theories necessarily assume them. In fact, a significant number of studies conclude that slippage of the particulate structures at the electrodes occurs, not for single chains of particles, but for columns or more highly organized structures that develop (47–49).

Polarization Mechanisms: The Basis of the ER Phenomenon

There are two extremes in the response of a material to a static or dc electric field. One is to establish a steady flow of charge or current between the electrodes, and the other is to cause local separation or segregation of charges leading to asymmetry of charge distribution or polarization which may be most generally meant to describe the response of any material to an electric field where bulk charge movement or a current does not take place. All real materials in an electrical sense lie somewhere between both extremes, and both currents and polarization may have to be considered where applicable. The situation becomes enormously more complicated because of the basic composition of ER materials, that is, a high concentration of particles in a nonconducting oil or liquid. Whereas the liquid phase must be nonconducting or else very large currents will result, the solid phases can be insulators, semiconductors, insulated metals, or insulating materials treated with various activators that typically increase the bulk conductivity of the fluid. Conduction occurs by the net flow of charge which may be accomplished by electrons or ions. Mechanisms of polarization in solids include electronic, ionic, and orientational. A fourth type, interfacial polarization, is a composite of conduction and dielectric mechanisms and of specific value in ER fluids.

Electronic polarization is due to displacement of electron clouds around atoms (16), whereas ionic polarization in solids is due to displacement of positive and negative atoms in ionic crystals. Electronic polarization occurs for all materials but is considered small and not of importance in ER. Ionic polarization can be very large in certain materials, specifically TiO_2 and BaTiO_3 , two materials that have been considered extensively in the development of ER because of their high permittivity. The latter are involved only in materials that contain some ionic bonding, but such materials, exceptions as mentioned, are not common in ER.

A third mechanism involves only solids whose molecular structures have asymmetric charge centers, that is, they contain permanent dipoles. As opposed to electronic and ionic polarization that involve distortion of electron clouds, orientation polarization involves electric-field-induced alignment of these dipoles that are normally random. All three of these mechanisms can occur in homogeneous materials and involve distortion at a molecular or atomic level which recovers after the field is removed, except for electrets.

A fourth type which occurs only in heterogeneous materials or dispersions of particles (17,19,22) involves the presence of a significant number of charge carriers and relatively long range movement of these charge carriers, electrons and/or ions across dimensions of a particle's size. These dispersions involve particles in a nonconducting liquid that have significantly greater permittivities and/or conductivities than the liquid phase. The basis of the phenomenon is that at the interface established between these materials, to satisfy requirements for continuity of displacement and current density across the interface, the charge carriers within the more conductive (particulate) phase must "pile up" at the appropriate interface, thus creating a macroscopic (particle) dipole. At the interface, the carriers experience an activation barrier that hinders their easy movement into the next phase. If infinite, this barrier would prevent any of these charge carriers from crossing it, however, there is always a finite probability that a carrier can penetrate (tunnel) through the barrier, and the result is transport of charge between the particles that results in a flow of charge between the electrodes and thus a current. The mechanism of charge transport between particles via a nonconducting liquid is very complex and not very well understood. However, it is a characteristic of interfacial polarization that a net current can hypothetically occur and does. All fluids, that is, the matrix phase, also have measurable currents as a result of impurity ions or very commonly in ER due to trace amounts of dissolved water. ER fluids that contain semiconducting particles have much greater currents than those that contain ionic carriers due to the very small size of the electrons that allow them to jump more easily between the particles or penetrate the barrier between the particles than the much larger ions.

It is generally felt the interfacial polarization is the polarization mechanism of most importance in ER and as a consequence, particle interactions can result from electrostatic interactions between particles due to the permittivity differences (dielectric properties) and due to polarization of particles as a result of the migration of unbound charge carriers to the interface.

An important distinguishing characteristic of these different polarization mechanisms involves their characteristic times or how fast the "dipole" can respond to an instantaneous field impulse. As illustrated in Fig. 10, electronic and ionic mechanisms respond in timescales of 10^{-16} and 10^{-12} /s, respectively, whereas orientation mechanisms can respond in timescales that range from very slow to about 10^{-6} s. For instance, electrets are very slow in recovering to a random state. This wide range of many orders of magnitude depends on temperature, polar group, and

Figure 10. Dielectric constant vs. log. frequency of imposed electric field. The relative positions of the various dispersions are indicated.

physical state of the solid because it involves physical rotation of the polar group under the constraints imposed upon it by its environment, such as crystal structure. Interfacial mechanisms are also relatively slow, and times range from many seconds to around 10^{-4} seconds. Whereas orientational polarization is related to the characteristic speed of dipolar rotation, interfacial polarization involves the drift mobility of charge carries through/on the solid phase. Thus, the mobility of electrons on metals is much greater than those on semiconductors which is typically greater than the mobility of ions on ionic conductors, and the characteristic times go in the reverse direction. The difference of mobilities is reflected in the resistivities of these materials.

Now, as opposed to electronic and ionic polarization which are resonant mechanisms, orientational and interfacial polarizations are relaxational; an identifying characteristic is a strong temperature dependence of the dielectric dispersion (see Fig. 3).

To repeat, electronic, ionic, and orientational polarizations involve electric-field-induced systematic disturbances on atomic or molecular dimensional scales and can occur in all materials, including single-phase materials (although only certain materials have ionic or orientational mechanisms). These determine the classic dielectric parameters of these materials or permittivity (complex permittivity to be correct). The interfacial mechanism, however, occurs only in heterogeneous materials or dispersions such as ER fluids and responds to an electric field in a way characterized by the permittivities and conductivities of both phases. Thus, it is not appropriate to describe an ER fluid (or any suspension) as strictly a dielectric or a conductor. The relative importance of the mechanisms that characterize the way they respond to an electric field reduces to the existence and magnitude of each mechanism and its characteristic time. In a high-frequency imposed field, conductive and possibly orientational (dielectric) mechanisms are prevented from operating, and only ionic and electronic dielectric mechanisms (such as in TiO_2 and BaTiO_3) will be operative. However, at lower frequencies or in a constant dc field, all appropriate mechanisms

operate and thus produce presumably the strongest force of interaction between the particles. A “space charge polarizability” can be defined in analogy to electronic, ionic, and orientational polarizabilities (16) so that this mechanism can be discussed along with the other three true dielectric mechanisms. The current state of thinking, then, is that conduction and dielectric mechanisms are important in the ER phenomenon and both are involved in the Maxwell–Wagner–Sillars (MWS) interfacial effect. Only dielectric mechanisms are operable at higher frequencies, whereas both conduction and dielectric mechanisms are operable at low frequencies and dc, thus giving an overall greater net polarizability as the sum of all possible mechanisms (48).

There are numerous other consequences of conduction and possible mechanisms, including conduction through the particle, conduction around the surface of the particle, conduction through the matrix fluid, situations involving the electrical double layer, polarization layers developing on the outside of the particles due to mobile charge carriers in the oil, greater conduction and different mechanisms at the point of contact of the particles due to the highly intensified fields, field-enhanced dissociation of the matrix phase, and mechanisms of charge transfer through non-conducting liquids. The resulting nonlinear conduction in which the current increases with field at a greater than linear rate has not been extensively studied (51–53) and is still poorly understood. Nonetheless, it is extremely important in electrorheology because it is the major barrier to the use of ER fluids in many applications at elevated temperatures, such as automotive shock absorbers, and is important in understanding the basic mechanisms involved in ER via the conduction theory. More in-depth discussions of conduction mechanisms in nonaqueous media are available from Morrison (54) and Anderson (55).

