MINERAL RESOURCES OF THE UNITED STATES FOR 1913—PART II.

MICA.

By Douglas B. Sterrett.

INTRODUCTION.

The term mica indicates a group of minerals having similar physical properties and related chemical structure. The physical properties characteristic of these minerals are monoclinic crystallization—the crystals being approximately hexagonal or orthorhombic in shape—and very perfect basal cleavage. The micas considered in this report are characterized by great flexibility and elasticity of the cleavage sheets. Some other species of mica cleave into brittle or inelastic sheets. Chemically, micas are silicates of aluminum and potassium containing varying amounts of magnesium and iron; some varieties contain also sodium, lithium, and other elements.

Of the several varieties of mica only two are available for commercial use on a large scale because of their physical properties. These are muscovite, or potash mica, and phlogopite, or magnesia mica. Lepidolite, or lithia mica, has been used in some quantity as a source of lithia. Muscovite is the most common variety. It is generally lighter in color than phlogopite, ranging from colorless in thin sheets to amber yellow, green, brownish red or "rum," and ruby red in sheets over one-sixteenth of an inch thick. Phlogopite is generally darker colored than muscovite, ranging from amber yellow to dark brown, even in rather thin sheets. Muscovite is the only variety of mica mined in the United States, no phlogopite deposits of commercial value having been found.

Some of the properties which render mica valuable are its occurrence in large crystals which can be split into thin sheets of various sizes, its transparency, flexibility, elasticity, nonconductivity of heat and electricity, and the brilliancy of its cleavage faces. Mica occurs in crystals ranging from small size up to several feet across. Crystals 2 feet in diameter are not unusual and those 10 or 12 inches across are common. This combination of properties is not found in any other natural or artificial product. Mica is sometimes called isinglass when used in stoves and lamp chimneys, but it should not be confused with the original isinglass, a gelatinous material obtained from certain fish.

The apparent approach to hexagonal or orthorhombic symmetry in mica is indicated by the nearly hexagonal and rhombic outlines often observed in the prisms, by the percussion and pressure figures, and by "ruled" and "A" mica.

Mica is of widespread occurrence in the rocks of the earth's surface, either as small grains or scales distributed through various types of rocks, or as larger crystals in distinctive types of rocks. Only the distribution of those deposits which contain mica of sufficient size to be of economic value will be noted here.

The principal mica-producing countries of the world at present are India, the United States, Canada, German East Africa, and Brazil. Small productions have been reported from South Africa, Ceylon, Norway, China, Japan, Argentina, and South Australia. Deposits of probable value are reported from other countries as New Zealand, West Australia, and the Philippine Islands.

In the United States the production of mica comes from a number of States, of which only a few are regular producers, the others having a more or less intermittent output. North Carolina has led in production for years, and the output from the following States has varied in importance: New Hampshire, South Dakota, Idaho, New Mexico, Colorado, Virginia, South Carolina, Alabama, and Georgia. Small outputs of mica from deposits which promise to be of future value have been reported from Wyoming, Utah, Nevada, Arizona, California, Washington, Maine, Connecticut, New York, Pennsylvania, and Maryland. The distribution of the mica-bearing rocks in these States may be better understood after a discussion of the geologic occurrence of mica, for mica deposits rarely occur outside of areas of old or metamorphic rocks.

GENERAL GEOLOGY.

Most of the mica deposits of the United States occur in regions of highly metamorphic rocks such as mica, garnet, kyanite, fibrolite, staurolite, hornblende, and granite gneisses and schists. A few deposits have been found in less altered granites or other igneous rocks. The highly metamorphic gneisses and schists are considered to be of pre-Cambrian age in most places; in some places the ages have not been determined.

Deposits of muscovite mica of commercial value are confined to pegmatite. This rock is quite variable in composition, but in its more normal phases is composed of feldspar and quartz, with or without mica and other minerals. It is therefore allied to granite in composition and has been called "giant granite." The texture grades from that of ordinary granite to masses in which the individual grains or minerals measure many feet across, and these variations may occur in the same deposit.

Orthoclase and microcline are the most common varieties of feldspar found in pegmatite. In many places, however, a variety of plagioclase, either albite or oligoclase, makes up part or all of the feldspar component. The feldspar occurs in masses and rough crystals, some of which may be several feet thick.

Quartz occurs in several ways in pegmatite, either intermixed with feldspar and mica in granitic texture, graphically intergrown with feldspar, or segregated out into large separate masses. In the latter case the quartz may form sheets or veins in the interior or along the walls, or it may occur in irregularly shaped bodies through the pegmatite. The quartz in these segregations is massive and generally granular, though locally showing rough crystallization.

The mica occurs in various positions in the pegmatite and no definite rule can be laid down as to where it may be expected to be found in different deposits. In these pegmatites in which quartz segregations are prominent the mica is generally richest near the quartz. In some deposits the mica follows one or the other wall, and in others it may be either regularly or irregularly distributed through the pegmatite. The mica crystals or blocks are generally rough and range in size from a fraction of an inch to several feet across.

Pegmatites occur in irregular masses, sheets, lenses, and stocks or chimneys, which range in size from small deposits to those many yards in thickness and length. These masses cut the country rock in various ways, either conformably with its bedding or at various angles to it. Some pegmatites are conformable with the bedding of the inclosing gneisses or schists through part of their extent and cut across it in other places. Some pegmatites fork or branch out from larger masses into two or more sheets. Inclusions of the wall rock or "horses" are common, and these may be in the form of sheets, lying parallel with the walls of the pegmatite, or of irregular masses occupying random positions through it.

MINING AND TREATMENT.

The occurrence of mica in deposits of such irregular nature as described renders its mining problematical. At a few deposits the pegmatite is in sheetlike bodies, which are not badly warped and are persistent for some distance. If the mica content is not too variable ordinary methods of mining can be applied to such deposits; that is, mining by regular shafts, adits or tunnels, drifts, and stopes; if the mica content varies much, stopes and other workings become more irregular. Where the pegmatite forks, rolls, is folded, pinches, or bulges out into large masses, the mining methods necessarily become more irregular. Such deposits lead to the type of mining called "ground hogging" or "gophering," in which the workings are very irregular, and waste rock is left to accumulate because difficult to remove through the small tunnels and openings.

If the pegmatite occurs in large masses rich enough to be worked for mica, regular quarry methods may be used. This is common in the New England mica mines, where open quarry work with derricks and incline tracks are used to remove ore and waste.

Much mica is mined each year in the United States from deposits operated in a small way without steam engines, pumps, or power drills. Hand power or, at most, horse power is used in such places to hoist mica, waste, and water from the workings, and drilling is done by hand. Tracks with mine cars may or may not be used.

As a general rule it is best to open a mica prospect by cuts, shafts, or tunnels in the pegmatite along the streak or deposit of mica and also in other positions that appear favorable until it has been determined that mica is present in paying quantities. Then only is it safe to develop by vertical shafts to one side of the vein or by long crosscut tunnels from lower levels on a hillside. Few prospects give evidence on the surface that they will warrant extensive development or large outlay in mining equipment.

In mining care is necessary to avoid drilling through good crystals of mica. Miners using either hand or power drills can generally tell by its clogging when the drill is in mica. In blasting only small charges of dynamite should be used around a pocket of mica, and black powder is even better, if it can be used.

Mica as it is obtained from the mine consists of rough crystals and blocks ranging from small size to several feet across. These crystals have to be treated before the mica is ready for the trade by cobbing, splitting, rough trimming, sorting, cutting into patterns, building up into large composite sheets, or grinding. In many places these operations are carried out in two or three different plants, but some of the better equipped companies prepare the mica for the trade in one conveniently located plant, either at the mine or elsewhere.

The rough mica crystals are cobbed and cleaned of adhering quartz, feldspar, or dirt, by rapping with hammers. They are then split with splitting knives or wedges into plates of about one-sixteenth of an inch or less in thickness. The rough edges are cut off these plates by knives held at an angle to the cleavage, and the mica is graded for size and quality. The graded mica is then ready for further splitting and trimming into patterns desired by the trade. Small sheets may be left with rough edges and used for punching into mica disks, washers, and other forms. "Thin splittings" are made from small mica. In making these the edges of the plates are ground on a bevel and these edges are pressed against a flat surface to open the cleavage. The mica is then "thin split" into sheets one five-hundredth of an inch or less in thickness by means of a thin-bladed knife. This work is generally done by girls as "piece work." The "thin splittings" are built up into mica board and flexible mica sheets. Mica board is built up either with or without tissue paper from several layers of thin splittings coated with shellac; it is made up into large sheets 2 by 3 feet square and is then subjected to great pressure under hydraulic presses. The sheets are heated during the pressing and are then baked to dry the shellac. The required thickness is obtained after baking by sanding and milling machines. Mica board can be cut or punched and treated like sheet mica.

Trimming mica into forms and patterns desired by the trade is accomplished by large shears and punches operated either by hand or by power. If shears are used, the mica is cut into the desired form around a templet of wood, metal, or composition laid against the mica. Mica punching machines are supplied with various dies to punch disks, washers, and other shapes.

The rough small mica and the waste from trimming sheet mica are ground. Two processes, wet grinding and dry grinding, are employed according to the uses to which the mica is to be put. Several methods of accomplishing each are used but most of them are held secret. In the wet-grinding process the following method has been used in some mills: Soft wood beaters with heavy spikes projecting from them are revolved in wooden tubs or vats containing scrap mica and water. The spikes beat and tear the mica into small scales forming a mush in the tubs. After the proper amount of grinding this mush is removed and spread over cloth-covered drying tables supplied with steam pipes below. When dry, the mica is removed in cakes or lumps, is beaten apart in disintegrators or pulverizers, and is then sent through bolters for sizing.

In dry grinding, the Raymond pulverizer or other type of pulverizing machinery is used in many places, and the mica is broken and torn up by beaters revolving at high speed in a chamber. The ground product is conveyed by air draft to bolters for sizing. One No. 0 Raymond pulverizer will supply two Barnard & Leas bolting machines.

USES.

The physical properties enumerated above render mica especially adaptable to many requirements in the industrial world, both as sheet mica and as ground mica. The largest use of sheet mica is in the manufacture of electrical apparatus and machinery, but a quantity is used in the glazing trade for stoves, gas-lamp chimneys, lamp shades, etc. Only clear mica of good grade and with perfect cleavage is used in the glazing trade.

In the manufacture of electrical apparatus and machinery mica is used in sheets of various sizes and shapes down to washers and disks for places in which a noninflammable insulating material is necessary. Thus properly trimmed sheets are used between the commutator segments of direct-current motors and dynamos, for tubes, sheets, and other forms in transformers, and for washers and rings around many bolts and screws requiring insulation. Large disks and washers are used in every arc light, and smaller ones in the sockets of incandescent lamps. Flexible mica-covered cloth and tape find varied uses in many pieces of electrical apparatus.

Ground mica is used in largely increasing quantities for the decoration of wall paper, for the manufacture of lubricants, fancy paints, rubber goods, molded mica, roofing papers, and as covering for steam pipes. Finely ground mica is applied to wall paper to furnish luster and brightness. For this purpose wet-ground mica is the most satisfactory because, it is claimed, the scales are cleaner and flatter than in the dry-ground product. Ground mica mixed with oil forms a good lubricant for axles and other bearings, and quantities are used for this purpose. For fancy and brocade paints ground mica is mixed with various pigments and serves the purpose of metallic paints. Many rubber goods contain finely ground mica used as an adulterant and to furnish certain qualities desired in the rubber. Ground mica mixed with shellac or plaster is used in the form of "molded mica" for insulation of trolley wire and for similar supports. Tar and other roofing papers are coated with coarse flakes or "bran" mica to prevent sticking when they are rolled for shipment. Bran mica and coarser grades furnish good fireproof and heat-retaining coverings for steam pipes and boilers when mixed with other materials.

Mica with a rich golden-bronze color and luster has been obtained by certain processes of calcining biotite found near Hecla, Chaffee County, Colo. Specimens of this mica and of the calcined product were kindly supplied by Mr. W. W. Kirby, of Denver, Colo. The mine product consists of a hydrated biotite resembling a chlorite. It is greenish black with rather dull luster. On heating it expands or exfoliates greatly and assumes various shades of silver to golden-bronze color, with metallic luster, according to treatment. Mr. Kirby is investigating the possibilities of this promising product for decorative and other purposes.

A new mica product called "micarta" is reported to have been developed by the Westinghouse Electric & Manufacturing Co.,[1] of Pittsburgh, Pa. It is intended to take the place of hard fiber, glass, porcelain, hard rubber, built-up mica board, rawhide, and molded compounds for use in commutators, bushings, brush-holder insulation, noiseless gear blanks, conduits for wiring, spools for spark coil and magnet windings, wireless-coil separators, and water-meter disks. Micarta is a tan-colored, hard, homogeneous material that can be sawed, milled, turned, and threaded. Thin sheets can be punched, and it is claimed that it will not warp, expand, or shrink beyond very small limits.

Two grades of "micarta" are made, one known as "bakelite micarta," which is infusible and will resist heat to a point where carbonization of some of the ingredients takes place. This variety is insoluble in nearly all ordinary solvents, such as alcohol, benzine, turpentine, and weak acid and alkali solutions.

PRODUCTION.

The total value of the mica produced in the United States in 1913 was $436,060. The production came from 11 States—North Carolina, New Hampshire, Idaho, New Mexico, South Dakota, South Carolina, Alabama, Virginia, Pennsylvania, Colorado, and New York, named in the order of the value of their output. Of these States no production was reported from Alabama, Virginia, and Pennsylvania in 1912. The value of the production of mica in 1913 exceeded by $104,164 that of 1912 and was the largest ever reported.

The production of sheet mica as reported to the Survey amounted to 1,700,677 pounds, valued at $353,517, as compared with 845,483 pounds, valued at $282,823, in 1912. The production of scrap mica in 1913 amounted to 5,322 short tons, valued at $82,543, as compared with 3,226 short tons, valued at $49,073, in 1912.

The figures given for sheet mica include both rough trimmed and cut or manufactured mica. Some of the producers manufacture their own mica and furnish figures for their product; others either sell in the rough or after first splitting and grading. It is impossible to separate the different classes of mica from the returns made by the producers, and the figures therefore include varying proportions of rough, graded, and trimmed mica. The output of rough trimmed or graded mica amounted to over 3,000,000 pounds, and the waste from the manufacture of this material is represented in the scrap mica.

The value of the production of mica in North Carolina in 1913 was $267,913, as compared with $256,549 in 1912. The production reported consisted of 803,462 pounds of sheet mica, valued at $230,674, and 2,729 tons of scrap mica, valued at $37,239. The production of sheet mica in 1913 exceeded that of 1912 by 313,863 pounds in quantity and $10,800 in value, and the excess of scrap mica was 237 tons in quantity and $564 in value.

In New Hampshire the total production of mica in 1913 was valued at $79,671, as compared with $37,338 in 1912. The output was

[1] Manufacturers' Record, Aug. 14, 1913.

reported as 731,478 pounds of sheet mica, valued at $65,765, and 692 tons of scrap mica, valued at $13,906. The value of the production of mica in South Dakota and Virginia amounted to $12,609 and $5,150, respectively. The production from the other States was reported by only one or two producers in each State and is therefore not given separately.

The production of mica in the United States since 1880 is shown in the following table:

Production of mica in the United States, 1880–1913.

Year.	Rough trimmed and cut mica.		Scrap mica.		Total value.
	Quantity.	Value.	Quantity.	Value.	
	Pounds.		*Short tons.*		
1880	81,669	$127,825			$127,825
1881	100,000	250,000			250,000
1882	100,000	250,000			250,000
1883	114,000	285,000			285,000
1884	147,410	368,525			368,525
1885	92,000	161,000			161,000
1886	40,000	70,000			70,000
1887	70,000	142,250			142,256
1888	48,000	70,000			70,000
1889	49,500	50,000			50,000
1890	60,000	75,000			75,000
1891	75,000	100,000			100,000
1892	75,000	100,000			100,000
1893	51,111		156		88,929
1894	35,943		191		52,388
1895	44,325		148		55,831
1896	49,156	65,441	222	$1,750	67,191
1897	82,676	80,774	740	14,452	95,226
1898	129,520	103,534	3,999	27,564	131,098
1899	108,570	70,587	1,505	50,878	121,465
1900	456,283	92,758	5,497	55,202	147,960
1901	360,060	98,859	2,171	19,719	118,578
1902	373,266	83,843	1,400	35,006	118,849
1903	619,600	118,088	1,659	25,040	143,128
1904	668,358	109,462	1,096	10,854	120,316
1905	924,875	160,732	1,126	17,856	178,588
1906	1,423,100	252,248	1,489	22,742	274,990
1907	1,060,182	349,311	3,025	42,800	392,111
1908	972,964	234,021	2,417	33,904	267,925
1909	1,809,582	234,482	4,090	46,047	280,529
1910	2,476,190	283,832	4,065	53,265	337,097
1911	1,887,201	310,254	3,512	45,550	355,804
1912	845,483	282,823	3,226	49,073	331,896
1913	1,700,677	353,517	5,322	82,543	436,060

PRICES.

The average price of sheet mica in the United States during 1913, as deduced from the total production, was 20.8 cents a pound, as compared with 33.4 cents a pound in 1912 and 16.4 cents in 1911. The average price of sheet mica in North Carolina was 28.8 cents a pound as compared with 44.9 cents a pound in 1912; in New Hampshire the average price was 8.8 cents a pound, as compared with 10.4 cents in 1912; in New Mexico it was 42.8 cents a pound; in South Dakota, 11.5 cents; in South Carolina, 11.4 cents; in Virginia, nearly $1 a pound. The average price of scrap mica in 1913, as deduced from the total production, was $15.51 a short ton, as compared with $15.21 in 1911; in North Carolina the price was $13.64; in New Hampshire, $20.09; in New Mexico, $15.26; in South Dakota, $17.60.

The following table shows the prices by the pound offered in North Carolina during part of 1913 for rough knife-trimmed mica, sorted to cut the sizes indicated:

Price of mica in North Carolina in 1913, by grades.

Size.	Grades Nos. 1 and 2.	Spotted or slightly clay stained.	Black "specked," heavily clay stained.
Punch mica	$0.035	$0.035	$0.03
1½ by 2 inches	.12	.07	....
2 by 2 inches	.30	.15	.07
2 by 3 inches	.70	.30	.25
3 by 3 inches	1.15	.70	.40
3 by 4 inches	1.35	1.00	.70
4 vy 6 inches	2.25	1.60	1.25
6 by 8 inches	4.00	2.25	1.60
8 by 10 inches	6.00	3.00	2.25

IMPORTS.

The imports for consumption of unmanufactured and trimmed sheet mica into the United States during 1913, as reported by the Bureau of Foreign and Domestic Commerce of the Department of Commerce, were valued at $943,018, compared with $748,973 in 1912. The quantity of imports was recorded for the first three quarters of the year only, during which time it amounted to 1,839,584 pounds, valued at $740,466. Ground mica to the value of $4,765 was imported during 1913, compared with $6,611 in 1912.

The quantity and value of mica imported for consumption into the United States annually from 1905 to 1913, inclusive, are shown in the following table:

Mica imported and entered for consumption in the United States, 1905–1913, in pounds.

Year.	Unmanufactured.		Cut or trimmed.		Total.	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
1905	1,506,382	$352,475	88,188	$51,281	1,594,570	$403,756
1906	2,984,719	983,981	82,019	58,627	3,066,738	1,042,608
1907	2,226,460	848,098	112,230	77,161	2,338,690	925,259
1908	497,332	224,456	51,041	41,602	548,373	266,058
1909	1,678,482	533,218	168,169	85,595	1,846,651	618,813
1910	1,424,618	460,694	536,905	263,831	1,961,523	724,525
1911	1,087,644	346,477	241,124	155,686	1,328,768	502,163
1912	1,900,500	649,236	88,632	99,737	1,989,132	748,973
1913	(a)	751,092	(a)	191,926	(a)	943,018

[a] Quantity not reported

CANADA.

The production of mica in Canada[1] during 1913 was valued at $170,112, as compared with $143,796 in 1912 (revised figures). The exports of mica from Canada during 1913 amounted to 817,152 pounds, valued at $240,775, as compared with 895,338 pounds, valued at $334,054, in 1912.

INDIA.

Figures for the output of mica in India in 1913 are not yet available. In 1912 the production reported to the Government[2] amounted to 43,835 hundredweight, valued at £97,286 ($473,442), as compared with 33,896 hundredweight, valued at £70,552 ($343,341) in 1911. The value of the exports in 1912 amounted to £284,290 ($1,383,497), as compared with £188,642 ($918,026), in 1911.

FUEL BRIQUETTING.

By Edward W. Parker.

INTRODUCTION.

The fuel-briquetting industry in the United States in 1913 was characterized by a net decrease of two in the number of operating plants and a decrease of 17 per cent in the quantity, but an increase of 5.8 per cent in the value of the manufactured product. If the future of this infant relative of the coal-mining industry is to be judged by the record in 1913, the judgment should be based on the increase in value rather than on the fewer plants and decreased tonnage. Briquetted fuel in the United States is essentially a domestic fuel, for which there was a slackened demand during the year, owing to the exceptional mildness of the winter of 1912–13 and of November and December, 1913. In consequence the consumption of briquets, like that of raw fuel for domestic purposes, was less in 1913 than in either 1911 or 1912. An exception to the general trend is to be noted on the Pacific coast, where there was an increase of one (from 3 to 4) in the number of operating plants and a production in 1913 exactly double that of 1912, with a gain in value of somewhat larger proportion. Three plants in the Eastern and Central States that made briquets in 1912 were out of commission in 1913. One of these, at Murphysboro, Ill., was destroyed by fire in the early part of 1912 and probably will not be rebuilt. One of the other inactive establishments had been built by the Rhode Island Coal Co., at Portsmouth, R. I., and with the failure of the coal-mining enterprise became useless. The third idle plant was one of small capacity and output, operating on peat at Fertile, Iowa. The inactivity of all three of these plants had little influence on the total production in 1913.

Of the 17 active plants in 1913, 8 in the Eastern States produced 62,244 short tons, valued at $240,643, compared with 107,181 tons, valued at $370,841, from 9 plants in 1912; 5 in the Central States produced 73,287 tons, valued at $360,408, compared with 7 plants producing 89,714 tons, valued at $400,624 in 1912; and 4 plants on the Pacific coast produced 46,328 tons, valued at $406,276, against 23,169 tons, valued at $180,796, by 3 plants in 1912. It will be observed that in each geographic division the average value per ton was higher in 1913 than in 1912, although in the Eastern and Central States the production fell off. The explanation for the higher values in the face of decreased demand appears to lie in the general enhancement of values of all industrial products in 1913, in which higher cost of manufacture was a factor. In the production of briquets in 1913, 7 plants used anthracite culm or fines; 1 used semianthracite; 1 semianthracite and bituminous slack mixed in proportions of 3 to 1; 1 used anthracite culm and bituminous slack, principally the former; 5 used bituminous or semibituminous slack; and 2 used carbon residue from gas works making gas from petroleum. Eight plants used coal-tar pitch for binder, 1 used asphaltic pitch, 1 used water-gas pitch, and 5 used mixed binders, the composition of which was not divulged. No additional binder is required in the briquetting of the carbon residue from oil-gas works. The two plants designed for the purpose of utilizing coke breeze, one at Point Breeze, Philadelphia, and the other at Detroit, Mich., have not been operated during the last two years, the abrasive action of the coke on the molds and machinery being too destructive for commercial success in these attempts to utilize an unmerchantable product of the coke ovens.

PRODUCTION.

The total quantity of manufactured fuel in the form of briquets, eggettes, coalettes, boulets, etc., all considered in this report under the general head of "briquets," amounted in 1913 to 181,859 short tons, valued at $1,007,327, compared with 220,064 tons, valued at $952,261, in 1912. Distributed by Eastern, Central, and Pacific coast divisions, this production in the two years was as follows:

Production of briquets in 1912 and 1913, by groups of States, in short tons.

	1912			1913		
	Number of plants.	Quantity.	Value.	Number of plants.	Quantity.	Value.
Eastern States:						
Maryland	1			1		
New Jersey	1			1		
New York	2			2		
Pennsylvania	3			3		
Rhode Island	1					
Virginia	1			1		
	9	107,181	$370,841	8	62,244	$240,643
Central States:

Washington	1			1		
	3	23,169	180,796	4	46,328	406,276
Total	19	220,064	952,261	17	181,859	1,007,327

In the six years 1907–1909 and 1911–1913 the production has been as follows:

Production of briquets in the United States in 1907, 1908, 1909, 1911, 1912, and 1913, in short tons.

Year.	Quantity.	Value.
1907	66,524	$258,426
1908	90,358	323,057
1909	139,661	452,697
1911	218,443	808,721
1912	220,064	952,261
1913	181,859	1,007,327

In order to meet with popular favor in this country briquets must be of convenient shape for shoveling and for permitting air to circulate in the fire box. They must be of sizes suitable for the purposes they are intended to serve and must possess sufficient cohesion to resist fracture and abrasion under rough handling. Some of the briquets manufactured in European countries, particularly in Germany, are made very large, for easy stowage in bunkers of steamships and tenders of locomotives, and are not adapted for use in this country. They must be handled and stowed by hand and must be broken up before they are shoveled into the fire. The high cost of labor in this country prohibits such handling.

The briquets which appear to meet with favor in the Eastern States are of the boulet type, pillow or egg shaped, and about the size of anthracite nut. Those that are practically smokeless, as they should be, make an ideal fuel for the open grate or kitchen range, holding their shape until entirely consumed and then falling, when stirred, into a pulverulent clinkerless ash. In the Central and Pacific Coast States the popular type of briquetted fuel appears to be the larger size, about that of egg coal, for which the raw materials available seem to be best adapted.

RAW MATERIALS.

It may be well again to call attention to the enormous quantities of raw material available for the manufacture of briquets and obtainable at little cost, though most of what follows is a repetition of what has been said in previous reports. The most desirable material for producing a smokeless product is anthracite culm, of which a plentiful supply still remains in the anthracite region of Pennsylvania and more is produced daily in the mining operations. It is not too much to believe or to hope that in the near future the small sizes of anthracite, such as buckwheat and smaller, which are now sold for making steam in competition with bituminous coal and at prices below the actual cost of production, will become more valuable as raw material for the briquet manufacturer. The output of these small sizes produced by crushing the large coal to obtain the domestic grades (egg, stove, and nut) exceeds 20,000,000 long tons annually, exclusive of 3,000,000 to 4,000,000 tons that are annually recovered from the culm banks by washeries. The present revenue from this product will not exceed $30,000,000. Washery and small-size coal is worth from 50 cents to $1.50 a ton, the price depending on the size. As briquetted fuel it should be worth as much as stove or egg coal, or from $3 to $4 a ton. The cost of briquetting is from $1 to $1.25 a ton. The uniform size of the briquets makes them highly desirable as a domestic fuel; besides, they are completely consumed, and if properly made they do not produce that bugbear to the housekeeper—clinkers. One objection raised to the use of briquets is that they will compete with the prepared sizes of anthracite. From the viewpoint of the consumer the objection lacks logic, and it seems equally illogical from the viewpoint of the producer when the apparent profit obtainable on the briquetted product is considered.

Slack from noncoking bituminous, subbituminous, and semianthracite coals is another cheap and abundant raw material. It is obtainable in all the coal-mining regions of the Middle West, where at many places it is now wasted or almost given away. Slack piles have sometimes been burned to prevent their cumbering the ground and more frequently have ignited spontaneously and devoured themselves. The quantities now used in the manufacture of briquets represents but a drop in the bucket of available material.

The vast and almost untouched areas of lignite in North Dakota and Texas contain enormous supplies of fuel that European experience has taught is well adapted to briquetting and that is much more usable in that form than in the raw state. The school of mines of the North Dakota University, under the direction of Prof. E. J. Babcock, has been making some interesting and valuable experiments in briquetting lignite and has already attained excellent results.

The large areas of peat beds in the United States are also available as a source of raw material. They are generally remote from the coal fields, and the briquetted fuel from peat, if properly prepared, makes an excellent substitute for coal. The peat now produced in the United States is used for stable litter, fertilizer, etc. None is used raw for fuel.

BINDERS.

As already stated, more than half of the briquetting establishments use coal-tar pitch as a binder, and if asphaltic and gas-tar pitch are added the binders of this type are used in two-thirds of the briquetting plants in which binders are employed. The five establishments using binders other than pitch employ mixtures whose constituents are principally of vegetable origin. Inorganic binders, such as cement and lime, have not given satisfactory results, for although they may be efficient in cementing qualities they have the serious objection of increasing the ash and of adding nothing to the combustible matter of the fuel. Binders of organic material, however, such as pitches from coal tar, gas tar, or asphalt or mixtures of vegetable origin, contribute combustible matter and do not increase the percentage of ash. A binder to produce an entirely satisfactory briquet should not materially add to the emission of smoke, particularly in communities where smokeless anthracite is customary, as a tendency to smoke creates a prejudice against the use of briquets.

BRIQUETTING PLANTS IN THE UNITED STATES IN 1912.

EASTERN STATES.

American Coal Boulet Co., Phoenix Mines, Md.—This plant, built in 1911, uses bituminous coal with a binder of secret character.

Eggette Coal Co., Trenton, N. J.—Plant began operations in 1912, using anthracite culm and patented binder, and produces a domestic briquet of about nut size. The capacity of the plant was considerably increased during 1913.

Coal Boulet Co., New York, N. Y.—Plant began operations in 1910, using anthracite coal and secret binder, and produces nut-size, egg-shaped briquets.

Robert Devillers, Brooklyn, N. Y.—Plant began operations in 1907, using anthracite culm and coal-tar pitch; was closed in August, 1913, because of the expiration of lease, and removal of machinery to Staten Island is contemplated. Regular product is a boulet weighing 2 ounces. During the time the plant was in operation in 1913 it briquetted experimentally about 300 tons of Texas and North Dakota lignite.

American Coalette Co., Philadelphia, Pa.—One of two new plants which began operations in 1913. Uses anthracite culm and patented binder.

Lehigh Coal & Navigation Co., Lansford, Pa.—Plant originally built in 1909, destroyed by fire in the same year, and reconstructed in August, 1911. Uses anthracite culm and coal-tar pitch and produces egg-shaped "boulets" about the size of anthracite nut, weighing 1½ ounces.

Scranton Anthracite Briquette Co., Dickson City, Pa.—In continuous operation since 1907, using anthracite culm and coal-tar pitch. Manufactures an egg-shaped briquet of egg or furnace and nut sizes, weighing 5 ounces and 1 ounce, respectively.

Virginia Coal Briquetting Co. (Inc.), Richmond, Va.—Began operations in November, 1912. Uses semianthracite from Pulaski, Va., with Hite patented binder. Makes pillow-shaped boulets, weighing 2 ounces.

CENTRAL STATES.

Indianapolis Pressed Fuel Co., Indianapolis, Ind.—Plant rebuilt in 1912, original establishment having been destroyed by fire in 1911. Uses principally bituminous coal slack with coal-tar pitch. Was operated to a considerable extent in 1913 on experimental and demonstration work, including tests with coke breeze and residue from water-gas plants. The briquet is cylindrical in shape and about the size of egg coal.

Detroit Coalette Fuel Co., Detroit, Mich.—Began operations in 1909, using slack coal from Pocahontas, Va., and coal-tar pitch. Produces cylindrical "coalettes" of egg or furnace size, weighing 11½ ounces.

Standard Briquette Fuel Co., Kansas City, Mo.—Began operations in 1909, using Arkansas semianthracite with coal-tar pitch. Produces a cylindrical "coalette" of egg or furnace size, weighing about 11 ounces.

Berwind Fuel Co., Superior, Wis.—Began operations in 1912, using Pocahontas semibituminous slack with coal-tar pitch. Produces a cylindrical "coalette" of egg size, weighing 12½ ounces. This is the largest plant in the United States.

Stott Briquet Co., Superior, Wis.—Began operations in 1909, using a mixture of anthracite culm and bituminous slack with coal-tar pitch. Produces a briquet in pillow form, of about range or stove size.

PACIFIC COAST STATES.

Los Angeles Gas & Electric Corporation, Los Angeles, Cal.—Began operations in 1905, using carbon residue from oil-gas manufacture, without binder. Produces a "coalette" of egg or furnace size, weighing about 10 ounces.

Western Fuel Co., Oakland, Cal.—Plant has been in operation since 1907, using screenings principally of Welsh anthracite from coal yards, with asphaltic pitch. Produces a cylindrical briquet of egg size.

Portland Gas & Coke Co., Portland, Oreg.—This is one of two companies which began operations in 1913. Like the Los Angeles Gas & Electric Corporation, this company uses the carbon residue from oil-gas works without any additional binder, the moisture and the volatile matter of the carbon residue having sufficient cementing qualities. The product is cylindrical in shape and averages 9 ounces in weight.

United Collieries Co., Seattle, Wash.—Plant constructed in 1911, using bituminous coal slack from Vancouver Island, British Columbia, with mixed binder. Makes eggette, weighing 4½ ounces.

SAND-LIME BRICK.

By Jefferson Middleton.

INTRODUCTION.

The sand-lime brick industry has been established in the United States since 1901, when the first plant was started at Michigan City, Ind. Since that time it has passed through the various stages of a new industry. In the beginning it suffered severely from the "boomer," on whose glittering promises to make brick for a few dollars a thousand that would sell in competition with high-grade face clay brick plants were established for the manufacture of sand-lime brick, without regard to market, transportation facilities, or even a supply of suitable material. Some plants constructed under these conditions never even attempted to market their product. Then came the natural reaction when the number of the plants and the value of the product decreased even more rapidly than commercial conditions would have seemed to warrant. Since that stage, within the last few years, the industry seems to have become firmly established and is now showing a reasonable growth.

In common with most new building materials, sand-lime brick has had to overcome prejudice in the minds of some architects and builders. This prejudice was sometimes justified by the poor brick resulting from ignorance or lack of technical skill. The plants making this poor material have either gone out of business or have improved their product, so that to-day at many places sand-lime brick is successfully meeting the competition of clay building brick.

The condition of the sand-lime brick industry in the United States in 1913 was on the whole encouraging. The number of active operators reporting decreased, and four States that reported production for 1912, dropped out of the list of producers in 1913. On the other hand, the quantity of brick reported and its value increased, and the average value also of output per plant increased from $16,905 in 1912 to $18,211 in 1913. When this material was first produced in the United States, it was thought that many applications of it would be made, such as wall coping, ornamental pieces for garden and lawn, window sills, trimmings, lintels, columns, and capitals. None of these have been made extensively, although some attempts were made to produce them. The tendency has been, however, to eliminate these special forms and uses and to make only building brick. For 1913 only the production of building brick was reported to the Survey.

The sand-lime brick industry showed progress in 1913 over 1912. In 1913 the value of the output reported attained its maximum, $1,238,325, or $12,556 more than in 1907, the year of maximum value prior to 1913. Compared with 1912, this was an increase of $38,102, or 3.17 per cent. In 1912 the value of sand-lime brick products increased over 1911, $302,559, or 33.71 per cent. The average value of output per active plant in 1907 was $13,040; in 1913 the average per plant was $18,211. Of the 24 States reporting production in

1913, 15 showed increase and 9 decrease. The increase was not confined to any one section of the country; the decrease was principally in the smaller producing States.

PRODUCTION.

The following table shows the production of sand-lime brick in the United States from 1903 to 1913, inclusive:

Value of production of sand-lime brick in the United States, 1903–1913.

Year.	Number of operating firms reporting.	Value of product.	Year.	Number of operating firms reporting.	Value of product.
1903	16	$155,040	1909	74	$1,150,580
1904	57	463,128	1910	76	1,169,153
1905	84	972,064	1911	66	897,664
1906	87	1,170,005	1912	71	1,200,223
1907	94	1,225,769	1913	68	1,238,325
1908	87	1,029,699			

This table shows that the value of sand-lime brick marketed and the number of operating plants reporting rose rapidly until 1907. In 1908 there was a decrease, in common with other industries. In 1909 and 1910 there were slight increases. In 1911 the lowest value was reached ($897,664) since 1904. In 1912 and 1913 there were gains in value, the total for 1913 being the maximum, though the number of active firms reporting was 3 less than in 1912.

The domestic production of sand-lime brick in 1912 and 1913 by States and kinds is shown in the following tables:

Production of sand-lime brick in the United States in 1912, by States and kinds.

State.	Number of operating firms reporting.	Common brick.		Front brick.		Miscellaneous (value).[a]	Total value.
		Quantity (thousands).	Value.	Quantity (thousands).	Value.		
California	5	1,511	$12,635	1,395	$20,875	([b])	$33,860
Colorado, Montana, and Washington	4	1,622	9,732	585	9,915		19,647
Connecticut, District of Columbia, Maryland, and Massachusetts	5	6,478	57,020	3,755	30,209	([b])	92,659

Total	68	178,352	1,118,402	11,307	119,923	1,238,325
Average price per M			6.27		10.61	

[a] Includes fancy brick.
[b] Includes the District of Columbia, Georgia, Kentucky, Ohio, and Washington.

These tables show that the value of the output in 1913 increased $38,102, or 3.17 per cent. The number of States in which production was reported in 1913 was 24, a decrease of 4 from 1912—Connecticut, Maryland, Mississippi, and Montana dropping out as producers. In order to avoid disclosing individual operations, it has been necessary to group the output of certain States together. Michigan continued to be the leading State, the value of its product constituting 25.94 per cent of the total value of all sand-lime brick in 1913, and 26.39 per cent of the total in 1912. New York was second in 1913, as in 1912, reporting 10.98 per cent in 1913 and 10.72 per cent in 1912. Minnesota regained third place, from which it was displaced by Florida in 1912, and Florida was fourth.

Of the States for which totals are given, 8—California, Massachusetts, Michigan, Minnesota, New Jersey, New York, Pennsylvania, and Wisconsin—showed increase in 1913 and 3—Florida, Idaho, and Indiana—showed decrease. None of these changes were very great, the largest gain being in Pennsylvania—$36,704, or 99.28 per cent. The largest proportionate gain was in Massachusetts—nearly 150 per cent. The largest decrease was in Florida—$41,699, or 34.35 per cent.

Michigan had the largest number (12) of operating firms reporting in 1913, an increase of 1 over 1912. California and New York each had 5 operating firms reporting in 1913, the same number as in 1912. No other State had as many as 5 producers in 1913.

The average price per thousand for common sand-lime brick was $6.27 in 1913, as compared with $6.46 in 1912 and with $6.09 in 1911; for front brick it was $10.61 in 1913, as against $10.41 in 1912 and $9.53 in 1911. In 1913 common brick represented 90.32 per cent of the value of all products and front and fancy brick 9.68 per cent. In 1912 common brick constituted 90.64 per cent of the total value and front brick 8.86 per cent.

SAND-LIME BRICK INDUSTRY BY STATES.

California.—Five plants in California marketed products in 1913. Conditions, on the whole, were better than in 1912, and the value of the sand-lime brick reported increased $4,979, or 14.7 per cent.

Colorado.—Only 1 company reported from Colorado in 1913. Building conditions were extremely dull and the plant was idle, but sales were made from the stock on hand at the beginning of the year.

District of Columbia.—There is only 1 sand-lime brick company in the District of Columbia. Business was very much better than in 1912, owing possibly to the exhaustion of some of the clay deposits of the District.

Florida.—Florida was fourth in the value of sand-lime brick in 1913 and third in 1912. The number of operators reporting for 1913 was 4, a decrease of 1. Business conditions were, on the whole, not so good as in 1912, and the value of the product decreased $41,699, the largest decrease in any State. Operators of 2 plants in Florida failed to report to the Survey for 1913.

Georgia.—Two companies reported from Georgia in 1913; one was active and the other was idle. Conditions were poor compared with 1192, and the value of the product showed a decrease in 1913.

Idaho.—Three plants reported sales of sand-lime brick in Idaho in 1913, the same number as in 1912. Business conditions were poor compared with 1912, and the value of the product decreased $8,642, or 34.4 per cent.

Indiana.—Four plants were active in Indiana in 1913, an increase of 1 over 1912. Business conditions were not very good, and notwithstanding the increase in the number of operators reporting, the total value of the product showed a small decrease—$1,379, or 2.3 per cent.