The situation however is even more complex because of numerous dramatic exceptions to these models. Nonetheless, these mechanisms must somehow be involved in a major way in the response of these materials to a field. Mathematically, the situation is impossible; very severe assumptions are required for any type of solution due

among other things to the high concentrations of particles (and mutual interactions), charge distributions on the particles, irregular particle shapes and sizes, and impurities.

Description of Alternative Model

It has been shown recently (47) that, upon application of an electric field, ER fluids under shear rapidly organize or regiment themselves into numerous tightly packed lamellar formations that are more or less parallel and periodic in relationship to each other. Tightly packed means that the particles are crowded together as closely as possible, if not even compressed together under the influence of the E field, consistent with the irregular size and shape of the particles. While under zero shear conditions, the particles agglomerate into columns under the influence of the E field, and under shear, the particles pack into continuous lamellar structures (i.e., walls) more or less equally spaced and of similar thickness. The relative arrangements and characteristics of these structures depend in a way not yet well determined on the magnitude of the electric field, the shear rate, the particle concentration, the time of shear, and the shear profile.

A major consequence of the tight packing of the particles into these structures is that it results in cooperative strengthening of the structure to failure under shear in the long dimension of the structure because the area of the shear plane increases with lamellar length and thickness and the lack of an easy path for slip planes to develop within the structures due to the irregular packing and irregular size and shapes of the particles.

Thus, it is hypothesized that the lamellar structures remain intact under flow and the most probable path of slippage under flow is at the interface between the particle structures and the electrodes. The structures themselves do not break or shear. Because polarization forces are responsible for holding the structures together, if the structures do not fail, then the forces are irrelevant to postyield behavior, as long as they are strong enough to maintain the structure. Postyield behavior is determined primarily by the mechanics of slippage between the ends of the structures and the adjacent electrode. Further, adjacent lamellar structures may adhere to opposite electrodes, and an additional mechanism of energy dissipation is provided when the matrix fluid is sheared between the lamellar structures. In this case, the slip planes would not be parallel to the electrodes but perpendicular to them and would more reflect the rheological properties of the matrix fluid sheared between them. Because shear between adjacent structures would depend on the gap between these structures as well as on the total number (or particle concentration), if the gaps were large due either to low particle concentration or to structure consolidation, the effect of the lateral shear between the lamellae would be reduced. In any case, it is suspected that shear between the ends of the lamellae and the electrodes is the more dominant source of energy dissipation in ER fluids under field and the source of the yield stress.

APPLICATIONS

Published applications involving the ER effect are numerous and diverse. Many are ingenious, and many are unrealistic in the sense that inventors assign unrealistic or uncharacteristic properties to the fluids. However, the more realistic of the applications are those that recognize the unique characteristics of the fluids and the phenomenon and seek to exploit those characteristics to improve the performance of routine functions, more efficiently, more reliably, in a smaller space, improved operation, better control, less precise tolerances, or to perform functions that cannot be performed any other way. The more unique of these characteristics, as mentioned, are that ER materials change their rheological properties rapidly and reversibly in response to a very low power electric field (less than milliwatts) and can be directly connected to computer control. This technology allows a reduction in the complexity of devices that enhances reliability and subsequently reduces size, weight, and cost.

The more important areas and those which have received the most attention and effort may be categorized as (1) those that involve an electrically variable coupling in "trapped fluid" devices such as clutches, fluid brakes, shock absorbers, or vibration control or isolation devices in general; and (2) those that involve a smart working medium in fluid power circuits where the fluid is pumped at elevated pressures through valves that control the pressure and volumetric flow rate to various actuator devices. The latter covers a wide range of uses from micromachines to heavy machinery, aircraft flight controls, and robotic type devices.

Damping Devices

Damping devices employing ER fluids can broadly be categorized as flow mode, shear mode, or mixed mode. Flow mode devices employ a pseudo-Poiseuille or pressure flow of ER materials, and the electrified flow boundaries are stationary with respect to the flow. Shear mode devices employ a pseudo-Couette flow of ER material, and one electrified flow boundary moves with respect to the flow. Mixed mode devices employ a combination of both shearing and channel flow. Fig. 11 presents three dampers employing the flow mode, mixed mode, and shear mode in ER dampers. In these devices, control of the electric field across the ER flow modulates the force that opposes the motion of the plunger.

Every damping device is simply a method for converting mechanical energy into heat energy. In a flow mode device, ER control is afforded only by the small amount of material in the orifice or valve. The rest of the fluid is not under ER control. This imposes severe requirements of shear rate and heating on the fluid as it passes through the valve. Although simple in nature and many devices incorporate this mode of control, it does not make optimum use of the properties of ER fluids. A shear mode damping device, however, exposes a very large amount of the fluid to shear and thereby makes optimum use of ER control. Such devices are considerably more complex than flow

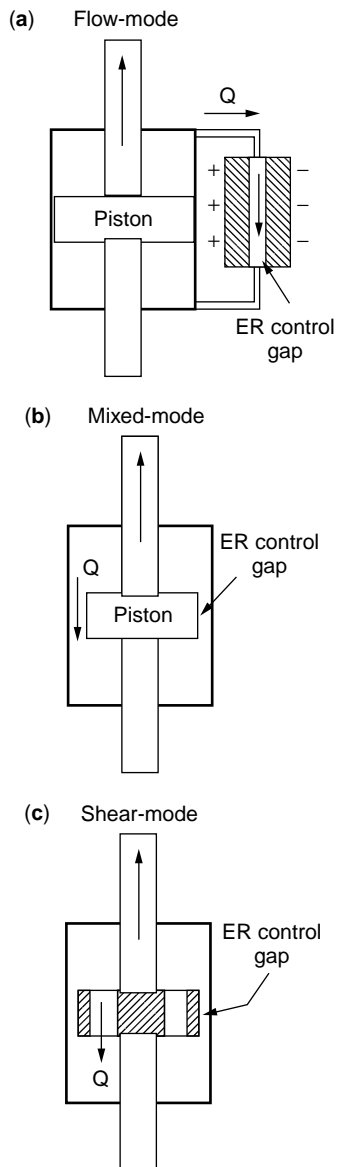

Figure 11. Illustration of three operating modes of an ER damper.

mode devices and involve a series of concentric cylinders that may displace longitudinally or rotate or stacks of discs that have alternate polarity and are fixed so that the fluid is sheared between alternate discs. The latter devices also require a method to transform linear to rotary motion. Although impractical, these devices use the ER phenomenon optimally by exposing the bulk of the fluid to shear flow and electric field control. Mixed mode devices are designed to incorporate both shear and flow modes of control.

Actual devices may be categorized according to the severity of the requirements that they impose on the ER fluid. Vibration isolation devices are meant to minimize or eliminate the transfer of sporadic or systematic vibrations to objects that are adversely affected by them. Examples include isolating vibration inherent in an internal combustion engine from the vehicle for passenger comfort

and safety, isolating vibration inherent in a helicopter from sensitive electronic equipment as well as weapons, isolating vibrations from an earthquake to prevent them from destroying a large structure such as a building or bridge, or protecting sensitive equipment on a ship, for instance, from vibration damage due to the impact of a bomb or torpedo. The most well known of such devices are used for automotive engine mounts. Such devices essentially use an ER fluid to control the flow rate of the active or ER fluid between two chambers, separated by an ER valve which is just a device across which a field can be established. Because of additional considerations, including simplicity in design, packaging, and because such devices are not generally exposed to very severe service, the most common are flow mode devices.

Hydraulic damping devices also transform mechanical energy into heat energy, but as opposed to isolation devices, are involved with much greater displacements or oscillations, have more severe requirements, and correspondingly expose the ER fluid to more severe conditions of shear rates and temperatures and place more severe requirements on the fluids. The most research specific application involves automobile suspension dampers or shock absorbers that have considerably greater flow rates and shear rates and expose the fluids to considerably higher temperatures. Such devices would be designed primarily as shear mode ER dampers; however, within the constraints of packaging and cost, the actual devices are either primarily flow mode and mixed mode devices. Again there are numerous ingenious devices in the patent literature, and considerable research is conducted on these devices primarily in Japan; however, at present no such devices have been commercialized. Although it is generally felt that the "strengths" of ER fluids are more than adequate for this application, a major reason, although not the only one, is the lack of an acceptable ER fluid. Of the currently available ER fluids, all show unacceptable levels of current at the operating temperatures of automobile shock absorbers. Cooling of the devices is unacceptable and impractical, and therefore, fluids that have lower current at high temperatures must be developed.

Torque Transmission Devices

One of the more important areas of application of ER fluids include transferring and controlling torque transfer from a power source or engine to any number of devices (Fig. 12). This is currently performed by torque converters and friction clutches in automobiles and various other types of magnetic or centrifugal clutches for less severe applications such as automobile air conditioners. Such devices present the potential of very simple devices that have direct computer control. These devices present unique problems in that in the uncoupled state or under zero field, fluids must have very low viscosity to minimize drag. However, upon increasing the electric field, the torque transferred is continuously increased thus controlling the rate of acceleration until final speed is attained where lockup or solidification of the fluid occurs. At this point, the device is locked up and results in no viscous losses in the device for the most efficient operation. The maximum amount of

Figure 12. Illustration of an ER clutch that has two plates or rotors.

torque that can be transferred is determined by the area of the shearing surface within the device as well as the apparent yield strength of the fluid. Thus, complex designs that range from series of concentric cylinders to stacks of parallel discs have been patented and are potentially capable of transferring sufficient torque for an automobile. However, at present, the sizes of the devices needed to reach the necessary torque levels do not differ substantially from current devices because of the current levels of yield strengths of available ER fluids. In effect the advantages of using ER clutches to replace conventional ones is not sufficiently cost-effective, primarily because of the fluids, to initiate the use of such devices.

Control of Hydraulic Circuits

One of the more intriguing uses of ER technology and that which potentially can have the most impact in terms of new technology is control in hydraulic systems or circuits. In analogy to electronic devices where a voltage is the driving force for electrons through wires and transistors or electron tubes are gates or valves for controlling the flow of electrons, in hydraulic devices, pressure is the driving force for fluid flow through tubes, and magnetic solenoids are gates or valves to control the flow. Despite the fact that transistors are limited in the currents and voltages that they can handle, their size and speed and low power requirements have resulted in the electronic revolution in solid-state devices, including integrated circuits and of course computers. Hydraulic circuits containing ER fluids, as opposed to large bulky solenoids that have high power requirements, can be controlled with ER valves that consist of little more than electrodes on either side of a hose that carries a fluid. Compared to solenoids, ER valves could modulate flows continuously from full open to full shut, would be much smaller, much faster, require much less power, and could be controlled directly by a computer. The primary control parameters in hydraulic circuits are pressure and volumetric flow rate. In this regard, ER controlled hydraulic circuits are poor compared to solenoid controlled circuits, and a primary limiting factor is the strengths, yield stresses, of the ER fluids. If an ER valve in a hydraulic channel circuit could be imagined as in Fig. 13, at a given flow rate, an increased pressure drop could be controlled by increasing the lengths of the plates. However, there must

Figure 13. Illustration of an ER valve in which the electrodes on either side of a tube through which an ER active fluid is flowing can be used to regulate the pressure drop across the tube.

be a corresponding drop in volumetric flow rate, when other dimensions are maintained. The volumetric flow rate could be increased by increasing the cross-sectional area of the channel; however, at some point, a practical limit on the length and width of the channel is reached. Long channel lengths are attained in compact spaces by using some ingenuity in the design of devices such as spiraling channels or stacks of plates in which the fluid flows back and forth through progressive layers of plates.

ENVIRONMENTAL AND PEOPLE APPLICATIONS

HIROAKI YANAGIDA
 University of Tokyo
 Mutuno, Atsuta-ku, Nagoya, Japan

INTRODUCTION

There are two major centers of R&D on intelligent/smart materials in Japan. One is an academic assembly called the Forum for Intelligent Materials and the other is the industrial consortium known as Ken-materials Research Consortium. This article describes only the activities in the Forum. The activities of the consortium are described in an other article. The groundwork for R&D on intelligent materials was completed in 1999, with the Frontier Ceramics Project sponsored by the Science and Technology Agency of the Japanese government.

FORUM FOR INTELLIGENT MATERIALS

The Forum for Intelligent Materials was begun in 1990 to open the field of materials science to interdisciplinary academic research. The concept of intelligent materials was proposed to the Agency in November 1989, which led to the Forum being established. These requirement for intelligent materials was that they have functions such as sensor, processors, and actuators for feedback and/or feed forward control systems within the material itself. Several international workshops were held through the efforts of the Forum in Japan. The first was in Tsukuba in 1989, the second in 1992 in Oiso, and the third in Makuhan in 1998. Recently, a large seminar was held on January 14, 2000, in Tokyo. The topics during the proceeding covered the state-of-the-art of intelligent materials and perspectives on their future. Included were discussions of intelligent biomaterials, intelligent fibers, biomedical applications of intelligent surfaces, taste sensors by intelligent materials, and intelligent ceramics materials (1).

To open academic activities to the interdisciplinary interaction, with the Forum was organized to consist of members from various fields such as organic polymers, ceramics, biochemistry, metallurgy, electronics medical sciences, and pharmaceuticals. The R&D of intelligent materials was directed toward the improvement and advancement of human safety and welfare, the environment, and energy savings and resources.

Introduced were some typical intelligent materials as follows (2):

1. The FeRh alloy developed by Otani, Yoshimura, and Hatakeyama as a temperature-sensitive magnetic material for optothermo magnetic motors. The material has interesting properties such as the magnetization increases with temperature up to the transition temperature, as shown in Fig. 1. The temperature increase is very sharp, and the transition temperature can be modified from -100 to $+280^{\circ}\text{C}$ by the addition of small amounts of alien

Figure 1. Temperature dependence of magnetization of FeRh.

elements. The mechanical stress or magnetic field can change the transition temperature. These characteristics are interesting examples of temperature sensors and actuators reflected by magnetic valves, magnetic fluid control switches and magnetic motors driven by temperature change in the form of pulsed light.

2. A chemomechanical system with polymers as polypyrrole(PPy) film developed by Okuzaki and Kunugi. The film shrinks or elongates with chemical environmental change. Its use may be to stimulate muscles in a living body.
3. An autonomous vibrating polymer gel with nonlinear reaction. In a living body there are some vibrational motions that are rhythmic. To these intelligent materials achieve mimesis of a living organ. The examples presented by Yoshida, Yamaguchi, and Ichijo are the Belousov-Zhabotinsky reaction of PIPAAm, poly-*N*-isopropylacrylamid, around its transition temperature between the reversible hydration-dehydration process.
4. The compatibility between strengthening and the capability of damage self-monitoring in CFGFRP, carbon-fiber and glass-fiber reinforced plastic bars developed by Yanagida et al.

FRONTIER CERAMICS PROJECT

Before 1999 there was a national Frontier Ceramics Project (FroC), instituted in 1994, that sought to analyze and design two-dimensional structures (3) and to observe interactions arising from the structures related to intelligent functions. The interfaces were found to promote novel nonlinear interactions between the two materials involving crystal axes orientations. The nonlinear interactions, were then categorized as shown in Fig. 2. The two-dimensional structures or their interfaces were compared according to whether the materials were the same or different, the structure was closed or open, and the transport phenomenon was taking place across or along the structure. This system gave rise to $2 \times 2 \times 2 = 8$ different interfaces.