Iowa.—There were 2 plants in Iowa at the beginning of 1913, but 1 of them ceased operations during the year. A new plant was under construction during the latter part of the year. The value of the output fell off markedly in this State in 1913.

Kansas.—Only 1 plant was in operation in Kansas in 1913. Business conditions were not good, but the value of the product was about the same as in 1912.

Kentucky.—There is only 1 sand-lime brick plant in Kentucky. The conditions of the industry were not good in Kentucky in 1913.

Massachusetts.—In Massachusetts 3 plants were active in 1913, an increase of 1 over 1912, and 1 was building. The value of the production in this State showed the largest proportionate increase in 1913. The demand was good, and the prospects for 1914 are encouraging.

Michigan.—Michigan has been the leading State in number of plants and in value of production of sand-lime brick since the beginning of the industry in this country, with the exception of one year, 1906. Twelve plants reported production for 1913. Two new plants began operations during the year, and 1 went out of business, a net gain of 1 over 1912. The gain in value of output, however, was only $4,513, or 1.42 per cent. Michigan's product in 1913 was valued at more than twice as much as that of the second State, New York, and constituted, as in 1912, over 25 per cent of the total value. The principal producing locality was Wayne County, in which Detroit is located. The other producing counties were Genesee, Houghton, Huron, Jackson, Kalamazoo, Kent, Manistee, Menominee, Oakland, and Saginaw.

Minnesota.—Four plants were in operation in Minnesota in 1913, and 1 was building. Business conditions were good and the production increased in value $16,379, or 14.52 per cent. Minnesota was third among the States in the value of sand-lime brick in 1913; in 1912 it was fourth.

Nebraska.—Two active operators reported from this State for 1913, an increase of 1 over 1912. The output showed an increase in value in 1913 over 1912, though as 1 plant was operated only a portion of the year the increase was not very large.

New Jersey.—Four plants were active in New Jersey in 1913, the same number as for 1912. The value of the product, however, showed a large proportionate increase—127.57 per cent.

New York.—New York was the second State in value of sand-lime brick in 1913, as for some years past, and reported a product valued at $136,013, an increase of $7,313, or 5.68 per cent, over 1912. Five active operators reported for 1913, the same number as for 1912. One new plant had not begun operations at the close of the year, and 4 plants reported no sales. Business conditions were good generally, with an increasing demand for this class of brick. The active plants were located in Erie, Monroe, Onondaga, Suffolk, and Warren counties.

North Dakota.—There is but 1 plant in this State, located in McHenry County. Business conditions were better in 1913 than in 1912, and the value of the product showed a considerable increase.

Ohio.—Ohio, the leading State in the clay-working industries, had but 1 active sand-lime brick plant in 1913, located in Montgomery County. Business conditions were better in 1913 than in 1912, and notwithstanding the loss of time caused by the Dayton flood this company reported a large increase in business in 1913.

Oklahoma.—One active plant reported from Oklahoma for 1913, as in 1912, and business conditions were reported about the same as in 1912.

Pennsylvania.—Pennsylvania was the sixth State in value of sand-lime brick in 1913, and showed a large increase in value of output—$36,704, or 99.28 per cent. There were one idle and three active operators in the State. The active plants were located in Dauphin, Lackawanna, and Lebanon counties.

South Dakota.—The 2 active plants in South Dakota reported much better business conditions in 1913 than in 1912. There was 1 idle plant in the State, and a new one that expected to begin operations in the spring of 1914. The value of the output showed a good increase over that of 1912.

Texas.—Two active operators reported from Texas in 1913, and 1 plant was building. Business conditions were about the same as in 1912.

Washington.—There were 2 active plants in Washington in 1913, an increase of 1, and 1 idle plant. One of the active plants, located in Island County, is new. Business conditions were reported to be about the same in 1913 as in 1912, though the value of the sand-lime brick produced increased considerably.

Wisconsin.—Wisconsin was the fifth State in the value of the sand-lime brick output in 1913. The value increased $6,769, or 9.56 per cent, over 1912. The 4 plants in this State, all of which were active in 1913, are located in Columbia, Dane, Milwaukee, and Washington counties. Business conditions were better than in 1912.

LITERATURE.

The literature in English on the sand-lime brick industry is very meager, though the Illinois State Geological Survey [1] published a list of 61 papers on the subject. The great majority of these are foreign, mostly German. The following list is taken principally from the Illinois Survey publication:

Curfman, L. E., Tests of sand-lime brick: Technograph, vol. 19, p. 72, 1905.

De Long, Daniel P., Sand-lime brick from the brickmaker's point of view: Am. Arch., vol. 84, p. 23, 1904.

SULPHUR, PYRITE, AND SULPHURIC ACID.

By W. C. Phalen.

SULPHUR.

PRODUCTION.

The marketed production of sulphur in the United States in 1913 was 311,590 long tons, valued at $5,479,849. As compared with the quantity of sulphur marketed in 1912, which was 303,472 long tons, valued at $5,256,422, this is an increase of 8,118 long tons in quantity and of $223,427 in value. Unsold sulphur stocked at the mines is not included in the above figures nor in the table of production given below. By reference to a subsequent page of this report it will be observed that the output of Sicilian sulphur amounted to 351,752 metric tons (346,213 long tons) for the year ending July 31, 1913. If the quantity of sulphur mined is considered, the United States now occupies the leading position among the sulphur-producing countries of the world.

The production of sulphur in the United States since 1880 is given in the following table:

Production of sulphur in the United States, 1880–1913.

Year.	Quantity.	Value.	Year.	Quantity.	Value.
	Long tons.			*Long tons.*	
1880	536	$21,000	1897	2,031	$45,590
1881	536	21,000	1898	1,071	32,960
1882	536	21,000	1899	4,313	107,500
1883	893	27,000	1900	3,147	88,100

1886	2,232	75,000	1903	[a] 233,127	1,109,818
1887	2,679	100,000	1904	127,292	2,663,760
1888	....	....	1905	181,677	3,706,560
1889	402	7,850	1906	294,153	5,096,678
1890	....	....	1907	[b] 293,106	5,142,850
1891	1,071	39,600	1908	[b] 369,444	6,668,215
1892	2,400	80,640	1909	[b] 239,312	4,432,066
1893	1,071	42,000	1910	[b] 255,534	4,605,112
1894	446	20,000	1911	[b] 265,664	4,787,049
1895	1,607	42,000	1912	[b] 303,472	5,256,422
1896	4,696	87,200	1913	[b] 311,590	5,479,849

[a] Includes the production of pyrite. [b] Marketed production.

In 1913 three States produced sulphur, namely, Louisiana, Texas, and Wyoming. The production of these three States can not be given separately, as individual output can not be disclosed. Louisiana, of course, led in the sulphur industry in the United States. Texas ranked second, but production in this State has just begun. The production in Wyoming was small.

In the following pages are given descriptions of the sulphur-mining operations in Texas and Wyoming and notes on certain desulphurizing processes which are of especial interest in connection with the smelter-gas problem. Notes are also given on certain phases of the sulphur situation in Sicily, together with brief descriptions of the rather recently developed sulphur deposits on White Island, Bay of Plenty, New Zealand.

IMPORTS.

The table of imports of sulphur for consumption shows that 22,605 long tons, valued at $448,564, were imported in 1913. This includes imports of all varieties of sulphur—crude, refined, flowers of sulphur, and other grades not specifically mentioned. In the second table following, the imports of crude sulphur alone are given by countries. This table shows that the crude sulphur imported came practically from two countries, Italy (Sicily) and Japan. The Italian product is entered at Atlantic ports, chiefly New York; the Japanese product is entered at the Pacific ports, San Francisco and Los Angeles, Cal.; and Willamette and Portland, Oreg.; and at Hawaii.

Sulphur imported and entered for consumption in the United States for the calendar years 1909–1913, by kinds, in long tons.

Year.	Crude.		Flowers of sulphur.		Refined.		All other.[a]		Total.	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
1909	28,800	$492,962	770	$23,084	966	$26,021	53	$7,565	30,589	$549,632
1910	28,656	496,073	1,024	30,180	1,106	25,869	47	6,489	30,833	558,611

EXPORTS.

In 1911 the United States exported 28,103 long tons of sulphur, valued at $545,420. In 1912 the exports amounted to 57,736 long tons, valued at $1,076,414. In 1913, the exports were 89,221 long tons, valued at $1,599,761. The excess of exports over imports for 1913 amounted to 66,616 long tons and the balance of trade in favor of the United States was $1,151,197.

OCCURRENCE AND INDUSTRY.

TEXAS.

BRYAN HEIGHTS.

The actual mining of sulphur in Texas began in November, 1912, near Bryan Heights at the mouth of Brazos River, Brazoria County. During 1913 progress was more or less intermittent, owing to delays and adjustments incident to the commencement of an important mining operation of this character. There was, however, a substantial output of sulphur reported for the year, and the statement seems to be justified that Texas is about to take a place among the important sulphur-producing districts of the world.

Bryan Heights[1] is well located for the production and exploitation of the sulphur there occurring. It is only a short distance from the Gulf coast and about 3 miles from the harbor of Brazos River, where the town of Freeport will be established. The general location is about 40 miles southwest of Galveston and about 60 miles south of Houston, two of the most important cities of eastern Texas. One of the unique features of the locality is that mining operations will be conducted practically on the coast itself. The general plans of the syndicate of financiers in charge of the operations contemplate a port city of ultimate importance located on the west side of Brazos River near its mouth—a natural landlocked harbor—also the necessary railroad and steamship facilities, together with a bank, hotel, and other civic improvements of a substantial character. These will help to constitute the city called Freeport.

The transportation facilities at the Texas mine are ample. The field is located a short distance from the projected inland waterway which will provide a new transportation route from Galveston to Matagorda Bay. A railroad is now under construction from the mine to Freeport, which will give the Freeport Sulphur Co. a shipping point with ample wharfage facilities within 3 miles of the deposit.

Oil is the fuel used for heating the water needed in the process of mining the sulphur. There is no expense of rail haul on this oil, which will be supplied, it is understood, from the oil fields in the Tampico district, Mexico, across the Gulf from Freeport, and which has water transportation from Tampico to the distributing tanks of the company at Freeport. From these tanks the oil is pumped direct to the plant at Bryan Heights, thus providing a plentiful supply of fuel at the lowest possible cost.

Other industries which may locate at Freeport in the future will also be able to avail themselves of this supply of cheap fuel.

---

[1] This description is based on the article by A. W. Davis, Min. Sci., August, 1913, pp. 99–102.

The occurrence of sulphur at Bryan Heights is in one of the structural domes characteristic of the Mississippi embayment. When these domes were drilled for oil in both Louisiana and Texas other mineral products were found in them, including gas, salt, sulphur, and gypsum. Little attention was paid to any of these products except the oil and gas until the Frasch process for the extraction of sulphur was put into successful operation in Calcasieu Parish, La., by the Union Sulphur Co. Then these mounds at once attracted attention as a source of sulphur. The area underlain by valuable sulphur deposits in the Texas locality has been proved to be large.

The process of mining used in Texas has already been fully described in these reports.[1] The sulphur is melted underground by means of superheated water and is then pumped or forced to the surface by an air lift. Sulphur recovered in this way requires the installation of a water-heating plant of great size, as large quantities of both heat and water are consumed. It is reported that one well will use an average of 1,000 barrels of fuel oil a day.

The large quantity of water required in the boilers and for the superheaters is provided by means of deep wells located 1½ miles from the plant. The water is forced to the surface by air, the pressure being furnished by an air compressor. The wells deliver more than 2,000,000 gallons of water a day to an artificial storage reservoir built adjacent to the plant and having a capacity at the 11-foot stage of 23,000,000 gallons and at the 12-foot stage of 33,000,000 gallons.

The heating plant at the Texas mine consists at present of one unit capable of developing the equivalent of 6,000 steam horsepower. Little steam, however, is used as power; except a very small quantity for the auxiliary machinery, it is applied to heating the water used in melting the sulphur. The initial plant as installed at the Bryan Heights mine consists of four 750-horsepower boilers, with a capacity of 100 per cent overload, that deliver steam at 100 pounds pressure to 2 heaters, in which water is heated to 387° F. The capacity of these boilers provides for the heating of 2,000 gallons of water a minute at this temperature. They are said to be the largest individual units in the South. Heaters are also used to feed water to the boiler. The equipment of the plant also contains a battery of twelve 10 by 6 by 12 duplex plunger pumps used in pumping water to the heaters and delivering it to the sulphur formation.

The water which is forced into the formation has a temperature of 337° F. at the ground, although sulphur melts at 239°. This heated water, which goes into the well, runs off into the cavities in the formation and does not return to the surface. After the hot water is forced into the ground for a number of hours a pool of molten sulphur forms at the bottom of the well. This accumulation is pumped to surface by an air lift.

Practice shows that when sulphur has been pumped from a well and a small percentage of water becomes mixed with it, the sulphur congeals to dust on reaching the surface. The water coming to the surface minutely commingled with the sulphur is relieved of pressure and necessarily cools to 212° F. very quickly, a temperature consider-

[1] U. S. Geol. Survey Mineral Resources, 1907, pt. 2, p. 674, 1908; idem, 1909, pt. 2, p. 686, 1911; idem, 1911, pt. 2, pp. 940-941, 1912.

ably lower than the melting point of sulphur. This tendency to cooling produces the dust mentioned above. When sulphur comes to the surface as dust, technically known as "blowing," it is known to the operators at the well that the accumulation of sulphur has been obtained. However, after a good well has been under steam a number of days, the pumping may be so regulated that a constant production can be obtained until the well becomes exhausted. This may not occur, however, for a year or more.

The hot water is forced into the formation during the entire time that the sulphur is being removed. The introduction of hot water and the removal of the sulphur is accomplished at the well by the use of a number of concentric pipes, the water passing downward between the outside pipes and the sulphur upward between the inside pipes.

The molten sulphur from the well is collected in huge plank bins whose capacities run into the hundreds of tons. When it is desired to ship the sulphur, the planking is removed and the sulphur, which hardens shortly after it reaches the surface, is broken up into pieces convenient to handle and is loaded into freight cars or on steamers as the case may be.[1]

Late reports in 1913 are to the effect that the Freeport Sulphur Co. is planning to build additions to its plant that will double the output of sulphur at Bryan Heights. The experience gained in operating the initial plant during 1913 indicates that the entire field should be rapidly developed. The original plant was built with provisions for additional units, and the proposed new installations comprise—a mining unit of fireproof construction with boilers to produce 8,000 horsepower; the remodeling of the old plant and the installation of additional pumps and compressors; the construction of mechanical loading devices both at the mine and at the steamship pier; the location of the 3-mile canal to extend from Brazos River to the mine at Bryan Heights; the erection of a pumping station at the river to pump water into the canal; the building of a water-treating plant at the mines to prepare the water for use in the boilers and heaters.

WYOMING.

The following notes on the operations of the Northwest Sulphur Co. at the southeast end of Cedar Mountain, Park County, Wyo., are by D. F. Hewett, of the United States Geological Survey.

The Northwest Sulphur Co. operates deposits of sulphur at the southeast end of Cedar Mountian in sec. 15, T. 52 N., R. 102 W., Park County, Wyo. They lie about 2 miles due south of those described by Woodruff [2] and about 4 miles southwest of the town of Cody.

Sulphur-bearing material is mined from three open cuts and from them is hauled by wagon 2,000 feet east to the refining plant. The largest and most eastern open cut is 100 feet long, 30 feet wide, and 15 feet deep. The open cut follows the north face of a low ridge composed of beds of dense gray sandstone, which probably are a portion of the Tensleep sandstone and at this point strike S. 65° W. and dip 10° SE. The sandstone is composed of clear quartz sand and is highly indurated. It is broken by numerous joints, of which a system extending approximately north and dipping 70° west predominates.

Sulphur occurs as an incrustation on blocks of sandstone in a very irregular zone, which is only locally controlled by the joints, but such material is low grade and is not

---

[1] Davis, A. W., op. cit.
[2] Woodruff, E. G., Sulphur deposits at Cody, Wyo.: U. S. Geol. Survey Bull. 340, pp. 451–456, 1908.

used as a source of sulphur. The material that is richest in sulphur is the surface débris or wash, which adjoins the sandstone ridge on the north. This débris is composed of angular fragments of sandstone and chert and round pebbles of andesite and is clearly of local origin. In places it probably contains as much as 40 per cent sulphur. The total thickness of débris is not exposed in the open cut, but it can scarcely exceed 25 feet. The material as mined probably contains from 15 to 25 per cent of sulphur.

A second pit lies about 800 feet west of the first. It is 85 feet long, 25 feet wide, and has a maximum depth of 12 feet. The pit has not disclosed the bedrock sandstone. Sulphur incrusts fragments of sandstone along highly irregular zones, but the superficial layer of débris is barren. The third pit, 200 feet south of the second, is 80 feet long, 35 feet wide, and 30 feet deep at the inner end. Bedrock is not exposed, and sulphur occurs sporadically in the surface débris.

Travertine and similar hot springs deposits such as are found near the deposits which were operated along Shoshone River are absent in the vicinity of these deposits. It is probable that the sulphur was deposited in its present position by the decomposition of hydrogen sulphide gas through oxidation. Water may accompany this gas in its ascent along fractures and may escape at lower levels to join the waters of Sage Creek, half a mile north.

The extent of the sulphur-bearing material can only be determined by exploration, as it is covered for the most part by a thin layer of barren material, but it is very doubtful that sulphur will be found as a persistent deposit between the several open cuts.

At the refining plant the sulphur-bearing rock is drawn into perforated steel cars which are run in groups of 3 into a retort. Steam is supplied from two 16-foot boilers, and the liquid sulphur is drawn into wooden tanks, where it is allowed to solidify. The sulphur is broken, crushed to pass through a 20-mesh sieve, and sacked for shipment.

FOREIGN SULPHUR INDUSTRY.

SULPHUR OUTPUT AND EXPORTS FROM SICILY.[1]

According to the official report of the Consorzio Obbligatorio per l'Industria Solfifera Siciliana, of Palermo (Compulsory Sicilian Sulphur Combine), for the seventh working year, from August 1, 1912, to July 31, 1913, the total production of sulphur in Sicily was 351,752 metric tons, as compared with 366,457 tons in 1911–12 and with 391,908 tons in 1910–11. These figures show a gradual decrease during the last two working years, the production declining 25,451 tons in 1911–12 as compared with that of 1910–11, and 14,705 tons in 1912–13 as compared with that of 1911–12.

The failure to reach a normal production of 400,000 tons, as was anticipated, or at least the production of the working year 1910–11, which was 391,908 tons, is again attributed to the general conditions pointed out in a previous report from this consulate and to the closing in 1913 of 7 mines in addition to the 16 closed in 1912. Among the general conditions affecting the industry are the destruction by explosion of one of the more important mines which had previously produced an average of about 30,000 metric tons a year; the failure to discover new deposits of sulphur during the last decade; the continual deepening of almost all the existing mines, with consequent increased cost of mining; the working out and inundation of a number of mines; the lack of labor and its increased cost due to continuous emigration; and, finally, the law of June 30, 1910, which restricted the granting of sulphur-mining concessions. All these causes lead to the belief that the annual output of Sicilian sulphur in the future will not exceed 400,000 metric tons.

The total sales of sulphur during 1912–13, including sales for future delivery, amounted to 497,246 metric tons, compared with 603,255

[1] U. S. Consul Hernando de Soto, Palermo, Italy, Daily Cons. and Trade Repts., Feb. 5, 1914, pp. 470–471.

tons in 1911–12 and 816,818 tons in 1910–11. On July 31, 1913, there remained to be delivered on sales made 589,477 metric tons, of which 249,783 tons were booked for delivery during 1913–14 and 339,694 tons during the following years.

The total exports declined from 447,638 metric tons in 1911–12 to 434,473 tons in 1912–13, as is shown by the following table:

Exports of Sicilian sulphur.

Country.	1911–12	1912–13	Country.	1911–12	1912–13
	Metric tons.	*Metric tons.*		*Metric tons.*	*Metric. tons.*
United States	7,125	1,792	Greece	14,762	14,606
Africa	13,327	16,175	Netherlands	12,625	12,518
Australia	12,648	13,944	Norway	3,738	9,016
Austria	37,265	34,543	Portugal	14,185	14,758
Belgium	12,152	12,399	Russia	22,838	27,358
British Indies	4,928	5,342	Southern Italy	78,954	82,348
Canada	16	376	Spain	6,952	7,036
Central America and South America	7,440	7,624	Sweden	25,339	28,771
Denmark	836	305	Turkey	834	5,186
France	112,897	79,927	Other countries	9,144	7,818
Germany	28,869	35,091	Total	447,638	434,473
Great Britain and Malta	20,764	17,540			

The most striking decline was in the exports to France, which was always considered the best customer and which took 32,970 tons less in 1913 than in the preceding year. This decline, the Consorzio believes, is due to the establishment by the Union Sulphur Co. of large refineries in France. On the other hand, the exports to Germany increased by 6,222 tons, to Norway by 5,278 tons, to Russia by 4,520 tons, to Turkey by 4,352 tons, to Sweden by 3,422 tons, which in part counterbalanced the smaller purchases by France. The exports to the United States further declined from 7,125 in 1912 to 1,792 tons in 1913.

The stock on hand on July 31, 1913, amounted to 354,169 metric tons (against 444,381 tons on July 31, 1912), of which 250,548 tons were deposited in the warehouses at Porto Empedocle, 90,001 tons at Palermo, 69,611 tons at Licata, and 3,395 tons at Termini Imerese in this consular district.

In its annual review the Government monopoly (the Consorzio) calls attention to the fact that the Union Sulphur Co. has also extended its activity over other European markets by erecting large storehouses in Harburg, near Hamburg, Germany, and by purchasing lands near Rotterdam in Holland, upon which warehouses, sulphur refineries, and grinding mills are in course of construction. It is also pointed out that the Union Sulphur Co. proposes to establish its headquarters in Rotterdam for the distribution of American sulphur in Europe and that it has added two large steamers to its fleet to carry its products across the Atlantic. The review continues:

Against this rather discomforting news it is to be hoped that the steady increase in consumption of sulphur and the limited production in Sicily will permit the coexistence of the two most important sulphur producers in the world's market without prejudice to the progress of the Sicilian sulphur interests.

The decline in the exports of Sicilian sulphur should not be regarded as indicating a smaller demand for sulphur. This falling off is chiefly due to the loss, in part, of the French market, from which, however, it should not be inferred that the actual consumption is declining. In fact, Russia, Germany, and Scandinavia considerably increased their purchases.

The general apprehensions that the foreign competition is liable to seriously damage the Silician sulphur industry should be dismissed for the following reasons:

First. That the Freeport Sulphur Co., which began operations in 1911 in exploiting the sulphur deposits in Texas, failed to obtain the results it had anticipated, due chiefly to considerable technical difficulties.

Second. That Japan has not increased its exports, which is evidenced by the increasing demand for sulphur from the Pacific markets.

Third. That the rumors of large sulphur deposits on White Island, in Oceania, have not been confirmed.

Fourth. That the sulphur deposits in Spain are completely exhausted.

Fifth. That no definite information has been received announcing the alleged increase of sulphur production in Mexico.

NEW ZEALAND.

In April, 1912, work began on the deposits of sulphur on White Island, New Zealand. White Island has an area of approximately 600 acres and is located in the Bay of Plenty, on the coast of the North Island of New Zealand, about 30 miles from the mainland.

The island has somewhat the shape of a horseshoe. About 150 to 200 acres are fairly flat, a part of this flat area being occupied by a lake. This flat portion is open to the sea on one side, except for a hill near the center of the opening. The rim around the rest of its edge attains a height of 900 feet. Thus the topography indicates an old crater. Back of the lake is a boiling spring, a further indication of former volcanism. The island is situated also on one of the lines of weakness which strike transversely across North Island through the Hot Lakes district and the pumice zone. This volcanic activity extending seaward 30 miles and possibly more found a vent in what is now White Island. From the cumulative evidence given above, the sulphur is considered to be of volcanic origin.

In the flat portion of the island between the lake and the sea, both brimstone and flowers of sulphur are found. Between 6,000 and 7,000 tons of this sulphur were found in such shape as to be easily extracted. A boiling spring back of the lake is also producing sulphur, and though the exact quantity obtainable from this source is not closely determinable, estimates place it at several tons an hour. It is, moreover, of good grade, being about 94 per cent pure. Sulphur has also been found in the bottom of the lake, the drainage of which has exposed supplies of nearly pure material that were formerly unsuspected.

At the time of the last report[1] there were about 4,000 tons of raw material on the dump, which ran from 60 to 70 per cent sulphur, and 700 to 800 tons which was so pure as to need no refining.

The company operating the deposits has erected several small houses and has laid tracks to handle the mined material easily and cheaply. The refining operations are conducted in a battery of three retorts, each with a capacity of 4 tons an hour. The process is very simple. The material is wheeled from dump to retorts, and the sulphur is melted in the latter by means of superheated steam. The liquid sulphur runs out into troughs. The gypsum remaining is saved, and it is hoped it may be disposed of later at a profit.[2]

DESULPHURIZING PROCESSES.

THIOGEN PROCESS.[1]

The Thiogen process has for its object the reduction of oxides of sulphur present in the gases given off by blast furnaces, reverberatories, and roasters, to elementary sulphur in such condition that most of it may be removed from the furnace gases before they are discharged into the atmosphere. In the process of S. W. Young this reduction is accomplished by fuel oil. When sulphur dioxide (SO_2) and a hydrocarbon of the ethylene series are heated together the reaction which ensues is approximately as follows: $3SO_2 + CH_2 = 3S + 2CO_2 + 2H_2O$. According to Young[2] this reaction is slow and incomplete and the use of some intermediate reagent has been found necessary. From the chemical point of view the sulphide of any sufficiently basic metal will do, but calcium sulphide, by virtue of certain physical properties, has been found to possess advantages. The reaction between sulphur dioxide and calcium sulphide may be represented as follows: $2CaS + 3SO_2 = 2CaSO_3 + 3S$. This reaction takes place in the dry state rapidly at a temperature of 100° C., but in the presence of water it takes place at ordinary temperatures.

If the mixture of sulphite and sulphur be heated, the free sulphur distils off and the residual calcium sulphite may be reduced at a moderate red heat by hydrocarbon oil, whereby the calcium sulphide is regenerated. The reduction is difficult except in the presence of small quantities of iron compounds; but when these are present the reduction takes place rapidly at a low heat, and the full reduction value of the hydrocarbon oil is realized. The reaction involved is as follows: $2CaSO_3 + 2CH_2 = 2CaS + 2CO_2 + 2H_2O$.

In practice if a mixture of sulphur dioxide and hydrocarbon vapor pass together over a mixture of calcium sulphite and calcium sulphide, the reactions given above take place simultaneously; that is, a portion of the sulphite is attacked by hydrocarbon and reduced to sulphide, which is in turn attacked by sulphur dioxide and reconverted into sulphite, and so on. Thus, the mixture of sulphite and sulphide behaves like a contact material.

Experiments having in view the placing of the process on a commercial basis, have been carried on for several months in the plant of the Penn Mining Co., at Campo Seco, Calaveras County, Cal. Many difficulties were encountered during the early stages of the process, but these were overcome one by one. The general scheme of operation is as follows:

> The roaster gases pass first through a dust settler, which leaves them fairly clean, small amounts of dust seeming to produce no deleterious effect for a considerable time. From the dust chamber the gas is passed to the fore chamber, where a certain amount of oil is introduced; thence the gas goes to the contact chamber, where additional oil is introduced. The relative amounts introduced at these places are adjusted by the temperature conditions which establish themselves in the contact chambers, the total amount being that necessary to burn out oxygen and reduce sulphur dioxide. The contact material is made from plaster of Paris, which is mixed with water containing a small amount of iron salts, allowed to set, and then broken into lumps. The issuing gases containing free sulphur pass to a cooling and condensing apparatus, where the sulphur deposits. Up to the present time practically no attention has been paid to the matter of condensation, other matters claiming all

[1] Young, S. W., Eng. and Min. Jour., vol. 95, pp. 369–370, 1913. [2] Young, S. W., loc. cit.

the time and knowledge of the experimenters. Sulphur has, however, been condensed several times on a small scale, but in a purely incidental way. Ordinarily it has been allowed to escape directly from the contact chamber at high temperature, under which conditions it reburns to sulphur dioxide.

The chief chemical difficulties met with have had to do with the "poisoning" of the contact material. Three causes may lead to this result: (1) If an excessive quantity of flue dust enters the contact chamber the contact mass soon becomes coated with it and its activity declines rapidly. To remedy this difficulty the flue dust is reduced to a minimum, small amounts, as stated above, having but little effect. (2) High temperatures also destroy the activity of the contact material. (3) The third source of trouble lies in foreign substances. The action of these substances is not clearly understood and is to be investigated further, as opportunity offers.

The plant has been run for periods of 10 to 12 days upon the same charge of contact material without loss of activity, during which time any degree of reduction desired could be obtained. During these runs no difficulty has been encountered in producing exit gases with practically no sulphur dioxide. Though all the problems are not yet settled, it is the opinion of those in charge of the work that those remaining present no serious obstacles to the ultimate success of the process.

HALL SULPHUR PROCESS.[1]

It was reported during 1913 that the First National Copper Co. is to undertake experiments on a working scale at its smelter at Coram, Cal., on the Hall process for desulphurizing smelter gases. The Hall sulphur process, named from William A. Hall, who devised it, is essentially a "controlled oxidation" process and—

> is based on the principle of removing the fixed sulphur atom of a sulphide by distillation and without permitting any considerable portion of the sulphur thus discharged to pass into any combined forms such as sulphur dioxide or sulphur trioxide.

The sulphur in the ore is removed therefrom in the elementary condition, and when the furnace operation is properly adjusted there is substantially no discharge from the furnace of combined sulphur, either as sulphur dioxide (SO_2), sulphur trioxide (SO_3), hydrogen sulphide (H_2S), or carbon oxysulphide (COS).

Many tests and demonstrations of the process have been made in France, England, and America under the direction of several metallurgical engineers and chemists. Analyses of the gases discharged have also been made. Such analyses have been made over continuous runs of several hours, and the total amount of sulphur in any gaseous condition has been found to average under 0.25 per cent by volume without any admixture of extraneous air. A set of analyses made by A. L. Walker and C. F. Chandler on the gases issuing is as follows:

Analyses of gases discharged in Hall sulphur process.

	Percentage SO_2.
First hour	0.025
Second hour	.028
Third hour	.023

[1] Hall, Wm. A., Eng. and Min. Jour., vol. 96, pp. 35-36, 1913. Liddell, D. M., Eng. and Min. Jour., vol. 96, p. 50, 1913; also Min. and Sci. Press, p. 2, July 5, 1913.

During this time the amount of hydrogen sulphide evolved is too small to be analytically determined.

In this demonstration the rate of decomposition was equivalent to that in treating 50 tons of ore per day in an 18-foot 6-hearth McDougall furnace, when roasting said ore from 40.5 per cent sulphur to 3.5 per cent sulphur. The rate of decomposition in the Hall process when conducted in multiple-hearth furnaces appears to be from 100 to 125 pounds of ore per square foot of hearth area per 24 hours, which makes it compare favorably with the capacity obtained in the best conducted roasting furnace. The action will be even more rapid if the desulphurization is not carried down to so sweet a roast and if the operation is stopped at a point where there is from 7 to 9 per cent total sulphur remaining, sufficient for matte formation. The cinder discharged is in excellent condition, comparing favorably with the best obtained in the roasting process.

The distillation of the sulphur is accomplished by direct application to the ore of a burning gas flame of slightly reducing or non-oxidizing character, accompanied by sufficient water, either in the shape of water of formation (from the combustion of hydrogen) or of small quantities of extraneous water in the form of steam. The water, from whatever source derived, is decomposed by the hot ore, the nascent oxygen going to the metal and the nascent hydrogen combining with any free oxygen that may enter the furnace through the atomizer through which the gases are admitted. There is thus created a sort of cycle of decomposition and of formation of water.

When the burners on the furnace are properly adjusted, the discharge of hydrogen appears to be in the form of water vapor; that is, complete balances are easily maintained, whereby there is substantially neither sulphur dioxide nor hydrogen sulphide in the discharge, the tests being made on samples taken within a distance of 6 inches from the furnace.

A great variety of ores has been experimented with, including pyrite, pyrrhotite, copper concentrates, crude blende, zinc concentrates, and chemically pure sulphide of iron. The action appears to be the same in all ores, the amount of sulphur produced, of course, depending on the amount originally present. To prove that the "fixed" atom is removed by distillation, the furnace has been operated on chemically pure sulphide of iron (FeS), which contains no "free" atom of sulphur. Only yellow-sulphur vapor was obtained, there being no sulphur dioxide or hydrogen sulphide in the discharge gases. Tests made abroad to determine the completeness of the desulphurization process show less than 1 per cent of sulphur in the residual cinder.

The analyses of the cinder when sulphide of iron has been used show it to be a mixture of the iron oxides Fe_2O_3 and Fe_3O_4. The oxidation of the metal after any "feeble" sulphur atom has been removed is due to the nascent oxygen from the decomposed water, it apparently being proved that nascent oxygen has a much greater affinity for the metal that decomposed the water than it has for the sulphur.

If producer gas is used for fuel, a larger amount of extraneous water is found necessary than when a gas is used that is high in hydrogen, such as water gas, and particularly oil gas. Gasified fuel oil appears to be an ideal fuel, as it contains substantially no nitrogen and has extremely high thermal values. When high-grade fuel oil is used there is a much smaller volume of fumes to be handled in the subsequent sulphur extractions. Where a gas is used that is high in carbon monoxide, a certain amount of carbon oxysulphide is formed, as carbon monoxide has a greater affinity for sulphur at elevated temperatures, but it has been found that when carbon oxysulphide and water vapor pass to a lower temperature—for example, less than 400° C.—there is a reaction resulting in the formation of hydrogen sulphide and carbon dioxide.

The temperature maintained in the furnace must be slightly above 700° C., as that is about the distillation point of the sulphur of a metallic sulphide, and it must be maintained below 900° C., the fusing point. The latitude of 200° C. gives a considerable range of safety in the operation.

The fumes coming from the smelter are of a heavy yellow appearance with no appreciable odor other than that of hot sulphur vapor. The sulphur is extracted from these fumes by simply washing. When the fumes are agitated with water the atmosphere is almost instantly clarified, the sulphur settling to the bottom of the apparatus. Any well-known gas-washing apparatus is considered to be adapted for the purpose, and tests have already been made with a few of them. The fumes have also been run through the Cottrell electric dust collector, which completely precipitated the sulphur. The solids precipitated by washing the fumes have been analyzed, and have been found to run from 98 to 99½ per cent sulphur, the impurities being fine dust or lead or zinc sulphides. The refined sulphur has been found to be more than 99½ per cent soluble in carbon bisulphide.

So far the process has been developed chiefly with the view of its attachment to multiple-hearth roasters, but it is understood that promising experiments have been made with reference to its attachment to blast furnaces.

The cost of producing sulphur by this method in American smelting works is calculated at from $3 to $5 per ton of crude sulphur derived.

PYRITE.

PRODUCTION.

The production of pyrite in the United States in 1913 amounted to 341,338 long tons, valued at $1,286,084. As compared with the production and value of pyrite in 1912 this is a reduction of 9,590 long tons in quantity and of $48,175 in value. Though the figures of production were less in 1913 than in 1912, nevertheless the industry can not be regarded as having gone backward, for when viewed for the last four years the average production will be found to be greatly in excess of what it was in 1910 and 1911.

The following table gives the production of pyrite by States during the last three years:

Production of pyrite in the United States, 1911–1913, by States, in long tons.

State.	1911			1912			1913

[a] Includes production of natural sulphur.

IMPORTS.

The pyrite imported into the United States in 1913 amounted to 850,592 long tons, valued at $3,611,137. As compared with 1912, this is a decrease in 1913 of 120,193 long tons in quantity and of $230,546 in value. Foreign pyrite is the controlling factor in the domestic market, the domestic production being insufficient to supply the demand.

The imported pyrite comes chiefly from Spain, in which country the principal deposits occur, though part of them are located in Portugal. The Huelva deposits are the most important. They occur in the Spanish Province of Huelva and the Portuguese Province of Alemtejo, between Rio Tinto and San Domingo, in a zone about 120 miles long and from 12 to 20 miles wide. The famous San Domingo, La Zarza, and Tharsis mines lie near the middle of this zone.

The ore in the Spanish deposits is compact, finely crystalline, and often banded or stratified. The color varies from a silver white in the San Telmo ores to a rich golden in the Granada. These colors depend on the relative percentages of iron, copper, and other metals present. Vogt estimates the entire area of the Huelva pyrite deposits as half a million square meters and the total mass of the deposit, omitting depletion through erosion and mining, as one billion metric tons.

The imported Spanish ore is admirably suited for the purpose of making sulphuric acid. The ores are of the compact, massive varieties and are of high grade, rarely falling under 47 per cent sulphur and reaching as high as 51 per cent. For export the ore is broken into uniform pieces about 2½ inches in average diameter, and in this form it is sold as "furnace size" ore. Generally there is a maximum guaranty of 5 per cent "fines" or material under one-quarter inch mesh. This uniform size and weight enables the ore to be handled more easily and burned more efficiently, and its additional cost is outweighed by the fact that no breaking and rehandling are necessary at the factory. In addition to the furnace size ore, there is also quite a large quantity of lump ore imported, varying in size from that of a pea up to masses weighing 100 to 200 pounds. The lump ore is initially cheaper per ton, but before it can be burned it has to be broken by sledges to furnace size. The labor and cost involved in this operation are considerable, and a large quantity of "fines" is formed which can not be used in lump burners but must be sold for use in "fines" burners. Besides the imports of lump and furnace size ores, there is also imported a fine ore about the size of a pea for use in "fines" burners.

The ores are sold on a unit basis—that is, at a certain price for every per cent or fraction thereof of available sulphur. These prices fluctuate, depending on the demand, output, chartering of boats, etc. From the best information obtainable, the water rate from Spain to Atlantic ports is somewhat over $2 a ton, and wharfage is about 45 cents a ton exclusive of the land freight rate. Spanish pyrite is at present quoted at 13 cents per unit f. o. b. for furnace size ore. The fine ore of the same grade is usually quoted at 1 to 2 cents less per unit than the furnace size. The final cost of the furnace size is less than that of lump ore of the same grade or even of higher grade, because added to the actual cost, plus freight charges, including water, rail, wharfage, etc., is the cost of breaking the lump at the factory, which is about 50 cents a ton. For this extra expense of breaking the company selling the ore usually allows about 30 cents a ton. But in addition to this added trouble and expense there are considerable fines formed which have to be disposed of at 2 cents less per unit than they cost. There are still some factories that buy lump ore and break it to furnace size at the works.[1]

The imports of pyrite for consumption for the last five years are given in the following table:

Imports for consumption of pyrite containing not more than 3.5 per cent of copper, 1909–1913, in long tons.

Year.	Quantity.	Value.	Year.	Quantity.	Value.
1909	688,843	$2,428,580	1912	970,785	$3,841,683
1910	803,551	2,748,647	1913	850,592	3,611,137
1911	1,006,310	3,788,803			

WORLD'S PRODUCTION OF PYRITE.

In the following table is given the world's production of pyrite and the quantity of pure sulphur which it is supposed to replace in the market, estimated on the assumption that the pyrite averages 45 per cent in sulphur.