Figure 2. Classification of two-layer structures.

To discuss this study, we will denote the interfaces between the same materials as S , and the interfaces between different ones D . Closed interfaces are suffixed as “cl,” and open ones as “op.” Transport phenomena taking place across the interfaces are indicated as or \parallel (parallel) accordingly. The eight interfaces are as follows:

1. Closed interfaces between the same materials where transport phenomena occur: S_{cl+} .
2. Closed interfaces between the same materials where transport phenomena occur: $S_{cl\parallel}$.
3. Open interfaces between the same materials where transport phenomena occur: S_{op+} .
4. Open interfaces between the same materials where transport phenomena occur: $S_{op\parallel}$.
5. Closed interfaces between different materials where transport phenomena occur: D_{cl+} .
6. Closed interfaces between different materials where transport phenomena occur: $D_{cl\parallel}$.
7. Open interfaces between different materials where transport phenomena occur: D_{op+} .
8. Open interfaces between different materials where transport phenomena occur: $D_{op\parallel}$.

Of the eight types of interfaces type 5 was the most intensively investigated. An example of the interface is the

p–n junction. Among the typical cases, the transport phenomenon across the grain boundaries was categorized as type 1, diffusion along the grain boundaries as type 2, and the mechanism of chemical sensors by way of porous semiconductors as type 3. The p–n hetero-contact chemical sensors, which our group proposed and further investigated, was type 7, (4). The mechanism of humidity sensing and its effect upon acid-base mixtures was analyzed as type of 8. This system of categorization proved specially useful in our analyses of the working mechanisms of chemical sensors.

The interactions between different materials were considered as nonlinear when the structure was an open one, the ambient air give rise to some interesting phenomena.

The hetero-contact between an n-type semiconductor and a p-type semiconductor, namely between ZnO and CuO doped with Na^+ , proved to be an intelligent chemical sensor. This is because the structure consisted of different materials, was open, and the subjected to electric current flows across the interface with the current changing with the ambient air. Usually chemical sensors of porous semiconducting materials, such as SnO_2 or ZnO, cannot distinguish the among flammable gaseous species. For instance, it was very difficult to distinguish CO from H_2 until this experimental structure was developed. The sensitivity and selectivity of carbon monoxide (CO) can be modified by a bias between the hetero-contact as seen in

Figure 3. Relationship between the gas sensitivity and the forward applied voltage in CuO/ZnO hetero-contact.

Fig. 3. One of the intelligent functions has included was a tuning-capability as described in an introductory paper in 1988 by Yanagida on intelligent materials (5). The first success in finding a chemical sensor based on hetero-contact was back in 1979 when a humidity sensor was made of N_1O and ZnO (6). In the later FroC project, there was proposed (7) a similarly selective carbon monoxide gas sensor as shown in Fig. 4. The working mechanism was analyzed (8) as a bias-enhanced oxidation of absorbed CO or H_2 gas. This meant that catalytic activity can be controlled by changing the bias between the hetero-contact.

From the results of the FroC project it was clear, that out that the categorization had to be developed further. Since then well-known intelligent functions such as the ZnO varistor and PTCR, positive temperature coefficient of resistivity of $BaTiO_3$ have been analyzed considering the axial relations. The electric carrier transport of the zinc

Figure 4. Selective molecular recognition of carbon monoxide from hydrogen.

oxide varistor was found to take place across the grain boundaries. However, it is now known that transport behaviors vary with crystal orientation and their relationships between the grains. When grains are the same, the interface will be alike between different materials. The relationship can be varied with poling in ferro-electric materials such as barium titanate.

Interfaces between the same materials but having a different crystal axis orientation must be considered as interfaces between different materials. In sum, intelligent functions were found to depend on the design of crystal axis orientation.

concentration-dependent. These assemblies range from a rigid-rod character at very dilute concentrations to a lyotropic liquid-crystalline gel at higher concentrations (5). Most interestingly, Meijer developed supramolecular polymers of type **5**, that are held together by quadruple hydrogen bonding between the ureidopyrimidone units. This material displays most, if not all, properties of macroscopic polymers based only on non-covalent connections (Fig. 4) (6).

Materials based principally on hydrogen bonding and other intermolecular interactions have been generated using low molecular weight organogelators (7). Recently, microcellular organic materials have been prepared by drying of organogels in supercritical CO_2 (8). The field of organogelation has evolved from molecules that have different structural and recognition properties to the rational design and fine-tuning of materials. In the following section, we describe advances in organogelation and the use of intermolecular interactions in developing these new supramolecular structures.

INTERMOLECULAR INTERACTIONS

Hydrogen Bonding

Hydrogen bonds are usually formed when a donor (D) that has an available acidic hydrogen is brought into close contact with an acceptor (A) that possesses a lone pair of electrons (Fig. 5).

Hydrogen bonding has been the subject of statistical investigations (9,10), X-ray diffraction analysis (11–13), and theoretical studies. The hydrogen bond can vary in strength from 1 kcal/mol for $\text{C-H}\cdots\text{O}$ hydrogen bonding (14,15) to 40 kcal/mol for the HF_2^- ion in the gas phase

(16,17). Hydrogen bonding has played a critical role in the development of areas such as self-assembly (18) and crystal engineering (19,20). Solid-state and solution studies of the hydrogen bond have provided evidence that this interaction is a highly ordered phenomenon, not a random event. In the solid state, Zaworotko demonstrated that the inorganic complex **6** that has four hydrogen bond donors oriented in a tetrahedral geometry can form hydrogen bonds to nitrogen and to π -systems (21). The crystal structures from this study show supramolecular diamond-like arrangements, where the size of the network cavities depend on the size of the hydrogen bond acceptor (see Fig. 6).

Hydrogen-bond strength is influenced by secondary electrostatic interactions. A particularly strong hydrogen-bonded complex is formed when a molecule which is comprised of all hydrogen-bond donors binds to an all hydrogen-bond acceptor (Fig. 7) (22). The calculated individual secondary electrostatic interactions in these complexes are ± 2.5 kcal/mol in chloroform (23). Schneider estimated the contribution of a related series of secondary interactions at ± 0.7 kcal/mol from a large number of examples in the literature (24).

The presence of a competitive hydrogen-bonding solvent can also influence the strength of hydrogen bonding. Lorenzi found that the dimerization constant of a small cyclic peptide is 80 M^{-1} in tetrachloromethane, whereas the same molecule does not dimerize in chloroform (25). Wilcox also studied the effects of the concentration of water on the binding free energy of hydrogen-bonding molecules in chloroform (26). In competitive solvents, such as water/methanol mixtures, guanidinium receptors and carboxylate substrates are highly solvated. Schmidtchen has observed that as the polarity of the solvent (higher percentage of water in methanol) increases, the enthalpic

Figure 5. Hydrogen bond formed between an acidic hydrogen (D-H) and an acceptor (A).

component of the binding free energy and the binding affinity decreases (27).