Wherever possible, the figures have been taken from the official Government publication of the country concerned. Where this was not possible the figures have been taken from the British Blue Book, known as Mines and Quarries, London. In the table below, the British Blue Book has been used for all countries with the exception

[1] From paper read by W. C. Dumas before the Georgia section of the Am. Chem. Society: Am. Fertilizer, vol. 36, No. 6, pp. 21–23. See also Beck, R., The nature of ore deposits, translated by W. H. Weed, vol. 2, pp. 483–485, 1905.

of Canada, Belgium, the German Empire, Italy, and the United States.

a Cupreous iron pyrites.
b Includes cupreous iron pyrites.
c Statistics not available.
d 1908: Composed of cupreous iron pyrites, 80,135 long tons, and sulphur ore, 24,136 long tons; 1909: Composed of cupreous iron pyrites, 194,861 long tons, and sulphur ore, 73,247 long tons; 1911: Composed of cupreous iron pyrites, 9,595 long tons, and sulphur ore, 263,274 long tons.
e Quantity not stated. Value, $54,101.
f Also 2,938,759 long tons in 1908, 2,908,715 long tons in 1909, 3,180,530 long tons in 1910, and 3,232,465 long tons in 1911, designated as "copper ore and cupreous iron pyrites.'
g 1908: Year ending March, 1908; 1909: Year ending March, 1909.
h Exported from Stratoni.
i Based on estimated 45 per cent of sulphur content.

PYRITE INDUSTRY BY STATES.

CALIFORNIA.

California ranked third among the States in the production of pyrite in 1913. The output was 70,536 long tons, valued at $218,525, an increase as compared with the preceding year, when it amounted to 61,812 long tons, valued at $201,453. California pyrite is reported from near Oakland and Leona Heights, Alameda County, and from Keswick, Shasta County. Some of the California pyrite is used by the companies producing it in the manufacture of sulphuric acid.

GEORGIA.

There was a substantial increase in the quantity of pyrite produced in Georgia in 1913, the output nearly doubling as compared with that of 1912. The pyrite mined came from Bremen, near the line between Carroll and Haralson counties, and from Villa Rica, Carroll County. M. K. Phillips operated at the former place and the Sulphur Mining & Railroad Co., the most important operator in the State, at the latter. The Franklin Pyrite & Power Co., of Creighton, Cherokee

County, reported in 1912 as doing considerable improvement work, also reported a small output for 1913.

ILLINOIS.

Illinois in 1913 ranked seventh among the States in the production of pyrite. During the two preceding years this State had ranked fourth in this industry, but the output for 1913 fell off markedly, amounting to less than half that of 1912. This is not due to any marked decrease in the number of companies producing this mineral, but to the decrease in individual production.

The pyrite is produced as a by-product in coal mining in Vermilion and Madison counties, the headquarters of the industry being at Catlin, Danville, and Oakwood, Vermilion County, and Glen Carbon, Madison County. Some of the coal mines operated only a part of the year, which accounts for part, at least, of the reduction in output.

INDIANA.

The production of pyrite in Indiana in 1913 was not so great as in 1912. As in Illinois, the pyrite is obtained as a by-product in the mining of coal, the principal headquarters of the industry being at Terre Haute, Vigo County.

MISSOURI.

The production of pyrite in Missouri in 1913 was made chiefly by the Rolla Mining Co., near Rolla, the shipping point for the ore being Cabeen, on the St. Louis & San Francisco Railroad. The material, which runs about 40 per cent sulphur on the dry basis, as mined, is used in the manufacture of sulphuric acid at East St. Louis, Ill. A small part of the Missouri production in 1913 is reported as having been obtained in coal mining. This pyrite came from Vandalia, Audrain County. No pyrite was reported from Leslie, Franklin County.

NEW YORK.

Northern New York, between the Adirondack Mountains and St. Lawrence River is a foothill country with hard granites and gneisses making up the hills, and limestones and soft schists constituting the flats and lowlands. The sedimentary rocks of this region have been highly metamorphosed and the original character of some of the outcropping masses can be told only with great difficulty, if at all. In general, the highly metamorphosed crystalline rocks strike northeast and southwest, parallel to St. Lawrence River. They dip northwest. The basement rock of the region is gneiss. Overlying this comes the Grenville series, made up of crystalline limestones, gneisses, and schists of Algonkian (?) age with which most of the mineral deposits are associated. These rocks are intruded by masses of granite which no doubt played an important rôle in the formation of the deposits. To the north and west of the pre-Cambrian deposits, and occurring also as occasional patches within the area of the older formations, are found Cambrian (Potsdam) sandstones.

One of the important mineral deposits of this region is pyrite, found in occasional places in a belt extending from near Antwerp on the southwest, through Gouverneur, De Kalb, and Hermon townships on the northeast, a distance of over 40 miles. The pyrite occurs both en masse or in segregated deposits and disseminated, giving rise by its oxidation to the familiar rusty schists and gneisses of the region. The segregations are large and are of importance, constituting the workable deposits of the region. They are variable in shape, in length, and in thickness, but in general, they conform to the structure of the inclosing rock.

During the year 1913 two pyrite mines were worked in this region. One of these was operated by the St. Lawrence Pyrites Co., at Stellaville, on a branch railroad running between Hermon and De Kalb Junction. The second mine, sometimes known as the Cole mine, from its location on the farm of J. Frank Cole, was operated by W. J. Bulger, jr. The latter mine is 4 miles northeast of Gouverneur, and is most conveniently reached from that place.

The St. Lawrence Pyrites Co., controlled by Ladenberg, Thalmann & Co., of New York, has been producing pyrites for some years, and ranks as one of the four principal companies in the United States. Its mines, better known as Stella mines, include 2 shafts on parallel deposits, 1,600 feet apart. The northwest shaft, known as the Stella, is not at present operated. At this mine, the ore body, averaging 10 feet thick, extends 1,100 feet along the strike and has been worked 900 feet down the dip of 20° to 30°; considerable pyrrhotite occurs in the ore. The Anna shaft, where present mining is in progress, is on a parallel lens about 1,000 feet in the footwall of the Stella mine; the ore averages 20 feet thick and has been followed 250 feet down at 45° dip and 1,200 feet along the strike. The walls are not sharply defined and the merchantable ore fades gradually into rusty gneiss. Following the general rule of the entire district, the deposits strike northeast and dip to the northwest.

The ore carries from 15 to 40 per cent sulphur, with an average of about 21 per cent. Practically all the mine output is concentrated; though a rather low-grade ore, it is free from arsenic and injurious impurities. The ore is put through a jaw crusher at the shaft house, from which it falls into bins and is loaded into railroad cars. The cars convey it to the mill, situated near the Stella shaft on a small creek. At the mill it is put through a gyratory crusher, trommels, and 3 sets of rolls, and is concentrated in two 25-foot Hancock jigs; the tails from the Hancock jigs are treated in Harz jigs, and the fines are concentrated on 10 Wilfley tables and 1 Deister table, the latter treating the slimes. During the winter the concentrates are dried to prevent freezing in a Ruggles-Coles cylindrical drier. This consists of a nearly horizontal cylinder with another cylinder inside, the concentrates being passed between the two. The hot gases enter the inner cylinder at the end, where the concentrates are wettest, and return between the cylinders, where they come in actual contact with the material. The mill was designed for 500 tons capacity per 24 hours, which is sometimes exceeded, and reduces the mine's output about one-half in weight, sending out concentrates running about 44 per cent in sulphur. The product is sold to sulphuric-acid manufacturers and to some extent to paper mills in the East; on account of the proximity of St. Lawrence River (about 20 miles by rail), some of the material is transferred to boats at Ogdensburg and shipped up the Lakes. Trouble has been encountered from protests of residents because of pollution of the creek by mill tailings; to obviate this, a circular concrete settling tank has been constructed near the mill and housed in, the plan being to use the same water over again with only small additions from the creek. * * *

The Cole mine, near Gouverneur, is a small mine, partly an open cut; only a depth of about 60 feet has been reached. The ore is shipped crude, the shipments averaging 30 per cent sulphur. One of the former lessees operated a small mill, later torn down by the St. Lawrence Pyrites Co., which held the lease at one time. The mine has recently been pumped out, after several years of idleness, by the Hinckley Fiber Co., which uses the output in its paper mill at Hinckley, N. Y., for making sulphurous acid to be used in a sulphite pulp process. The ore appears to lie in two parallel bodies separated by 15 feet of siliceous rock; the lower ore body was first worked as an open pit, and later through an inclined shaft. The upper ore body has been worked a little through a raise from the lower stope. The dip appears to be to the northwest and the strike northeast.[1]

OHIO.

The production of pyrite in Ohio in 1913 was less than in 1912. Pyrite in Ohio is obtained as a by-product in coal mining and is often referred to by the miners as sulphur. The by-product pyrite in Ohio mines comes from Stark, Jefferson, and Tuscarawas counties, and at least 10 communities are headquarters of the industry.

VIRGINIA.

Though the production of pyrite in Virginia was less in 1913 than in 1912, the State still ranked first in the production of this mineral. The pyrite came from the Cabin Branch Mining Co., Dumfries, Prince William County., from the Arminius Chemical Co., and the Sulphur Mining & Railroad Co., near Mineral, Louisa County, and from the Pulaski Mining Co., Monarat, Carroll County.

The holdings of the United States Fidelity & Guaranty Co., near Mineral, Louisa County, were stated in this report for 1912 to have been sold to a new corporation organized in the spring of 1913 under the laws of Virginia and known as the Boyd-Smith Mines (Inc.). Development work was done at this mine during the year.

At the Gossan Mine of the Pulaski Mining Co., located at Monarat, Carroll County, in southwestern Virginia, the ore mined is pyrrhotite. This is shipped to the Pulaski works of the General Chemical Co., where it is crushed and roasted and used in the manufacture of sulphuric acid. The residue is nodulized and smelted for iron in a neighboring blast furnace.

WISCONSIN.

The production of pyrite (marcasite) in southwestern Wisconsin and northwestern Illinois is given in this report as from the State first mentioned, both for the reason that nearly all the production comes from Wisconsin and for the additional reason that it is impossible to differentiate the production of the two States. This latter condition is due to the fact that low-grade blende containing marcasite and originating in both States is shipped to separating plants in both Wisconsin and Illinois, after which it is impossible to correctly credit the original State quotas. Part of this pyrite is obtained in connection with the zinc ores mined in the southwestern part of Wisconsin in what is usually known as the Wisconsin or Upper Mississippi Valley zinc district, which includes also Illinois and Iowa.

This pyrite (marcasite) comes chiefly from the Linden, Platteville, Cuba City, and Benton districts, in Wisconsin, but a small quantity comes also from the Galena district of Illinois. The zinc sulphide and the iron sulphide from both States are separated by the Linden Zinc Co. at Linden, the Empire Roaster at Platteville, the National Zinc Separating Co. at Cuba City, the Wisconsin Separating Co. at Benton, in Wisconsin, and by the Joplin Separating Co. at Galena, in Illinois.

The greater part of the marcasite credited to Wisconsin is, however, not obtained by any process of separation, but is sold as mined. This marcasite is produced at the Wilkinson mine, operated by the Vinegar Hill Zinc Co., in the Benton district, Wisconsin.

The production from this district greatly increased in 1913 as compared with 1912, the increase amounting to more than 40 per cent.

Much of the pyrite from this region is high grade and averages 45 per cent sulphur.

UTILIZATION OF PYRITE RESIDUES.

In 1913, 3,538,980 short tons of sulphuric acid of 50° Baumé, valued at $22,366,482, were made in the United States. Of this production, 790,296 short tons, valued at $4,346,272, represents by-product acid, that is, acid made in connection with copper and zinc smelting. The difference, amounting to 2,748,684 tons, valued at $18,020,210, represents acid made from both domestic and imported pyrite. This acid is used in various ways, such as in the manufacture of superphosphates and explosives, in the refining of crude oil, and in making a host of chemical substances enumerated on a subsequent page.

Practically all the last-mentioned quantity of acid is made from pyrite, marcasite, or pyrrhotite, the different sulphides of iron, which are roasted in various types of roasting furnaces, the product, sulphur dioxide, being subsequently oxidized and treated with water vapor or steam to form the final product.

Pyrite contains 53.4 per cent sulphur and 46.6 per cent iron. Pyrrhotite, the other important iron sulphide and the mineral used at Pulaski, Va., contains usually from 38.4 to 39.6 per cent sulphur and from 60.4 to 61.6 per cent iron. Though the commercial pyrite now placed on the market does not contain the theoretical percentages of sulphur and iron given above, the figures approach near enough to the theoretical to make them of very practical interest. The average in sulphur content of the pyrite shipped from the Virginia pyrite mines ranges from 43 to 45 per cent. The following analyses show the general character of the Louisa County (Va.) pyrite; the fourth analysis being that of pyrrhotite from the southwestern part of the same State:

Composition of Virginia pyrite and pyrrhotite.

	1	2	3	4
Sulphur (S)	48.02	50.00	49.27	34.06
Iron (Fe)	42.01	43.00	43.62	53.15
Iron oxide (Fe_2O_3)	1.93			
Silica (SiO_2)	7.60			2.99
Insoluble		6.02	4.23	
Sulphur trioxide (SO_3)	.44			
Copper (Cu)	None.			[a].866
Arsenic (As)	None.			
Zinc (Zn)			.38	
Lime (CaO)			1.32	
Magnesia (MgO)			1.32	
Manganese				.306

[a] Copper.

The residual material, after the sulphur is removed by burning, as will be observed from the analyses given above and from the domestic production of pyrite plus the imports, is large in quantity and for the most part constitutes the equivalent of a good grade of iron ore. Most of the calcined residue contains approximately 2 per cent of sulphur, and some contains enough copper to make its removal profitable either by leaching or by other means. The material which is sometimes called "blue billy" resembles a reddish-brown iron ore, and except for its comparatively high sulphur content, its occasional copper content, and its finely divided condition, would pass for an ordinary red iron ore.

The problem, before utilizing the iron residues in the furnace, is to get rid of the comparatively large amount of sulphur which remains in the "blue billy" after as much sulphur as possible has been burned away as sulphur dioxide in the manufacture of the acid. This sulphur content is ordinarily much too high to permit the direct use of the residue in the manufacture of pig iron. The claim that many acid plants burn pyrite until the sulphur amounts to only 0.5 to 1 per cent is scarcely ever realized in practice and the pyrite cinder on the market contains, as a rule, 2 per cent or more of sulphur. "Blue billy" is therefore regarded as an undesirable iron ore and consequently brings a low price. Still another objection is the finely divided condition in which it comes from the acid factory, making it especially unsatisfactory where heavy blasts are used. This objection does not obtain where lump pyrite is used in the manufacture of acid, but here again such pyrite is apt to contain a larger content of sulphur than the fines.

During recent years several attempts or installations have been reported using one process or another for desulphurizing these residues and smelting them for iron. With the eventual depletion of our iron ore reserves (although far removed), it seems quite probable that this tendency will increase and that in time pyrite cinder will not be wasted, as has been so long the case, but will constitute an important source of iron. A few of these installations have been described in this chapter in previous years.

At the mines of the Pulaski Mining Co. in southwestern Virginia the procedure which obtained a few years ago, and which is presumably still in use, is as follows: The pyrrhotite is dead roasted; sulphuric acid is made, and the resulting cinder is used as part of the charge in an iron blast furnace. The ore is mined from open cuts; it is crushed and then conveyed to Herreshoff roasters. The cinder from these roasters is then clinkered in a 100-foot rotary cement kiln into which powdered coal is blown at the end opposite the feed. The pyrite cinder when fed to the kiln contains from 4 to 7 per cent sulphur; after going through the clinking process the sulphur content is reduced to 0.05 per cent. The cinder is sold to the Pulaski Iron Co., whose furnace is only a short distance away.

At the plant of the Pyrites Co. (Ltd.), which is engaged in the manufacture of sulphuric acid from Rio Tinto pyrite, there has just been put into operation a 150-ton Dwight-Lloyd sintering machine for sintering the cinder. About 8 per cent of coke dust is mixed with the cinder; the cost of the operation is considerably less than in nodulizing in kilns, the sulphur being reduced from 2 to 0.04 per cent. There is a tendency at present to use copper-bearing steel for rails for railway service, and if the use of steel containing copper should increase it is not at all improbable that the burning of copper-bearing pyrite for the manufacture of sulphuric acid, nodulizing the residue, and smelting in the blast furnace to yield a copper-bearing pig iron will become an important phase of future practice.[1]

SULPHURIC-ACID INDUSTRY IN THE UNITED STATES.

INTRODUCTORY NOTE.

The year 1913 is the third for which statistics of sulphuric acid have been collected by the United States Geological Survey. As stated in the report for 1911, the first year during which such statistics were published, one of the reasons for adding the subject of sulphuric acid to the chapter on sulphur and pyrite is because it is a commodity so extensively used in the manufacture of other chemicals that it has come to be regarded as a criterion or gage of the activity of the country in chemical manufactures in general. Another reason of recent importance since the beginning of the manufacture of by-product acid in the copper and zinc smelting industry is that through sulphuric acid is offered the only means of expressing the value of the sulphur in those sulphides now used in making by-product acid—that sulphur which formerly went to waste in the air in the form of sulphur dioxide and sulphur trioxide.

GENERAL USES.

Sulphuric acid is probably used in a greater variety of ways in the chemical arts than is any other substance. According to Lunge[1] the principal applications of the acid are as follows:

1. *In a more or less dilute state (say from 144° Twad. downward).*—For making sulphate of soda (salt cake) and hydrochloric acid, and therefore ultimately for soda ash, bleaching powder, soap, glass, and innumerable other products. Further, for superphosphates and other artificial manures. These two applications probably consume nine-tenths of all the sulphuric acid produced. Further applications are for preparing sulphurous, nitric, phosphoric, hydrofluoric, boric, carbonic, chromic, oxalic, tartaric, citric, acetic, and stearic acids; in preparing phosphorus, iodine, bromine, the sulphates of potassium, ammonium, barium (blanc fixe), calcium (pearl-hardening); especially also for precipitating baryta or lime as sulphates for chemical processes; sulphates of magnesium, aluminum, iron, zinc, copper, mercury (as intermediate stage for calomel and corrosive sublimate); in the metallurgy of copper, cobalt, nickel, platinum, silver; for cleaning (pickling) sheet iron to be tinned or galvanized; for cleaning copper, silver, etc.; for manufacturing potassium bichromate; for working galvanic cells, such as are used in telegraphy, in electroplating, etc.; for manufacturing ordinary ether and the composite ethers; for making or purifying many organic coloring matters, especially in the oxidizing mixture of potassium bichromate and sulphuric acid; for parchment paper; for purifying many mineral oils, and sometimes coal gas; for manufacturing starch, sirup, and sugar; for the saccharification of corn; for neutralizing the alkaline reaction of fermenting liquors, such as molasses; for effervescent drinks; for preparing tallow previously to melting it; for recovering the fatty acids from soapsuds; for destroying vegetable fibers in mixed fabrics; generally, in dyeing, calico printing, tanning, as a chemical reagent in innumerable cases; in medicine against lead poisoning, and in many other cases.
2. *In a concentrated state.*—For manufacturing the fatty acids by distillation; purifying colza oil; for purifying benzene, petroleum, paraffin oil, and other mineral oils; for drying air, especially for laboratory purposes, but also for drying gases for manufacturing processes (for this, weaker acid also, of 140° Twad., can be used); for the production of ice by the rapid evaporation of water in a vacuum; for refining gold and silver, desilvering copper, etc.; for making organo-sulphonic acids; manufacturing indigo; preparing many nitro compounds and nitric ethers, especially in manufacturing nitroglycerin, pyroxylin, nitrobenzene, picric acid, and so forth.
3. *As Nordhausen fuming oil of vitriol (anhydride).*—For manufacturing certain organo-sulphonic acids (in the manufacture of alizarin, eosin, indigo, etc.); for purifying ozokerite; for making shoe blacking; for bringing ordinary concentrated acid up to the highest strength as required in the manufacture of pyroxylin; and for other purposes.

---

[1] Manufacture of sulphuric acid and alkali, vol. 1, pt. 2, pp. 1169–1170, ed. 1903.

The most important of the classes of manufacture enumerated above, so far as the consumption of the acid is involved, are in (1) the manufacture of fertilizer; (2) the refining of petroleum products; (3) the iron, steel and coke industries; (4) the manufacture of nitrocellulose, nitroglycerin, celluloid, etc.; and (5) in general metallurgical and chemical practice.

PRODUCTION.

The statistics of sulphuric acid have previously been collected at each census, beginning with the census of 1870; and at the censuses of 1889, 1899, and 1904, the quantity and value of each of the important grades were ascertained. The statistics of production in the tables which follow for the years prior to 1911 have been taken from the census reports for 1899 and 1904.[1]

In the production reported to the Survey for 1911, 1912, and 1913 all sulphuric acid is given regardless of whether it was sold as such or consumed in the factories where it was made. It is well known that nearly all the sulphuric acid made at fertilizer works is there consumed in the manufacture of superphosphates, that in factories where explosives are manufactured the sulphuric acid is combined with nitric acid and is used in making nitroglycerin and guncotton, and that, finally, in petroleum refineries much of the acid is consumed in refining the crude oil. In the earlier census reports the sulphuric acid consumed in establishments where manufactured and that produced by establishments engaged primarily in the manufacture of other products was listed separately, which is not done in the Survey's figures for 1911, 1912 and 1913, except in the case of the sulphuric acid manufactured at smelters as a by-product.

Sulphuric acid is produced in several grades: (1) 50° Baumé acid, also known as chamber acid, containing an average of 50.76 per cent SO_3, or 62.18 per cent H_2SO_4; (2) 60° Baumé acid, containing an average of 63.41 per cent SO_3, or 77.67 per cent H_2SO_4; (3) 66° Baumé acid, known as oil of vitriol, containing approximately 76 per cent SO_3, or approximately 93.19 per cent H_2SO_4. Higher strengths of acid usually contain SO_3 dissolved in sulphuric acid; for example, pyrosulphuric acid and fuming or Nordhausen acid. Oleum is a grade which contains 30 to 60 per cent of free SO_3, or a total of 87 to 92 per cent of free and combined SO_3. It is essentially a solution of SO_3 dissolved in sulphuric acid.[2]

The production of sulphuric acid published by the Survey represents bona fide returns from producers, and the figures in the following tables are not estimates. For this reason the figures may be either equal to or less than the actual production. It is obvious that they can not exceed it so long as the returns are correct.

In the following table the quantity, value, and price per ton are given of the three main grades of acid, and also similar data for other strengths of acid combined. With the exception of the quantity of acid indicated in the footnote the output is also expressed in terms of 50° Baumé acid for the sake of comparison.

Total	2,339,593	18,338,019	7.84	3,013,509	22,684,526	7.53
Total reduced to 50° Baumé acid	[f] 2,876,000	[f] 17,572,837	6.11	[g] 3,538,980	[g] 22,366,482	6.32

[a] Includes 764,355 tons, with an assigned value of $7,032,066, consumed in establishments where manufactured; and also sulphuric acid produced by establishments engaged primarily in the manufacture of other products.
[b] Reported as oleum by the census.
[c] Includes 968,445 tons, with an assigned value of $7,232,675, consumed in establishments where manufactured; and also sulphuric acid produced by establishments engaged primarily in the manufacture of other products.
[d] Includes 1,271,535 tons, with an assigned value of $6,694,436 consumed in establishments where manufactured; and also sulphuric acid produced by establishments engaged primarily in the manufacture of other products.
[e] Exclusive of acids of strength greater than 66° Baumé.
[f] Exclusive of electrolyte and acids of strength greater than 66° Baumé.
[g] Exclusive of 22,947 short tons of fuming acid, not convertible, valued at $318,044.

NOTES ON SULPHURIC ACID FIGURES.

The pyrite imported for consumption during the calendar year 1913 (which must not be confused with the total imports for that year), amounted to 850,592 long tons, according to the Bureau of Foreign and Domestic Commerce. If to this figure of imports the domestic production of pyrite given in a preceding table, namely, 341,338 long tons, be added there results a total available for 1913 of 1,191,930 long tons of pyrite. On the basis of an average content in this pyrite of 45 per cent available sulphur and on the basis of a yield of 50° acid amounting to 4.7 times the available sulphur, there would result from the total pyrite indicated above 2,520,934 long tons, corresponding to 2,823,446 short tons, of acid from pyrite alone. In the tables already given the total output of 50° acid produced in 1913 is given as 3,538,980 short tons. Of this total, the quantity of by-product acid manufactured in connection with copper and zinc smelting operations amounted to 790,296 short tons. The difference, namely, 2,748,684 short tons, represents the actual quantity of acid made, based on actual returns from the producers themselves. The latter figures appear to indicate that not all of the pyrite produced and imported was consumed, for it will be observed that the calculated and the actual results differ by 74,762 tons, or approximately 2 per cent, based on the total acid production. If the acid excluded from the grand total, as indicated in the footnote to the first table, be added to the production, the small discrepancy would be correspondingly reduced.

There are certain factors in the situation which are not indicated in these calculations. In the first place, the total quantity of imported pyrite reported by the producers as used in the manufacture of sulphuric acid in 1913 was not the imports as furnished by the Bureau of Foreign and Domestic Commerce, but a very much larger quantity, including what is reported to the Survey by acid makers as foreign copper-bearing pyrite. Also the quantity of domestic pyrite reported as used in the manufacture of acid is not nearly so great, apparently, as the output of pyrite represented in the table giving the domestic production of this mineral. Another complicating factor in the sulphuric acid calculation is the fact that an important quantity of sulphur (nearly all domestic), which in 1913 amounted to more than 16,000 long tons, is used in making acid. It may be added in this place that the sulphuric acid figures of the Survey for previous years have always included the acid that has been made from sulphur. The remaining sulphide ore that is utilized in the manufacture of sulphuric acid is made up of domestic copper-bearing pyrite and domestic gold and silver bearing pyrite not used in the preparation of by-product acid and which presumably, either entirely or for the most part, is reported to the Survey as pyrite. The total quantity of such copper, gold, and silver bearing pyrite when added to the pyrite reported as being utilized in the manufacture of acid does not bring the total up to the total pyrite figures reported independently to the Survey. If the sum of these different items reported directly to the Survey by the sulphuric acid manufacturers are taken, and the factors indicated above are used, the production of acid calculated should be theoretically the same as that actually reported. Such calculation has been made by the writer and was found to differ by about 1 per cent from the actual returns, a difference considered to be within the limit of error.

Theoretically, as indicated, the production of domestic pyrite added to the imports should furnish a base on which to calculate the quantity of acid made in a given year. This collective figure should afford an index of the acid industry based on it. There are, however, certain elements of uncertainty involved in such calculations. For example, in addition to the points already enumerated, it is more than probable that a certain part of the stock of one year may hold over and be used the next year. During a period of several years, however, this element of uncertainty would be practically negligible, its importance diminishing inversely as the length of time. Another variable factor is the percentage of sulphur that is actually burned, which depends not alone on the original quantity of sulphur present, but also on the physical condition of the ore, the type of furnace used, the efficiency of manipulation, and perhaps on other conditions. It is obvious, therefore, from the large number of uncertain factors involved that estimates or calculations, though very interesting, have only a limited value. The Survey has therefore published in the past only actual returns from producers and since the work on sulphuric acid was inaugurated three years ago it has endeavored to get into closer touch with all the producers of this commodity. It is believed that during 1913, this has been practically accomplished and that the figures for that year are very close to the truth. The cordial spirit of cooperation evinced by the producers in the past has been highly appreciated and this opportunity is taken to acknowledge it.

PRODUCTION OF SULPHURIC ACID FROM SMELTER GASES.

In the following table is given the quantity of sulphuric acid recovered from the gases from smelters throughout the United States. By comparison with the preceding table it will be observed that this is approximately 22 per cent of the total sulphuric acid produced in the United States[1] during the year 1913. The figures given in the table, however, do not include acid manufactured from copper-bearing Spanish pyrite.

Production of sulphuric acid from copper and zinc smelters in 1911, 1912, and 1913, in short tons.[a]

[Reduced to 60° Baumé acid.

MINERAL PAINTS.

By James M. Hill.

INTRODUCTION.

As in the reports of the last few years, the mineral paints treated in this chapter are divided into three groups—(1) natural mineral pigments, (2) pigments made directly from ores, and (3) chemically manufactured pigments. Of the three classes the first two are included in the Survey's annual summary of the mineral production of the United States, as they are thought to represent values of crude material taken directly from the earth or material which at most has passed through simple or merely preliminary treatment. The chemically prepared pigments are not included in that statement of production because the quantity and value of the original minerals included in most of these pigments have been reported elsewhere, so that the publication of the statistics of the manufactured products would result in duplication.

Group 1, or natural mineral pigments, comprises ocher, umber, sienna, hematite, siderite, limonite, and ground slate and shale. The principal bases of metallic paints and mortar colors are the three ores of iron—hematite, siderite, and limonite. Many other minerals or mineral products are used in the paint trade, such as asbestos and products derived from it, aluminum, asphalt, barytes, clay, graphite, gypsum, magnesite, mica, pyrite, quicksilver, shells, silica, talc, and tripoli, and many by-products; but these are not considered here, since most of them are reported elsewhere in Mineral Resources, and for some of them statistics are not available.

Group 2, pigments made directly from ores, comprises zinc oxide, leaded zinc oxide, sublimed white lead, and sublimed blue lead. The last two are also known to the trade as basic sulphates of lead.

Group 3, the chemically manufactured pigments, comprises the chemical products—basic carbonate white lead, litharge, red lead, orange mineral, lithopone, and Venetian red.

The total quantity and value of pigments sold during 1913 and considered in this report were less than in 1912. There was a slight increase in the production of the natural mineral pigments, but in both the other classes there was a marked decrease in output. The output of the pigments made directly from ores fell off 8.4 per cent and the production of pigments made chemically decreased about 3.7 per cent.

The following table shows the total marketed production of the three groups of pigments for the last two years:

Quantity and value of mineral paints sold in 1912 and 1913, in short tons.

	1912		1913	
	Quantity.	Value.	Quantity.	Value.
Natural mineral pigments	74,657	$561,693	75,595	$522,410
Pigments made directly from ores	106,497	9,507,895	97,573	9,020,896
Chemically manufactured pigments	228,135	26,356,232	219,644	25,123,167
Total	409,289	36,425,820	392,812	34,666,473

Since the publication of the 1912 report there have been no new publications giving the results of the paint tests which are being carried on in various parts of the country. The last published reports are contained in Bulletins 34, 35, and 36 of the Scientific Section of the Paint Manufacturers' Association of the United States.

NATURAL MINERAL PIGMENTS.

MARKETED PRODUCTION.

The marketed production of the natural mineral pigments in the United States in 1913, as reported to the Survey, amounted to 75,595 short tons, valued at $522,410. Compared with 1912 this was an increase of 938 short tons, or slightly more than 1 per cent. The value of these pigments in 1913 decreased $39,283, or nearly 7 per cent. There was an increased output of ocher, metallic paint, and ground slate and shale. The production of umber and sienna decreased by 29 short tons. The greatest decrease was in the output of mortar colors. This is in part accounted for by the fact that some material heretofore classed as mortar colors is now included with the output of metallic paint. The output of slate and shale in 1913 showed a gain of 822 short tons over that of 1912; ocher gained 2,309 short tons; metallic paint 1,751 short tons; but mortar colors decreased by 3,915 short tons. The table given below shows the prices per ton at the point of production of the different mineral paints. The market price of all the pigments, except ocher, shows a slight decrease from the average prices received in 1912. The marked decrease in the price of metallic paint from $6.40 a ton in 1912 to $5.69 in 1913 and of mortar colors from $9.45 in 1912 to $6.62 in 1913 is partly due to the fact that the price paid for crude iron ore extensively used in the manufacture of these products was low, being not greatly in excess of the prices paid for iron ore used in the manufacture of pig iron.

Average price per short ton of natural mineral pigments, 1910–1913.

	1910	1911	1912	1913
Ocher	$9.60	$9.35	$9.78	$9.90
Umber and sienna	26.31	26.09	27.30	26.79
Metallic paint [a]	6.28	7.08	6.40	5.69
Mortar color	10.82	9.66	9.45	6.62
Slate and shale	5.81	6.39	5.79	5.55

[a] Includes crude iron ore sold for paint, which accounts in part for the low value per ton.

The following table gives the marketed production and value of the natural pigments during the last four years:

Marketed production of natural mineral pigments, 1910-1913, in short tons.

Pigment.	1910		1911		1912		1913	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
Ocher	11,711	$112,445	11,703	$109,465	15,269	$149,289	17,578	$173,944
Umber } Sienna }	1,015	26,700	1,005	26,225	805	21,975	776	20,790
Metallic paint	29,422	184,869	25,599	181,163	28,347	181,352	30,098	171,264
Mortar colors	9,960	107,780	7,922	76,517	9,272	87,595	5,357	35,443
Slate and shale, ground	16,515	96,001	16,510	105,451	20,964	121,482	21,786	120,969
Total	68,623	527,795	62,739	498,821	74,657	561,693	75,595	522,410

This table represents approximately the output of natural mineral pigments; the figures are the best obtainable under present conditions. With increasing appreciation of the value of impartial Government statistics it is hoped that the cooperation of all of the producers of these products with the Survey will eventually be complete.

The natural pigments are used for the most part by the manufacturers of linoleum and ready-mixed paints; some, of course, reach the market in dry ground form. The market for natural paint materials is, therefore, limited, and is believed to a certain extent to be dominated by a group of large producers whose plants are so situated that they practically cover the United States. The margin of profit in mining, preparing, and marketing the natural mineral pigments is not great, and it seems that a large and efficient organization is necessary in most cases to make a success of the business. There are probably hundreds if not thousands of deposits of the natural mineral pigments which have not been worked and which probably never will pay to work until there is a marked increase in the demand for the products.

OCHER.

MARKETED PRODUCTION.

The quantity of ocher sold in 1913 was 17,578 short tons, valued at $173,944, compared with 15,269 short tons, valued at $149,289, in 1912, an increase of 2,309 short tons in quantity and of $24,655 in value. The average price per ton in 1912 was $9.78 and in 1913 it was $9.90, an increase of 12 cents a ton.

The following table gives the quantity of ocher sold by States from 1910 to 1913, inclusive:

Marketed production of ocher, 1910-1913, by States, in short tons.

State.	1910		1911		1912		1913	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
California	118	$1,730	(a)	(a)	(a)	(a)	(a)	(a)
Georgia	7,011	70,388	7,395	$69,447	10,107	$101,790	11,420	$123,090

Other States [b]	331	2,138	1,295	11,917	1,331	12,203	2,223	18,679
Total	11,711	112,445	11,703	109,465	15,269	149,289	17,578	173,944

[a] Included in "Other States."

[b] Includes, 1910: Iowa, Kentucky, Oregon, and Tennessee; 1911: California, Iowa, Vermont, and Virginia; 1912: California, Iowa, and Virginia; 1913: Alabama, California, Iowa, Vermont, and Virginia.

IMPORTS.

In the following table are given the imports of ocher for the last five years:

Imports of ocher, 1909–1913, in pounds.

Year.	Crude.		Dry.		Ground in oil or water.		Total.	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
1909	340,593	$3,501	13,337,310	$106,224	17,847	$939	13,695,750	$110,664
1910	181,176	2,055	11,849,921	129,308	10,213	483	12,041,310	131,846
1911	128,328	1,870	11,090,798	108,205	15,406	857	11,234,532	110,932
1912	160,117	1,884	15,863,678	145,699	14,069	723	16,037,864	148,306
1913	[a] 321,671	3,282	[a] 12,126,238	104,212	[a] 13,068	770	16,697,098	143,720

[a] Figures for Jan. 1 to Oct. 3, inclusive, 1913; since Oct. 4, under the new tariff, the figures for crude, dry, and ground in oil or water are given together by the Bureau of Foreign and Domestic Commerce. Total figures are correct for the year.

The imports of crude and dry ocher and ocher ground in oil or water amounted in all to 16,697,098 pounds, or approximately 8,349 tons, in 1913. The imports of crude and dry ocher for the first three quarters of the year amounted to 6,224 tons, valued at $107,494. This was about 35 per cent of the domestic production reported, which is supposed to be in these two forms. The value of the imported crude and dry ocher was less than that of the domestic output by $66,450.

NOTES ON OCHER.

Ocher is a hydrated ferric oxide permeating a clay base. It has a specific gravity of about 3.5 and a decidedly golden-yellow color. As viewed under the microscope and with a considerable enlargement the particles composing ocher appear flocculent and uniform. Good grades should contain 20 per cent or more of iron oxide, though there is a wide variation in the iron content of the material sold as ocher. Ferruginous shale is often ground and the product marketed as ocher, but unless the material is actually an ocher, as defined above, such product is classed under slate and shale in this chapter.

In 1913 ocher was produced in Georgia, Pennsylvania, Virginia, Alabama, California, Iowa, and Vermont, the States being named in the order of their producing importance. The Georgia output, practically all of which came from the vicinity of Cartersville, Bartow County, was 65 per cent of the total production of the United States. Mines located in Berks, Northampton, and Lehigh counties, Pa., produced a little over 22 per cent of the ocher mined in the country. In Virginia the production was as usual from Page and Pulaski counties. Alabama reentered the class of ocher producers, a new mine being opened in Clarke County. The ocher mines of Stanislaus and Calaveras counties, Cal., were worked to a limited extent, and it seems possible, according to trade reports, that the deposits near Michigan Bar, Sacramento County, may be reopened.

Ocherous clays and true ocher are not unusual in most parts of the country. The Survey is constantly in receipt of samples of yellow material, some of which would undoubtedly make good paints, but many of which are certainly not salable for use as pigments. During the year promising deposits have been newly opened in Utah, California, and Wisconsin, and several samples have been received from new workings in the old Virginia field.

OCHER IN CANADA.

According to a recent report issued by the department of mines[1] of Canada, the ochers are commercially mined in the Provinces of Quebec and Ontario, and deposits are found in many parts of Canada. The chief producing localities in the Province of Quebec are near Three Rivers and in Nicolet County. In Ontario the deposits of the Algoma district and those in Nassagaweya Township and Halton County are the most important; the deposits of Colchester County also have been worked to a small extent.

UMBER AND SIENNA.

MARKETED PRODUCTION.

The total quantity of umber and sienna sold in the United States in 1913 as reported to the Survey was 776 short tons, valued at $20,790, a decrease of 29 tons in quantity and of $1,185 in value, as compared with the production of 1912. The average price of umber and sienna per ton in 1913 was $26.79, as compared with $27.30 in 1912 and with $26.09 in 1911.

In the following table is given the marketed production of umber and sienna in the United States for the period 1909–1913:

Marketed production of umber and sienna, 1909–1913, in short tons.

Year.	Quantity.	Value.
1909	1,276	$33,472
1910	1,015	26,700
1911	1,005	26,225
1912	805	21,975
1913	776	20,790

IMPORTS.

In the following table are given the imports of umber and sienna for the last five years:

Imports for consumption of umber, 1909–1913, in pounds.

Year.	Dry.		Ground in oil or water.		Total.	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
1909	3,104,037	$26,125	4,953	$256	3,108,990	$26,381
1910	3,994,286	28,819	11,813	734	4,006,099	29,553

[a] Figures for Jan. 1 to Oct. 3, inclusive; since Oct. 4, under the new tariff, the figures for dry and ground in oil or water are given together by the Bureau of Foreign and Domestic Commerce. Total figures are correct for the year.

[1] Economic minerals and mining industry of Canada: Canada Dept. Mines, Mines Branch, Ottawa, pp. 49–50, 1913.

Imports for consumption of sienna, 1909–1913, in pounds.

Year.	Dry.		Ground in oil or water.		Total.	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
1909	2,402,901	$32,913	6,114	$421	2,409,015	$33,334
1910	3,048,203	46,866	6,233	453	3,054,436	47,319
1911	2,845,938	36,296	14,039	923	2,859,977	37,219
1912	3,056,064	45,354	6,021	440	3,062,085	45,794
1913	[a] 2,367,963	34,793	[a] 2,502	92	3,273,217	48,535

[a] Figures for Jan. 1 to Oct. 3, inclusive; since Oct. 4, under the new tariff, the figures for dry and ground in oil or water are given together by the Bureau of Foreign and Domestic Commerce. Total figures are correct for the year.

The imports to October 3, 1913, as given in the tables are expressed in pounds. The quantity of dry umber imported in 1913 amounted to a little less than 2,268 short tons, considerably more than the domestic production of umber and sienna combined. The imports of dry sienna amounted to 1,184 short tons, making the total for both products 3,452 short tons, or 2,676 tons in excess of the domestic output. The value of the imported dry ground umber and sienna in 1913 was $66,269, or more than three times as much as that of the domestic production reported for the year.

NOTES ON UMBER AND SIENNA.

Umber consists of iron and aluminum silicates, containing varying quantities of manganese oxide, which influence its color accordingly. The raw variety is drab, but becomes reddish brown on burning. A marked percentage of large-sized particles is present in this pigment. The calcined material is referred to as burnt umber. The only State reporting a production of this pigment to the Survey in 1913 was Pennsylvania.

Sienna is composed essentially of silicates of iron and aluminum with less manganese oxide than umber and is of a lighter color. Large particles are present in the raw sienna, but burnt sienna is fine grained. According to some authorities, sienna and umber owe their color to the manganese oxide. Sienna and umber are used principally as pigments in the manufacture of ready-mixed paints and linoleum. Sienna was produced in Pennsylvania and California in 1913.

Umber has been mined at three localities in Pennsylvania, namely, Quaker Hill, Northampton County; Doylestown, Bucks County; and Bethel, Berks County. This limitation is strange in view of the fact that most of the Pennsylvania ochers carry manganese oxide. Apparently in most of the deposits the quantity of this oxide is too small to give the material the necessary color. The Pennsylvania umbers are always closely associated with deposits of ocher, and the origin, method of mining, and preparation of the material for market are similar to those of the yellow pigment.

It would seem that the United States could produce all the sienna needed for consumption, but the foreign pigments have always been considered superior to the domestic in color. The Survey has within the last year received a number of samples of exceptionally good siennas from deposits in Colusa County, Cal., Cherokee County, Ala., and Campbell County, Va.

A possible source of these pigments was suggested by the examination of certain oxidized gold ores obtained from Blaine County, Idaho. These ores are manganese-bearing limonitic material carrying free gold. After crushing and the removal of the gold by amalgamation, the tailings, if milled and settled, could be utilized for pigments. The samples obtained when roasted produce a good sienna brown equal to any of the standards, either foreign or domestic, in the Survey collection.

PRODUCTION IN PRINCIPAL COUNTRIES.

The following table gives the output of ocher and umber in certain of the principal producing countries from 1908 to 1912, inclusive, as far as statistics are available:

Production of ocher and umber in principal producing countries, 1908–1912, in short tons.

Year.	United States.		United Kingdom.		France.		German Empire (Bavaria and Saxony).

[c] Figures not available.
[d] Production of Bavaria only figures for Saxony not yet available.
[e] Umber exports.

METALLIC PAINT.

MARKETED PRODUCTION.

The marketed production of metallic paint reported to the Survey in 1913 was 30,098 short tons, valued at $171,264, as compared with 28,347 short tons, valued at $181,352 in 1912. The effort is being made to put the production as nearly as possible on the basis of the material entering into metallic paint and to credit it to the individual State in which it was originally mined and first placed on the market. The production of metallic paints is reported from some States mainly in terms of the dry ground product, the average price per ton of which is considerably greater than of the crude ore produced in the same States and sold as such to the paint mills. The maximum price, that of ground paint in Pennsylvania, was $12.77, which shows that a large part of the production averages considerably below that figure, such portion being material that comes on the market originally in the form of unground iron ore. The price of the crude ore sold in that condition apparently varies between $1.16 and $2.88 a ton. The higher average value for metallic paint is probably to be explained by the fact that the large producers operate théir own mines and the material is marketed by them in the ground form.

The following table gives the marketed production of metallic paint from 1910 to 1913, inclusive:

Marketed production of metallic paint, 1910–1913, by States, in short tons.

State.	1910		1911		1912		1913	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.

a Maryland is included in Tennessee.
b Included in "Other States."
c Principally crude iron ore sold for paint.
d Includes, 1910: California, Georgia, Michigan, Missouri, Washingtom; 1911: Georgia, Michigan, Missouri, Virginia, Washington; 1912: Michigan, Missouri, Tennessee, Virginia, Washington; 1913: California, Georgia, Maryland, Michigan, Tennessee, Virginia, Washington.

NOTES ON METALLIC PAINT.

Metallic paint consists chiefly of red and brown iron oxides, produced either by grinding natural iron oxides, anhydrous or hydrated, or by roasting natural iron carbonate. The beds of Clinton hematite in New York, Tennessee, and Georgia, the red hematite of the Lake Superior region in northern Michigan, and the gray siderite found near Lehigh Gap, Pa., are the chief sources of the raw-ore supply. Several secondary materials are used to an important extent in the manufacture of metallic paint. Blast-furnace dust, a grayish-brown mixture of oxide of iron and coke that is collected at many furnaces, particularly in the Pittsburgh, Pa., district, yields on grinding a seal-brown powder. In the manufacture of sulphuric acid from pyrite large quantities of "blue billy," a purplish oxide of iron, is produced that is sometimes ground to form a pigment which, unless carefully prepared, is said to be unsatisfactory for structural iron paints, as it may contain free sulphur or sulphuric acid. In 1913 1,425 short tons of metallic paint from pyrite cinder were produced, which sold for $21,608, or $15.16 a ton. This product has not been included under natural pigments. Another by-product that has been utilized as a metallic paint is the residue left after extracting aluminum salts from bauxite. This residue, resembling a ferruginous clay and containing in the neighborhood of 54.25 per cent ferric oxide (Fe_2O_3), produces a brick-red material when roasted in a rotary kiln. This pigment is apt to retain appreciable quantities of soluble aluminum salts, which can hardly be considered as desirable ingredients in paints. Ferrous sulphate or copperas is roasted with lime or gypsum and sold as metallic paint. Differences in the conditions surrounding the roasting produce different shades of iron oxide, called by various names. as Indian red and purple oxide.

The metallic paints as considered here are, therefore, both browns and reds. Commercially the browns are known as metallic brown and certain of the reds as Indian red. All the paints made from by-product substances can not strictly be classed in group 1, but as a rule the production of these materials is not reported to the Survey.

Metallic paints, both natural and artificial, if of good grade, are practically inert to the ordinary atmospheric agencies. They are extensively used for painting structural ironwork and by railroads for box-car colors.

MORTAR COLORS.

MARKETED PRODUCTION.

The marketed production of mortar colors reported to the Survey in 1913 was 5,357 short tons, valued at $35,443, a decrease of 3,915 tons in quantity and of $52,152 in value as compared with 1912. This apparent great decrease in the output and value of mortar colors in 1913 is partly explained by the fact that heretofore a large amount of the iron-oxide ores have been reported as ground for mortar colors. Since the Survey is striving to give accurate statistics, it was thought best, upon the discovery of this condition, to include such iron oxide with the metallic paint figures rather than under mortar colors. It was found to be impossible to revise the figures of production for previous years, but it is hoped that in the future the producers of this class of material will aid the Survey in its endeavors to express correctly the output of the various natural mineral paint materials.

It is questionable whether figures for mortar colors should be included as a separate item of production, since a large part of the material sold under that name should probably be included with metallic paint or ground slate and shale. The material is used for tinting mortar, cement, and concrete, and the colors are usually of the various shades of red, brown, purple, blue, and black. The average price per ton for mortar colors was $6.62 in 1913, as compared with $9.45 in 1912. The material entered the market first in the dry ground condition, for which the prices are given.

In the following table is given the production of mortar colors from 1910 to 1913, inclusive:

Marketed production of mortar colors, 1910–1913, by States, in short tons.

State.	1910		1911		1912		1913	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
New York	5,200	$50,000	2,518	$24,723	3,309	$29,969	5,357	$35,443

[a] Includes—1910: Maryland, Ohio, and Tennessee; 1911, 1912, and 1913: Maryland and Tennessee.

SLATE AND SHALE.

MARKETED PRODUCTION.

The quantity of slate and shale ground for paints and fillers in 1913 was 21,786 short tons, valued at $120,969, an increase of 822 short tons in quantity, but a decrease of $513 in value, as compared with 1912. The average price of the material in 1911 was $6.39 a ton; in 1912 it was $5.79; and it was further reduced to $5.55 in 1913.

The following table gives the production of slate and shale ground for pigment during the last five years:

Quantity and value of slate and shale, ground for pigment, 1909-1913, in short tons.

Year.	Quantity.	Value.
1909	14,944	$98,176
1910	16,515	96,001
1911	16,510	105,451
1912	20,964	121,482
1913	21,786	120,969

NOTES ON SLATE AND SHALE.

Slate and shale for use in pigments and as fillers in the manufacture of oilcloth and linoleum were produced in 1913 in Pennsylvania, New York, New Jersey, Indiana, and Georgia, named in the order of their producing importance.

Pennsylvania in 1913 produced over 93 per cent of the paint slate and shale output of the United States. In this State the shales used in the paint trade may be divided into three classes—black, yellow, and red shales. Black shales, sold under the name "mineral black," are widely distributed throughout the State. In many places the material has been dug for use in paint. The refuse about slate quarries and the culm from anthracite coal mines have also been shipped to paint factories. Black shale is used to some extent in paint for buildings, but chiefly in the manufacture of a black filler for ironwork. Yellow shales occur in many places throughout the State. In a number of places these shales, after grinding, have been utilized in the manufacture of paint. Their principal use, however, is in the manufacture of oilcloth and linoleum. They are considerably lighter in color than the ochers and contain a much lower percentage of hydrous iron oxide, though they are usually called ochers. Red shales in many places in the State have been employed in the manufacture of paint.

A company has recently been formed to grind the black shales occurring near Brigham City, Utah, which were supposed to contain graphite. The samples sent to the Survey do not contain appreciable amounts of graphite, but are in reality carbonaceous shales.

WHITING.

Whiting was produced in Kentucky and Missouri in 1913. As only two companies producing ground whiting reported to the Survey, the statistics of production can not be given. It is doubtful if whiting should be included in the production of mineral paints, for it seems probable that only a small part of the output is actually used as a pigment.

Whiting is prepared by grinding various forms of white limestone and calcite. Some whiting, prepared artificially, is finer grained and a little lighter in weight than the natural whiting. It is used largely in the manufacture of putty, in distemper work, and in small quantities in ready-mixed paints.

A deposit of calcite from which whiting is made, occurring on the south side of Kentucky River about 8 miles from the town of Harrodsburg, Ky., appears to be in the form of a vein varying from 3 to 9 feet in width. Some samples of good-grade, fine-grained calcareous material suitable for the manufacture of whiting were received by the Survey from Uvalde County, Tex., and from Salt Lake County, Utah.

A company recently formed is marketing a very fine-grained rhyolitic tuff found in large deposits in Los Angeles County, Cal. It is said to make a good calcimine and to be suitable in the manufacture of rubber and as a filler for light-colored linoleums.

PIGMENTS MADE DIRECTLY FROM ORES.

PIGMENTS AND ORES.

The pigments here discussed are zinc oxide, leaded zinc oxide, sublimed white lead or "basic lead sulphate," and sublimed blue lead or "blue fume."

The white pigments having zinc for a base, either wholly or in part, are zinc oxide and leaded zinc oxide. No zinc lead has been produced in this country for a number of years. In the United States these pigments are usually made directly from the franklinite ores of New Jersey and the zinc and lead ores of the Mississippi Valley and of certain of the Western States.

In the upper Mississippi Valley lead and zinc region the zinc carbonate ore, smithsonite, locally known as "drybone," has been used almost altogether for pigment manufacture by the Mineral Point Zinc Co., but the sulphide ores of lead and zinc have also been used. In the Joplin region the mixed silicate and carbonate ores of zinc have been used for zinc-pigment manufacture. Zinc carbonate ore from New Mexico and southern Nevada and mixed sulphide ores of lead and zinc from these and various other Western States have also been extensively used in making zinc and zinc-lead pigments. Zinc carbonate ores imported from Mexico have also been used in the manufacture of zinc pigments. During 1913 zinc oxide and leaded zinc made directly from ores were reported from Pennsylvania, Wisconsin, Virginia, and Kansas.

The pigments containing lead known under the copyrighted name of "sublimed white and blue lead," or as basic lead sulphate and blue fume, are produced by the direct sublimation of lead ores largely derived from the Mississippi Valley deposits.

MARKETED PRODUCTION.

In order to conceal individual returns, the statistics of production of zinc oxide, leaded zinc, and of white lead and blue lead produced by sublimation have to be combined as in the last two years. The total quantity of material marketed amounted to 97,573 short tons, valued at $9,020,896. As compared with the production of 1912 this was a decrease of 8,924 tons, or about 8 per cent, in quantity and of $466,999, or about 5 per cent, in value.

The following table gives the production and value of pigments made directly from ores during the last four years:

Marketed production of pigments made directly from ores, 1910–1913, in short tons.

Pigment.	1910		1911		1912		1913	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
Sublimed blue lead ("blue fume"); Sublimed white lead ("basic lead sulphate"); Leaded zinc oxide	16,681	$1,613,859	80,611	$7,343,762	106,497	$9,507,895	97,573	$9,020,896
Zinc oxide	58,481	5,238,945						
Total	75,162	6,852,804	80,611	7,343,762	106,497	9,507,895	97,573	9,020,896

IMPORTS OF ZINC OXIDE.

The following table gives the imports of zinc oxide into the United States during the last five years:

Imports for consumption of zinc oxide, 1909–1913, in pounds.

Year.	Dry.		In oil.		Total.	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
1909	6,119,328	$342,999	535,024	$54,085	6,654,352	$397,084
1910	6,137,362	365,701	393,248	30,874	6,530,610	396,573
1911	5,012,308	316,972	548,708	40,494	5,561,016	357,466
1912	5,350,515	342,985	524,542	43,168	5,875,057	386,153
1913	6,580,944	410,493	284,150	23,663	6,865,094	434,156

ZINC OXIDE.

Zinc oxide is the most important of the zinc pigments. It is a white powder consisting, when chemically pure, of 80.34 per cent zinc and 19.66 per cent oxygen. When examined under the microscope, the fineness and structure of the particles composing this pigment are clearly evident. On account of its stability, whiteness, opaque nature, and slight tendency to chalk, it is invaluable as a pigment for use as a constituent in a combination formula. Its extreme hardness renders it less resistant to temperature changes when used alone. Zinc oxide is manufactured by two processes, one known as the American and the other as the French process.

The ores from which zinc oxide is made are the franklinite ore of New Jersey, the sulphide ores of the Mississippi Valley, and the sulphide, carbonate, and silicate ores of Colorado, New Mexico, and Nevada. The plants which produced zinc oxide in 1913 were the New Jersey Zinc Co. of Pennsylvania, with plants located at Palmerton and Freemansburg, Pa.; the Mineral Point Zinc Co., located at Mineral Point, Wis.; and the Bertha Mineral Co., located at Austinville, Va. The Ozark Smelting & Mining Co. produced no zinc oxide at its Coffeyville plant, and its Joplin plant is being dismantled. The

Western Zinc Mining & Reduction Co. is building a 50-ton Wetherill plant at Leadville, Colo., to treat zinc carbonate ores. This plant will operate in 1914 and its capacity may be increased to 250 tons daily.

LEADED ZINC OXIDE.

Leaded zinc oxides are pigments consisting of zinc oxide and lead sulphate. They are made with definite percentages of lead sulphate, usually ranging from 6 to 20 per cent, according to the purpose for which they are to be used. These oxides are produced from western zinc ores that carry a certain proportion of lead sulphide. In fineness they are similar to zinc oxide but are not quite so white. Leaded zinc pigment is manufactured at the Coffeyville plant of the Ozark Smelting & Mining Co., and by the Mineral Point Zinc Co., Mineral Point, Wis.

No zinc-lead pigment was produced in the United States during 1913, according to reports received by the Survey.

SUBLIMED WHITE LEAD AND SUBLIMED BLUE LEAD.

Sublimed white lead or "basic lead sulphate" is made directly from the lead sulphide ore, galena. It is manufactured from ore produced in the Joplin, Mo., district or from any other soft (non-argentiferous) lead ore. Cleaned galena ore ground to a powder and charged with carbon into a furnace is volatilized, and in the presence of air the lead sulphide is oxidized to a basic lead sulphate, while some free sulphur dioxide is formed. This product is cooled by being drawn by suction through a long series of pipes, goosenecks, and settling chambers, and then is collected in bag houses. This material finds use not only in mixed paints, but in the manufacture of putty and rubber. The basic lead sulphate is thought to be composed of two molecules of lead sulphate ($PbSO_4$) linked to one of lead oxide (PbO). It contains approximately[1] 77 per cent of lead sulphate, 17 per cent of lead oxide, and 6 per cent of zinc oxide. Notable properties of this pigment are its great fineness, the uniform size of its particles, and its relative chemical stability. It has a snow-white color and is very opaque, but since it is extremely fine and of amorphous texture it requires blending with coarser pigments to give it "tooth."

In the sublimation of galena a peculiar bluish-gray compound of lead is formed, which is known commercially as sublimed blue lead or "blue fume." Analyses have shown the presence in it of about 2 per cent carbon, 4.5 to 5 per cent lead sulphide, 1 to 2.5 per cent zinc oxide, 0.36 to 1.44 per cent lead sulphite, 50 to 53 per cent lead sulphate, and 37.5 to 41.3 per cent lead oxide. It is used in the same industries as the white lead produced by sublimation.

Two firms manufacture these products in the United States. The Picher Lead Co., of Joplin, Mo., was for years the sole producer and registered the trade-mark "sublimed white lead." The St. Louis Smelting & Refining Co., whose plant is located at Collinsville, Ill., produces a similar pigment sold under the name "basic lead sulphate."

CHEMICALLY MANUFACTURED PIGMENTS.

MARKETED PRODUCTION.

The chemically manufactured pigments treated in this report include basic carbonate white lead, both dry and in oil, red lead, litharge, and orange mineral among the lead pigments, and lithopone and Venetian red. The last two pigments contain no lead, but are chemically precipitated pigments, the process of whose manufacture will be given later.

The marketed production of chemically manufactured pigments in 1913 amounted to 219,644 short tons, valued at $25,123,167. This is a decrease from the production in 1912 of 8,491 tons in quantity and of $1,233,065 in value.

The following table shows the marketed production and value of chemically prepared pigments during the last four years:

Marketed production of chemically manufactured pigments, 1910–1913, in short tons.

BASIC CARBONATE WHITE LEAD.

Basic carbonate of lead has a specific gravity of 6.8 and contains about 85 per cent lead oxide and 15 per cent of carbon dioxide and water. Variously sized particles are present. Its opaque nature and excellent body render white lead extremely valuable as a pigment. Its life and wearing properties are considered by many paint manufacturers to be increased when mixed with zinc oxide and other pigments. Checking and chalking progress rapidly when the pigment is used alone.

The marketed production of basic carbonate (corroded) white lead in 1913, as reported to the Survey, was 142,626 short tons, valued at $18,112,219. Of this total, 118,430 short tons, valued at $15,603,431, were reported sold in oil, and 24,196 short tons, valued at $2,508,788, were reported sold dry. The sales for 1913 represented a net decrease from those for 1912 of 4,207 short tons in quantity and of $571,242 in value.

The average price per ton of basic carbonate white lead ground in oil was $131.75 in 1913, as compared with $133.02 in 1912, a decrease of $1.27 per ton; and the average price per ton of dry white lead was $103.69 in 1913, as compared with $100.69 in 1912, an increase of $3 per ton.

This pigment is manufactured by 4 firms in Pennsylvania, by 3 firms in Illinois, by 2 firms each in California and New York, and by 1 firm in each of the following States: Michigan, Missouri, Nebraska, New Jersey, and Ohio. The 2 New York plants produce more than all of the remaining manufacturers of basic carbonate white lead.

Basic carbonate white lead is made by one of the following three processes:

Dutch process.—Clay pots containing dilute acetic acid and lead cast in buckles are stacked in tiers and covered with tanbark. By the interaction of fermenting bark and acid, carbon dioxide gas is produced, which reacts with the lead to form the basic carbonate. The buckles not always entirely corroded are cleaned in revolving drums and the white carbonate is ground, floated, dried, and packed for shipment. This process requires several days for completion.

Quick process.—By the action of acetic acid and carbon dioxide on atomized metallic lead contained in revolving drums, the basic carbonate is produced in a few hours.

Mild process.—This process is claimed by some to produce the most pure pigment. Air is passed through water containing finely powdered lead, forming a basic hydroxide of lead. Carbon dioxide gas is then run into this solution and the basic carbonate lead is produced.

RED LEAD.

The marketed production of red lead in 1913 was 17,635 short tons, valued at $2,127,976, a decrease of 3,485 short tons in quantity and of $443,726 in value from the output of 1912. The average price per ton decreased from $121.77 in 1912 to $120.67 in 1913, a decrease of $1.10. Red lead is produced by heating litharge in reverberatory furnaces. The particles of this pigment vary much in size. It has proved a good inhibitive paint and is used alone and in combination with other pigments as a protective coating for iron and steel. Red lead was made in 1913 at 4 plants in Pennsylvania, at 2 plants each in Missouri and New York, and at 1 plant each in California, Michigan, New Jersey, and Ohio.

LITHARGE.

The marketed production of litharge in 1913 as reported to the Survey was 23,093 short tons, valued at $2,524,707, as compared with 29,111 short tons, valued at $3,194,194 in 1912, a decrease in quantity of 6,018 tons and in value of $669,487. The average price per ton was $110.09 in 1911, but this decreased to $109.72 per ton in 1912 and was further reduced to $109.33 per ton in 1913.

Litharge, or lead monoxide, a buff-colored powder, is made directly by rapid oxidation of lead or indirectly in the metallurgy of silver, and also from acetate of lead. It is used in paints, in glazes, in storage batteries, and in fire-assaying for gold and silver. It is produced at 2 plants in New York and Missouri, at 5 plants in Pennsylvania, and by 1 manufacturer in California, Massachusetts, Michigan, New Jersey, and Ohio.

ORANGE MINERAL.

The marketed production of orange mineral as reported to the Survey was 434 short tons, valued at $71,625 in 1913, as compared with 545 short tons, valued at $88,245 in 1912. The apparent average price per ton was $165.03 in 1913, as compared with $161.92 in 1912. The output given above does not include all orange mineral manufactured, as some producers combined their returns for orange mineral and red lead.

Orange mineral, one of the higher oxides of lead, is prepared by calcining a more or less basic carbonate of lead. It is valued according to the depth and color of its bright orange shade. It is made at 4 plants in Pennsylvania, at 2 plants in New York, and at 1 plant each in California, Michigan, Missouri, and Ohio.

LITHOPONE.

The marketed production of lithopone in 1913 was reported as 29,685 short tons, valued at $2,170,445, as compared with 24,220 short tons valued at $1,702,119, in 1912, an increase in quantity of 5,465 tons and in value of $468,326. The average price of lithopone in 1912 was erroneously printed as $72.28 a ton, whereas the correct figure is $70.28. The average price per ton in 1913 was $73.12, an increase of $2.84.

Lithopone, a very white pigment, is precipitated by mixing solutions of zinc sulphate and barium sulphide, thereby forming an intimate mixture of zinc sulphide and barium sulphate. It contains approximately 70 per cent barium sulphate, from 25 to 29 per cent zinc sulphide, and from 1 to 5 per cent of zinc oxide. It has a characteristic flocculent, noncrystalline appearance when examined under the microscope. The peculiar property which it possesses, of darkening under the actinic rays of the sun, makes it essential that it be combined with other more stable pigments to prolong its life when exposed to weather. It is excellently suited for interior decoration and is used in the manufacture of enamels and flat wall finishes. One company in the United States is marketing a lithopone which it guarantees to be absolutely sun-proof. In 1913, lithopone was made at 3 plants in New Jersey, at 2 plants in Pennsylvania, and at 1 in Delaware.

VENETIAN RED.

The marketed production of Venetian red in 1913, as reported to the Survey, was 6,171 short tons, valued at $116,195, compared with 6,306 short tons, valued at $116,511 in 1912, a decrease in quantity of 135 tons and in value of $316. The apparent average price per ton was $18.83 in 1913, as compared with $18.48 in 1912.

Venetian red is made in different ways, such as by grinding red iron oxide with gypsum, or by roasting ferrous sulphate with lime and grinding the residue—in either case the red is a mixture of iron oxide and calcium sulphate, or by grinding red iron oxide with calcium carbonate, or by calcining pyrite and ferrous sulphate with terra alba, and in sundry other ways. It is sometimes marketed as metallic paint.

PAINT TESTS.

In this report in previous years brief notices and descriptions have been given of the paint tests of the scientific section of the Paint Manufacturers' Association of the United States, of the work of the Institute of Industrial Research, and of the publications regarding the tests in the Proceedings of the American Society for Testing Materials. The most recent publication known to the writer on the result of these tests is contained in volume 13 of the proceedings of the society just referred to and in bulletins 34, 35, and 36 of the scientific section of the Paint Manufacturers' Association of the United States, which are cited in the bibliography at the end of this chapter Since the publication of this report for 1912, neither of these societies have issued any additional data relative to the tests.

LEGISLATION AFFECTING THE MINERAL PAINT INDUSTRY.

On October 3, 1913, the Underwood tariff bill (H. R. 3321) was passed. Certain sections of Schedule A of interest to the producers of metallic paints are given below:

51. Baryta, sulphate of, or barytes, including barytes earth, unmanufactured, 15 per centum ad valorem; manufactured, 20 per centum ad valorem; blanc-fixe, or artificial sulphate of barytes, and satin white, or artificial sulphate of lime, 20 per centum ad valorem.

52. Blues, such as Berlin, Prussian, Chinese, and all others, containing ferrocyanide of iron, in pulp, dry, or ground in or mixed with oil or water, 20 per centum ad valorem; ultramarine blue, whether dry, in pulp, or ground in or mixed with oil or water, and wash blue containing ultramarine, 15 per centum ad valorem.

53. Black pigments, made from bone, ivory, or vegetable substance, by whatever name known; gas black and lampblack, dry or ground in or mixed with oil or water 15 per centum ad valorem.

54. Chrome yellow, chrome green, and all other chromium colors in the manufacture of which lead and bichromate of potash or soda are used, in pulp, dry, or ground in or mixed with oil or water, 20 per centum ad valorem.

55. Ocher and ochery earths, sienna and sienna earths, and umber and umber earths, 5 per centum ad valorem; Spanish brown, venetian red, Indian red, and

colcothar or oxide of iron, not specially provided for in this section, 10 per centum ad valorem.

56. Lead pigments: Litharge, orange mineral, red lead, white lead, and all pigments containing lead, dry or in pulp, and ground or mixed with oil or water, not specially provided for in this section, 25 per centum ad valorem.

58. Varnishes, including so-called gold size or japan, 10 per centum ad valorem: *Provided*, That spirit varnishes containing less than 10 per centum of methyl alcohol of the total alcohol contained therein, shall be dutiable at $1.32 per gallon and 15 per centum ad valorem.

59. Vermilion reds, containing quicksilver, dry or ground in oil or water, 15 per centum ad valorem; when not containing quicksilver but made of lead or containing lead, 25 per centum ad valorem.

60. Whiting and Paris white, dry, and chalk, ground or bolted, $\frac{1}{10}$ cent per pound; whiting and Paris white, ground in oil, or putty, 15 per centum ad valorem.

61. Zinc, oxide of, and pigments containing zinc but not containing more than 5 per centum of lead, ground dry, 10 per centum ad valorem; when ground in or mixed with oil or water, lithopone and white sulphide of zinc, 15 per centum ad valorem.

62. Zinc, chloride of and sulphate of, $\frac{1}{2}$ cent per pound.

63. Enamel paints, and all paints, colors, pigments, stains, crayons, including charcoal crayons or fusains, smalts, and frostings, and all ceramic and glass fluxes, glazes, enamels, and colors, whether crude, dry, mixed, or ground with water or oil or with solutions other than oil, not specially provided for in this section, 15 per centum ad valorem; all paints, colors, and pigments commonly known as artists' paints or colors, whether in tubes, pans, cakes, or other forms, 20 per centum ad valorem; all color lakes, whether dry or in pulp, not specially provided for in this section, 20 per centum ad valorem.

152. Lead-bearing ores of all kinds containing more than 3 per cent of lead, $\frac{3}{4}$ cent per pound on the lead contained therein: *Provided*, That on all importations of lead-bearing ores the duties shall be estimated at the port of entry and a bond given in double the amount of such estimated duties for the transportation of the ores by common carriers bonded for the transportation of appraised or unappraised merchandise to properly equipped sampling or smelting establishments, whether designated as bonded warehouses or otherwise. On the arrival of the ores at such establishments they shall be sampled according to commercial methods under the supervision of Government officers, who shall be stationed at such establishments, and who shall submit the samples thus obtained to a Government assayer, designated by the Secretary of the Treasury, who shall make a proper assay of the sample and report the result to the proper customs officers, and the import entries shall be liquidated thereon, except in case of ores that shall be removed to a bonded warehouse to be refined for exportation as provided by law. And the Secretary of the Treasury is authorized to make all necessary regulations to enforce the provisions of this paragraph.

153. Lead dross, lead bullion or base bullion, lead in pigs and bars, lead in any form not specially provided for in this section, old refuse lead run into blocks and bars, and old scrap lead fit only to be remanufactured; lead in sheets, pipe, shot, glaziers' lead, and lead wire; all the foregoing, 25 per cent ad valorem on the lead contained therein.

162. Zinc-bearing ores of all kinds, including calamine, 10 per cent ad valorem upon the zinc contained therein: *Provided*, That on all importations of zinc-bearing ores the duties shall be estimated at the port of entry and a bond given in double the amount of such estimated duties for the transportation of the ores by common carriers bonded for the transportation of appraised or unappraised merchandise to properly equipped sampling or smelting establishments, whether designated as bonded warehouses or otherwise. On the arrival of the ores at such establishments they shall be sampled according to commercial methods under the supervision of Government officers, who shall be stationed at such establishments, and who shall submit the samples thus obtained to a Government assayer, designated by the Secretary of the Treasury, who shall make a proper assay of the sample and report the result to the proper custom officers, and the import entries shall be liquidated thereon, except in case of ores that shall be removed to a bonded warehouse to be refined for exportation, as provided by law. And the Secretary of the Treasury is authorized to make all necessary regulations to enforce the provisions of this paragraph.

163. Zinc in blocks, pigs, or sheets, and zinc dust; and old and worn-out zinc fit only to be remanufactured, 15 per cent ad valorem.

It is rather early to estimate what effect, if any, the new tariff will have upon the industry. It is certain, however, that during the last year, while a number of economic questions troubled the country, there has been a hesitation in the activities of many industries. As is shown by this report, the output of practically every paint fell off in 1913, and as a rule the prices were lower than in 1912. A marked exception to this statement may be seen in the output of lithopone. Its greater production is possibly to be explained by the growing use of the pigment as a base for flat wall finishes, which are daily becoming more popular.

Possibly the hesitancy of the railroads of the country to invest in new equipment or do much toward rehabilitating old equipment during the last year, while they have been somewhat uncertain as to their relations to the public, had some influence on the output of all classes of mineral paints, as they are among the largest consumers of these products.

A number of States have passed, or are considering, laws to regulate the sale of adulterated paints. The opinion seems to be generally held that laws to regulate branding of paints are more desirable than those to enforce the printing of the formula of the material on a container. Laws embodying the former doctrine are in force in Ohio and Massachusetts. The question of employers' liability has been raised against the paint manufacturers, particularly the makers of white lead. Many companies which produce this pigment have voluntarily provided hospitals, free medical attention, and pensions for their employees, and thus have shown that the policy of supervision has a correct foundation.

In France a law prohibiting the use of white lead in the preparation of paints is to go into effect on January 1, 1915. Just what effect this law will have upon the industry in the United States is not clear, yet it may prove to be of benefit for a time in that the foreign-made zinc oxides and lithopones will find a market nearer home, as a result of which the foreign competition may not be so strong for a time as it has been in the past in the various pigments which might be used instead of white lead.

SLATE.

By A. T. Coons.

PRODUCTION.

GENERAL CONDITIONS OF THE INDUSTRY.

CHANGES IN OUTPUT AND VALUE.

An increase of $132,158, or 2.19 per cent, marked the slate production of the United States in 1913 as compared with 1912. The output in 1913 was valued at $6,175,476 and in 1912 at $6,043,318. In 1912 there was an increase of $315,299, or 5.50 per cent, over the output of 1911, which was valued at $5,728,019.

The increase in value of the slate output in 1913 as compared with 1912 did not represent any unusual activity in the slate trade; it was caused by an advance in the average price both of roofing slate (with decrease in quantity sold) and of mill stock, although this latter class of slate increased also both in quantity and in value of output. Since 1879, when the statistics of slate production were first collected, the industry has shown only very gradual progress, fluctuating but slightly with changes in trade and financial conditions. In fact, as compared with 1904, 10 years ago, when the slate output was valued at $5,617,195, the output in 1913 shows an increase in value of only $558,281, or less than 10 per cent. The average price per square of roofing slate has fluctuated but little in these 10 years; it was $3.78 in 1904 and $4 in 1913, the latter being the highest average price per square ever reported.

As stated in previous reports, the statistics of the production of slate represent the output as reported by the quarrymen, and include the quantity and value of roofing slate and of mill stock sold by them and the value of a quantity of slate sold for other purposes. The values given for both mill stock and roofing slate represent prices f. o. b. at the point of shipment, and the mill stock being classed as rough or manufactured, according to the condition in which it is sold by the quarrymen, whether as rough blocks to slate mills or in a finished or partly finished condition from mills at the quarries.

In 1912 the slate operators in general reported a better demand and better conditions of trade in the latter part of the year; for 1913 the reports show that the slate trade was much more active from January to September than in the latter part of the year. All the States except New York and Virginia showed an increase in average price per square with decrease in output, but the increase in average price per square in such a large slate-producing district as Northampton County, Pa., was a large factor in the increase for the entire country. The roofing-slate production decreased in quantity but increased in average price per square from $3.87 in 1912 to $4 in 1913. The quantity of mill stock, exclusive of the blackboard and school-slate output, increased both in quantity and in value, with proportionate increase in price per square foot. The output of slate used for blackboards, school slates, and minor purposes increased both in quantity and in value in 1913 as compared with 1912.

All the States except Maryland, Vermont, and Virginia increased in total value of output of slate, the largest increase, 14.62 per cent, being in Maine. New York was the only State that showed increase in quantity of roofing slate produced, and the only increase in value of roofing slate was in New York and Pennsylvania. The production of mill stock in Pennsylvania, including blackboards and school slates, increased, as did that of mill stock alone in Maine and Vermont.

In 1913 eight States contributed to the commercial output of slate in the United States. These States, in order of output, were Pennsylvania, Vermont, Maine, Virginia, New York, Maryland, New Jersey, and Georgia. In 1912 the rank was the same—except that in 1913 Georgia took the place of Arkansas. Of more than 280 firms owning slate deposits, 171 companies were active in 1913. In 1912 175 firms reported as active. The other firms reported their quarries as idle, as in course of development, or as abandoned.

CLASSIFICATION OF SLATE.

Mill stock.—For general purposes slate is classified as mill stock and roofing slate, and the use for these different purposes depends largely although not entirely on the character of the slate. Mill stock requires a finer, more even-grained, and more compact slate than roofing slate, with a smooth cleavage surface. It must be of a fairly uniform color and not too hard to be easily worked by the slate-dressing machinery. The slates of Maine and Vermont and the "soft vein" slates of Lehigh and Northampton counties, Pa., are well adapted for this purpose, and these slates are also among the best of the roofing slates. The Arkansas slate has been used for both electrical and roofing purposes, and the Maryland and New York quarries also furnish a small quantity of mill stock. Much of the slate that goes on the dump from a roofing-slate quarry might be utilized as mill stock.

The value of mill stock, including slate sold for all purposes other than roofing, increased from $1,407,133 in 1912 to $1,714,414 in 1913, a gain of $307,281. Exclusive of blackboard and school slates, the mill stock increased from 5,765,273 square feet, valued at $1,013,220, in 1912, to 6,312,011 square feet, valued at $1,233,838, in 1913, an increase of 546,738 square feet in quantity and of $220,618 in value. The average price per square foot was $0.195 in 1913 and $0.176 in 1912. The greater part of the slate was either entirely milled by the producer or sold partly finished to other mills.

Mill stock includes slate used for blackboards, school slates, flooring, wainscoting, vats, tiles, sinks, laundry tubs, grave vaults, sanitary ware, refrigerator shelves, flour bins and dough troughs for bakeries, electrical switchboards, mantels, hearths, well caps, and billiard, laboratory, kitchen, and other table tops. This material is made in the form of slabs from 1 inch to 3 inches or more thick, and is sold at prices ranging from 4 cents to 50 cents per square foot, according to the size, thickness, and quality of the slate and to the work done on it. It is sold in rough slabs by the quarrymen to the slate mills, or is milled by quarrymen operating their own mills.

Lehigh and Northampton counties, Pa., report the only stock produced for school slates and blackboards. The quarries in these counties can best produce this material on account of the unusually fine cleavage of the slate and the thickness and size of the beds. The quantity and value of the slate produced for these uses increased in 1913.

Roofing slate.—Slate used for roofing is not necessarily of so fine a texture nor with so smooth a cleavage as the mill stock, but it must be hard, strong, and tough, and should not contain carbonates or iron pyrites, which decompose or oxidize under atmospheric conditions. The color should be uniform and free from streaks, and although the slate amy fade somewhat upon exposure, it is not therefore undesirable unless it weathers mottled, owing to irregular distribution of the coloring matter, and thus produces an unsightly roof. A description of the process of dressing roofing slates was given in the report for 1911.

Roofing slate is sold in the United States by the "square," a "square" being a sufficient number of pieces of slate of any size to cover 100 square feet of roof, with allowance generally for a 3-inch lap. The size of the pieces of slate making up a square ranges from 7 by 9 inches to 16 by 24 inches, and the number of pieces in a square ranges from 85 to 686, according to the size of the pieces. The ordinary thickness of a piece is from one-eighth to three-sixteenths of an inch, and the approximate weight per square is about 650 pounds. The slate is generally shipped in carload lots, each lot consisting of 50 to 100 squares, according to the size of the pieces.

The price per square for ordinary slate of No. 1 quality ranges from $3.50 to $10 per square f. o. b. at the quarries and depends on the color, size, thickness, smoothness, straightness, and uniformity of the pieces. Specially prepared slate, with pieces carefully selected with regard to color, quality, extra thickness and size, and extra cutting commands from $30 to $200 per square. For ordinary slate the red slates of New York command the highest prices. The red slates of New York and the green slates of Vermont are the kinds generally prepared for special work.

About 72 per cent of the value of the slate production in the United States in 1913 was represented by slate for roofing, and the roofing-slate output from Pennsylvania and Vermont represented, respectively, about 58 and 30 per cent of the total value of the roofing slate produced. Besides roofing slate, Pennsylvania and Vermont produce also millstock; practically the only use of slate from the other producing States, except Maine, is for roofing.

In 1913 the output of roofing slate was reported as 1,113,944 squares, valued at $4,461,062, the average price per square being $4; in 1912 there were reported 1,197,288 squares, valued at $4,636,185, with an average price per square of $3.87, a decrease in 1913 of 83,344 squares in quantity and of $175,123 in value, while the average price per square increased. All the States except New York showed a decrease in the quantity of roofing slates sold, and New York, Vermont, and Virginia were the only States that did not show an increase in average price per square. The large increase in the total average price per square was, however, caused by the increase in average price in Northampton County, Pa.

QUANTITIES AND VALUES.

The following table shows the number of squares, the value, and the average price per square of roofing slate, and the quantity and the value of millstock, by years, from 1879 to 1913, inclusive:

Quantity and value of roofing slate and millstock produced in the United States, 1879–1913.

Year	Roofing slate.			Millstock.			Other uses (value).	Total value.
	Number of squares.	Value.	Average price per square.	Quantity (square feet).	Value.	Average price per square foot.		
1879	367,857	a $1,231,221	$3.35					a $1,231,221

a Included in other States.

b Composed of 4,482,571 school slates, valued at $38,852; 2,898,742 square feet of blackboard material, valued at $352,109; and slate used for structural and other purposes, valued at $1,566.

c Includes, in 1912, Arkansas and New Jersey; in 1913, Georgia and New Jersey.

d Composed of 6,174,526 school slates, valued at $51,313; 3,504,162 square feet of blackboard material, valued at $426,703; and slate used for structural and other purposes, valued at $1,467.

IMPORTS.