π - π Interactions

Planar aromatic molecules, it is known, interact with one another in three possible geometrical arrangements: stacking (e.g., face-to-face overlap of duroquinone, Fig. 8); offset stacking (e.g., laterally shifted overlap in [18]annulene); and herringbone (e.g., T-shaped edge-to-face interactions in benzene, Fig. 8) (20). The greatest van der Waals interactive energy is found in the face-to-face overlap arrangement in which there is the highest number of C \cdots C intermolecular contacts. If van der Waals forces were solely to

determine the packing of flat aromatic molecules, the offset stack and herringbone arrangements would not be commonly observed. In effect, there is a barrier to face-to-face stacking due to $\pi \cdots \pi$ repulsions. As a result, the offset stack arrangement is the most commonly observed (28). Similarly, the herringbone interaction in many aromatic hydrocarbons offers evidence for the C(δ^-)-H(δ^+) nature of this interaction (29). The slightly electrostatic character of the herringbone interaction may predispose molecules during crystallization toward inclined geometries and reflects its character as a weak C-H \cdots π hydrogen bond (30).

van der Waals Interactions

Van der Waals interactions are dispersive forces caused by fluctuating multipoles in adjacent molecules that lead to attraction between them. In the solid state, the packing of aliphatic side chains is governed by van der Waals interactions. When the side chains are longer than five carbon atoms, H \cdots H interactions predominate. Similar effects have been observed in molecular recognition solution studies. Kataigorodskii's close-packing principle assumes that the potential energy of the system is minimized by

Figure 6. The hydroxyl groups of inorganic complex **6** can hydrogen bond to 4,4-dipyridine or benzene to form diamondoid networks (a).

molecules making a maximum number of intermolecular interactions (31). Therefore, because van der Waals interactions are nondirectional, the energy differences between alternative molecular arrangements are small. However, computational studies of rigid molecules that assemble into one-dimensional aggregates give insight into the importance of van der Waals and coulombic terms (32,33). The importance of van der Waals interactions in organogelation should not be underestimated because most organogelators have long alkyl chain groups.

ORGANOGELEATION

Many attempts have been made to define the phenomenon of gelation. In 1993, Kramer and colleagues proposed that use of the term “gel” be limited to systems that fulfill the following phenomenological characteristics: (1) They consist of two or more components, one of which is a liquid, and (2) they are soft, solid, or solid-like materials (34). The authors further described their definition of “solid-like” and also reviewed other existing definitions of gels. However, there is no precise definition for gelation, and in recent literature it is a phenomenon that is described rather than defined. Organogels are usually formed when an organogelator is heated and dissolved in an appropriate solvent. The mixture is allowed to cool to its gel transition temperature resulting in the formation of a matrix that traps the solvent due to surface tension. In general, the

Figure 8. The most common π - π interactions are stacked, offset stacked, and edge-to-face.

amount of organogelator needed to gel a certain solvent is small with respect to solvent, and concentrations can be as low as 2% by weight.

Organogelators are usually divided into two distinct classes based on the nature of the chemical forces that stabilize them. Chemical organogelators are formed through covalent networks; examples include cross-linked polymer gels and silica gels. One common feature of these gels is that their formation is irreversible. In contrast, physical gels are stabilized by noncovalent forces that range from hydrogen bonding to π - π stacking interactions. These types of gels are thermoreversible from the gel phase to solution. The molecules that encompass this class of

Figure 7. Repulsive and attractive secondary interactions in triple hydrogen-bonded donor-acceptor complexes.

Repulsive secondary interactions

Attractive secondary interactions

compounds range from peptides to carbohydrates to very simple organic molecules. We focus most of our discussion on these types of organogelators.

Several papers discuss the structures of organogelators and their properties. Terech and Weiss presented extensive research on anthryl and anthraquinone appended cholesterol derivatives (35). Extensive work on amide and urea organogelators is presented in van Esch and Feringa's 1999 book chapter (36). Hamilton and co-workers reported examples of organogelator design derived in many cases from molecular recognition and self-assembly (37).

Although the mechanism of gelation is not fully understood, there have been many attempts to understand the structure of gels. In a recent paper, Terech discussed and compared three methods for measuring phase transition temperatures in physical organogels (38). The three methods analyzed were the "falling ball" technique, nuclear magnetic resonance (NMR) spectroscopy, and rheology. The authors concluded that the rheology method is the most reliable.

Examples of Organogelators

Low molecular weight organogelators encompass a variety of compounds that can self-assemble into a fibrous matrix that can trap solvent molecules within its cavities. The noncovalent interactions that hold these structures together are various in nature. As a result, organogelators are usually classified by their chemical constitution. We will use this same type of classification previously employed by Terech, Weiss, van Esch, and Feringa.

Fatty Acid and Surfactant Gelators. Some of the first organogelators were based on substituted fatty acids. 12-Hydroxyoctadecanoic acid **7** and its monovalent salts form organogels in a variety of solvents (Fig. 9) (39,40). Observation of circular dichroism was used as evidence for the formation of supramolecular helical strands, although the

maximum of the signal depended on the solvent. For D-**7**, most of the helices were left-handed, whereas for L-**7** they were right-handed. Tetraalkylammonium derivatives such as compound **8** behave as surfactants and organogelators (41). Gemini (dimeric) surfactants formed by cetyltrimethylammonium ions (CTA) with various counterions gel organic solvents (see Fig. 9) (42). The most probable structure for the gels of **9** and **10** is an entangled network of long fibers that have polar groups at the core of the aggregate and long alkyl chains in contact with the solvent. These compounds gel chlorinated solvents most effectively at concentrations as low as 10 mM. However, they gel other solvents such as toluene, xylenes, chlorobenzene, and pyridine at concentrations from 20–30 mM.

Anthracene and Anthraquinone Derivatives. Anthracene and anthraquinone derivatives gel various alkanes, alcohols, aliphatic amines, and nitriles. These aromatic structures to form gels through π - π interactions. However, when the anthryl ring of **11** is partially hydrogenated, compounds **12** and **13** still form organogels (Fig. 10) (43). The interesting photochromatic properties of anthraquinones, such as **14**, has led to the study of substitution patterns on the ring. Dialkoxy-2,3-anthraquinone derivatives are the most effective agents (44). Both anthracene and anthraquinone substituents have been coupled to cholesterol groups for organogelation purposes. These are discussed later.

Amides and Ureas. The hydrogen bonding properties of amides and ureas have been the subject of solid-state and solution studies. Many low molecular weight organogelators have been designed by using this recognition element. The amide functional group can form eight-membered, hydrogen-bonded dimers and one-dimensional infinite arrays (Fig. 11). Primary and secondary amides (45) and pyrimidones (46) form cyclic dimers.

Figure 9. Examples of gemini surfactants and fatty acid organogelators.

Figure 10. Examples of organogelators based on anthracene and anthraquinone derivatives.

Hanabusa reported that *trans*-cyclohexane-1,2-diamide **15** gels organic solvents, silicon oil, and liquid paraffin at concentrations as low as 2 g/L (47). Enantiomerically pure **15** produces stable gels, and circular dichroism indicates a chiral helical arrangement of the diamides. Electron micrographs of a gel produced from **15** in acetonitrile showed the presence of the helical superstructures. However, the racemic mixture of **15** and **16** produces only unstable gels. The authors believe that the helical superstructures could arise from stacked, hydrogen-bonded, infinite aggregates. Therefore, the orientation of the amide groups in a

antiparallel *trans* configuration (both equatorial) is critical for the complementary interaction. Interestingly, **17** which has *cis*-amide groups (one equatorial and one axial) cannot form this interaction favorably and is not observed to gel any solvents (Fig. 12). This type of stacked amide hydrogen bonding has been observed in the crystal structure of a cyclohexane-1,3,5-triamide reported by Hamilton (48).

Shirota reported similar amide-containing molecules in which the hydrogen-bonding groups are arranged around a rigid core. Compound **18** gels various solvents. To prove that hydrogen bonding is essential in the gelling ability of these molecules, the *N*-methyl analog **19** was synthesized, and no gelation was observed (49). Increasing the distance between the hydrogen-bonding groups does not have adverse effects on the gelling capacities of these compounds (Fig. 13), as was observed for **20** (50).