Practically no slate is imported into the United States. In 1913, slate valued at $5,479 was imported in the form of mantels, chimney pieces, roofing slate, slabs, etc. In 1912, the imports were valued at $14,768 and included the same articles.

The tariff act of October, 1913, reduced the duty on imported slate by half. Formerly the duty on slates, slate chimney pieces, mantels, slabs for tables, roofing slates, and all other manufactures of slate was 20 per cent ad valorem; at present, the rate is 10 per cent ad valorem.

EXPORTS.

For a period of nine years, from 1897 to 1905, inclusive, the United States had a large export trade in slate, the years 1898 and 1899 showing exports valued at more than $1,000,000. About two-thirds of these exports were to Great Britain, where a strike in the large Welsh quarries enabled slates from other countries to gain a foothold. Since 1905 there has been a marked decrease in slate exports from the United States, until in 1909 the exports amounted to only $209,383. From 1910 to the latter half of 1912 exports of slate were not kept separate from exports of other varieties of stone. In 1912 the exports of slate from July 1 to December 31 amounted to $171,775, and the exports for the entire year 1913 amounted to $226,413.

According to the Slate Trade Gazette, of London, the exports of slate from the United States to Great Britain in 1912 were 4,441 tons, valued at £18,133. In 1913 these exports decreased to 2,498 tons, valued at £9,362, or about one-fifth of the total slate exported.

SLATE INDUSTRY BY STATES AND LOCALITIES.

The slate production of the United States is practically confined to the northeastern part of the country. Although scattered deposits, more or less developed, occur elsewhere, this eastern slate is shipped to supply markets on the western coast as well as in the central and southern parts of the country. The locations of the principal deposits, whether producing in commercial quantities or in process of development, are given below by States.

The slate of most of the deposits in the various States has been described either in Bulletin 275 of the United States Geological Survey, or in previous reports on the slate industry. Bulletin 275 is out of print, but a new revised edition will soon be printed as Bulletin 586 of the Survey.

Arizona.—No operations, other than assessment work, were carried on during 1913 at the slate deposits in Maricopa County, Ariz., belonging to the Arizona Slate Co., and the Phoenix Slate Co.

Arkansas.—There was little activity in the development work at the slate properties in Arkansas in 1913. Lack of transportation is the principal drawback to the development of the industry. The deposits are in Garland, Montgomery, Polk, Pulaski, and Saline counties. The slate is of good quality, both for roofing and for mill stock, and is found in red, green, gray, and black colors.

Full descriptions of these deposits may be found in Bulletins 275 and 430 of the United States Geological Survey, and in a report by the Arkansas Geological Survey.[1]

California.—There was no commercial production of slate in California in 1913. The Eureka Slate Co., owning quarries near Placerville and Slatington, Eldorado County, reported that it expected to resume operations in the spring of 1914. No commercial operations at the recently opened quarry of the California Slate Co., near Planada, Merced County, were carried on in 1913. Slate from this quarry was described in the report for 1911. No work was done at the deposit at Hornitos, Mariposa County. High prices charged for eastern slates are stated to have lessened the demand for slate on the Pacific coast.

Colorado.—No work other than for assessment was done at Marble, Gunnison County, Colo., in 1913.

Georgia.—Slate has been quarried in Georgia at irregular intervals for many years near Rockmart, Polk County, and a small quantity was produced there in 1913. The Rockmart slate is a very dark bluish gray "black" slate. Most of the quarries that have been opened at this place are now abandoned. Near Bolivar, Bartow County, the Southern Green Slate Co., lessee of the slate property of the Georgia Green Slate Co., operated the quarries for about six months, doing development work principally. Good demand was reported for this slate which is a rather light greenish gray in color, and which was described in the report on the slate industry for 1910.

Maine.—Four companies, the Brownsville & Boston Slate Co., the Maine Slate Co., of Monson, the Monson Maine Slate Co., and the Portland-Monson Slate Co., operated slate quarries in Maine during 1913, with an increase of over 14 per cent in the value of the output. The entire output of the State is from Piscataquis County and increased in value from $282,678 in 1912 to $323,998 in 1913, a gain of $41,320. About two-thirds of the product is mill stock, of which the output in 1913 was 513,745 square feet, valued at $234,065, an increase of 85,056 square feet in quantity and of $47,466 in value as compared with the product of 1912, which was 428,689 square feet, valued at $186,599. Much of this mill stock is used for electrical purposes, for which it is especially adapted. The roofing-slate output, which, with some of the companies, is simply a by-product, amounted in 1913 to 15,593 squares, valued at $89,933; in 1912 the roofing slate output was 16,640 squares, valued at $96,079, a decrease in 1913 of 1,047 squares in quantity and of $6,146 in value. The average price per square was $5.77 in 1913, the same as in 1912.

Maryland.—There were but three companies operating in Maryland in 1913—the Peach Bottom Slate Co., of Harford County, the Peerless Slate Co., and the Proctor Slate Manufacturing Co. These companies all work in the "Peach Bottom" district near Cardiff, Harford County, and produce the same slate as that quarried in York County, Pa. This is a black slate well known in the markets all over the world and is used almost entirely for roofing. Notwithstanding the fact that the quarrymen reported a very good demand, the output

[1] Dale, T. N., and others, Slate deposits and slate industry of the United States: U. S. Geol. Survey Bull. 275, pp. 51–55, 1906.
Purdue, A. H., Slates of Arkansas: U. S. Geol. Survey Bull. 430, pp. 317–334, 1910.
The slates of Arkansas: Arkansas, Geol. Survey, 1909.

decreased nearly 9 per cent in 1913 as compared with 1912. Improvements were made in quarry conditions and better prices prevailed partly on account of the selling of the slate by the producers themselves rather than through agents. A new firm, the Maryland Slate, Brick & Tile Co., reports that it expects soon to begin operations on a quarry near Woodsboro, Frederick County, producing green and purple slate.

The roofing-slate output decreased from 18,236 squares, valued at $90,993, in 1912 to 15,913 squares, valued at $82,981, in 1913, a falling off of 2,323 squares in quantity and of $8,012 in value. The average price per square increased from $4.99 in 1912 to $5.21 in 1913.

New Jersey.—The quarries of the Newton Slate Co., of Newton, and the Lafayette Slate Co., of La Fayette, both in Sussex County, were not operated to any large extent in 1913, but considerable sales of slate from stocks on hand were made and this is included in the total for 1913. This practically unfading black slate is used almost entirely for roofing. The sales were somewhat more in 1913 than in 1912, and the average price per square increased from $4.45 in 1912 to $4.68 in 1913.

New York.—The New York slate is used almost entirely for roofing and was all produced in Washington County in 1913, in the northeastern part of the State and adjacent to the slate-producing region of Rutland County, Vt. The output was about 7 per cent greater in 1913 than in 1912, but the average price per square decreased from $5 in 1912 to $4.69 in 1913. The production increased from 27,024 squares, valued at $135,136, in 1912 to 29,868 squares, valued at $139,970, in 1913, a gain of 2,844 squares in quantity and of $4,834 in value. Less demand was reported for red slate, which commands the highest prices. The increase or decrease of sales of this slate causes considerable variation in the yearly average prices of New York slate. Some of the red slate is used in the manufacture of paint.

Pennsylvania.—Pennsylvania showed an increase in value of output in 1913 of over 7 per cent, as compared with an increase of a little over 1 per cent in 1912. The value of the production for 1913 was $3,733,581; in 1912, $3,474,247, an increase in 1913 of $259,334, or 7.46 per cent. Pennsylvania slate is used both for roofing and for mill stock. In 1913 Pennsylvania produced 60.90 per cent of the total quantity and 58.41 per cent of the total value of the output of roofing slate in the United States. The average price per square in Pennsylvania in 1913 was $3.84, compared with $3.53 in 1912, an advance of $0.31. Besides leading in the production of roofing slate, Pennsylvania has a larger output of mill stock than any other State, producing in 1913, exclusive of blackboard stock and school slate, 52.54 per cent of the total value and 66.70 per cent of the total quantity of this material for the United States.

The fluctuations were as follows: In 1913 the output of roofing slate was 678,396 squares, valued at $2,605,882; in 1912, 716,770 squares, valued at $2,528,791, a decrease of 38,374 squares in quantity and an increase of $77,091 in value. The average price per square advanced from $3.53 in 1912 to $3.84 in 1913. The mill stock sold, exclusive of blackboard and school-slate material, was 4,210,515 square feet, valued at $648,216, in 1913 and 4,101,200 square feet, valued at $552,929, in 1912, an increase of 109,315 square feet in quantity and of $95,287 in value. The average price per square foot advanced from 13.4 cents in 1912 to 15.4 cents in 1913. Slate for blackboards, school slates, and a few minor purposes increased in value $86,956, from $392,527 in 1912 to $479,483 in 1913. Pennsylvania produced 60.46 per cent of the value of the total slate product in the United States in 1913, as compared with 57.48 per cent in 1912; 59.90 per cent in 1911; 59.98 per cent in 1910; 53.15 per cent in 1909; and 61.79 per cent in 1908.

Blackboard slate increased from 2,898,742 square feet, valued at $352,109, in 1912 to 3,504,162 square feet, valued at $426,703, in 1913, an increase of 605,420 feet in quantity and of $74,594 in value. The average price per square foot was 12 cents in 1912 and 12.2 cents in 1913. The average thickness of this slate is three-eighths of an inch.

School slates increased from 4,482,571 slates, valued at $38,852, in 1912 to 6,174,526 slates, valued at $51,313, in 1913, a gain of 1,691,955 slates in quantity and of $12,461 in value. The average price per thousand was $8.67 in 1912 and $8.31 in 1913. The average size of the slates as reported is 7 by 11 inches—sometimes sold by the square of about 500 pieces.

In 1913 slate was quarried in Lancaster, Lehigh, Northampton, and York counties. The quarry in Carbon County, the slate from which was described in the report for 1909, has not been operated since 1911. No further development was made on the deposit in Dauphin County, slate from which was described in the report for 1910.

The slate from Lehigh County is used for roofing and for ordinary mill stock, and also, on account of the fineness of its cleavage, for school slates and blackboard material. In 1913 Lehigh County produced 22.10 per cent of the quantity and 19.69 per cent of the value of the Pennsylvania roofing-slate output and 12.85 per cent of the quantity and 11.50 per cent of the value for the entire United States. In 1912 the Lehigh County production was 22.12 per cent of the quantity and 22.59 per cent of the value of the Pennsylvania roofing slate and 13.24 per cent of the quantity and 12.32 per cent of the value of the United States. There was a decrease both in quantity and in value of the roofing slate produced in this country in 1913 as compared with 1912, and the number of producers was two less. Although most of the producers reported a good demand for slate in the early part of 1913, many reported dull trade, poor demand, and prices about the same as 1912. The average price per square of roofing slate, however, decreased but slightly, or from $3.60 in 1912 to $3.58 in 1913. There was a considerable decrease in quantity of mill stock, but an increase in value of output. This same condition also prevailed in 1912 as compared with 1911. Blackboard and school-slate stock increased, both in quantity and in value, in 1913.

The slate of Northampton County has the same uses as the Lehigh County slate, but the total value of the output is over three and one-half times as large. In 1913 Northampton County produced 77.43 per cent of the quantity and 78.12 per cent of the value of the Pennsylvania roofing slate, and 47.16 per cent of the total quantity and 45.63 per cent of the total value for the United States. In 1912 the Northampton County output was 75.34 per cent of the quantity and 73.46 per cent of the value of the Pennsylvania roofing slate, and 45.10 per cent of the quantity and 40.06 per cent of the total value for the United States. There was an increase of $296,756 in the output of this county as compared with 1912. The value in 1913 was $2,897,205; in 1912 it was $2,600,449. Although the majority of the producers in Northampton County reported the demand in 1913 for roofing slate as less than or about the same as in 1912, many reported especially good trade the first part of the year and poor trade in the latter part; but almost without exception the prices were reported as better than in 1912, which is shown by the increase in average price of 44 cents per square in 1913, from $3.44 in 1912 to $3.88 in 1913, while the number of squares sold decreased. The decrease in quantity with increase in value in a county representing so large a proportion of the production of the United States, was largely accountable for the increased average price for the entire country. The figures for the two years are as follows: In 1912 there was sold in Northampton County 525,286 squares, valued at $2,035,796; in 1912, 540,032 squares, valued at $1,857,712, a decrease of 14,746 squares in quantity, and an increase of $178,084 in value.

Demand for structural slate and slate for blackboards and school slates was reported by the producers as greater in 1913 than in 1912, and this is shown in the increase in both quantity and value of the slate sold for these purposes.

York County produces nothing but roofing slate of the same Peach Bottom variety as that of Harford County, Md. There was a decrease in production for this county in 1913, but an increase in average price—from $5.50 in 1912 to $5.71 in 1913.

The Pennsylvania slate is mostly of a dark-gray or other dark color. Many of these dark slates, however, become somewhat lighter in color on exposure to the atmosphere.

The table following shows in detail the production of slate in Pennsylvania, by counties and uses, in 1912 and 1913:

Production of slate in Pennsylvania in 1912 and 1913, by counties and uses.

County.	Number of operators.	Roofing slate.			Millstock.								Other (value).	Total value.
		Number of squares.	Value.	Price per square.	Manufactured.		Rough.		Blackboards.		School slates.			
					Quantity.	Value.	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.		
1912.														
					Sq. ft.		*Sq. ft.*		*Sq. ft.*		*Number.*			
Lancaster	2	18,135	$99,810	$5.71	....	....	....	....	....	....	....	....	....	$99,810
York ("Peachbottom slate")	3			5.50

Tennessee.—The deposits of slate in Tennessee where more or less development work has been done in recent years are in Blount, Monroe, and Washington counties. The Southern Slate Co., of Columbus, Ohio, with a quarry located at Chilhowee, Blount County, reports that operations at this deposit will probably be begun early in 1914. Analyses made of this slate by Prof. A. F. Gilman at the laboratory of the University of Tennessee are as follows:

Analysis of slate from Chilhowee, Blount County, Tenn.

	Black slate.	Gray slate.
Silica (SiO_2)	57.61	58.51
Lime (CaO)	.412	.68
Carbon dioxide (CO_2) with the lime	.324	.54
Magnesia (MgO)	2.54	2.139
Carbon dioxide (CO_2) with the magnesia	2.79	2.352
Alumina (Al_2O_3)	28.72	29.49
Ferric oxide (Fe_2O_3)	2.02	1.53
Ferrous sulphide (FeS_2)	3.01	.57
Water (H_2O)	2.56	4.18
Total	99.986	99.991

At Tellico Plains the Tellico Co. and the Tennessee Slate Co., represented by W. F. Payne, are owners of slate deposits. Mr. Payne is also interested in a slate deposit at Washington College, Washington County, where arrangements are reported as being made to install machinery for operations in the near future.

Utah.—The Utah Slate & Granite Co., owning slate deposits near Provo, Utah County, did no work in 1913.

Vermont.—Vermont is second among the slate-producing States, being ranked by Pennsylvania. In 1913 Vermont produced 27.49 per cent of the total slate quarried in the United States, and Pennsylvania 60.46 per cent. In 1912 these figures for Vermont and Pennsylvania were 30.61 and 57.48 per cent, respectively—a decrease for Vermont and an increase for Pennsylvania in 1913. The total value of the slate production in Vermont decreased 8.22 per cent in 1913, that of Pennsylvania increased 7.46 per cent. About four-fifths of the slate marketed in Vermont is roofing slate. This amounted to 332,642 squares, valued at $1,351,175, in 1913, as compared with 373,638 squares, valued at $1,576,294, in 1912, a decrease of 40,996 squares in quantity and of $225,119 in value. The average price per square declined from $4.22 in 1912 to $4.06 in 1913. The total mill stock manufactured increased from 1,234,384 square feet, valued at $273,582, in 1912, to 1,566,409 square feet, valued at $346,645 in 1913, an increase of 332,025 square feet in quantity and of $73,063 in value. The average price per square foot was 22.1 cents in 1913, as compared with 22.2 cents in 1912.

Of the mill stock (exclusive of blackboards and school slates) produced in the United States, Vermont supplied 28.09 per cent of the total value in 1913 compared with 52.54 per cent from Pennsylvania. Notwithstanding the decrease in output of roofing slate, most of the producers report the demand much better than in 1912, but with lack of activity both in demand and in prices during the latter part of the year. The Vermont slate is practically all from Rutland County, and the quarries are in the same belt as the New York slate quarries. The Rutland County slate varies in color and is known in the trade as "sea-green," "grayish green," "unfading green," "greenish gray," "purple," "purplish brown," "variegated," and other variations of green, gray, and purple.

Virginia.—Virginia ranks fourth among the slate-producing States, with productive quarries at Esmont, Albemarle County, and Arvonia and Penlan, Buckingham County. This slate is used entirely for roofing, and the production in 1913 was 38,330 squares, valued at $175,774, or $4.59 per square. This was a decrease of 3,890 squares in quantity and of $19,618 in value as compared with 1912, when the output was 42,220 squares, valued at $195,392, or $4.63 per square. The average price per square decreased $0.04 in 1913. Development and prospecting work was also done at Snowden, Amherst County, but no slate was sold.

PUBLICATIONS ON SLATE.

Requests are continually coming to the United States Geological Survey for reports on the distribution, production, and composition of slate and on the methods of working slate quarries.

Bulletin 275 of the Survey,[1] which is a very comprehensive report on the slate deposits and slate industry of the United States, is now out of print, but it can be consulted in libraries or purchased from dealers in secondhand books. This report, however, has been revised, and a new edition will be issued in 1914 as Bulletin 586 of the Survey.

Maps showing the commercial deposits of slate are published in the reports on the stone industry of the United States for 1912 and 1913.

The United States Geological Survey has published a report on the slates of Arkansas, by A. H. Purdue.[2]

The State geological surveys of Arkansas, California, Maryland, and New Jersey have also published descriptions of the slate and slate deposits of these States, and information as to these publications may be had by applying to the respective State geologists.

A publication by E. C. Eckel[3] contains a chapter on slate, which gives information on the slates of the United States and of foreign countries, and also many analyses and tests of slate.

POTASH SALTS: SUMMARY FOR 1913.

Compiled by W. C. Phalen.

PROGRESS OF INVESTIGATION DURING 1913.

INVESTIGATIONS BY THE UNITED STATES GEOLOGICAL SURVEY.

The activities of the United States Geological Survey in the investigation of potash salts during 1913 were more restricted than in previous years. In the field drilling was carried on in two areas, Columbus Marsh and Black Rock Desert, Nevada; but it was of short duration, owing to the inaccessibility of the area for an unusually long period of the year on account of the heavy rains, which made it impossible to transport apparatus to the drill sites. A general plan involving the stratigraphic study of the so-called "red bed" salines of certain of the Southwestern States, including New Mexico, Arizona, and Utah, was begun by N. H. Darton, and several months of field work was done. A brief review of certain basins in the Great Basin region of California and Nevada was made by H. S. Gale in the further general study of the hypothesis that potash deposits may be found in desiccated lake basins.

In the laboratory attention has been directed to a few definite problems indicated by the preceding general experimental work.

POTASH SALTS IN THE GREAT BASIN REGION.

DEEP DRILLING EXPLORATIONS.

In addition to the drilling explorations carried out by the Survey and mentioned in the introductory paragraph, the Railroad Valley Co., of Tonopah, Nev., did some deep drilling during the year. Since this company began operations, more than two years ago, it has drilled more than 10,000 feet in seven wells located in Railroad Valley, Nye County, Nev.

During July, 1913, the company in its well No. 2 encountered buried soda-bearing beds made up chiefly of the mineral gaylussite ($Na_2CO_3.CaCO_3.5H_2O$). These were penetrated a distance of 127 feet without reaching bottom. Since potash salts are more soluble than the mineral gaylussite, they would in a normally deposited saline series overlie that mineral. On this basis it was assumed that they did overlie the gaylussite in some other part of the basin, namely, in the deepest part, in which, consequently, they would cover a smaller area than the gaylussite deposits. In the work the gaylussite bed was counted on as furnishing a datum plane to aid in tracing the contours of the basin, and hence in locating the deepest part in which the potash salts were expected to be found. Proceeding on this hypothesis, four additional wells were drilled, but without conclusive results. Two of these wells did not encounter the gaylussite deposit at all. It was also found that the upper portion of the gaylussite beds was flatter and more variable than was expected—conditions which rendered precise correlation and determination of contours impossible. Operations on the seventh well drilled had to be suspended before it reached the depth at which the hoped-for data were expected to be obtained.

The gaylussite beds were encountered only in wells Nos. 2, 4, and 6. In No. 2 they were penetrated a distance of 127 feet, in well No. 6 a distance of 194 feet, and in well No. 4 a distance of only a few feet, In no well was the gaylussite drilled through, but it was found to be purer and more solid toward the bottom. The precise correlation of the two gaylussite deposits found—the one in well No. 2 and the other in well No. 6—was not considered possible, and it was also found impossible to establish synchronism between any two particular beds of wells No. 2 and No. 6. Still, there seems little doubt that the gaylussite series of wells No. 2 and No. 6 are synchronous and represent the same stage of concentration of the same saline solutions.

The most important question confronting the company at present is whether well No. 6 is in or near the deepest depression or whether such depression lies an unknown distance to the south. This doubt can be settled only by further drilling. If such drilling indicated no southward extension of the basin, the chances of finding important segregations of potash salts are very slight. If it be proved that the basin does extend farther to the south, then probably several wells will have to be drilled to obtain some idea of its size and character and of the existence of other saline deposits in it.

In the event that no potash salts are found, it is possible that the gaylussite bed itself may be of value. The extent of this bed will have to be ascertained by drilling, and methods will have to be devised both for mining it and for producing soda from it.

The report of E. E. Free, consulting geologist to the Railroad Valley Co., from which these data were obtained, was transmitted January 2, 1914. This report contains, in addition to the information given, a map showing the location and records of the wells, together with an appendix describing gaylussite and its possible utilization.

It is reported that the Nevada Potash Co., with headquarters at Goldfield, Nev., plans to explore Clayton Lake, 20 miles west of Goldfield.

EXPLANATION OF THE TERM "POTASH."

To meet the numerous inquiries that have been addressed to the United States Geological Survey regarding the exact meaning of the terms "potash," "actual potash," and "potassium," the following explanation is given:

The element potassium, represented by the symbol K, is the basis of all potash salts or compounds. This substance is a metal; that is, it possesses metallic properties. To prevent rapid change it must be kept from air and water, with both of which it combines with great avidity. Combined with oxygen it forms potassium oxide, represented by the symbol K_2O, known as potassa, but popularly as "potash." In estimating the quantity of potassium in the different products of the Stassfurt deposits, this compound, K_2O, is employed as a standard, the object being to establish a basis of comparison for all potassium salts. Among chemists as well as laymen there has grown up the practice of using for this standard the term "potash." When only the term "potash" is used in speaking of potash products, it is understood to refer to the potassium oxide (K_2O) present. As a matter of fact, however, potash salts are not sold in the form K_2O, but as the sulphate or the chloride.[1] By the term "potassium sulphate" is meant potassium (K) combined with the acid radicle of sulphuric acid (SO_4), or potassium oxide (K_2O) combined with sulphur trioxide (SO_3), making the compound K_2SO_4. By "potassium chloride" is meant potassium (K) combined with another element, chlorine (Cl).

In the following table are given the percentages of the element potassium and also the combination known as potash in or obtainable from the common potassium compounds and minerals:

Potassium and "potash" in potassium compounds.

Name.	Symbol.	Percentage of potassium (K).	Chemical equivalent in terms of "potash" (K_2O).
Element:			
Potassium	K	100	120
Potassium salts or "potash salts":			
Potassium chloride (mineral sylvite)	KCl	52	63
Potassium muriate (same as chloride).			
Potassium sulphate	K_2SO_4	45	54
Potassium nitrate (saltpeter)	KNO_3	39	47
Potassium carbonate [a]	K_2CO_3	57	68
Potassium hydrate or caustic potash	KOH	70	84
Potassium cyanide	KCN	60	72
Stassfurt minerals:			
Carnallite	$KMgCl_3.6H_2O$	14	17
Kainite	$MgSO_4.KCl.3H_2O$	16	19

[a] The term "potash" is often applied to this compound.

DEVELOPMENT OF SALINE POTASH DEPOSITS.

CALIFORNIA.

SEARLES LAKE.

A description of the saline deposits of Searles Lake, Cal., was published in this report for 1912.[2]

Searles Lake, known also as Borax Flat, is a dry lake basin much like many other desert basins in the western arid region. It is a broad, somewhat circular valley or depression lying between the Slate and Argus ranges in the extreme northwestern part of San Bernardino County, and near Kern and Inyo counties. The camp known as The Borax is about 25 miles by road from Searles post office, formerly Garden station, near the Mohave-Owenyo branch of the Southern Pacific Railroad. Searles Lake at present may be reached by the regular stage that runs from Johannesburg by the way of Garden station, or Searles, to Searles Lake, and thence on to Ballarat and Skidoo.

[1] The chloride is also known in the trade by the chemically obsolete term "muriate of potash."
[2] Gale, H. S., Potash salts: U. S. Geol. Survey Mineral Resources, 1912, pt. 2, pp. 884-889, 1913.

Searles Lake for many years was an important source of borax. Later the California Trona Co. was organized to produce soda ash from the deposits; and the lake has now become of interest in connection with the contemplated exploitation of its potash-salts deposits.

The announcement of Searles Lake as a possible source of potash salts was made as the result of the collection and analysis of a set of brine samples from it in March, 1912, by E. E. Free, then of the United States Bureau of Soils, and Hoyt S. Gale, of the United States Geological Survey. A notice was at that time given to the press stating that reports which had been received concerning the unusually high potash content of the brine in this deposit were apparently confirmed by the results of these tests. Analyses of six brine samples taken at considerable depth in old wells at points distributed over the main salt flat showed that an average of 6.78 per cent of the total dissolved salts was potash (K_2O), corresponding to 10.73 per cent potassium chloride (KCl). The individual results obtained were 7.63, 6.23, 6.89, 6.06, 7.27, and 6.57 per cent. The uniformity of these results seemed to indicate, although it did not prove, homogeneity in composition of the brine throughout the salt deposit. Based in part on the logs of the wells that had already been drilled, a statement was also made at that time that "existing data give reasonable assurance that the brine-saturated salt body is at least 60 feet thick and covers an area of at least 11 square miles. On the assumption that the salt constitutes 25 per cent by volume of the brine, the total amount of potassium oxide available is estimated as over 4,000,000 short tons [equivalent to approximately 6,000,000 tons of potassium chloride]. This estimate is based on incomplete data, but it is believed to be conservative."

During the year 1913 the American Trona Co. was incorporated to operate works for refining and marketing the different saline constituents of the Searles Lake deposits. It is proposed to spend $3,000,000 in completing a railway from Searles to the lake and in building a plant to have a capacity of 2,000,000 gallons of brine a day.

Many deep drillings have been made at Searles Lake by the company, and the study of many hundred samples secured has enabled those in charge of the enterprise to devise a process for the treatment of the salines.

The new works will draw from the lake approximately one-tenth of an inch of brine a day; the natural evaporation is much larger and varies from one-fourth to one-half inch a day. The plan of treatment consists in first precipitating the soda as the bicarbonate. The next step involves crystallization in furnaces of simple type but large capacity. The process has been worked out with considerable care, but to insure against possible loss an initial unit with a capacity equal to 1 per cent that of the final plant will be erected and placed in operation before the main plant is built. It is expected that the daily output of the plant will be: Borax, 225 tons; soda ash, 508 tons; salt, 1,507 tons; sodium sulphate, 593 tons; and potassium chloride, 489 tons. The company will depend for its revenue mainly on the potash salts, the soda ash, and the borax. The salt may ultimately be marketed, and it is possible that at some future time a use will be found for the sodium sulphate; but for the present these constituents are not taken into account.[1]

[1] Min. and Sci. Press, June 14, 1913, p. 888.

According to the latest information the experimental unit referred to above is nearing completion and it is expected to be ready for operation in the latter part of 1914. The 31-mile railroad from Searles on the Nevada & California Railroad (Southern Pacific) is completed to the new town of Trona, where the new works are being built. It is expected that 20,000 gallons of brine will be handled daily at the new plant, and that the works will be enlarged at a later date. It is unlikely that the salts from the Searles Lake deposit will enter the market regularly until the latter part of 1914.[1]

OKLAHOMA.[2]

Common salt is found in what are generally termed "salt plains" in Oklahoma; that is, over broad areas in which incrustations of salt occur. This common salt has come from springs, which flow at particular places, or from saline ground waters, which permeate the soil below the saline crusts. Such saline ground waters may also have originated in springs with subterranean outlets. Most of the salt is supposed to have come from salt beds in the so-called "red beds."

One group of these salt plains is found in Jackson County. This group numbers three in all, lying close together on the west side of Sandy Creek, about 3 miles from its mouth, and approximately the same distance south of Eldorado. The northern plain lies in the E. ½ sec. 31, T. 2 S., R. 23 W., the middle one in the NE. ¼ sec. 5, T. 3 S., R. 23 W., and the southern plain in the NW. ¼ sec. 5 of the same township and range. All three plains are on small tributaries which flow northeast into Sandy Creek. The northern and southern plains are each about 100 yards wide and 400 yards long; the middle plain is only 40 yards wide, but is one-fourth of a mile long. The sandy floor of the plains is covered by a thin saline incrustation, and the water does not seem to be saturated.

The analyses of the soluble salts which have been made by the Oklahoma Geological Survey are not given in detail in the reference cited. According to Snider, the analyses that have been made indicate the presence of much more sodium sulphate than sodium chloride; the potassium sulphate is also high. In the incrustation from the middle plain the proportion of sodium chloride is greater than in the two others, and there seem to be sufficient sodium and potassium sulphates to make the commercial recovery of common salt a question. It is possible that the potassium sulphate from the middle plain may be utilized as a by-product.

TEXAS.[3]

In the search for a deep source of potable water at Spur, Dickens County, Tex., a deep well has been drilled by S. M. Swenson & Sons, of New York. The total depth of the well is reported as nearly 4,500 feet. The upper 900 feet of strata penetrated consist chiefly of red sand, beds of shale, gypsum, and anhydrite, and two beds of rock salt, each about 10 feet thick and both more than 500 feet from the surface. Below the 900-foot level occurs a 250-foot bed, consisting chiefly of fine sand, silt, and salt, the proportion of salt varying from 20 to 60 per cent. From the 1,250-foot level to the 2,050-foot level the character

---

[1] Eng. and Min. Jour., vol. 97, No. 9, p. 484, Feb. 28, 1914.
[2] Snider, L. C., Oklahoma Geol. Survey Bull. 11, pp. 213-214, 1913.
[3] Udden, J. S., Potash in the Permian rocks of Texas: Am. Fertilizer, Dec. 14, 1912, pp. 40-41.

of the rock passed through is not known from samples, but is thought to consist chiefly of dolomitic limestone. Below this is found red silt or clay, dolomitic and shaly limestone, and anhydrite; then dolomitic limestone; then very pure anhydrite. At 3,060 feet a dark-gray soft shale was met.

The presence of so much anhydrite and salt in the section led to the suggestion by J. A. Udden, of the Bureau of Economic Geology and Technology of the University of Texas, of the possibility of the presence of potash salts in the deposits. The well had in the meantime been cased below 1,300 feet. A sample, however, was taken after the water had been bailed to a depth of 2,200 feet. This sample was examined by S. H. Worrell, also of the bureau, with the following results:

Analysis of water from well at Spur, Tex.

	Grains per gallon.
$CaSO_4$	1, 688. 4
$CaCl_2$	814. 1
$MgCl_2$	263. 2
NaCl	4, 095. 0
KCl	389. 2
	7, 249. 9

The potassium chloride amounts to 6.65 grams per liter and constitutes more than 5.4 per cent of the total salts. As this amount of potash salts is somewhat high for a natural water, arrangements were later made for obtaining samples from different depths below the foot of the casing (1,350 feet). Fourteen samples were next obtained and tested for potash salts, but in only one of them, namely, the sample from the same depth at which the earlier tests showed marked results in the content of potassium chloride, was any considerable quantity of potash salts again found, but the quantity found was approximately only one-third of that shown in the earlier sample. The results seem, therefore, to indicate the presence of a potash-bearing layer, bed, or stratum approximately 2,200 feet below the surface in the well.

ALUNITE AS A SOURCE OF POTASH SALTS.

COMPOSITION AS MINERAL.

The mineral alunite is a hydrous sulphate of potassium and aluminum with the symbol $K_2O.3Al_2O_3.4SO_3.6H_2O$. Theoretically it contains 11.4 per cent K_2O, 37 per cent Al_2O_3, 38.6 per cent SO_3, and 13 per cent water. The composition of alunite found at Marysvale, Utah, a locality at which the mineral occurs on a considerable scale, as will be seen from the table of analyses that follows, is very close to the composition of the pure mineral as given above:

Analyses of alunite from deposit near Marysvale, Utah.

	18	19	Dana.

H_2O-	.09	.11	....
SiO_2	.22	5.28	....
	100.10	100.18	100.0

No. 18 is a selected specimen of the supposedly best material. It consists of clear pink, subtransparent, coarsely granular, crystalline rock. No. 19 is a selected specimen of a light pink, very finely granular rock, of almost porcelain-like conchoidal fracture and no distinct structure.

METHOD OF RECOVERING POTASH.

Experiments conducted in the laboratory of the United States Geological Survey have shown that on igniting powdered alunite all the water and three-fourths of the sulphuric acid are driven off. When the residue is leached with water, potassium sulphate dissolves and insoluble alumina is left. The average quantity of potassium sulphate leached from the ignited mineral is 17.9 per cent of the original material used. As the coarsely crystallized alunite was found to contain 19.4 per cent potassium sulphate, 92 per cent of the total potash present was obtained by simple ignition and subsequent leaching. According to the laboratory experiments 32.7 per cent of the ignited alunite consists of available potassium sulphate, which may be obtained by leaching and evaporation. The remaining 67.3 per cent is nearly pure alumina. Several foreign deposits of alunite have been successfully worked for the manufacture of alum.[1]

UNITED STATES GEOLOGICAL SURVEY WORK ON ALUNITE.

There have been incorporated in this chapter in past years notices of all the occurrences of alunite that have been reported and described by members of the United States Geological Survey. The bibliography at the end of this chapter contains the references to this work. Occurrences that have been noted are those near (1) Marysvale, Piute County, Utah; (2) at five localities in the San Cristobal quadrangle, southwestern Colorado; (3) near Bovard, Esmeralda County, southwestern Nevada; and (4) in the Palmetto mining district, 5 miles south of Patagonia, Santa Cruz County, Ariz. E. S. Larsen, who described the occurrence in the San Cristobal quadrangle, Colorado, reports the mineral also at five or six different places in the Uncompahgre quadrangle, also in southwestern Colorado.

NEW OCCURRENCE OF ALUNITE IN UTAH.

Specimens containing alunite were sent to the Survey early in 1914 from the Newton mining district, about 9 miles northeast of Beaver, Beaver County, Utah, by William A. Wilson, of Salt Lake City. The material was said to have been collected from the locality known as Sheep Rocks, situated on the western flank of the same mountain range under geologic conditions similar to those of the occurrence near Marysvale.

The material sent to the Survey has been examined by B. S. Butler and found to be a mixture of the minerals alunite and quartz, there being approximately 30 to 40 per cent of the latter. It should be borne in mind that the presence of alunite in the proportion given above is based on results obtained from the examination of a single specimen. Whether further search will develop a considerable body of the mineral is entirely problematical. It is interesting, however,

[1] Butler, B. S., and Gale, H. S., Alunite, a newly discovered deposit near Marysvale, Utah: U. S. Geol. Survey Bull. 511, pp. 10–11, 1912.

to note, as stated elsewhere in this report, the rather general distribution of alunitization, as this form of rock alteration may be called.

Attention on the part of the owners and others interested in these and other similar deposits should be given to the interesting results obtained in experiments with alunite as a fertilizer both in the raw and in the roasted form. These results are outlined in another part of this report.

UTILIZATION OF ALUNITE.

Though the mineral alunite, since attention has been directed to it as a possible source of potash salts and alumina, has been found to be quite widespread in occurrence in certain of the Western States and has come to be recognized as a rather common form of rock alteration, the Marysvale, Utah, deposit is the only one that has been regarded as of any commercial importance up to the present time. The composition of the Marysvale mineral has already been indicated.

One of the companies interested in the occurrence near Marysvale is the Florence Mining & Milling Co. This company issued a prospectus in 1913 outlining the benefits of potash as a fertilizer and giving some concrete data on the company's holdings of alunite near Marysvale.

Certain newspaper reports regarding the future exploitation of the Marysvale deposits which have come to the Survey's attention but which must be distinctly understood as not authenticated by it, are as follows:

Among the plans for the exploitation of the Marysvale alunite is one for the erection of a roasting and grinding plant, which is to be installed in the spring of 1914. Because of the possible injury to the forests from the fumes of the oxides of sulphur given off during the roasting of the mineral, it is thought that the plant will not be permitted in the mountains near the occurrence itself. It is probable, therefore, that it will be built near the Denver & Rio Grande station at Marysvale, at which locality the prevailing winds will carry the acid fumes into the barren foothills of the ranges east of the valley. An aerial tram is projected to convey the ore from Cottonwood Canyon to the plant.

Method of utilizing alunite.—A process for obtaining sulphate of potash and alumina has been devised by H. F. Chappell and is described in patent No. 1070324 dated August 12, 1913. According to the specifications in this patent, sulphate of potash and aluminum oxide are obtained from natural deposits of alum stone, alum rock, and alunite by heating them at a temperature of about 800° to 1,000° C. until the aluminum compounds present are converted into insoluble aluminum oxide and the potassium compounds present are converted into potassium sulphate. The latter salt is then extracted by lixiviation.

KELP AS A SOURCE OF POTASH SALTS.

PRIVATE INVESTIGATIONS.

The utilization of kelp as a source of potash salts has been discussed in detail in this chapter in the last two years. In the report for 1911, especially, the results of private investigation and those of the Bureau of Soils were outlined. These results will not be repeated here, but the outline of the progress of the work to date and the more important results which apparently have been derived therefrom will be given.

The occurrence of potash salts in large amounts in kelp has been known for many years. The experiments of David M. Balch [1] on the Pacific coast kelps began early in 1905. Balch gives in the article cited a concise description of the range, relative abundance, life habits, and chemical composition of the three most important giant kelps of the Pacific coast. He also considers their econonic value and the practical methods of utilizing their products.

INVESTIGATIONS BY THE BUREAU OF SOILS.

During the spring and summer of 1911 work on the Pacific coast kelps was begun by the Bureau of Soils of the Department of Agriculture. During that year field observations were made on Puget Sound, on the California coast from Golden Gate to Point Sur, and from Cape Conception to Point Loma. Laboratory investigations were carried out on the material collected. The work was continued during 1912, and as a result there have been prepared maps of the kelp groves covering an area of 230 square miles on the Pacific coast from Puget Sound in the United States to the Cedros Islands in Mexico. The details of the work accomplished are contained in different publications of the Bureau of Soils, which have appeared in both official and unofficial journals.

During the season 1913 work both in the field and in the laboratory was done by the bureau. Two parties were engaged in locating and determining the extent and important characteristics of the kelp along the shore line of Alaska. Another party investigated on the ground the possibilities of developing a combined fish scrap and kelp industry on Puget Sound and in Alaska. Observations were made at La Jolla and Point Firmin, Cal., and at Friday Harbor, Wash., on the life history of these algæ, especially in relation to cutting and harvesting them.

Three papers—one on the leaching of potash from freshly cut kelp,[2] the second on the analyses of certain of the Pacific coast kelps,[3] and the third on the composition of the giant kelps [4]—appeared during 1913 or early in 1914. From the experiments of Merz and Lindemuth it is shown "that it is a matter of considerable difficulty to obtain a fair average sample of wet kelp," and also "that freshly cut kelp when immersed in seawater does not, at least at first, lose its potash content very rapidly." In a later paper by Merz [5] the conclusions arrived at by Merz and Lindemuth referred to above were corroborated.

With reference to the composition of giant kelps Merz has found—

> that Nereocystis of Alaskan waters is, as respects potash content, of as great importance as an economic source of potash salts as that of the more southern waters. Macrocystis contains a lower percentage of potassium than does Nereocystis, while Alaria contains a decidedly lower percentage. The seaweeds Fucus and Porphyra are evidently valueless as sources of potash on an economic scale.

[2] Merz, A. R., and Lindemuth, J. R., Jour. Ind. and Eng. Chem., vol. 5, No. 9, pp. 729-730, September, 1913.

[3] Parker, E. G., and Lindemuth, J. R., Jour. Ind. and Eng. Chem., vol. 5, No. 4, pp. 287-289, April, 1913.

[4] Merz, A. R., Jour. Ind. and Eng. Chem., vol. 6, No. 1, pp. 19-20, January, 1914.

[5] Op. cit., p. 19.

Another observation made in connection with Merz's work is that in every instance where stems and leaves were separately analyzed the total salt content and similarly the potash content in the stem exceeded that in the leaves, a conclusion at variance with that previously but tentatively drawn by Cameron. It was also found that (1) the ash content is generally higher in the leaves than in the stem of the same plant, and (2) that the nitrogen content is generally larger in the laminæ than in the stipe of the same plant.

The work of Parker and Lindemuth [1] on the giant kelps has enabled them to draw the following conclusions. These kelps are the most important from an economic point of view, both from their size and from the large amount of potash salts which they contain. They occur from 30 to 200 feet in length and in specific cases much longer, while the smaller varieties occur only from 2 to 12 feet in length. In the northern areas the commercial species are *Nereocystis luetkeana* and *Macrocystis pyrifera;* in the southern areas the commercial species are *Macrocystis pyrifera* and *Pelagophycus porra.* Other conclusions which these workers have been able to draw from their experiments are (1) that the average content in potassium chloride in the giant kelps is high; (2) that apparently no definite relation exists between the different constituents of kelp; (3) that apparently the northern kelps are richer in potassium chloride than the southern; (4) that the potash content of Nereocystis is greater than that of Macrocystis; and (5) that the iodine content of the northern and southern kelps shows no conclusive differences.

In a paper by F. K. Cameron [2] on kelp and other sources of potash, the recent information regarding kelp as a source of potash is summarized up to the time of publication. From the averages of the many existing analytical data Cameron states the following conclusions, derived in part at least from the work of his colleagues of the Bureau of Soils: (1) No definite quantitative relations exist between the different constituents of kelp; (2) the potassium content of Nereocystis is greater than that of Macrocystis; (3) the potassium content of northern kelp is higher than that of southern kelp; and (4) there is no positive difference in iodine content between northern and southern kelps. So far as results obtained are available, Cameron considers that the following conclusions also seem justified—(5) the proximity of the mouth of a fresh-water stream has no appreciable effect on the potash and nitrogen content of kelp; (6) there are no essential differences between the potash and nitrogen content of fronds and stipes [which conclusion was changed by the subsequent work of Merz already referred to]; and (7) there are no essential differences in the potash and nitrogen content of old and young plants, but further data on this point are desirable as well as on the possible variations in the potash content with the season.

COMMERCIAL UTILIZATION OF KELP.

Since interest has been aroused in kelp as a source of potash salts, several companies have been formed having in view its commercial exploitation either in the dried form as a fertilizer or for the potash salts and the other valuable ingredients, such as iodine, which it con-

---

[2] Franklin Inst. Jour., vol. 176, No. 4, pp. 347-383, October, 1913.

tains. The names of 11 companies formed ostensibly to engage in the kelp industry have been brought to the attention of the Survey during the last year. In geographical distribution these companies are located in the vicinity of Puget Sound, with headquarters chiefly at Seattle, and on the southern California coast near Long Beach, Los Angeles, and San Diego. Two of these companies were mentioned in this report for 1912.

The American Potash Co. with offices at Los Angeles, Cal., plans to utilize the kelp in the vicinity of Long Beach. This company was formed by the merging of two other companies, one of which was the Coronado Chemical Co., of San Diego and Cardiff. It is stated that work will begin early in 1914 on the manufacture of potash and other by-products from kelp at a plant to be built at Long Beach. The plant is to be erected on the unit system, and construction work on it began early in 1913. The work of manufacturing potash will begin on the completion of the new buildings that are expected to be finished about April 1, 1914.

The Pacific Products Co., of San Pedro, Cal., with a capital of $100,000, is reported to have a factory site on the California coast opposite the kelp grove outside of Point Firmin.

The Pacific Products Co., of Seattle, Wash., capitalized at $125,000, will build a factory for the manufacture of fertilizer materials and by-products from fish and kelp at Port Townsend, Wash. Several beds of kelp have been optioned at the head of Puget Sound, where a large quantity of seaweed will be harvested each year and transferred to the factory at Port Townsend. This company will also make a business of obtaining dogfish and of utilizing the offal from the fish canneries in the vicinity. The first unit of the plant for converting kelp and dogfish into fertilizer material was reported completed in July, 1913.

The Pacific Kelp Mulch Co. is located at Terminal Island, 1 mile east of East San Pedro, on the San Pedro, Los Angeles & Salt Lake Railroad. The company has been gathering kelp from the ocean during the last two years and disposing of it to the farmers and fruit growers as a fertilizer. The company has developed a machine which harvests the kelp rapidly and on a large scale. The kelp is cut from 4 to 6 feet under water, and care is taken not to disturb the roots of the growing plants. It is loaded on a barge and brought to the boat landing of the plant. Here it is pitchforked from the barge on a belt conveyer which conveys it to the cutter, being subjected during the passage to a steaming process which is practically instantaneous and which, it is asserted, removes all the adhering common salt ($NaCl$) but none of the potash salts. The cutter chops it into pieces 6 to 8 inches long—that is, of a length to be conveniently handled with a manure fork or to be harrowed under the soil after being spread. From the cutter the kelp falls into wagons or to the floor. It is then carted to the railroad and dumped into freight cars and shipped to the centers of consumption. This company has the distinction of being the first to harvest and market kelp on a commercial scale.

The material is said to have many advantages as a fertilizer, and these are explained in a small pamphlet which has been issued by the company.

The other companies whose names have come to the Survey as proposing to engage in the production of kelp on a commercial scale are the following:

Ocean Products Co., Seattle, Wash.
North Pacific Kelp Potash Co., Seattle, Wash.
Pacific Coast Kelp Potash Co., Seattle, Wash.
Puget Sound Kelp Potash Co., Seattle, Wash.
Aquatic Products Co., Seattle, Wash.
Kelp Products Co., San Francisco, Cal.
Mexican Kelp Fertilizer Co., Los Angeles, Cal.

The Survey has no first-hand knowledge of the activities of these companies.

ALUNITE AND KELP AS FERTILIZERS.

In experiments with alunite as a source of potash Waggaman[1] found that a large quantity of water is required to free the ignited residue entirely from soluble salts and that the subsequent evaporation is tedious and expensive. He suggested, therefore, that it might be more economical to use ignited alunite directly as a fertilizer than first to leach the residue for the potassium sulphate contained in it.

Experiments have been made by Skinner and Jackson[2] with alunite as a fertilizer in which both the raw and the ignited mineral have been used. The sample of raw alunite containing 10 per cent potash (K_2O) was finely ground, as was also the sample of the ignited mineral, which contained 14.7 per cent potash. These minerals were applied to the soil in such quantities as would furnish 25, 50, 100, 200, and 500 pounds of potash to the acre. Experiments with kelp were also tried, the material used being in the dried state and containing 19.8 per cent potash. This likewise was applied to the soil in such quantities as to furnish 25, 50, 100, 200, and 500 pounds of potash per acre. Check experiments were also made containing equivalent quantities of potash in the forms of the sulphate and the chloride, while in still another experiment no fertilizer was used. This last was in the nature of a control experiment.

The cultural methods employed and the results obtained from these experiments are as follows:

The soil was weighed into pans, 3 pounds to each pan. The soil in one pan received no fertilizer and was used as a control. To each of the other pans the fertilizer to be tested was added. To the different pans of soil were added raw alunite, ignited alunite, kelp, potassium sulphate, and potassium chloride, each in quantities of 25, 50, 100, 200, and 500 pounds of potash (K_2O) per acre, based on an acre half-foot of soil weighing 2,000,000 pounds.

The soil used in the first experiment was the Carrington loam—a soil which is known to respond well to potash fertilizers in field practice. The soil was treated with the various fertilizers in pans on October 22, was well mixed by sifting, and was potted October 28. Three pots, each holding about a pound of soil, were used for each treatment. Six wheat plants were planted in each pot. The plants grew until November 29. At the end of the experiment the plants were cut and the green weights recorded. The results of the test are given in the accompanying table. The last column gives the relative growth of the different treatments. The growth of the check or control is taken as 100. The second column gives the green weights of the three cultures in each treatment.

	100	4.50	134	
	200	4.37	130	
	500	4.40	131	

By examination of the table it is seen that each of the potash fertilizers produced an increased growth over the untreated soil. The raw alunite used in amounts of 25 to 500 pounds of K_2O per acre increased growth from 10 to 20 per cent. The best results were secured with 50 to 100 pounds of potash (K_2O) per acre. The average increase over the untreated soil of the five amounts was 14 per cent. When the growth is compared with that produced by the ignited alunite it is seen that this caused larger growth with each amount used than did the raw alunite. The increase in growth with ignited alunite over the untreated soil varied from 35 to 43 per cent, the average increase being 40 per cent. The growth with the raw alunite was not so good as with similar amounts of potash as potassium sulphate and potassium chloride. The average increase with potassium sulphate was 38 per cent and with potassium chloride was 31 per cent. The effect of ignited alunite was about the same as that of potassium sulphate, and greater than that of the potassium chloride.

Kelp produced a considerable increase in growth over the untreated soil. The increase varied with the different amounts, from 17 to 43 per cent. The average increase over the untreated soil was 31 per cent. The increased growth was about the same as that produced by potassium chloride and was slightly less than that resulting from the use of potassium sulphate. It should be here noted that the potash in the kelp is in the form of the chloride.

Another experiment was made to test the effect of these potash compounds, using this time a different soil. Otherwise, the details of the experiment were the same as in the first test. The soil used in this test was the Volusia silt loam. The plants grew from November 19 to December 21. Three pots were used for each treatment. The results are given in the table which follows.

Effect of alunite and kelp, as compared with that of potassium sulphate and potassium chloride on growth.

Treatment.	Quantity of K_2O added per acre.	Green weight.	Relative growth.	
	Pounds.	*Grams.*	*Per cent.*

	50	3.50	123	
	100	3.50	123	
	200	3.74	131	
	500	3.60	127	

Each of these potash fertilizers had a beneficial effect on Volusia silt loam. The raw alunite again produced less increased growth than the ignited alunite. This was true with each amount of the substances used. The raw alunite was not as effective as potassium sulphate and potassium chloride. However, the ignited alunite was more effective. The average increase for the raw alunite was 16 per cent, for the ignited alunite 31 per cent, for potassium sulphate 25 per cent, and for potassium chloride 22 per cent.

As in the first experiment kelp again produced considerable increase in growth. The effectiveness in producing plant growth was practically the same as that of potassium sulphate and potassium chloride. Kelp gave as an average 23 per cent increase in growth, potassium sulphate 25 per cent, and potassium chloride 22 per cent increase. In addition to the amount of potash added to the soil by the kelp, it contains a small amount of nitrogen and phosphorus, which should be effective in the soil. From these two experiments it seems that the dried kelp and ignited alunite are about as effective potash fertilizers as the salts, potassium sulphate and potassium chloride.

POTASH SALTS FROM THE SILICATE ROCKS.

If the interest in the problem of the derivation of potash salts from the silicate rocks is to be judged from the number of processes which have been devised and patented, then the year 1913 showed no abatement in this interest. Several patents have been secured covering such processes and a few articles on the subject have also appeared in the scientific literature. The more important of these processes are briefly reviewed below.

Process of Morse and Sargent.—H. W. Morse and G. W. Sargent (patent No. 1041327, dated Oct. 15, 1912) have invented a process in which feldspar is subjected at an elevated temperature, first, to the action of sulphate of lime (gypsum), and, second, to that of an alkaline chloride such as commom salt or to a chloride of an alkaline earth metal as calcium chloride. There are produced oxides of sulphur, a soluble compound of potassium and residual material which may be converted into Portland cement. According to the claims of the patentees, it is the production of the oxides of sulphur and the cement material in connection with that of the soluble potassium compound that makes possible the economical manufacture of the latter.

Process of Gelléri.—In the process of S. Gelléri (patent No. 1058686, dated Apr. 8, 1913) silicates are burned with lime or with an oxide or carbonate of an alkaline earth metal or magnesium for the purpose of decomposing the silicate and obtaining potash and cement clinker. After the silicates have been decomposed in this manner, a large portion of the alkalies in them is still not in a condition whereby it may be leached with water. According to Gelléri's process this disadvantage is overcome by subjecting the silicates in a closed chamber to the action of ammonium carbonate vapor under pressure either after they have been burned with the oxides or carbonates of the alkaline earth metals or without this preliminary burning. By so doing the silicates are completely decomposed, and the whole of the alkali metal may be obtained in the form of an alkali carbonate by leaching with water. The decomposition takes place according to the following reaction:

$$\underset{\text{(feldspar)}}{6KAlSi_3O_8} + 3(NH_4)_2CO_3 + 3H_2O = 3K_2CO_3 + 3Al_2O_3.6SiO_2.6H_2O + 6NH_3 + 12SiO_2.$$

This process has the advantage that the whole of the ammonia in the ammonium carbonate is liberated, and, after the reaction is completed, the free ammonia may be used over again to make ammonium carbonate. This is most economically accomplished by saturating the ammonia with carbon dioxide from the furnace in which the silicates are burned with limestone. In order that a separate furnace may not be necessary to heat the silicates with ammonium carbonate, the furnace gases coming from the burning kiln may be used.

If the silicates have been burned with lime before being treated with ammonium carbonate, they contain all the constituents corresponding with the composition of Portland cement, so that it is possible to burn the silicates which have been decomposed and freed from alkalies to Portland cement by heating them again.

Process of Hart.—According to E. Hart (patent No. 1062278, dated May 20, 1913), when feldspar or similar rock is mixed with potassium or sodium sulphate and carbon and heated to fusion in a furnace, there is formed a soluble glass consisting of a potassium or sodium aluminum silicate. This glass may readily be decomposed by the addition of a suitable acid like sulphuric, which forms practically pure silica and a solution from which potassium and aluminum may be obtained in the form of common potash alum, leaving a mother liquor which contains sulphates of potassium, sodium, or aluminum, some free sulphuric acid, and other sulphates formed by the action of the acid.

The mother liquor is evaporated to dryness and fused with a suitable amount of carbon. The residue consists chiefly of aluminate of soda or potash, or both, or of one or more of these substances, together with alumina. If water be added to the residue, the aluminate of soda or potash will be largely dissolved, and there will be left an insoluble residue consisting chiefly of sulphide of iron, with possibly some alumina. From the solution of the aluminate of soda or potash alumina may be obtained by the usual methods.

Process of Bassett.—An invention by H. P. Bassett (patent No. 1072686, dated Sept. 9, 1913) relates to the treatment of feldspar or feldspathic rock to obtain potash and has particular reference to a process of not only obtaining potash salts from feldspar or feldspathic rock, but also of obtaining, in the form of a by-product, material which is adapted for use in manufacturing pottery.

Bassett has found that potash may be economically and satisfactorily obtained from feldspar by treatment with salt alone, and that the potash salts and by-products of the reaction may be obtained in relatively pure form. In practice, he adds to disintegrated and preferably finely ground feldspar or feldspar-bearing rock, about one-half its weight of sodium chloride. The mixture is next heated to a yellow heat, preferably from 800 to 900° C., in the presence of air, for about one to two hours. The mass is then dumped while still hot into a vat of water in the proportion of about 2 to 5 parts by weight of water to 1 part of the fused mass. The mass is then leached with water and the potash and sodium salts are obtained in any desired manner, preferably by evaporation of the solution to dryness. The potassium and sodium salts are later separated, for example, by crystallization. The leached residue, which corresponds in composition closely with that of the feldspathic rock, except that the potassium is replaced by sodium, and that any iron present in the original rock will have been volatilized as iron chloride, and thus removed, is then dried and ground, the resulting product being a white mass that may be used for pottery or other purposes, such as a paper filler or enamel ware. The feldspar or feldspar-bearing rock may be ground to any desired fineness before treatment, but preferably not less than 40 mesh; finer grinding than 100 mesh is unnecessary. The leached residue is dried and ground and is then ready for use.

Process of Cowles.—Early in 1913 A. H. Cowles[1] described the results of certain experiments having to do with the extraction of potash alum and other soluble potash salts from the insoluble potash silicates. Cowles's experiments differ from those which have been described in that he mixes rock phosphate with the feldspar, thus incorporating a second fertilizer element into the resulting mixtures.

In the first experiments potash feldspar was ground with rock phosphate in such proportion as to furnish two molecular weights of lime to each molecular weight of silica in the feldspar. The mixture was heated to a sintering temperature of about 1,000° C. and the resulting product was leached with sulphuric acid. The resulting yield was practically 100 per cent. The products formed were insoluble dicalcium silicate, soluble potash alum, and orthophosphoric acid.

In the subsequent experiments less acid was used and the results of the leaching gave a product containing all the potash and alumina in the feldspar but only part of the phosphoric acid. Duplicate experiments have been carried out in which hydrochloric instead

[1] Paper read at the joint meeting of the American Electrochemical Society, the American Chemical Society, and the Society of Chemical Industry, New York, Feb. 7, 1913: Jour. Ind. and Eng. Chem., Apr., 1913, pp. 331–335.

of sulphuric acid was used. The solutions in the two cases gave either potash alum or the double chloride of potash and aluminum together with the phosphoric acid in the rock phosphate used in the experiment. Any iron present in the raw material used goes into solution with the aluminum and potash. From either the potash alum or the double chloride of aluminum and potash the opportunities for securing alumina are good. If the potash alum is heated to a dull red heat, the aluminum sulphate breaks down into alumina (Al_2O_3) and sulphuric acid (SO_3) and the potash sulphate may be leached away. If the double chloride of aluminum and potash is treated with water at a low temperature, hydrochloric acid is given off with the formation of alumina. The potassium chloride remains and may be leached away. The Cowles process for obtaining alumina has been described in this volume (Pt. I) in the chapter on bauxite and aluminum and will not be again described in detail in this place.

PRIVATE ENTERPRISE IN CONNECTION WITH THE EXTRACTION OF POTASH SALTS FROM THE SILICATES.

The Spar Chemical Co., with headquarters at Baltimore, Md., has done some experimental work on the extraction of potash salts from the silicate rocks at a plant located at Curtis Bay on the outskirts of the city. It is understood that the products are made according to the Thompson method, an outline of which was published in this chapter for 1911; this outline is repeated below.

Thompson's process is described in patent No. 995105, dated June 13, 1911. It consists first of grinding feldspar rock so that it will pass through a 100-mesh sieve. The powdered rock is then mixed wth an acid alkali sulphate and an alkali chloride, preferably acid sodium sulphate and sodium chloride, respectively. The proportions of the materials used are: Feldspar rock, 5 parts by weight; acid sodium sulphate, 5 parts by weight; sodium chloride, 1.8 parts by weight. This mixture is heated from one to two hours at a bright red heat and becomes thereby partly fused. The mass is then allowed to cool, is ground again, and is leached with water, which removes a mixture of sulphates of potassium and sodium. These salts are then separated by crystallization. The reactions are believed to be as follows: (*a*) The sodium acid sulphate reacts with the sodium chloride to produce hydrochloric acid gas and normal sodium sulphate. (*b*) The hydrochloric acid gas at the high temperature employed reacts on the feldspar, producing potassium chloride. (*c*) The potassium chloride is in turn acted upon by more of the acid sodium sulphate, producing hydrochloric acid gas and potassium sulphate.

The yield of potash is ordinarily from 80 to 90 per cent of the potash in the rock. For the best results the temperature must be controlled within rather narrow limits.

SHIPMENTS FROM GERMAN POTASH MINES.[1]

From data obtained from reliable sources the following table, showing the shipments of potash salts and potash fertilizers in metric tons from the German potash mines for native and foreign consumption during the last two years, has been compiled:

Shipments of potash salts from German mines in 1911 and 1912.

Potash salts.	1911.	1912.
	Metric tons.	*Metric tons.*
Muriate of potash	443,357	471,435
Sulphate of potassium	110,123	115,728
Magnesium, 48 per cent K_2O	49,014	55,987
Magnesium, 40 per cent K_2O	144	173
Manure salts:		
Minimum, 38 per cent K_2O	38,620	48,059
Minimum, 20 per cent K_2O	169,812	174,867
Minimum, 30 per cent K_2O	57,502	64,514
Minimum, 40 per cent K_2O	379,790	483,877
Kainit and sylvinit	3,312,632	3,251,003
Carnallite, etc	80,660	70,462
Total	4,641,654	4,736,105

Changes have been made in the method of preparing the statistics for 1912 so as to preclude comparison in all cases between the shipments of that year with 1911. The following table, however, shows the exports of German potash salts for 1911 and 1912 and the amount shipped to the United States in metric tons, with comparisons where possible:

Exports of German potash salts in 1911 and 1912.

Potash salts.	1911		1912	
	Total.	To United States.	Total.	To United States.
	Metric tons.	*Metric tons.*	*Metric tons.*	*Metric tons.*
Muriate of potash	329,751	229,431	286,528	190,775
Sulphate of potassium	109,529	56,893	85,452	35,366
Sulphate of potassium-magnesium	*a* 282,574	*a* 143,775	48,540	14,172
Carnallite with at least 9 per cent and less than 12 per cent K_2O			6,853	(*b*)
Raw potash salts with from 12 to 15 per cent K_2O			852,984	461,279
Raw potash salts with more than 15 per cent and less then 20 per cent K_2O	*c* 1,167,972	....	35,529	29,533
Manure salts, including potash salts with 38 per cent K_2O.			373,665	149,907
Abraum salts, Stassfurter salts, etc			31,322	9,578
Total	1,889,826	....	1,720,873	890,610

a Includes manure salts.
b Not stated.
c Only the total exports of the last five salts for the year 1911 are given in the new statistics, and the shipments to the United States during that year are not specified.

[1] Daily Cons. and Trade Repts., June 18, 1913.

CONSUMPTION OF POTASH SALTS IN THE UNITED STATES.

In the following table are given the total imports of potash salts in pounds for the years 1910 to 1913, inclusive:

Potash salts imported into the United States for the calendar years 1910–1913, in pounds.[a]

	1910		1911		1912		1913

[a] Including refined.

It will be observed that there was a slight decrease in both quantity and value of potash salts imported in 1913 as compared with 1912. The quantities of carbonate, cyanide, nitrate, and "all other salts" of potassium increased, while the quantity of caustic potash, chloride, and sulphate diminished. The results, especially in the case of the two latter salts, are of interest, for among the potassium salts imported it is presumably these two that enter most largely into the commercial fertilizer industry.

The importation of potash salts given in these tables is only a part of that entering the United States from Germany. To it should be added the importation of kainite and manure salts. The importation of fertilizers, including kainite and manure salts, is given in the following table:

Fertilizers imported and entered for consumption in the United States, 1909–1913, in long tons.

Fertilizer.	1909		1910		1911	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.

Potassium sulphate	43,375	1,769,676	39,538	1,633,114
Sodium nitrate (Chile saltpeter)	486,352	16,554,404	625,862	21,630,811
Domestic phosphate rock	2,973,332	11,675,774	3,111,221	11,796,231
Total	....	46,121,765	....	52,907,974

[a] Imports are "total imports."

This table requires some explanation. In the first place, the imports given in it are "general imports," or total imports. General imports are those entered at the customhouse for immediate consumption and also imported articles entered for the warehouse but not necessarily removed therefrom for consumption, and hence, strictly speaking, not necessarily consumed in the year under which they are given. This, however, does not destroy the value of comparisons between different years. In the second place, all the sodium nitrate reported is not used in the fertilizer industry. A large part of it is converted into nitric acid and potassium nitrate, the latter being used for making gunpowder and other explosives, matches, pyrotechnics, in assaying, in metallurgical and analytical operations, for curing meat, etc. The magnitude of the importation of this material is, however, very significant. This sodium nitrate is another commodity for which the United States is entirely dependent on a foreign country. Lastly, it is probable that not quite all the potassium chloride and potassium sulphate are used in the fertilizer industry.

The following table shows imports for consumption of materials entering largely into the domestic fertilizer industry:

Materials entering largely into the fertilizer industry in the United States for the years 1911–1913, in long tons.

	1911		1912		1913	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
Imports: [a]						
Fertilizers	1,029,375	$10,762,472	999,338	$8,893,090	955,436	$10,819,253
Potassium chloride	226,148	7,651,693	215,415	7,229,121	212,170	7,075,745
Potassium sulphate	54,335	2,240,631	43,856	1,783,846	39,597	1,677,429

FULLER'S EARTH.

By Jefferson Middleton.

INTRODUCTION.

The fuller's earth industry showed considerable progress in 1913, the marketed production increasing in both quantity and value, the former from 32,715 short tons in 1912 to 38,594 short tons in 1913, and the latter from $305,522 in 1912 to $369,750 in 1913.

According to Parsons:[1]

Fuller's earth is a variety of clay that has high capacity for adsorbing basic colors and can remove these colors from solution in animal, vegetable, or mineral oils, as well as from some other liquids, especially water. It is valuable when its adsorptive powers are strong enough to permit it to compete actively with fuller's earth already accepted as of standard quality for refining oils.

Analyses of various samples of fuller's earth vary so greatly that chemical analyses are now well understood to be no criterion whatever in determining whether or not a particular clay shall be classified as a fuller's earth. Like all other clays, fuller's earth is a hydrous, aluminum silicate containing small proportions of other substances. Most fuller's earths contain a higher percentage of water of composition than most clays, but this water is not an essential factor in the bleaching properties of all fuller's earths; some bleach fully as well after it has been driven off as before, and others lose much of their bleaching power when this water is removed.

OCCURRENCE.

Fuller's earth occurs in Alabama, Arkansas, California, Colorado, Florida, Georgia, Massachusetts, Minnesota, Mississippi, Nebraska, New York, South Carolina, South Dakota, Texas, Utah, and Virginia; but it was produced for the market in 1913 in only seven States, namely, Arkansas, California, Colorado, Florida, Georgia, Massachusetts, and South Carolina, the same number as for 1912, but Texas dropped out in 1913 and South Carolina reentered the list of producers.

MINING AND PREPARATION.[2]

In this country fuller's earth, except in Arkansas, is generally mined with pick and shovel or by mechanical means. When mined it contains more or less water, and is dried either in the sun or by artificial means. After being dried it is ground to suitable mesh, 15 to 80, according to the use to which it is to be put, and is then ready for shipment. In England the earth is washed in long, narrow troughs very much like hydraulic sluice boxes, a large percentage of the mate-

[1] Parsons, C. L., Fuller's earth: Bur. Mines Bull. 71, p. 6, 1913.
[2] For a full discussion of mining and milling methods see Parsons, C. L., idem, pp. 13–17.

rial being allowed to settle out as sand, while the lighter material goes off into settling tanks, where it is dried; it is then sold in the resulting lump form.

USES.

The original use of fuller's earth, from which it obtains its name, was the fulling of cloth. But little is now used in this country for this purpose, its principal use being in the bleaching, clarifying, or filtering of fats, greases, and oils. It is also used in the manufacture of pigments for printing wall papers, for the detection of certain coloring matters in some food products, and as a substitute for talcum powder.[1] The common practice with mineral oils is to dry the earth carefully, after which it is ground to suitable sizes and run into long cylinders, through which the crude, black mineral oils are allowed to percolate slowly. As a result, the oil that first comes out is perfectly water white, and much thinner than that which follows. The oil is allowed to continue percolating through the earth until the color reaches a certain maximum shade.

With the vegetable oils the process is radically different. The oil is heated in large tanks beyond the boiling point of water; from 5 to 10 per cent of its weight of fuller's earth is then added; and the mixture is vigorously stirred and then filtered off through bag filters. The coloring matter remains with the earth, the filtered oil being of a pale straw color, provided the operation has been conducted with sufficient care.

HISTORY.

Fuller's earth was first discovered in the United States in 1891 near Alexander, Ark., by John Olsen, who is still a producer. This earth was used for a time by the Southern Cotton Oil Co., at Little Rock, but its use was finally abandoned.[2] In 1893 fuller's earth was discovered near Quincy, Fla., by accident. An effort was made to burn brick on the property of the Owl Cigar Co.; the effort failed, but an employee of the company called attention to the close resemblance of the clay used to the German fuller's earth. In consequence of this discovery there was considerable excitement and supposed deposits of fuller's earth were reported from a number of States. The material in the most of these deposits was found to be of no value as fuller's earth.

From the inception of the industry Florida has been the leading producing State. At first the production was from only two or three States. In 1897–1899 it was reported from Florida, Colorado, and New York, with a very small production from Utah; in 1901 Arkansas was added to the list. From 1904 to 1907 Arkansas was the second largest producer. Fuller's earth was found in Georgia soon after its discovery in Florida, but Georgia did not appear as a producer until 1907, when it was the third largest producing State; it has ranked second since 1909. In 1904 Alabama and Massachusetts, and in 1907 South Carolina and Texas first reported production; in 1909 California entered the list.

PRODUCTION.

The following table shows the production of fuller's earth in the United States from the beginning of the industry:

Marketed production of fuller's earth in the United States, 1895-1913, in short tons.

Year.	Quantity.	Value.	Average price per ton.	Year.	Quantity.	Value.	Average price per ton.
1895	6,900	$41,400	$6.00	1905	25,178	$214,497	$8.52
1896	9,872	59,360	6.01	1906	32,040	265,400	8.28
1897	17,113	112,272	6.56	1907	32,851	291,773	8.88
1898	14,860	106,500	7.17	1908	29,714	278,367	9.37
1899	12,381	79,644	6.43	1909	33,486	301,604	9.01
1900	9,698	67,535	6.96	1910	32,822	293,709	8.95
1901	14,112	96,835	6.86	1911	40,697	383,124	9.41
1902	11,492	98,144	8.54	1912	32,715	305,522	9.34
1903	20,693	190,277	9.20	1913	38,594	369,750	9.58
1904	29,480	168,500	5.72				

In 1913 the production increased 5,879 short tons, or 17.97 per cent, over that of 1912, and the value increased $64,228, or 21.02 per cent. The production in 1913 was but 2,103 tons, or 5.17 per cent, less in quantity, and $13,374, or 3.49 per cent, less in value than the output of 1911, the year of maximum production. The average price, $9.58 per ton, was the highest yet reached for domestic fuller's earth, and was 17 cents higher than the highest price prior to 1913.

The following table shows the marketed production of fuller's earth in 1912 and 1913, by sections of the country:

Marketed production of fuller's earth in the United States, 1912-1913, in short tons.

	1912				1913			
	Number of operators.	Quantity.	Value.	Average price per ton.	Number of operators.	Quantity.	Value.	Average price per ton.
Eastern States [a]	8	31,496	$291,099	$9.24	7	37,869	$361,175	$9.54
Western States [b]	5	1,219	14,423	11.83	3	725	8,575	11.83
Total	13	32,715	305,522	9.34	10	38,594	369,750	9.58

[a] Includes, 1912: Florida, Georgia, Massachusetts, Texas; 1913: Florida, Georgia, Massachusetts, and South Carolina.
[b] Includes, 1912 and 1913: Arkansas, California, Colorado.

Owing to the small number of producers in each State, it is impossible to give State totals, and the table has been made to show simply the production of the Eastern and the Western States. The eastern section of the country continues to produce by far the larger portion of the fuller's earth marketed, its 7 operators reporting 98.12 per cent of the quantity and 97.68 per cent of the value of the entire output. In quantity and value of production Florida was the leading State in 1913, Georgia was second, Arkansas was third, and Massachusetts fourth. Florida and Georgia together contributed over 97 per cent of the quantity and value of the fuller's earth marketed in 1913.

The increase in output and value was in the Eastern States, the Western States decreasing over 40 per cent. The average price per ton increased in the East from $9.24 in 1912 to $9.54 in 1913, and in the West it was the same in both years, namely, $11.83. The number of active firms reporting decreased 3 in 1913, 1 in the Eastern and 2 in the Western States.

NOTES ON THE FULLER'S EARTH INDUSTRY BY STATES.

Arizona.—The Arizona Earth Products Co. reports having located a fuller's earth claim near Benson, Cochise County, Ariz. No shipments were reported for 1913, but operations were expected to begin early in 1914.

Arkansas.—Only 1 of the 6 mine owners in Arkansas reported production in 1913, namely, John Olsen, the original discoverer of fuller's earth in the United States. The earth from this State is reported as having been used in refining edible oils.

California.—Of the 8 fuller's earth miners in California only 1, the Eight Oil Co., reported a marketed product. The California fuller's earth is reported as being suitable for the refining of animal, vegetable, and mineral oils.

Colorado.—The American Clay Co., Akron, Colo., is the only producer in the State. Its earth is used in bleaching cottonseed oil.

Florida.—Of the 6 owners of fuller's earth properties in Florida, 3 firms were active in 1913, namely, the Atlantic Refining Co., at Ellenton; the Floridin Co., at Quincy and Jamieson; and the Fuller's Earth Co., at Midway. This fuller's earth is reported as having been used in filtering mineral and vegetable oils. Florida is the leading fuller's earth producing State, having reported for 1913 over two-thirds of the marketed output of the entire country.

Georgia.—There are but 2 operators in Georgia, both of whom were active in 1913, the Lester Clay Co., with mine at Attapulgus, and the General Reduction Co., with mine at Dry Branch. The demand was reported good, and the fuller's earth was used in refining mineral, vegetable, and animal oils.

Massachusetts.—Only one firm has produced fuller's earth in Massachusetts for several years—J. E. & R. M. Farnworth, of Lancaster. The earth is reported as used for fulling woolen goods.

Minnesota.—The only known deposit of fuller's earth in Minnesota is near Austin, and was not worked in 1913. It is owned by the P. D. McMillan Land Co., of Minneapolis.

Mississippi.—A large deposit of fuller's earth, said to be suitable for clarifying vegetable oils, is reported to occur at Bay Springs, Miss. It has not been developed. The deposit is owned by A. H. Longino, of Jackson.

New York.—The only developed deposit of fuller's earth in New York is that of the New York Fuller's Earth Co., in Oneida County. It was not worked in 1913.

South Carolina.—Of the three known deposits of fuller's earth in South Carolina only one, that of the Palmetto Kaolin Co., was operated in 1913, and this was worked only in an experimental way.

South Dakota.—Three operators reported from South Dakota for 1913—the Argyle Fuller's Earth Co., Argyle; Willaim Bodenner, Fairburn; and the South Dakota Fuller's Earth Co., Rapid City. All were idle.

Texas.—None of the operators in Texas reported sales of fuller's earth in 1913. Three of the 10 operators have retired from the business.

Utah.—The only deposit of fuller's earth in Utah known to the Survey was not worked in 1913. It is located in San Pete County, and is owned by George F. Young, whose address is North Powder, Oreg.

IMPORTS.

The following table shows the imports of fuller's earth for consumption from 1897 to 1913, inclusive:

Fuller's earth imported for consumption into the United States, 1897 to 1913, in short tons.

Year.	Unwrought or unmanufactured.			Wrought or manufactured.			Total.		
	Quantity.	Value.	Average price per ton.	Quantity.	Value.	Average price per ton.	Quantity.	Value.	Average price per ton.
1897 *a*	2,585	$14,283	$5.53	2,395	$20,037	$8.37	4,980	$34,320	$6.89
1898	2,283	15,921	6.97	7,073	55,123	7.79	9,356	71,044	7.59
1899	4,192	23,194	5.53	7,366	46,446	6.31	11,558	69,640	6.03
1900	2,723	14,750	5.42	6,431	50,047	7.78	9,154	64,797	7.08
1901	3,266	17,230	5.28	8,792	63,467	7.22	12,058	80,697	6.69
1902	4,239	26,635	6.28	10,895	75,945	6.97	15,134	102,580	6.78
1903	4,260	28,339	6.65	12,840	92,332	7.19	17,100	120,671	7.06
1904	1,975	9,546	4.83	8,247	64,460	7.82	10,222	74,006	7.24
1905	1,705	12,798	7.51	12,858	93,199	7.25	14,563	105,997	7.28
1906	2,905	20,129	6.93	11,920	88,566	7.43	14,825	108,695	7.33
1907	2,490	16,833	6.76	13,916	105,388	7.57	16,406	122,221	7.45
1908	2,363	16,242	6.87	9,803	77,171	7.87	12,166	93,413	7.68
1909	1,802	12,492	6.93	10,950	88,659	8.10	12,752	101,151	7.93
1910	2,160	14,399	6.67	14,427	118,146	8.19	16,857	132,545	7.86
1911	1,881	10,877	5.78	16,343	132,717	8.12	18,224	143,594	7.88
1912	1,970	11,619	5.90	17,139	133,718	7.80	19,109	145,337	7.61
1913	1,916	12,344	6.44	16,712	133,657	8.00	18,628	146,001	7.84

a July to December.

The imports decreased in 1913 in quantity and increased in value, the quantity decreasing 481 tons, or 2.52 per cent, and the value increasing $664, or 0.46 per cent. The average value per ton of imported fuller's earth increased in 1913—unwrought, 54 cents; wrought, 20 cents—the average increase being 23 cents. The imports are nearly all of wrought or manufactured earth, 89.71 per cent of the quantity and 91.55 per cent of the value being of that classification.

In the following table is shown the quantity and value of the fuller's earth imported from 1867 to 1883 by fiscal years. The wrought and the unwrought earths were not classified separately during this period. From July 1, 1883, to June 30, 1897, fuller's earth was not reported separately in the customhouse returns to the Treasury Department, but was included in minerals "not elsewhere specified."

Imports of fuller's earth into the United States, 1867–1883, in short tons.

Year ended June 30—	Quantity.	Value.	Year ended June 30—	Quantity.	Value.
1867	314	$3,113	1876	277	$3,097
1868	236	2,522	1877	448	4,460
1869	363	3,587	1878	375	4,095

CEMENT.

By Ernest F. Burchard.

INTRODUCTION.

The present practice of the United States Geological Survey with regard to the collection and publication of statistics of the cement industry is to issue some time during the month of January a statement of production and shipments of Portland cement in the United States by commercial districts for the year just closed, and then to publish as early as is practicable the advance chapter from Mineral Resources on the cement industry, which contains complete figures for all classes of cement. The estimate referred to is based on telegraphic data from the larger companies, which report actual figures for the first 11 months of the year, plus estimates for December. The figures in the advance chapter are based on complete reports from every manufacturer. Occasion is taken here to express thanks to those firms whose prompt replies have rendered it possible to prepare early estimates and to those manufacturers whose complete returns have made it possible to prepare this report at an earlier date than formerly. To those manufacturers who heretofore have been indifferent as to the date of making their reports an earnest request is made for prompt cooperation in the future, for the value of this report to the cement industry depends equally on two factors, viz, early publication and completeness. It has been the custom of the writer to use only the reports of producers as a basis for the statistics presented in the chapters on the cement industry and to decline to estimate the output or value of the product of any mill. To an industry of the magnitude of the cement-manufacturing business the importance of having statistics based on actual figures is obvious, and since delay in receipt of reports from only one or two mills correspondingly delays the compilation of all the statistics, the writer feels justified, in the interest of the cement industry, to urge that every firm, in the future, send complete returns to the Survey before the close of January.

The estimate of Portland cement production, which was released to the press on January 22, 1914, prophesied that the increase in production in 1913 would approximate 9,967,900 barrels over that of 1912. The final returns show an actual increase in production of 9,659,035 barrels.

The noteworthy features of the cement industry in 1913 were the substantial increase in average price for which Portland cement was sold and the large increase in production. The increase in average price amounted to 19.2 cents per barrel—the largest recorded since 1902—and the increase in production was the largest since 1910.

The production and price of puzzolan cement both showed an increase in 1913. The decline in the production of natural cement continued, although the price of this commodity rose slightly.