Hanabusa also reported long alkyl chain trisubstituted organogelators based on a flexible core (51). *cis*-1,3,5-Cyclohexanetricarboxamide derivatives **21–24** show a trend in improved gelation when the alkyl chains are longer (Fig. 14). These results suggest that intermolecular hydrophobic interactions among the alkyl chains are critical in stabilizing the gel network. These molecules increase the viscosity of solvents at very low concentrations. Compound **22** causes an increase in the viscosity of CCl_4 to 250.0 cP at 25°C from 0.908 cP in the absence of the gelling agent.

Figure 11. Amides can form linear array (a) or dimers (b) through hydrogen bonding.

Figure 12. Organogelators based on 1,2-diaminocyclohexane derivatives.

Figure 13. Low molecular weight organogelators based on amide hydrogen bonds.

Recent applications of organogelators have included trapping liquid crystals within the gel matrix. Kato used **15** to gel liquid crystals such as **25** and **26** (Fig. 15) in concentrations as low as 1 mol% (52). These gels were stable at room temperature for several months. Measurements of the response to an electric field were made on gels of **15** and **25**, and interestingly, the threshold voltage of the gel (5.0 V) is larger than that of the liquid crystal alone (1.1 V). The authors propose that the solvent (liquid crystal) is oriented within the gel and that the structure resembles the cartoon shown in Fig. 15. As a result of this property, these materials may have applications in electro-optical devices.

Organogels formed by hydrogen bonding of small molecules have also been stabilized by polymerization. For example, Masuda used amide hydrogen bonds as in 1-aldosamide **27** to template the position of diacetylene groups close to each other for polymerization (53a). IR stretching frequencies were consistent with additional hydrogen bonding between the aminosaccharides. Robust nanofibers are observed in **27** using electron microscopy. However, 1-galactosamide containing **28** forms amorphous solids presumably due to steric hindrance by the axial OAc group that leads to the formation of an infinite amide

hydrogen-bonded network. Polymerization of **27** was confirmed by UV absorption and gel permeation chromatography. In a similar example, Shinkai polymerized **29** *in situ* (53b). The absorption spectra of the gels before and after photoirradiation show a distinct change that is consistent with polymerization (Fig. 16).

Recently, Tamaoki published on the gelation and polymerization of **30** (see Fig. 17) (54). Compound **30** contains two cholesteryl ester units at the ends of a diyne spacer. **30** shows liquid crystal behavior when heated between 101 and 133°C and gels nonpolar solvents at low concentrations. Gels formed in cyclohexane were irradiated by UV light (500-W high-pressure Hg lamp), and their color changed from colorless to dark blue. The absorption spectra provided evidence for the presence of the exciton band of polydiacetylene. The T_{gel} for a gel at 5.3 mM was 45°C before polymerization. However, after UV irradiation, the gel maintained its shape even above the boiling point of cyclohexane (80.7°C).

Ureas have been studied in detail due to their hydrogen-bonding complementarity to carboxylates and other anions. Moran synthesized **31** (Fig. 18), which has additional hydrogen-bonding groups to promote stronger association (55). The bis-urea **32** developed by Rebek

Figure 14. Long alkyl chain organogelators derivatives with hydrogen bonding groups around a cyclic core.

Figure 15. Compound 15 can gel liquid crystals 25 and 26. It is believed that the structure of the gels is as depicted in the illustration.

Figure 16. Aldosamide 27 is stabilized by one-dimensional hydrogen bonds, whereas 28 has axial acetyl groups that hinder the formation of such structures. Diamide 29 also forms one-dimensional strands and polymerizes *in situ*.

Figure 17. Polymerization of the gel formed by **30** in cyclohexane causes it to turn deep blue after 1 minute of photoirradiation.

Figure 18. Urea molecules used for binding carboxylates. Molecule **31** has additional hydrogen-bonding sites, and **32** has chiral R groups for enantioselective recognition.

complexes carboxylates enantioselectively when R is chiral (56).

Etter and co-workers observed that bidentate hydrogen bonding predominates in bis-ureas in the solid state. Graph sets and hydrogen-bonding rules were derived from this data and used to predict hydrogen-bonding patterns in related structures (57). Lauher has published crystal structures of a family of ureylenedicarboxylic acids that form hydrogen-bonded sheets through the carboxylic acid dimer, as well as urea hydrogen-bonded one-dimensional strands (58,59). Examples are shown in Fig. 19.

Hanabusa synthesized and studied gelators based on the urea hydrogen-bonding group. Molecules that have rigid spacers between the urea functional groups **33** and **34** gel only toluene and tetrachloromethane, respectively (60). However, cyclic bis-ureas **35–37** show remarkable gelling properties in different organic solvents. Similar to the results with 1,2-bisamidocyclohexanes, these molecules show gelation that depends on the length of the alkyl chains. The antiparallel orientation of the bis-urea groups is also important because the cis analog does not gel any solvent. See Fig. 20.

Bis-urea molecules have been reported by Kellogg and Feringa (see Fig. 21) (61). The morphology of the dried gels observed is thin rectangular sheets. These compounds gel only a selective number of solvents at concentrations around 10 mg/mL. These gels are stable up to temperatures of 100°C and for months at room temperature.

Hamilton reported a family of bis-urea molecules, shown in Fig. 22, that gels mixtures of solvents at 5°C (62).

The crystal structure of **38** confirmed the formation of extensive hydrogen-bonded arrays by both urea groups. As seen in Fig. 22, all of the urea groups point in the same direction, which makes the aggregates chiral. In this particular case, chirality is translated to the entire crystal because all strands point in the same direction. The urea hydrogen bonding distances N–H...O are 2.18 and 2.23 Å, which are within the expected range.

Cyclic bis-ureas derived from trans-1,2-diaminocyclohexane and 1,2-diaminobenzene derivatives have been extensively studied by Kellogg and Feringa (63). They prepared polymerizable derivatives **39** and **40** (Fig. 23). It is interesting to note that **39** forms gels only in tetralin, but **40** gels a variety of solvents. After photoirradiation and polymerization of the methacrylate groups, there is a slight turbidity and stability increase in the gels. A highly porous material was obtained after removing the solvent by freeze-drying. Functional organogels can also be generated by introducing reactive groups in the spacer between the ureas. Thiophene **41** and bis-thiophene **42** show efficient charge transport within the organogels that they form (64). These gels have potential application as organic semiconductors and have been further investigated. Molecular modeling of 1,2-bisaminocyclohexane and 1,2-bisamidobenzene derivatives indicates that trans-antiparallel orientation of the bis-urea groups is the most favorable for forming an extensive hydrogen-bonding network. However, in crystal structure **43**, both urea groups are oriented in the same direction (65). The authors used a variety of techniques, such as infrared spectroscopy, differential scanning calorimetry

Figure 19. Formation of urea bidentate hydrogen-bonded chains prevail in the presence of other hydrogen-bonding groups such as carboxylic acids.

and electron microscopy, to elucidate the supramolecular structure of the gelators.

Barbiturate-Melamine and 2,6-Diaminopyridine-Barbiturate Organogelators. Hydrogen-bond complementarity between two different functional groups has been studied in many systems for recognition in host-guest chemistry and for the formation of infinite aggregates in solution and in the solid state. Two of these patterns that have been incorporated into organogelators are the barbiturate-melamine pair and 2,6-diaminopyridine-barbiturate.