Since the publication in 1913 of Bulletin 522 on the Portland cement materials and industry in the United States the Survey has carried on no field investigations of cement materials. This bulletin and the advance chapter from Mineral Resources on the cement industry in 1910, both illustrated by maps which show the general distribution of limestones suitable for cement manufacture, are available for free distribution by the Survey. The Survey activities in connection with the cement industry are now limited to field studies of cement materials and to the preparation of statistical reports, but requests continue to be received for laboratory examinations of raw materials and for tests of cement and concrete. This is probably because of the fact that the Survey a few years ago conducted laboratories for testing structural materials at St. Louis, Mo., and at Pittsburgh, Pa. The laboratory at St. Louis has long since been discontinued, and the laboratory at Pittsburgh has passed under control of the Bureau of Standards, which carries on at Pittsburgh and at Washington, D. C., certain chemical and physical investigations of structural materials. Inquiries pertaining to tests of cement and concrete should, therefore, be addressed to the Director, Bureau of Standards, Washington, D. C.

The Bureau of Standards is publishing the results of the Survey's tests as well as the results of its own later work in a series of circulars and technologic papers, the following of which are now (March 28, 1914) available:

Circular No. 33: United States Government specification for Portland cement. 28 pp. 1912.

Circular No. 39: Specifications for and measurement of standard sieves. 14 pp. 1912.

Technologic Paper No. 2: The strength of reinforced concrete beams; results of tests of 333 beams. 200 pp. 1912.

Technologic Paper No. 3: Tests of the absorptive and permeable properties of Portland cement mortars and concretes, together with tests of damp proofing and waterproofing compounds and materials. 127 pp. 1912.

Technologic Paper No. 5: The effect of high-pressure steam on the crushing strength of Portland cement mortar and concrete. 25 pp. 1912.

Technologic Paper No. 12: Action of the salts in alkali water and sea water on cements. 157 pp. 1913.

Technologic Paper No. 18: Electrolysis in concrete. 157 pp. 1913.

Technologic Paper No. 29: Variation in results of sieving with standard cement sieves. 16 pp. 1913.

PRODUCTION OF ALL CEMENTS.

The total quantity of Portland, natural, and puzzolan cement produced in the United States in 1913 was 92,949,102 barrels, valued at $93,001,169, as compared with 83,351,191 barrels, valued at $67,461,513 in 1912. This represents an increase in quantity of 9,597,911 barrels, or 11.51 per cent, and in value of $25,539,656, or 37.86 per cent. It should be noted here that any table in which the production of these three kinds of cement is combined to form a total of barrels is necessarily inconsistent, for the weights per barrel of each kind of cement are different. Portland cement is sold in barrels weighing 380 pounds, natural cement in 265-pound barrels, and puzzolan cement in 330-pound barrels. The percentage of increase in quantity is considerably greater than that of 1912 over 1911, which was 4.78 per cent, but the value increased in far greater proportion, the increase for 1912 having been only 1.13 per cent.

The distribution of the total production among the three main classes of cement is shown in the following table for the years 1911, 1912, and 1913:

Total production of cement in the United States in 1911, 1912, and 1913, by classes.

Class.	1911		1912		1913	
	Quantity (barrels).	Value.	Quantity (barrels).	Value.	Quantity (barrels).	Value.
Portland	78,528,637	$66,248,817	82,438,096	$67,016,928	92,097,131	$92,557,617
Natural	926,091	378,533	a 821,231	367,222	a 744,658	345,889
Puzzolan	93,230	77,786	a 91,864	77,363	a 107,313	97,663
Total	79,547,958	66,705,136	83,351,191	67,461,513	92,949,102	93,001,169

a Shipments.

PORTLAND CEMENT.

PRODUCTION AND SHIPMENTS.

The total production of Portland cement in the United States in 1913, as reported to the United States Geological Survey, was 92,097,131 barrels, valued at $92,557,617; the production for 1912 was 82,438,096 barrels, valued at $67,016,928. The output for 1913 represents an increase in quantity of 9,659,035 barrels, or nearly 11.72 per cent, and an increase in value of $25,540,689, or 38.11 per cent. The value assigned to the production is proportionate to the value of the Portland cement shipped in 1913.

The shipments of Portland cement from the mills in the United States in 1913 were, according to reports received by the Survey, 88,689,377 barrels, valued at $89,106,975, compared with 85,012,556 barrels, valued at $69,109,800, shipped in 1912. The shipments therefore represent an increase in quantity of 3,676,821 barrels, or 4.31 per cent, and in value of $19,997,175, or 28.94 per cent. The average price per barrel in 1913, according to these figures, was a trifle less than $1.005, compared with 81.3 cents in 1912. This represents the value of cement in bulk at the mills, including the labor cost of packing, but not the value of the sacks or barrels. The average price per barrel for the country is about 16.7 cents higher than the average price received for Portland cement in the Lehigh district, where it was sold at the lowest price, and is near the average price received in Illinois, Indiana, and Missouri, but falls 45.6 cents below the average price received on the Pacific coast, where Portland cement brought the highest figure during the year.

The quantity of Portland cement produced, 92,097,131 barrels of 380 pounds, is equivalent to 15,623,620 long tons, and the value per long ton is $5.92. Compared with the production of pig iron for 1913, 30,966,152 long tons,[1] the Portland cement production is nearly 50.5 per cent of the quantity of pig iron, but the total value of the cement does not greatly exceed 20 per cent of the value of the pig iron. The value of the cement per ton is about 40 per cent of that of pig iron.

[1] Am. Iron and Steel Inst. Special Stat. Bull., May 15, 1914.

The average price of Portland cement in the United States has been increased slightly over the average for ordinary gray cement by the inclusion in the total of 160,582 barrels of white Portland cement, valued at $2.34 a barrel. The greater part of this white cement was produced in the Lehigh district, so that the value for that district has been increased in greater proportion than that of the other districts. Three mills produced white Portland cement in 1913, 1 being in California and 2 in Pennsylvania, 1 of which produced white cement exclusively.

PRODUCTION AND SHIPMENTS BY STATES.

In the following two tables the production and shipments of Portland cement for 1912 and 1913, by States, are arranged in the order of rank for 1913 where there are three or more producers or shippers in a single State. By the term "producer" is meant a Portland cement manufacturing company, whether the company operates one or more plants. In the table the term "producing plant" is applied to a mill or group of mills located at one place and operated by one company, but each establishment at a different place is counted as a plant. There were producing plants in 24 States in 1912, and in 25 States in 1913, but only 14 of these States contained three or more plants; therefore it has been necessary to group together in these tables a large number of States not closely related geographically. This disadvantage is, however, compensated for in the table "Production and shipments of Portland cement by commercial districts," in which statistics are given for groups, not generally exceeding three in number, of States geographically related.

In the table of shipments will be found the total value of the shipments by States and the average price per barrel of the cement in bulk at the mills.

Production of Portland cement in the United States in 1912 and 1913, by States.

State.	1912		1913		Percentage of change, 1913.

PRODUCTION AND SHIPMENTS BY COMMERCIAL DISTRICTS.

In addition to considering the Portland cement industry by States, it is also of interest, and perhaps of more practical importance, to regard the commercial district as the geographic unit. Accordingly, beginning in 1911, the plants producing Portland cement were grouped together into 11 districts, the grouping being based to some extent on the relations of the plants to their trade territory. These relations are of course governed largely by transportation facilities and rates, and it has been found advisable to divide Pennsylvania, Indiana, and Texas in order to accomplish a logical grouping. The same grouping was followed in both the 1911 and the 1912 reports, but it has appeared advisable that the Southeastern States should be subdivided, and this has been done in the report for 1913.

The following table summarizes, by commercial districts for 1912 and 1913, the number of active plants producing and shipping Portland cement, the production and shipments, with percentage of change in 1913, and the average factory price per barrel in bulk, with the percentage of change in price in 1913:

Production and shipments of Portland cement in 1912 and 1913, by commercial districts.

[a] Includes Arizona in 1913.

According to this table there was in 1913, compared with 1912, a decrease in production in only 1 district—Kentucky and southern Indiana, and a decrease in shipments in only 3 districts—Ohio and western Pennsylvania, Kentucky and southern Indiana, and the district comprising Maryland, Virginia, and West Virginia. All these decreases were insignificant, except that of shipments in Kentucky and southern Indiana, which amounted to 8.71 per cent. The largest percentages of increase both of production and of shipments were reported from the Tennessee-Alabama-Georgia district, being, respectively, 27.83 and 16.27 per cent. The mills in New York made nearly parallel increases in production and in shipments, the increases being, respectively, 15.92 and 13.05 per cent. In all the districts but the Rocky Mountain States the increases in shipments fell below the increases in production, but in this group of States the increase in production was 13.91 per cent compared with an increase of 15.83 per cent in shipments. In the Maryland-Virginia-West Virginia district, one of those which showed a decrease in shipments, the increase in production amounted to 14.72 per cent, and in the Illinois-northwestern Indiana, Tennessee-Alabama-Georgia, Great Plains, Iowa-Missouri, and Pacific coast districts the percentage of increase in production exceeded the percentage of increase in shipments by 9 to 11 per cent; in the others there was less difference.

The net change for the country at large was an increase in both production and shipments, amounting to 9,659,035 barrels, or 11.72 per cent, for the former, and to 3,676,821 barrels, or 4.31 per cent, for the latter. In 1912 the shipments exceeded the production of Portland cement by 2,574,460 barrels, or 3.1 per cent of the production; but in 1913 the relation between production and shipments was reversed, and the production exceeded the shipments by 3,407,754 barrels, or 3.7 per cent of the production. This relation was practically a repetition of conditions in 1911.

LEHIGH DISTRICT.

The production of Portland cement in the Lehigh district of eastern Pennsylvania and western New Jersey in 1913 was 27,139,601 barrels, as compared with 24,762,083 barrels in 1912, an increase of 9.6 per cent. The shipments from mills in this district amounted in 1913 to 26,659,537 barrels, as compared with 26,013,891 barrels in 1912, an increase of 645,646 barrels, or 2.48 per cent. Both the production and shipments in the Lehigh district reached a new high record in 1913. The total value of the Portland cement shipped from this district in 1913 was reported as $22,342,102, an average price of 83.8 cents a barrel in bulk at the mills as compared with $17,538,989, or 67.4 cents a barrel, in 1912. The production of white Portland cement from 2 plants in this district is included in the figures for 1913. As the average value reported for the white cement was considerably higher than that reported for ordinary gray cement, the average price for the district is slightly higher than if it represented gray Portland cement alone.

Twenty-two plants produced and shipped Portland cement from the Lehigh district in 1913 as compared with 22 producers and 25 shippers in 1912.

The Lehigh district of eastern Pennsylvania-New Jersey has, except in four years, shown a steady increase in production of Portland cement from 1890 to the present time. The years in which slight decreases were recorded are 1893, 1908, 1911, and 1912. The first two decreases were coincident with years of general business depression, but the decrease in 1911 and 1912 may perhaps be attributed in large part to an overproduction in 1910 and to the building of many mills in other parts of the United States which have restricted the trade territory of the Lehigh district. The percentage which the Lehigh total bears to the total for the United States is slowly but steadily decreasing.

The following table shows the annual production of Portland cement in the Lehigh district since 1890, the total production for the country, and the percentage of the Lehigh district output each year compared with the total production, and the curve, figure 1, illustrates graphically the trend of production during the same period:

Portland cement production in the Lehigh district and in the United States, 1890–1913, in barrels.

Year.	Lehigh district output.	Total output, United States.	Percentage of total manufactured in Lehigh district.	Year.	Lehigh district output.	Total output, United States.	Percentage of total manufactured in Lehigh district.
1890	201,000	335,500	60.0	1902	10,829,922	17,230,644	62.8

PRODUCTION ACCORDING TO RAW MATERIALS.

In the following table the production of Portland cement in the United States is classified according to the kinds of raw materials

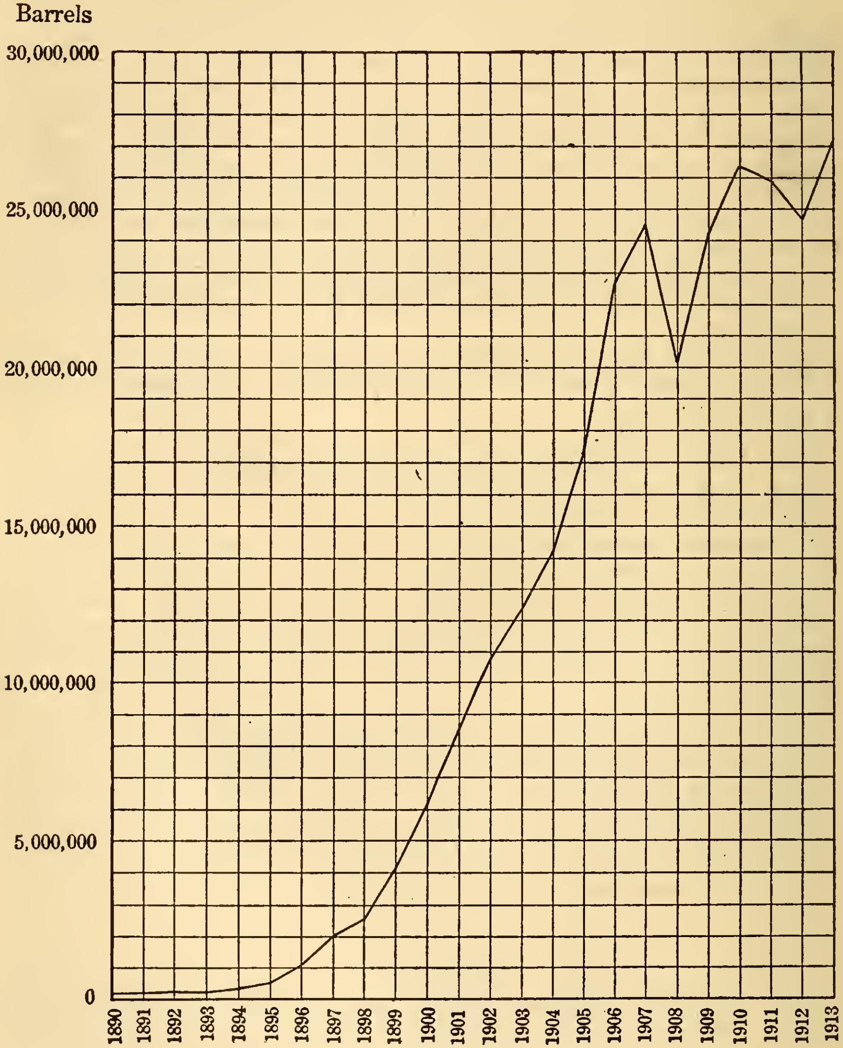

FIGURE 1.—Production of Portland cement in the Lehigh district, 1890–1913.

from which the cement is manufactured. The production is grouped as follows:

Type 1 includes cement produced from a mixture of argillaceous limestone ("cement rock") and pure limestone. This is the combination of materials used in all the cement plants of the Lehigh district of Pennsylvania and New Jersey, and also at a few middle and western plants.

Type 2 includes cement made from a mixture of comparatively pure limestone with clay or shale. This mixture is employed at the majority of plants in the United States.

Type 3 includes cement manufactured from a mixture of marl and clay. This type of mixture is used in certain plants in the States of Michigan, Ohio, Indiana, New York, and Utah.

Type 4 includes Portland cement manufactured from a mixture of limestone and blast-furnace slag.

This table shows, generally, a decrease in the relative production from cement rock (type 1) and from marl (type 3), and a corresponding increase in the production from limestone (type 2) and from blast-furnace slag (type 4).

Production, in barrels, and percentage of total output of Portland cement in the United States according to type of material used, 1898–1913.

Year.	Type 1. Cement rock and pure limestone.		Type 2. Limestone and clay or shale.		Type 3. Marl and clay.		Type 4. Blast-furnace slag and limestone.

STOCKS ON HAND.

Reports were received by the Survey from all the mills in the United States which shipped any Portland cement in 1913, giving stocks of finished cement on hand December 31, 1913. The stock on hand at the end of 1913, according to these reports, amounted to 11,220,328 barrels, compared with 7,811,329 barrels on hand at the close of 1912, thus indicating an increase in stock of 3,408,999 barrels, or 43.64 per cent, during 1913.

The two tables following give the stocks on hand by States and by districts at the close of 1912 and 1913, together with the percentage of change in 1913.

Stocks of Portland cement Dec. 31, 1912, and Dec. 31, 1913, by States, in barrels.

State.	Quantity.		
	1912	1913	Percentage of change, 1913.
California	485,182	651,101	+34.20
Illinois	321,116	641,334	+99.72
Indiana	1,193,612	1,888,543	+58.22
Iowa	436,877	542,575	+24.19
Kansas	442,426	520,917	+17.74
Michigan	370,956	473,563	+27.66
Missouri	456,843	855,272	+87.21
New Jersey	231,398	415,799	+79.69
New York	555,989	556,557	+ .10
Ohio	200,800	228,548	+13.82
Pennsylvania	2,135,969	2,835,945	+32.77
Texas	255,494	257,837	+ .92
Utah	113,439	94,914	−16.33
Washington	121,807	406,081	+233.38
Other States [a]	489,421	851,342	+73.95
Total	7,811,329	11,220,328	+43.64

[a] Alabama, Colorado, Georgia, Kentucky, Maryland, Montana, Oklahoma, Tennessee, Virginia, and West Virginia in 1912, with Arizona additional in 1913.

Stocks of Portland cement Dec. 31, 1912, and Dec. 31, 1913, by districts, in barrels.

District.	Quantity.		
	1912	1913	Percentage of increase, 1913.
Lehigh district (New Jersey and eastern Pennsylvania)	1,927,495	2,448,400	27.02
New York	555,989	556,557	.10
Ohio and western Pennsylvania	640,672	1,031,892	61.06

Tennessee, Alabama, and Georgia	163,649	287,300	75.56
Iowa and Missouri	893,720	1,397,847	56.41
Great Plains States (Kansas, Oklahoma, and central Texas)	708,657	848,949	19.80
Rocky Mountain States [a] (Colorado, Utah, Montana, and western Texas)	222,037	[a] 246,241	10.90
Pacific Coast States (California and Washington)	606,989	1,057,182	74.17
Total	7,811,329	11,220,328	43.64

[a] Includes also Arizona in 1913.

The next table gives the total stocks of Portland cement on hand at the mills in the United States at the close of each of the last three years, covering the period that data have been gathered on this subject by the Survey:

Stocks of Portland cement at the close of 1911, 1912, and 1913.

	Barrels.
1911	10,385,789
1912	7,811,329
1913	11,220,328

QUANTITY CONSUMED.

An approximate estimate of the total consumption of Portland cement in the United States might be made as follows: To the shipments add the imports and from the sum, which represents the total available supply, subtract the exports, which leaves the total apparent consumption. Of course, there is at all times a variable, but considerable, stock of cement in transit, in warehouses at distributing points, and awaiting use on the ground at large jobs, so that at best the data in this form furnish only a rough approximation. Still another uncertain element in this estimate is the fact that records of imports and exports are classed as hydraulic cement and do not discriminate between Portland and other cements. Portland cement, however, constitutes by far the greater portion of the exports, and, as is shown by the tables, the imports are small. As compared with the apparent consumption in 1912, which amounted to 80,865,527 barrels, the domestic consumption in 1913 increased 4,944,122 barrels, or 6.1 per cent, as compared with an increase of 11.4 per cent in 1912.

The following tabulation gives the figures necessary for estimates of consumption so far as available, since prior to 1911 no records are at hand for stocks:

Apparent consumption of Portland cement, 1911–1913, in barrels.

Year.	Shipments.	Imports.	Exports.	Apparent consumption.
1911	75,547,829	164,670	3,135,409	72,577,090
1912	85,012,556	68,503	4,215,532	80,865,527
1913	88,689,377	84,630	2,964,358	85,809,649

GROWTH OF PORTLAND CEMENT PRODUCTION, 1890–1913.

The growth of the production of Portland cement and its annual value for the years 1890 to 1913, inclusive, also the shipments of Portland cement from 1911 to 1913, are illustrated graphically in figure 2. For comparison the decline in the production of natural cement is plotted on the same diagram.

In the following table statistics are given covering the annual production of Portland cement in the United States from the beginning of the industry in the early seventies to the present day:

Production of Portland cement in the United States, 1870–1913, in barrels.

Year.	Quantity.	Value.	Year.	Quantity.	Value.
1070–1879	82,000	$246,000	1898	3,692,284	$5,970,773
1880	42,000	126,000	1899	5,652,266	8,074,371
1881	60,000	150,000	1900	8,482,020	9,280,525
1882	85,000	191,250	1901	12,711,225	12,532,360
1883	90,000	193,500	1902	17,230,644	20,864,078
1884	100,000	210,000	1903	22,342,973	27,713,319
1885	150,000	292,500	1904	26,505,881	23,355,119
1886	150,000	292,500	1905	35,246,812	33,245,867
1887	250,000	487,500	1906	46,463,424	52,466,186
1888	250,000	487,500	1907	48,785,390	53,992,551
1889	300,000	500,000	1908	51,072,612	43,547,679
1890	335,500	704,050	1909	64,991,431	52,858,354
1891[1]	454,813	967,429	1910	76,549,951	68,205,800
1892	547,440	1,153,600	1911	78,528,637	66,248,817
1893	590,652	1,158,138	1912	82,438,096	67,016,928
1894	798,757	1,383,473	1913	92,097,131	92,557,617
1895	990,324	1,586,830			
1896	1,543,023	2,424,011	Total	682,288,061	654,800,516
1897	2,677,775	4,315,891			

[1] The figures for 1890 and previous years are estimates made at the close of each year and are believed to be substantially correct. Since 1890 the official figures are based on complete returns from all producers.

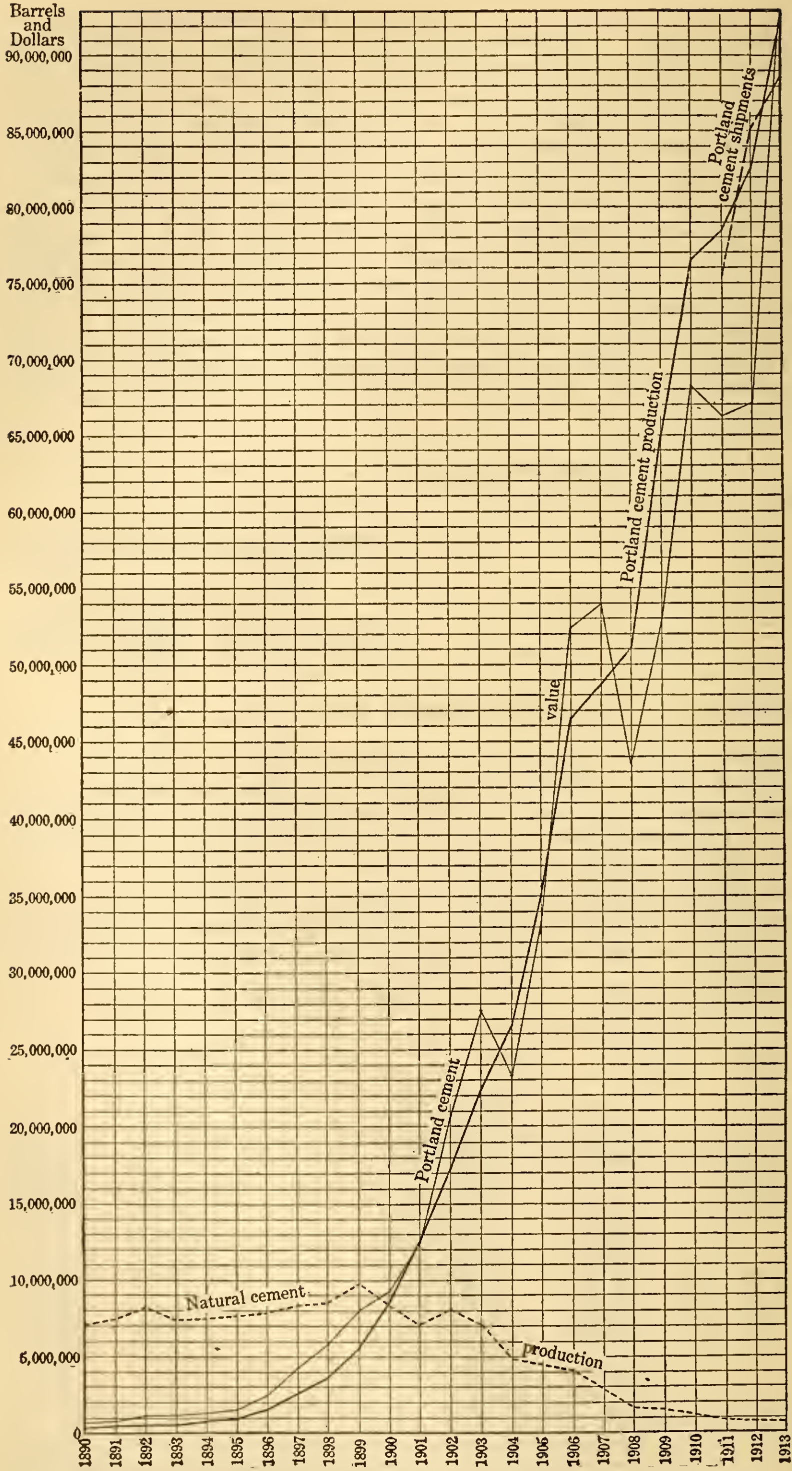

FIGURE 2.—Production of Portland and natural cements and value of Portland cement in the United States, 1890–1913, and shipments of Portland cement, 1911–1913.

The following table summarizes the shipments of Portland cement and their value during the three years that data on this subject have been gathered by the United States Geological Survey:

Shipments of Portland cement in the United States, 1911–1913, in barrels.

Year.	Quantity.	Value.
1911	75,547,829	$63,762,368
1912	85,012,556	69,109,800
1913	88,689,377	89,106,975

The table and the curve of production indicate that the Portland cement industry showed a fair rate of growth from the beginning in the seventies until 1895. At the latter date, however, a rapid development commenced, coincident with the burning of powdered coal in the rotary kiln. This rapid rate of growth continued until 1907, when it was checked temporarily by the financial troubles of that year. Still later there was another short era of growth more rapid than ever before, only to be checked in 1911 by a combination of factors, the most important of which were overproduction in 1910 and generally quiet business conditions in 1911.

In 1912 the rate of growth increased slightly compared with 1911, owing in part to a resumption of construction work that had been deferred. This resumption was no doubt encouraged by the low price at which cement might be obtained. In 1913, encouraged by better prices and an increased demand, the output of Portland cement was pushed up to a total far above that anticipated by the most optimistic manufacturers. The demand, however, did not keep pace with the production, and the year closed with large stocks on hand and diminishing kiln activity.

The output of Portland cement has so far shown an increase each year, rising from 42,000 barrels in 1880 to 335,500 barrels in 1890, to 8,482,020 barrels in 1900, and to 92,097,131 barrels in 1913. The output of natural cement, on the other hand, reached its maximum in 1899, with an output of 9,868,179 barrels. Since that year it has shown an almost continuous decrease annually, until now it is less than three-quarters of a million barrels, and has become a relatively unimportant factor in the cement market.

PRICES.

Average prices of Portland cement per barrel in bulk at the mills are shown in the tables of shipments by States and districts during 1912 and 1913. According to these figures the price in 1913 ranged between 83.8 cents in the Lehigh district and $1.478 in California, as compared with 67.4 cents and $1.348, respectively, in 1912. The average price for the whole country was $1.005 in 1913 as compared with 81.3 cents in 1912, an increase of 19.2 cents a barrel, or 23.6 per cent. This represents the largest increase since 1902, when the price rose 22 cents a barrel. In 1906 there was an apparent rise of 19 cents a barrel, which comes close to the present record. Inspection of these tables shows that in no instance was there a decrease of average price in individual States or districts. The smallest percentage of increase, 7.58 per cent, was reported from the Pacific coast States, where the highest prices have prevailed during recent years, and the largest percentage of increase, 34.67 per cent, was reported from the Illinois-northwestern Indiana district. Substantial increases

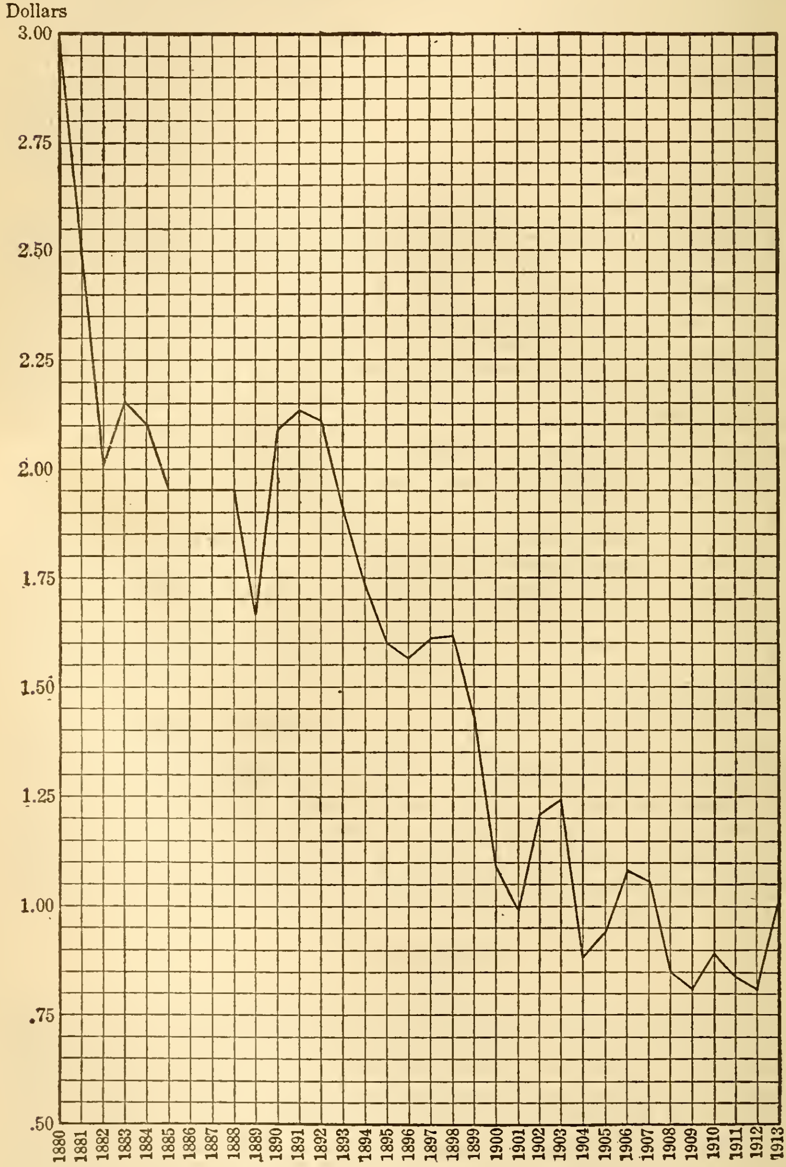

FIGURE 3.—Range in average price per barrel of Portland cement, 1880–1913.

were reported from all the districts, the only ones besides the Pacific coast to fall below a 20 per cent increase being Maryland-Virginia-West Virginia and the Rocky Mountain group of States.

Figure 3 illustrates graphically the rapid early decline and the recent fluctuations in Portland cement prices.

The following table gives the average factory price of Portland cement per barrel in bulk from 1870 to 1913:

Average price per barrel of Portland cement, 1870–1913.

1870–1880	$3.00	1894	$1.73	1905	$0.94
1881	2.50	1895	1.60	1906	1.13
1882	2.01	1896	1.57	1907	1.11
1883	2.15	1897	1.61	1908	.85
1884	2.10	1898	1.62	1909	.813
1885–1888	1.95	1899	1.43	1910	.891
1889	1.67	1900	1.09	1911	.844
1890	2.09	1901	.99	1912	.813
1891	2.13	1902	1.21	1913	1.005
1892	2.11	1903	1.24		
1893	1.91	1904	.88		

PORTLAND CEMENT INDUSTRY.

BUSINESS CONDITIONS.

At the close of 1913 one of the journals devoted to the interests of the cement and concrete industry obtained from officials of many cement companies summaries of the business of the year and views as to the business situation at that time and for the immediate future.[1] From the published statements a quotation is taken. Charles Catlett, president of the Security Cement & Lime Co., gives one of the most comprehensive statements and covers most of the points brought out by other officials:

The increase in the consumption of cement is due primarily to its wonderful properties and the more general distribution of information as to how and where it can be used. This increase in the consumption has continued without intermission since 1890, and even in years when people could get along with less iron, which is so generally considered the barometer of business, they have called for more cement. This annually increased consumption has taken place in spite of panics and broad depressions, and there is no question that the demand will largely increase in the future. It must supplement iron and take the place of lumber. The demand is increasing in old ways and in new ones, and by far the largest new use which is developing is for road making. This use is destined to exercise a material influence on the industry. Even as a student of cement and more or less familiar with its wonderful properties, it has been hard for me to realize that a road made entirely of concrete would be so satisfactory. But the evidence is overwhelming that a concrete road properly made of good material more perfectly meets the requirements of modern highways traffic than anything that has yet been devised when first cost, upkeep, and adaptability are considered. The consumption will continue to grow, and it is to be hoped that the industry is getting on a firmer financial basis. This has not been true for a number of years, some thirty-odd cement companies having gone into the hands of receivers. These receiverships have been partly due to bad promotion, location, and management, but more largely from a fundamental misconception of the profits in the business—a failure to recognize the true or commercial cost. This has been coupled with a failure to recognize the great difference in raw material and the high cost and the long time necessary before a new plant can expect to operate on a normal basis; and, finally, promoters of new plants overlook the fact that the sudden interjection of their output immediately breaks their own local market. These facts have been borne in upon the banking and investment public, and new development will probably only be made, and should be made, where the market requires it. This will do much to insure the stability of the industry.

Practically all who comment on the uses for cement agree that road building will furnish the largest outlet for the product for some years.

[1] Business situation as viewed by the companies: Cement Era, January, 1914, pp. 70–72.

DEPRECIATION AND OBSOLESCENCE OF PLANTS.

The moderate increase in the average factory price of Portland cement during 1913 perhaps comes in response to the growing conviction in the minds of cement manufacturers that recent prices have been little, if any, greater than the bare factory cost of the product. Some profitable discussion of this latter topic began in the latter part of 1911 and was continued during 1912 and 1913 at the meetings of the Society of Mechanical Engineers and the Institute of Chemical Engineers.

The following extracts and notes indicate that engineers are now making efforts to solve the problem of an adequate selling price for cement.

At the moment[1] the question of the depreciation factor in the cost of producing Portland cement is commercial rather than technical. Its urgent importance as a business proposition overshadows its scientific interest. The manufacturers of cement have so notably failed to define the cost of production that few of them have a surplus or depreciation fund of any kind to deal with. In recent years numerous plants have yielded returns little if any greater than bare factory cost, and the commercial rating of the industry as a whole has suffered. The value which a technical discussion of depreciation may have, therefore, will consist chiefly in defining for the commercial end of the business the elements which should be considered to make up a satisfactory price for a barrel of cement. * * * There are then three principal factors to be considered in estimating a depreciation factor: (*a*) Wear and tear; (*b*) obsolescence (the form of depreciation due to improvements in methods or in machines which makes it necessary to modify plant and scrap machinery which is still in good running order); and (*c*) the carrying charges during repairs. * * *

The ordinary procedure of cement plants is to limit their cost data to a monthly cost sheet. This deals simply with factory cost and usually, and quite properly, with only a part of the factory cost. The real and only useful purpose of these monthly cost sheets is to enable operating officers to institute comparisons, locate leaks, and cut down regular operating cost items. Unfortunately, and quite generally, the cement people have made the serious commercial blunder of regarding these factory cost sheets as really representing the cost to be kept in view when making prices. * * *

A factory cost sheet to be useful for comparison of cost items from month to month and from year to year should exclude all occasional or extraordinary expenditures. If items of this character were introduced at random as they occurred the value of the cost sheet would be destroyed. Such occasional or extraordinary expenditures, which are really depreciation charges, must be provided for annually by appropriating a sum for plant renewals to be accounted for separately from the cost sheet. This appropriation can be an arbitrary one, or may vary from time to time as the superintendent's report may indicate the renewal requirements.

Mr. Lewis proposes a method of figuring depreciation involving the assumption that each of the several items of a cement plant will be renewed once in 25 years, and that at the end of that period the entire plant will have reached the end of its usefulness. A given factory cost per barrel of cement, including all ordinary repairs, is assumed, and to this is added, in terms of cents per barrel, a given amount each for depreciation fund, plant renewal fund, administration and selling expenses, and interest on investment. The total amount to be added to the assumed factory cost and ordinary repairs as proposed by Mr. Lewis amounts to about 50 per cent, or 28.6 to 30 cents per barrel, although it is stated that these figures are subject to modification and

[1] Lewis, Frederick H., Some remarks on the depreciation factor in the cost of producing Portland cement: Am. Soc. Mech. Eng. Jour., February, 1913, pp. 257-261.

that it will require a higher average price if the business is to have a credit balance outside of depreciation. Mr. Lewis concludes:

On some such basis as this any manufacturer can estimate a safe selling price, using the actual facts of his own books for capitalization, factory cost, and administration and selling expense. If this is done, most manufacturers will find that current prices have been too low in recent years, and still are so; many will find that an excessive capitalization must be scaled down if business is to continue; and some will find themselves facing conditions which make it impossible to continue the industry.

Mr. Struckmann[1] emphasizes the fact that the rapid development of the cement industry has made it necessary to make continued changes and improvements in plants and has caused the depreciation due to obsolescence to be greater than depreciation due to wear and tear. He also states that a large percentage of the cement mills of this country are equipped with machinery which is out of date, but as provision has been made by hardly any of the manufacturers to replace their machinery they must continue to operate, at a handicap, old and, in some places, obsolete machinery. Where capital stock is increased for the purchase of new machinery the new machinery frequently has to produce sufficient profits to pay interest on the lost capital as well as on the increased capitalization. Mr. Struckmann adds:

Depreciation must be defined as a loss in value which may be due to use, age, or obsolescence, or a combination of these with several contributory causes, and in a cement factory the amount of depreciation is the measure of loss in invested capital.

In the same discussion Mr. Brown[2] calls attention to another important feature, viz, the supply of raw material:

Entirely apart from the mill proper, in every cement-producing plant there is an item of depreciation which must be considered, and that is the depreciation of quarry. Many plants are so situated that this item can be entirely overlooked. The quantity of raw material at hand is so large that for practical purposes it may be considered unlimited. Other plants are situated, however, where the body of raw material is circumscribed, and in such places it is very necessary that a proper depreciation account should be opened to replace the raw material at the expiration of a fixed time.

As to the amount per barrel that should be set aside for depreciation and obsolescence there is still much uncertainty, owing to the varying conditions under which different plants have been financed and are operating. Several investigators believe that 10 cents a barrel would cover this item. On the other hand, Meade,[3] estimating on the basis of a large new Portland cement plant, believes that the sum of 10 cents a barrel is much too high and estimates that a figure not exceeding 4 cents a barrel should cover the needs of a plant operating for 40 years and making 900,000 to 1,000,000 barrels of cement a year.

MANUFACTURING CONDITIONS.

In 1913 there were 113 plants reported as having produced Portland cement, as compared with 110 plants in 1912. The total number of rotary kilns in the producing plants was 873, as compared

[1] Struckmann, H., Depreciation and obsolescence in Portland cement plants: Am. Soc. Mech. Eng. Jour., February, 1913, pp. 262-264.
[2] Brown, G. S., Am. Soc. Mech. Eng. Jour., February, 1913, p. 267.
[3] Meade, R. K., Depreciation and obsolescence: Jour. Indust. and Eng. Chem., September, 1913, pp. 762-766.

with 867 in 1912. These kilns ranged in length from 40 to 240 feet, and the lengths as reported were distributed as follows:

Lengths of rotary cement kilns in the United States, 1912 and 1913.