Whitesides and Lehn exploited the hydrogen-bonding complementarity of melamine-barbituric/cyanuric acid (13,66). The focus of their research was to study the

preferential formation of cyclic or linear aggregates. Their approach was to use steric hindrance to enhance formation of cyclic aggregates over linear ones. When the melamine derivative has methyl substituents on the phenyl rings (**44**) or an *n*-butyl substituent at the 3-position on the melamine derivative (**45**), the aggregates cocrystallize with diethylbarbiturate **46** in a linear arrangement. However, when the substituents were bulky, as in *t*-butyl-substituted phenyl groups (**47**), the cocrystallized aggregates were cyclic (see Fig. 24).

These types of molecular recognition motifs have been coupled to long alkyl chains to generate two-component organogelators. Hanabusa used a 1:1 mixture of **48** and **49** to gel *N,N*-dimethylformamide, chloroform, tetrachloromethane and cyclohexane at concentrations as low as 0.04 mol/mL (Fig. 25) (67).

Figure 25. Two-component complementary organogelators based on melamine–barbiturate hydrogen bonding.

Hamilton has made extensive use of 2,6-diaminopyridines in designing receptors for barbiturates. This hydrogen-bonding group has been incorporated into macrocycles **50** and **51** (Fig. 26), which also have the appropriate size cavity to form a 1:1 host–guest complex with **46** (68). When coupled to a thiol nucleophile, these receptors show large increases in the rates of thiolysis reactions of barbiturate-active ester derivatives (69).

Shinkai synthesized host–guest organogelators based on cholesterol-substituted 2,6-diaminopyridines. Gels formed by **52** and **53**, when combined with **46**, are stabilized by different mechanisms (Fig. 27) (70). The complex of **46** with **52**, which has flexible spacers between hydrogen bonding groups forms gels by intermolecular stacking of the host–guest complex. Whereas, in **46:53** the alignment of the complex is not optimal, leaving free N–H and C=O groups for intermolecular hydrogen bonding, and leading to cross-linking of the aggregates to form gels. The linking of known organogel forming molecules to cholesterol substituents has been exploited in designing many organogelators. In the following section, we present organogelators based on structures that have already been discussed in previous sections.

Cholesterol Derivatives. In 1989, Weiss and co-workers published a report of a family of organogelators termed ALS (71) that contain an aromatic (A) and a steroidal (S) group linked by atoms (L). These compounds contain a 2-substituted anthracenyl group coupled to the C3 of the steroid group (see Fig. 28). Because there is no strong hydrogen-bonding group in these molecules, it is believed that the gels are stabilized by dipolar and van der Waals interactions. Nonetheless, these forces are strong enough for gels from 2% concentrations to retain their properties for several months. Results from fluorescence, circular dichroism, X-ray diffraction, and ^1H NMR studies indicate that **54** forms gels by a stacked helical arrangement of the molecules, where the anthracenyl group partially overlaps the aromatic region of neighboring molecules. The organogels formed by **54** were also studied in decane and butanol by neutron and X-ray scattering techniques (72). The results show that the aggregates are composed of long, rigid fibers. The diameter of the fibers is sensitive to the solvent: 160 Å in decane and 192 Å in butanol. The results from this and previous studies showed that interactions between the aromatic groups play an important role in determining gel structure, stability, and aggregate type.

Figure 27. Cholesterol derivatives of 2,6-diaminopyridines **52** and **53** form hydrogen-bonded gels with barbital **46**.

Figure 28. Example of an anthranil-cholesterol organogelator.

A fluorescence spectroscopic study of gels formed from cholesterol–stilbene and cholesterol–squaraine gelators showed similar fibrous structures (73). Studies using a variety of probes showed that the solvent is in a liquid-like phase in the gel matrix microenvironment. Furthermore, Swanson and Whitten captured a series of time transient images to monitor the sol-to-gel phase transition of **55** in 1-octanol (Fig. 29) on highly oriented pyrolytic graphite (74). Using AFM and the assumption that solvent molecules fill the separations between the fibers, they estimated that 30% of solvent molecules are inside the fibers and 70% are in the space between the fibers. The authors suggest that this finding provides a foundation for the selectivity that many organogelators

show among the solvents that they most effectively gel.

Shinkai studied thermal and photochemical control of cholesterol-based gelators that contain azobenzene groups coupled to the C3 of a steroid through an ester linkage (75). The results indicated that when the configuration at C3 is the naturally occurring (*R*), the gelators are effective in polar solvents, whereas when the stereocenter has (*S*) configuration, apolar solvents are gelled. Scanning electron microscopy established that the gelators form three-dimensional networks of helical fibrils. The gels prepared from **56** in cyclohexane showed a right-handed helical signal by circular dichroism (CD) when the configuration of the C3 center was *R*. The left-handed helix was observed

55

Figure 29. Time transient AFM images of sol-gel phase transition for **55**. These images were acquired after the heated solution was cooled to room temperature for (a) 0, (b) 10, (c) 15, (d) 18, (e) 21, and (f) 31 minutes. Images scale is $12 \times 12 \mu\text{m}$. (These images are reproduced with permission of the Journal of the American Chemical Society.)

Figure 30. Gelation of azo-cholesterol derivatives can be photolithically controlled.

for the other stereoisomer. Another interesting result from this study is that the sol–gel phase transition of **57** was induced by photoresponsive *cis*–*trans* isomerism of the azobenzene group (see Fig. 30).

Shinkai exploited the gelation of cholesterol derivatives by generating a series of interesting organogelators. For example, the isocyanuric acid 2,3,6-triaminopyrimidine pair **58** was generated (Fig. 31) (76). Gelation in this system is remarkably dependent on the cooling rate of the mixture, as well as the nature of the solvents and

the concentrations used. Interestingly, the mismatched hydrogen-bonding combination leads to gelation, whereas the formation of molecular tapes results in precipitation.

Other interesting functional gels using the cholesteryl group have included a porphyrin substituent (**77**). The derivative with (*S*) C-3 configuration (**59**) effectively gelled a number of solvents, whereas the (*R*) isomer was ineffective with all solvents used. The absorption spectra showed a new λ_{max} at 444 nm and its corresponding CD band only in the gel phase, indicating that gelation leads to ordered

Figure 31. Cholesterol derivatives of isocyanuric acid and 2,4,6-triaminopyrimidine pair **58**.

Figure 32. Porphyrin-cholesterol derivative **59** gels organic solvents and has potential photochemical properties. Mixtures of **60** and **61** are used as templates for preparing hollow fiber silica.

porphyrin assemblies. Shinkai also recently used organic cholesteryl gels as templates for preparing hollow fiber silica (78).

It was found that molecules such as **60** gel liquid silanol derivatives. The fibrous organic matrix can serve as a template in forming the silica gels. The pyrolytic removal of the organic matrix resulted in forming well-grown, fibrous silica whose tube edges contain cylindrical cavities 50–200 nm in diameter. When mixtures of **60** and **61** were used, a helical hollow fiber silica resulted (79). This finding is particularly interesting because it represents the transfer of chirality from a template into an inorganic matrix (see Fig. 32).

Maitra and co-workers generated a donor–acceptor organogelator by using bile acid derivatives, such as those shown in Fig. 33 (**80**). Compound **62** gels organic solvents (primarily alcohols) only in the presence of **63** (Fig. 33). The stoichiometry required for gelation is 1:1, and the gels are colored due to charge-transfer effects. The intensity of the charge-transfer band changes substantially during gelation suggesting that this interaction is important in the gelation process.

Amino Acid Gelators. Gelatin is a polypeptide that has a high content of glycine, proline, and 4-hydroxyproline.

It is usually obtained from denatured collagen. Therefore, it is not surprising that short peptide derivatives gel organic solvents. It is believed that the amide group in these systems plays a key hydrogen-bonding role.

N-Benzyloxycarbonyl-L-alanine-4-hexadecanoyl-2-nitrophenyl ester **64** can form thermoreversible gels at less than 1% concentration by mass in methanol or cyclohexane (81). Transmission and scanning electron microscopy revealed that the gels are formed by rod-like fibers that in turn are presumably assembled through N–H...O hydrogen-bonding between adjacent carbamate groups. Several analogs of **64** were studied by FT-IR and circular dichroism to determine the role of these interactions (82). The study suggests that π – π stacking, dipole–dipole interactions, and hydrophobic forces together with hydrogen bonding work cooperatively to form aggregates. The alkylamine of *N*-benzyloxycarbonyl-L-valyl-L-valine **65** can also gel a variety of solvents at very low concentrations (83). FT-IR and thermodynamic parameters suggest that the gels form by intermolecular hydrogen bonding between the N–H and C=O groups of the carbamate (see Fig. 34).

Hanabusa also reported diketopiperazines[cyclo(dipeptides)] as gelators for a variety of solvents, including edible oils, glyceryl esters, alcohols, and aromatic molecules

Figure 33. Donor–acceptor gels are formed by **62** in the presence of **63**.

Figure 35. Cyclo(dipeptides) can gel a variety of organic solvents.

Figure 36. Examples of sugar-based organogelators.

(see Fig. 35) (84). An interesting feature is that even short alkyl chain derivatives are effective in gelling many solvents. However, introducing long chains does result in an increase in the gelation ability of the molecules.

Bhattacharya and co-workers reported a gelator family based on L-phenylalanine derivatives (85). Both mono and bis-carbamate derivatives of this amino acid were synthesized. This study shows a wide range of compounds. The investigation included many spacers between the carbamates. The gels were characterized by FT-IR, calorimetry, and X-ray diffraction studies.

Similar to the cholesteryl templates used to form hollow fiber silica, the amino acid derivative Z-L-Ile-NHC₁₈H₃₇ was used as a template in the polymerization of titanium tetraisopropoxide (86). Interestingly, after calcining the organic matrix, the result was porous titania that had fibrous structures.

Sugar-Based Gelators. The structure of the sugar component seems to play an important role in the gelation properties of sugar-based organogelators (87). In compounds that contain *p*-nitrophenyl groups, the chirality of the helical fibers formed by the gelator was monitored by CD spectroscopy (88). The *p*-aminophenyl derivatives were synthesized to have reinforce the formation of the gels through a metal coordination effect (Fig. 36) (89).

CONCLUSION

In this article, we have presented the development of organogelation from its initial stages of identifying intermolecular interactions through the development of functional organogelators. The applications of these materials range from the absorption of different solvents to a role as a template in forming fibrous silica. Microcellular organic materials formed by noncovalent interactions have also been prepared from gels by removing the solvent from their structure. The study of gels has been challenging, but the potential rewards in terms of understanding this form of matter between solid and liquid are considerable. The relative ease with which organogelation can be generated, the partial order that is present in their structure, and the potential for novel functionalization and reactivity all suggest that organogels will find many industrial and academic applications in the coming years.

GELS

ANTHONY M. LOWMAN
 THOMAS D. DZIUBLA
 Drexel University
 Philadelphia, PA

INTRODUCTION

Hydrogels are three-dimensional, water-swollen structures composed mainly of hydrophilic homopolymers or copolymers (1). They are rendered insoluble by chemical

or physical cross-links. The physical cross-links can be entanglements, crystallites, or weak associations such as van der Waals forces or hydrogen bonds. Cross-links provide the network structure and physical integrity. It is possible to design hydrogels whose swelling behavior depends on the external environment. During the last thirty years, there has been significant interest in the development and analysis of environmentally or physiologically responsive hydrogels (2).

Hydrogels are classified in a number of ways (1,3). They can be neutral or ionic based on the nature of the side groups. They can also be classified on the basis of network morphology as amorphous, semicrystalline, hydrogen-bonded structures; supermolecular structures; and hydrocolloidal aggregates. Additionally, in terms of their network structures, hydrogels can be classified as macroporous, microporous, or nonporous (1,3,4).

Since the development of poly(2-hydroxyethyl methacrylate) gels in the early 1960s, hydrogels have been considered for a wide range of applications, most notably for biomedical and pharmaceutical devices, due mainly to their high water content and rubbery nature which resembles natural living tissue more than any other class of synthetic biomaterials (1,5). Furthermore, the high water content gives these materials excellent biocompatibility. Some applications of hydrogels include contact lenses, biosensors, sutures, dental materials, and controlled drug delivery (1,5–9). Two of the most important characteristics in evaluating the ability of a polymeric gel to function in a particular controlled release application are the network permeability and the swelling behavior. The permeability and swelling behavior of hydrogels depend strongly on the chemical nature of the polymer(s) that composes the gel and on the structure and morphology of the network. As a result, there are different mechanisms that control the release of drugs from hydrogel-based delivery devices. Such systems are classified by their drug release mechanism as diffusional-controlled release systems, swelling-controlled release systems, chemically controlled release systems, and environmentally responsive systems (3).

Hydrogels may exhibit swelling behavior that depends on the external environment. Thus, in the last 30 years, there has been major interest in developing and analyzing these smart or responsive hydrogels (2). These hydrogels may drastically change their swelling ratios due to changes in their external pH, temperature, ionic strength, nature of the swelling agent, and electromagnetic radiation. Some advantages of environmentally or physiologically responsive hydrogels are relevant in numerous drug delivery applications, such as chemomechanical systems and drug targeting. In an exceptional new review in the field, am Ende and Mikos (10) offer a thorough physicochemical and mathematical interpretation of the conditions for diffusional release of various bioactive agents in hydrogels and other polymeric carriers; they emphasize the conditions of stability of peptides and proteins during delivery.

In this article, we present an overview of smart hydrogels and models that characterize the structure and

properties of these materials. Additionally, we review important contributions in this area and emphasize new synthetic methods that promise to lead to the development of exciting new structures for solutions to drug delivery problems.

STRUCTURE AND PROPERTIES OF HYDROGELS

To evaluate the feasibility of using a hydrogel in a particular application, it is important know the structure and properties of the polymer network. The structure of an idealized hydrogel is shown in Fig. 1. The most important parameters that define the structure and properties of swollen hydrogels are the polymer volume fraction in the swollen state $\nu_{2,s}$, the effective molecular weight of the polymer chain between cross-linking points \bar{M}_c , and the network mesh or pore size ξ (11).

The volume fraction of the polymer in the swollen gel is a measure of the amount of fluid that a hydrogel can incorporate in its structure:

$$\nu_{2,s} = \frac{\text{volume of polymer}}{\text{volume of swollen gel}} = \frac{V_p}{V_{\text{gel}}} = 1/Q. \quad (1)$$

This parameter can be determined by equilibrium swelling experiments (12). The molecular weight between cross-links is the average molecular weight of the polymer chains between chemical and physical junction points. This parameter provides a measure of the degree of cross-linking in the gel. This value is related to the degree of cross-linking in the gel X as

$$X = \frac{M_0}{2\bar{M}_c} \quad (2)$$

Here, M_0 is the molecular weight of the repeating units that make up the polymer chains.

Figure 1. Schematic representation of the cross-linked structure of a hydrogel. \bar{M}_c is the molecular weight of the polymer chains between cross-links (\bullet), and ξ is the network mesh size.

The network mesh size represents the distance between consecutive cross-linking points and provides a measure of the porosity of the network. These parameters, which are not independent, can be determined theoretically or by a variety of experimental techniques.

Equilibrium Swelling Theories