Length.	Number of kilns. 1912	Number of kilns. 1913	Length.	Number of kilns. 1912	Number of kilns. 1913
Feet.			*Feet.*		
40 to 60	173	157	125	172	157
60 to 90	135	145	125 to 140	63	63
100	103	93	150 or more	29	38
110	106	117			
120	86	103	Total	867	873

There was a gain in the number of operated kilns 90 feet, 110 feet, 120 feet, and over 150 feet in length, but a decrease in the number of 60-foot, 100-foot, and 125-foot kilns. There was a net increase of 6 kilns, and the total number of kilns 100 feet or more in length was 571, as compared with 559 in 1912.

The apparent total annual kiln capacity in 1913 of plants, either active or only temporarily closed, according to producers' reports, due allowance being made for the customary loss of time from breakdowns and from necessary shutdowns for repairs, was about 115,000,000 barrels of Portland cement. This is an increase of 5,000,000 barrels from the total capacity for 1912, which was estimated on the same basis, but the figures for 1913 appear rather high. The total production for 1913, 92,097,131 barrels, was, according to these figures, between 79 and 80 per cent of the normal cement-producing capacity of the country. The apparent average output per kiln in 1913 was about 105,500 barrels, as compared with 95,000 barrels in 1912.

A summary of kiln fuels in 1913 shows that 88 plants, employing a total of 695 kilns, operated with powdered coal as a kiln fuel; 18 plants, with 119 kilns, burned oil; and 7 plants, with 59 kilns, burned natural gas. As compared with 1912 this shows an increase of 3 coal-burning plants, but of no kilns; a decrease of 2 plants and 7 kilns using oil as fuel; and an increase of 2 plants and 13 kilns burning natural gas.

The following table summarizes these data for 1912 and 1913, together with the quantities and percentages of Portland cement produced with coal, oil, and gas:

Summary of Portland cement kiln fuels in 1912 and 1913.

Fuel.	1912				1913			
	Number of plants.	Number of kilns.	Barrels.	Percentage of total.	Number of plants.	Number of kilns.	Barrels.	Percentage of total.
Coal	85	695	69,546,889	84.4	88	695	78,508,891	85.2
Oil	20	126	9,674,276	11.7	18	119	10,013,206	10.9
Natural gas	5	46	3,216,931	3.9	7	59	3,575,034	3.9
Total	110	867	82,438,096	100.0	113	873	92,097,131	100.0

NEW PORTLAND CEMENT PLANTS.

Four new plants produced Portland cement in 1913, 1 each in Arizona and New York and 2 in Washington. The plant of the Arizona Portland Cement Co., at Portland, near Phoenix, Ariz., consists in part of the plant formerly operated by the United States Reclamation Service at the Roosevelt Dam. As reconstructed the plant is reported to comprise two 70-foot kilns, operated on the dry process, to burn oil in the kilns, and to have a capacity of 400 barrels daily of "Arizona" brand. The Thomas Millen Co. has started a plant a Jamesville, N. Y., using limestone and shale, with coal for fuel. This plant is reported to have one 125-foot kiln with a capacity of 800 barrels per day. The 2 plants in Washington are those of the Olympic and the International Portland cement companies. The former plant is situated near Bellingham, uses limestone and clay, with oil for fuel, and is equipped with two 170-foot kilns, wet process, having a total capacity of about 1,700 barrels per day of "Olympic" brand. The International plant is situated at Irvin, on the outskirts of Spokane. This plant uses limestone, cement rock, and shale, and burns coal. It is equipped with two 160-foot kilns, dry process, having a total capacity of 1,600 barrels daily of "Spokane" brand. In addition to these new plants the mills of the Altoona Portland Cement Co. and of the Monarch Cement Co., both in Kansas, which were reported as inactive in 1912, reported some production in 1913. There were 3 plants which were active in 1912, but which suspended operations during 1913, viz, the plant of the Los Angeles Aqueduct, at Monolith, Cal., and plants of the Chanute and the Great Western companies, both in Kansas. Thus, with 4 new plants and 2 revived plants as against 3 inactive plants there was a net gain of 3 producers in 1913, making 113 active producing plants during the year, all of which shipped cement as well. Progress was reported on the construction of 1 or more new plants in each of the States of California, Iowa, Oklahoma, and Oregon.

INVESTIGATIONS OF CEMENT AND CONCRETE.

As stated in the introduction, the Bureau of Standards is carrying on active laboratory investigations of cement and concrete and has published the results of certain of these investigations in a series of circulars and technologic papers. Progress in certain of these investigations, such as waterproofing concrete and relations of cements to alkalies and sea water, were reviewed in this chapter of Mineral Resources for 1911, Part II, pages 508–510.

ACTION OF ALKALI AND SEA WATERS.

The field of investigation of action of the salts in alkali water and sea water on cements[1] is of such general interest that the summary of the latest publication on these tests is quoted here:

> The conclusions must be limited by the scope of this investigation and since the physical tests reported cover a period of exposure not exceeding three and one-half years the conclusions should be considered as somewhat tentative.

---

[1] Bates, P. H., Phillips, A. J., and Wig, R. J., Action of the salts in alkali water and sea water on cements: U. S. Bur. Standards Tech. Paper 12, pp. 100–102, 1913.

1. Portland cement mortar or concrete, if porous, can be disintegrated by the mechanical forces exerted by the crystallization of almost any salt in its pores, if a sufficient amount of it is permitted to accumulate and a rapid formation of crystals is brought about by drying; and as larger crystals are formed by slow crystallization, there would be obtained the same results on a larger scale, but in greater time if slow drying were had. Porous stone, brick, and other structural materials are disintegrated in the same manner. Therefore in alkali regions, where a concentration of salts is possible, a dense nonporous surface is essential.

2. While in the laboratory a hydraulic cement is readily decomposed if intimately exposed to the chemical action of various sulphate and chloride solutions, field inspection indicates that in service these reactions are much retarded if not entirely suspended in most cases, due probably to the carbonization [carbonation?] of the lime of the cement near the surface or the formation of an impervious skin or protective coating by saline deposits.

3. Properly made Portland cement concrete, when totally immersed, is apparently not subject to decomposition by the chemical action of sea water.

4. While these tests indicated that Portland cement concrete exposed between tides resisted chemical decomposition as satisfactorily as the totally immersed concrete, it is felt that actual service conditions were not reproduced, and therefore further investigation is desirable.[1]

5. It is not yet possible to state whether the resistance of cements to chemical disintegration by sea water is due to the superficial formation of an impervious skin or coating, which is subsequently assisted by the deposition of shells and moss forming a protective coating, or by the chemical reaction of the sea salts with the cement forming a more stable compound without disintegration of the concrete, or by a combination of both of these phenomena.

6. Marine construction, in so far as the concrete placed below the surface of the water is concerned, would appear to be a problem of method rather than materials, as the concrete sets and permanently hardens as satisfactorily in sea water as in fresh water or in the atmosphere, if it can be placed in the forms without undue exposure to the sea water while being deposited.

7. Natural, slag, and other special cements tested in concrete mixtures showed normal increase in strength with age both in sea water and in fresh water.

8. In the form of neat briquettes most of the Portland cements of high iron content, several of the cements of high or normal alumina content, and one special slag cement did not show any marked difference in tensile strength whether exposed to fresh or sea water for all periods up to two years. Other cements of various compositions showed signs of disintegration after a few weeks.

9. All cements resisted disintegration in sea water better in mortar mixtures than in the form of neat briquettes. In most cases the mortar briquettes had normal strength up to two years' exposure.

10. The physical qualities of the cement, which depend essentially upon the method of manufacture, would seem to determine its resistance to decomposition when brought into intimate contact with the sulphate and chloride solutions.

11. Contrary to the opinion of many, there is no apparent relation between the chemical composition of a cement and the rapidity with which it reacts with sea water when brought into intimate contact.

12. Tricalcium sulpho-aluminate could not be formed, and therefore disintegration could not result from this cause.

13. In the presence of sea water or similar sulphate-chloride solutions: (*a*) The most soluble element of the cement is the lime. If the lime of the cement is carbonated it is practically insoluble. (*b*) The quantity of alumina, iron, or silica present in the cement does not affect its solubility. (*c*) The magnesia present in the cement is practically inert. (*d*) The quantity of SO_3 present in the cement up to 1.75 per cent does not affect its solubility, but a variation in the quantity present may affect its stability by affecting its rate of hardening.

14. The change which takes place in sea water when brought into intimate contact with the cement is as follows: (*a*) The magnesia is precipitated from the sea water in direct proportion to the solubility of the lime of the cement. (*b*) The sulphates are the most active constituents of the sea water and are taken up by the cement. Their action is accelerated in the presence of chlorides. No definite sulphate compound

---

[1] In service the concrete extends from the sea bottom to a point above high tide, where the wall or pile would always be exposed to the atmosphere. With this condition the sea water could be drawn up the wall by capillarity, the moisture evaporating and leaving the salts, which would become concentrated, and thus possibly cause disintegration, especially if mixture is porous. An additional series of tests is now being made in which short piles 7 feet in length are being placed in sea water so that 2 feet of the center portion will be exposed to the atmosphere. After various periods of exposure the piles will be sawed and the various sections tested for elastic properties and compressive strength.

was established. (c) The quantity of chlorine and sodium taken up by the cement is so small that no statement can be made as to the existence of any definite chloride or sodium compound formed with the cement.

15. The SO_3 added to a cement in the plaster to regulate the time of set is chemically fixed so that it will not go into solution when the cement is brought into intimate contact with distilled water.

16. Metal reinforcement is not subject to corrosion if embedded to a depth of 2 inches or more from the surface of well-made concrete.

It is to be hoped that these investigations may be prolonged. As stated in the quotation, the conclusions should be regarded as somewhat tentative. On certain of them few writers are yet in full agreement. The inference expressed in paragraph 11 with regard to the relation between the chemical composition of a cement and the rapidity with which it reacts with sea water, in particular, seems not to accord closely with experimental data acquired by certain other investigators.

MICROSCOPIC ANALYSES.

A field of investigation of interest to geologists, particularly to those trained in the use of the petrographic microscope, is the study of the constitution of Portland cement clinker by means of the microscope. The pioneer work in this line by Day, Shepherd, Wright, and Rankin was briefly outlined in this chapter of Mineral Resources for 1910 (Part II, pp. 485–486). Some additional work has been done by P. H. Bates and A. A. Klein, of the United States Bureau of Standards, Pittsburgh, Pa. At this laboratory a miniature rotary cement kiln, together with the necessary grinding apparatus, has been installed so that various types of cements can be burned at will; for instance, if the alumina and iron oxide content be kept approximately constant a burn may range from a low silica and high lime content to a high silica and low lime content, the limit in each case being the limiting product which can be obtained in the rotary kiln. The burns made on pure materials in the laboratory are reported [1] to have checked the results obtained in the Carnegie geophysical laboratory, and it is therefore assumed that commercial Portland cement may contain tricalcium silicate, dicalcium silicate, calcium aluminates, in which the lime and alumina are combined in the ratios of either 3:1, 5:3, or 1:1, and that there is present also free lime. Details of many tests, illustrated by photomicrographs, are given, together with methods and results of microscopic quantitative analyses of the constitution of cement in a given quadrilateral field of a thin section.

In addition to microscopic work on cement clinker it would seem that there is also an opportunity for much interesting microscopic work on cement mortar and concrete.

BLENDED OR SAND CEMENTS.

Notes have been given in the chapter on cement in Mineral Resources for 1910, 1911, and 1912 concerning the manufacture and use of blended or tuff cement, a cement made by regrinding Portland cement with several varieties of tuff (latite tuff, rhyolite tuff, and andesite tuff), in connection with the construction of the Los

[1] Bates, P. H., The constitution of Portland cement: Concrete-Cement Age, Cement mill section, January, 1913, pp. 3–7.

Angeles aqueduct, a project which required about 1,500,000 barrels of cement. A summary of this subject has been published by Lippincott.[1] The service tests of this material will be watched with interest by engineers and cement manufacturers in succeeding years. Studies by Coglan [2] and other chemists and engineers of the United States Reclamation Service have shown that various rocks, when finely ground, may be suitable for making blended cement. Among such rocks are basalt, tuff, and sandstone from Elephant Butte, N. Mex.; granite from near Boise, Idaho; tuffs from Los Angeles aqueduct, and from Lahontan, Nev.; and quartz. It is stated by Coglan in the article just referred to that chemical analyses reveal the fact that several of the igneous and intrusive rocks, as well as sandstones, contain colloidal silica in varying amounts, but it is not shown that the presence of this material is essential to the successful manufacture of sand cement.

The Reclamation Service is reported [3] to have decided to use sand cement in so far as practicable on two of its important projects, the Arrowrock Dam, 22 miles above Boise, Idaho, and the Elephant Butte Dam, on the Rio Grande, in New Mexico. At the Arrowrock Dam, where about 550,000 cubic feet of concrete will be laid, the blending material will be granite from the spillway excavation. Here a sand-cement plant with a capacity of 1,000 barrels per 24 hours, consisting of a crusher and sand rolls, rotary drier, ball mill, mixing machine, and 3 tube mills, all electrically driven, with the necessary bins, hoppers, and conveying machinery, has been erected at a cost of about $46,000 and was put into operation in the latter part of 1912. At the Elephant Butte Dam about 520,000 barrels of cement will be required in the next three years. A sand-cement plant in which Portland cement will be blended with 50 per cent by volume of sandstone has been erected at a cost of approximately $48,000.

Regarding the use of sand cement Charles H. Paul [4] states:

> The use of sand cement in mass work, where the requirements are enough to justify the installation of the necessary grinding machinery, where suitable blending material is available, and where the transportation charges on Portland cement amount to a considerable portion of its cost laid down, will result in a marked saving in construction costs, and will give a product which is at least the equal of the Portland cement from which it was made, in fact, one which for ordinary requirements is not open to the least suspicion.

Mr. Coglan [5] concludes:

> It is to be hoped that the Portland cement manufacturers will interest themselves in this product, and that if it proves its worth its manufacture may become more widespread. Cheaper cement would mean more cement sold, more cement houses and cement work done in the cities and country.

Experiments by E. H. McAlester [6] with blends of Portland cement with natural and artificial puzzolanic materials in Oregon have led to the suggestion that blended cement be used in concrete roads.

[5] Op. cit., p. 1273.

[6] McAlester, E. H., Puzzolan mixtures tested for Oregon roads: Cement Era, October, 1913, pp. 66-68.

The puzzolanic materials used in the experiments consisted of tuffs that are abundant in the Willamette Valley and near Grants Pass and Clackamas, diatomaceous earth from near Eugene, and blast-furnace slag from Oswego.

CONCRETE ROADS.

The construction of concrete roads already requires large quantities of cement, and the building of this type of road has little more than begun. The interest in this subject is so keen that there is a great deal of literature available concerning the experiences of States, counties, and municipalities in building and maintaining concrete roads and pavements, together with detailed figures of costs. The work of Wayne County, Mich., is perhaps the best known, but other portions of the country, particularly in the Middle West and on the Pacific coast, are no less progressive. The United States Government through its Office of Public Roads has constructed a little more than 1 mile of experimental road in Chevy Chase, Md., just beyond the boundary of the District of Columbia.[1]

It is not practicable to review here the voluminous literature on the subject of concrete roads and pavements for the year 1913, but the reader is referred to the September issue of the Concrete-Cement Age, Detroit, Mich., and to the October issue of the Cement Era, Chicago, Ill., for many special articles on the subject.

IMPORTS OF FOREIGN CEMENT.[2]

The following table shows the quantities of foreign cement imported for consumption into the United States during the years 1878 to 1913, inclusive. Owing to the manner in which import statistics are grouped, the quantities given include not only Portland cement but all other hydraulic cements. The Portland cement, however, probably makes up 95 per cent of the total in each year.

The imports in 1913 were approximately 84,630 barrels, of 380 pounds, valued at $138,187, or about $1.63 a barrel as compared with 68,503 barrels, valued at $93,558, or $1.37 a barrel, in 1912. It should be stated here that the number of barrels given in the following table is slightly in excess of the true quantity. The imports of cement as reported by the Bureau of Foreign and Domestic Commerce are given in pounds, and include the weights of barrels, sacks, and other packages. There are no data at hand at present to show what proportion of the imports are received in barrels or in sacks, although it is understood that the greater part of the material is imported in sacks, which of course weigh very little.

The table shows a continuous decline in the imports of foreign cement for the six years ending with 1912. In 1906 and 1907 the imports were much greater than those of 1905, principally on account of the rebuilding of San Francisco following the fire.

1889	1,740,356	1901	939,330	1913	84,630

EXPORTS.[2]

The United States has a comparatively small export trade in cement. In 1913 the total quantity exported was only 2,964,358 barrels, most of which was Portland cement, valued at $4,270,666, or approximately $1.44 a barrel, as compared with 4,215,232 barrels, valued at $6,160,341, or about $1.46 a barrel, in 1912. The quantity exported in 1913 was only about 3 per cent of the total production of hydraulic cements in 1913. The exports in 1910, 1911, and 1912 showed increases, respectively, of 135 per cent, 27 per cent, and 26 per cent over those of each preceding year, but those of 1913 decreased 29.6 per cent as compared with the exports in 1912.

The following table gives the quantity and value of all classes of hydraulic cement exported during the years 1900–1913, inclusive, and the proportion of exports to the total quantity of hydraulic cement manufactured in the United States. The exports are almost wholly of Portland cement at present.

Exports of hydraulic cement, 1900–1913, in barrels.

Year.	Quantity.	Value.	Percentage of total.	Year.	Quantity.	Value.	Percentage of total.
1900	100,400	$225,306	0.6	1907	900,550	$1,450,841	1.7
1901	373,934	679,296	1.9	1908	846,528	1,249,229	1.6
1902	340,821	526,471	1.3	1909	1,056,922	1,417,534	1.6
1903	285,463	433,984	.95	1910	2,475,957	3,477,981	3.2
1904	774,940	1,104,086	2.4	1911	3,135,409	4,632,215	3.9
1905	897,686	1,387,906	2.2	1912	4,215,532	6,160,341	5.1
1906	583,299	944,886	1.1	1913	2,964,358	4,270,666	3.2

PORTLAND CEMENT IN CANADA.

The following extract is quoted from the preliminary report on the mineral production in Canada during the calendar year 1913, issued by the Canada department of mines, mines branch, February 24, 1914, pages 18–19:

The financial stringency during 1913 had an immediate effect in the restriction of building operations of all kinds, and its results are shown in the statistics of production and consumption of structural materials. In the case of cement, while a very substantial increase in production is shown, this has seemed chiefly to displace imported

[1] The statistics from 1899 to the present represent "Imports for consumption." The figures for all preceding years are for "Total imports."
[2] Statistics according to Bureau of Foreign and Domestic Commerce, Department of Commerce.

material, the increase in consumption being only 4 per cent as against an increased production of 24 per cent. Canadian mills supplied over 97 per cent of the consumption in 1913 as against 83 per cent in 1912. The industry has been marked by the extension of old and the completion of new plants, the latter west of the Great Lakes. The total capacity of completed plants at the end of the year is about 50,000 barrels per day as compared with 36,500 barrels at the end of 1912. New plants were placed in operation at Winnepeg, Marlboro west of Edmonton, Princeton, British Columbia, and at Tod Inlet, Vancouver Island, British Columbia. The plants of the Imperial Portland Cement Co. at Owen Sound and of the Crown Portland Cement Co. were not operated during the year.

The total quantity of Portland cement, including slag cement and natural Portland, made in 1913 was 8,880,983 barrels, an increase of 1,739,979 barrels, or 24 per cent over 1912. The quantity of Canadian cement sold or used was 8,658,922 barrels, valued at $11,227,284, or $1.29⅝ per barrel, an increase of 1,526,190 barrels, or 22 per cent, and of $2,120,728, or 23 per cent, in total value. The total imports of cement were 889,324 hundredweight equivalent to 254,092 barrels of 350 pounds each and valued at $409,303, or an average of $1.61 per barrel, as compared with imports of 1,434,413 barrels, valued at $1,969,529, or an average of $1.37, in 1912. The total consumption of Portland cement, therefore, neglecting a small export, was 8,913,014 barrels as compared with a consumption of 8,567,145 barrels in 1912, an increase of 345,869 barrels, or only 4 per cent.

The average price per barrel at the works in 1913 was $1.29⅝, as compared with $1.28 in 1912 and $1.34 in 1911 and 1910.

The imports of cement in 1913 included 77,356 barrels from Great Britain, 172,298 barrels from the United States, 3,443 barrels from Hongkong, and 995 barrels from other countries. The average price per barrel was $1.61, as against an average of $1.37 on imports in 1912.

NATURAL CEMENT.

PRODUCTION.

The natural cement produced in the United States during 1913 amounted to 744,658 barrels of 265 pounds, valued at $345,889, as compared with an output of 821,231 barrels, valued at $367,222, in 1912, a decrease in 1913 of 76,573 barrels, or 9.3 per cent, in quantity, and of $21,333, or 5.8 per cent, in value. The averago price of the natural cement per barrel at the mills in 1913 was 46.4 cents, as compared with 44.7 cents in 1912.

Natural cement was produced in 1913 in 13 plants distributed in 8 States, as compared with 15 plants in 9 States in 1912. The net decrease in 1913 of 2 plants resulted from a decreaso of 1 plant each in Georgia, Pennsylvania, and Texas, and an increase of 1 plant in Ohio. In the following table the natural cement production of 1913 is outlined by States:

Production of natural cement in 1912–13, by States.

State.	1912			1913		
	Producing plants.	Quantity (barrels).	Value.	Producing plants.	Quantity (barrels).	Value.
New York	4	366,236	$162,376	4	255,709	$114,067
Pennsylvania	2			1		
Illinois	1			1		
Indiana	1	229,901	91,787	1	a 266,949	a 121,422
Ohio	1			2		
Minnesota	2	213,500	104,625	2	222,000	110,400
Kansas	1			1		
Georgia	2	11,594	8,434	1	(a)	(a)
Texas	1			0		
Total	15	821,231	367,222	13	744,658	345,889

a In 1913 no production was reported from Texas; therefore the production of Georgia is included with that of Illinois, Indiana, and Ohio.

THE NATURAL CEMENT INDUSTRY, 1818-1913.

The following table contains statistics of production of natural cement since the beginning of its manufacture in this country in 1818. It will be seen that the natural-cement trade reached its greatest prosperity in the period 1887–1903, inclusive, its year of maximum output being 1899, when 9,868,179 barrels of natural cement were manufactured in the United States. Beginning with 1904, the industry has shown a continuous decline in production each year, and its production for 1913 is the lowest on record since before 1880. See also the curve of production, figure 1.

Production of natural cement in the United States, 1818–1913, in barrels of 265 pounds.

1818–1829	300,000	1895	7,741,077
1830–1839	1,000,000	1896	7,970,450
1840–1849	4,250,000	1897	8,311,688
1850–1859	11,000,000	1898	8,418,924
1860–1869	16,420,000	1899	9,868,179
1870–1879	22,000,000	1900	8,383,519
1880	2,030,000	1901	7,084,823
1881	2,440,000	1902	8,044,305
1882	3,165,000	1903	7,030,271
1883	4,190,000	1904	4,866,331
1884	4,000,000	1905	4,473,049
1885	4,100,000	1906	4,055,797
1886	4,186,152	1907	2,887,700
1887	6,692,744	1908	1,686,862
1888	6,253,295	1909	1,537,638

1890	7,082,204	1911	926,091
1891	7,451,535	1912	821,231
1892	8,211,181	1913	744,658
1893	7,411,815		
1894	7,563,488	Total	232,271,122

PUZZOLAN AND OTHER SLAG CEMENTS.

Puzzolan cement was manufactured during 1913 at 3 plants in the United States—at North Birmingham, Ala., Struthers, Ohio, and Sharon, Pa.—and Collos cement was made at Buffalo, N. Y. The output of puzzolan and Collos cements in 1913 was 107,313 barrels, valued at $97,663, compared with 91,864 barrels, valued at $77,363, in 1912. This represents an increase in quantity of 15,449 barrels and in value of $20,300. The average price per barrel of these slag cements in 1913 was 91 cents, and in 1912 it was 84.2 cents, an increase in 1913 of 6.8 cents a barrel, or 8.1 per cent. In 1912 the average price of slag cement was 2.9 cents higher than that of Portland cement, but this lead was not maintained in 1913. One reason why a good average price should be commanded by puzzolan cement is that a considerable quantity of this product is of a light color and is considered to be nonstaining.

The following table summarizes the number of active plants and the production of puzzolan cement during the last five years:

Statistics of the puzzolan cement industry, 1909–1913.

	1909	1910	1911	1912	1913
Number of plants reporting production:					
Alabama	1	1	1	1	1
New York[a]			1	1	1
Ohio	2	2	1	1	1
Pennsylvania	1	1	1	1	1
Total	4	4	4	4	4
Production in barrels of 330 pounds	160,646	95,951	93,230	91,864	107,313
Value of production	$99,453	$63,286	$77,786	$77,363	$97,663

[a] Includes production of Collos cement in 1911, 1912, and 1913.

The following table gives the annual production of puzzolan cement in the United States since 1896, when the first output of this cement was reported. The figures for 1912 and 1913 represent marketed production.

Output of puzzolan cement in the United States, 1896–1913, in barrels of 330 pounds.[1]

1896	12,265	1906	481,224
1897	48,329	1907	557,252
1898	150,895	1908	151,451
1899	335,000	1909	160,646
1900	446,609	1910	95,951
1901	272,689	1911	93,230
1902	478,555	1912	91,864
1903	525,896	1913	107,313
1904	303,045		
1905	382,447	Total	4,694,661

[1] Includes output of Collos cement in 1911, 1912, and 1913.

FELDSPAR.

By Frank J. Katz.

REVIEW OF THE FELDSPAR TRADE.

The marketed production of feldspar in the United States in 1913 was 120,955 short tons, valued at $776,551. Both in quantity and in value this was the largest recorded annual production. Each important producing State—California, Connecticut, Maine, Maryland, New York, North Carolina, and Pennsylvania—showed an increase in both quantity and value. During the year about 50 quarries marketed feldspar. Ten of them were new producers. Notwithstanding the increase in quantity and the production from new sources the average price per ton of the total production was higher than in any other year. The average price per ton of the combined crude and ground output was about 25 cents more than in the best preceding year (1911). The prevailing prices f. o. b. quarries for crude material were about the same as in previous years, but the average price f. o. b. mills of ground feldspar was considerably higher (10 to 12.5 per cent), than in recent years. The feldspar market appears therefore to have been unusually strong and to have consumed an increased production at a rising price. The year should have been a profitable one for the feldspar grinders.

COMPOSITION, OCCURRENCE, AND USES.

Bulletin 420 of the Survey, "Economic geology of the feldspar deposits of the United States," by Edson S. Bastin, published in 1910, is so complete a treatise on the subject that it is not deemed necessary in this place to go into detail regarding the composition and occurrence of feldspar in the United States. All who are interested in the subject are referred to that bulletin, which may be had on application to the Director, United States Geological Survey, Washington, D. C.

In June, 1913, the Bureau of Mines issued Bulletin 53, "Mining and treatment of feldspar and kaolin in the southern Appalachian region," by A. S. Watts, who investigated the pegmatite deposits of the mountain region from Marietta, Ga., to Lynchburg, Va. He describes the pegmatites and discusses prospecting and sampling them for feldspar, quartz, and kaolin, from the point of view of a ceramic engineer. Methods of analyzing and testing feldspar and kaolin for use in pottery are fully described, and analyses and results of tests on feldspar from many deposits are included in the bulletin. Of particular value to feldspar and kaolin producers and to pottery manufacturers is the suggestion[1] by Watts to substitute for part of the feldspar of porcelain mixtures the "semikaolinized" feldspars which occur so abundantly in the pegmatite dikes of the region described.

This publication may be secured by application to the Director, Bureau of Mines, Washington, D. C.

Feldspar is a compound of silica, alumina, and one or more of the bases potash, soda, and lime. There are two principal commercial varieties—the potash spar and the soda spar. Both of these may be present in the same deposit or in the same crystal. The principal members of the potash group are orthoclase and microcline. These varieties are alike in chemical composition ($KAlSi_3O_8$, or $K_2O.Al_2O_3.6SiO_2$) and so nearly alike in physical properties as to be considered commercially identical. The theoretical composition of pure orthoclase or microcline is silica 64.7 per cent, alumina 18.4 per cent, and potash 16.9 per cent. The potash may be partly or completely replaced by soda. When the soda content is greater than the potash content the feldspar is called anorthoclase.

Potash feldspars range in color from white to reddish; some are gray. The soda feldspars vary from white to pale green in color. When first taken from the quarry feldspar is so hard that it is with difficulty scratched with a knife.

Most of the feldspar mined in the eastern part of the United States is of the potash or the soda variety or a mixture of the two. These varieties are used in the pottery industry because after being melted and cooled they form a glass, whereas lime-soda feldspar under these conditions becomes crystalline.

The principal use of feldspar is in the manufacture of pottery, enamel ware, enamel brick and tile, and electrical ware. Of these applications the most important is its use in the body and glaze of the various grades of pottery and vitrified sanitary ware, in which it constitutes from 10 to 35 per cent. Its value in pottery is that it melts at a lower point than the other ingredients and serves as a flux, binding the clay and quartz particles together. In glazes the percentage of feldspar used is higher than in the body and runs from 30 to 50 per cent. Other uses of feldspar, which do not require the high grade demanded by the pottery trade, are in the manufacture of emery and corundum wheels, where it serves as a binder; in the manufacture of opalescent glass; as a poultry grit; as a constituent of roofing material; and for surfacing concrete work. Small quantities of the purest grades of potash feldspar are used in the manufacture of artificial teeth. For this purpose it brings the highest prices—from \$6 to \$8 a barrel of 350 pounds. It is also used in the manufacture of scouring soaps and window wash. Ground feldspar has been used as a fertilizer, but with results of doubtful value. Attempts are being made to extract from feldspar its content of potash. Experiments along this line have not yet developed a commercial process, but it may well be that some of the efforts will be successful.

---

PRODUCTION.

The marketed production of feldspar in 1913 was 120,955 short tons, valued at $776,551. This, the largest recorded annual production, was an increase over 1912 of 34,383 tons, or 39.72 per cent, in quantity and of $255,989, or 49.18 per cent, in value. The production of crude spar was 45,391 short tons, valued at $148,549, an increase of 18,929 tons, or 71.53 per cent, in quantity and of $59,548, or 66.91 per cent, in value as compared with 1912. The production of ground spar was 75,564 short tons, valued at $628,002, an increase of 15,454 tons, or 25.71 per cent, in quantity and of $196,441, or 45.52 per cent, in value as compared with 1912.

The average price per ton in 1913 for crude spar was $3.31, compared with $3.36 in 1912 and $3.14 in 1911. The average price per ton in 1913 for ground spar was $8.31, compared with $7.18 in 1912 and $7.60 in 1911. The average price per ton in 1913 for the combined crude and ground output was $6.49, compared with $6.01 in 1912 and $6.25 in 1911. Of the total output, 37.53 per cent was sold by the producer crude and 62.47 per cent was sold ground. Of the total value, that sold crude represents 19.13 per cent and the ground 80.87 per cent.

It has been impossible to determine very accurately the proportions of the feldspar output used for various purposes. The following figures are estimates based on incomplete data, but are believed to be reasonably reliable. Of the production in 1913, approximately 4,000 tons, valued at approximately $20,000, representing about 3.5 per cent of the total quantity and about 3 per cent of the total value, was used for abrasives; approximately 7,000 tons, valued at approximately $30,000, representing about 6 per cent of the total quantity and about 4 per cent of the total value, was used for roofing; concrete surfacing and other structural uses consumed about 3,000 tons, valued at $6,000, representing nearly 3 per cent of the total quantity and under 1 per cent of the total value. Approximately 1,000 tons, valued at $3,500, representing about 1 per cent of the total quantity and about 0.5 per cent of the total value, were sold as chicken grits; approximately 1,200 tons, valued at $10,000, representing 1 per cent of the total quantity and about 1.5 per cent of the total value, was used for making glass. Very small quantities were used in chemical work and in experiments on potash extraction and on the direct use of feldspar as a fertilizer. The remainder of the output, over 100,000 tons, or 85 per cent of the total quantity, valued at $700,000, or 90 per cent of the total value, was used in the ceramic industries.

The following tables show the production of feldspar in 1912 and 1913, by States, with the increase or decrease in quantity and value in the several States for 1913 as compared with 1912, and the totals for the United States classified as crude and ground from 1909 to 1913. These figures include feldspar for all purposes, and show the marketed product rather than the quantity actually quarried.

Marketed production of feldspar in 1912 and 1913, by States, in short tons.

FELDSPAR INDUSTRY, BY STATES.

Sales of feldspar in 1913 were reported from the following States, named in order of magnitude of their output: Maine, New York, Connecticut, Maryland, North Carolina, Pennsylvania, California, Vermont, and Minnesota. A shipment was also made for tests or experimental purposes from a quarry in Virginia, and preparation for shipment was made in Colorado.

California.—Five operators reported production of feldspar in California in 1913. One quarry was reported idle and two as being developed. Of those operating, 4 are new quarries near Exeter, Springville, Sulphur Springs, and Lemon Cove, in Tulare County. Other quarries were opened in Tulare County, but no record of production or other information about them could be secured. The quarry near Lakeside, San Diego County, was reported idle. The quarry at Chualar, Monterey County, was active as usual. The entire California output was used for pottery, manufactured at National City and Richmond, in that State. The production for the State in 1913 was 1,113 short tons, valued at $3,838. This was an increase over the production reported for 1912 of 329 tons, or 41.96 per cent, in quantity and of $1,038, or 37.07 per cent, in value.

Colorado.—A feldspar deposit near St. Peters, El Paso County, Colo., was opened, and preparations for shipment of spar were made. Development of the prospect was interrupted by the death of the operator. The writer has seen samples of excellent spar from this property.

Connecticut.—Connecticut was third in the size of its feldspar production in 1913, being exceeded only by Maine and New York. Connecticut's production in 1913, which came from Middlesex and Hartford counties, was 20,288 short tons, valued at $115,770, an increase over 1912 of 1,213 tons, or 6.36 per cent, in quantity and of $21,673, or 23.03 per cent, in value. The price in Connecticut for crude and ground spar ranged from $3.15 to $4.50 a ton and from $7.05 to $10 a ton, respectively. There were 7 producing quarries, and 3, which have in recent years been active, were idle. Three mills were operated. One of these was closed in August and is reported for sale. Connecticut feldspar was used for pottery, enamel ware, tiles, glass, abrasives, and soaps.

Maine.—Maine ranked first in feldspar production in 1913. Seven quarries, in Androscoggin, Oxford, and Sagadahoc counties, were in operation, two of which were new as feldspar producers. Still another quarry made a test shipment. The production was 38,114 short tons, valued at $346,779, which was an increase of 19,090 tons, or 100.35 per cent, in quantity and of $173,883, or 100.57 per cent, in value over 1912. The price of crude spar in Maine was for the most part $3 a ton; some sold at $6. Ground spar sold at prices ranging from $8 to $9.33 a ton. Maine feldspar was used for pottery. Three mills were in operation. The new mill of the Maine Feldspar Co. at Topsham, noted in the 1912 report, ground a large quantity of spar. That company's new quarry, at Cathance, also made a large output. New development began late in the year on an old mica quarry in Peru, Oxford County, which resulted in a small shipment, and a test shipment was made from another new quarry in the same town.

Maryland.—Maryland stood fourth as a producer of feldspar in 1913. There were 12 active quarries, situated in Baltimore, Carroll, Cecil, and Montgomery counties, 5 of which were new; and 6 quarries, which were recently producers, were idle. There is but one mill in the State, that of the Earth Products Co., near Laurel, which is equipped for coarse grinding and sizing. The company plans to install fine-grinding apparatus. The production of the State in 1913 was 16,702 short tons, valued at $82,833. This was an increase of 7,471 tons, or 80.93 per cent, in quantity and of $26,835, or 47.92 per cent, in value. The prices for Maryland crude spar in 1913 ranged from $3.50 to $5.50 a ton. Maryland spar ground at Trenton, N. J., sold at $8.73 to $9.50 a ton. Maryland spar was used chiefly for pottery. Some was sold for chicken grits.

Massachusetts.—There was no production of feldspar in Massachusetts in 1913.

Minnesota.—The one quarry in Minnesota, the product from which was used exclusively for abrasive paper, was not in operation in 1913. Small shipments were made in 1913 of material mined in 1910.

New York.—New York was second in rank as a feldspar producer in 1913. Nearly half of the output of 1913 here listed was unsorted pegmatite which was only crushed or coarsely ground and used for for coating "ready roofing," for concrete facing, and for poultry grit. The remainder is ground finely for use in pottery, enamel ware, glass, and abrasive soaps. There were 5 large quarries in Saratoga, Westchester, and Essex counties, in operation, and some small ones, not listed, whose production is reported by feldspar mills. One recently operated was idle. There are 2 mills for coarse grinding, at Crown Point and Ticonderoga, and 1 for fine grinding at Bedford. The total production for the State was 22,750 short tons, valued at $119,060, an increase of 558 tons, or 2.51 per cent, in quantity and of $17,535, or 17.27 per cent, in value. The average prices in New York for 1913 for crude spar and crushed pegmatite ranged from $2.50 to $5 a ton; ground spar sold at $6 to $8.32 a ton.

North Carolina.—North Carolina in 1913 took sixth place as a feldspar producer. The output was almost entirely by two companies in the Spruce Pine district, Mitchell County. The product was ground at Trenton, N. J., and at East Liverpool, Ohio. Other companies are developing quarries in the Spruce Pine district, and it is reported that the Carolina, Clinchfield & Ohio Railway is building a feldspar mill. There was no progress in the development of feldspar quarries in other parts of the State.

Pennsylvania.—Pennsylvania was fifth among the feldspar producing States in 1913. Nine large quarries in Chester and Delaware counties and several unlisted small ones, whose output is purchased and reported by larger operators, produced 9,629 short tons, valued at $75,851, an increase over 1912 of 178 tons, or 1.88 per cent, in quantity and of $4,564, or 6.40 per cent, in value. Prices for Pennsylvania spar ranged in 1913 from $2 to $4.50 a ton for crude, and from $8 to $9.50 a ton for ground. The Edgemont quarries have again changed hands, having been purchased by the Harris Chemical Co., which reported a small production for "chemical purposes." Pennsylvania feldspar was used for pottery, tile, enamel ware, glass, poultry grits, roofing, and abrasive soaps.

Tennessee.—The Clinchfield Mineral & Milling Corporation began the development of a feldspar quarry at Erwin, Unicoi County. No shipment was made during 1913.

Vermont.—The A. L. Stone Manufacturing Co. continued to be the single feldspar producer in Vermont operating a quarry and mill at Chester, Windsor County.

Virginia.—No feldspar from Virginia quarries was sold in 1913. All quarries were idle, except for the shipment of less than a ton for experimental purposes.

PRODUCTION IN OTHER COUNTRIES.

The following table gives such figures as are available on the production of feldspar in recent years in the United States and other countries:

Production of feldspar in the principal producing countries, 1909–1913, in short tons.

Country.	1909 [a]		1910 [a]	
	Quantity.	Value.	Quantity.	Value.

TALC AND SOAPSTONE.

By J. S. Diller.

DEVELOPMENT OF THE TALC AND SOAPSTONE INDUSTRY.

The talc and soapstone industry has gradually expanded from a marketed production of 97,843 short tons, valued at $908,488, in 1901, to 175,833 short tons, valued at $1,908,097, in 1913. The comparatively uniform development of the industry indicates its stability and gives promise for continued increasing demand.

The following tables illustrate the development of the talc and soapstone industry in the United States since 1880:

Production of talc and soapstone in the United States, 1880–1913, in short tons.

Year.	Quantity.	Value.	Year.	Quantity.	Value.
1880–1900	969,928	$11,224,652	1907	139,810	$1,531,047
1901	97,843	908,488	1908	117,354	1,401,222
1902	97,954	1,140,507	1909	130,338	1,221,959
1903	86,901	840,060	1910	150,716	1,592,393
1904	91,189	940,731	1911	143,551	1,646,018
1905	96,634	1,082,062	1912	159,270	1,706,963
1906	120,644	1,431,556	1913	175,833	1,908,097

The total marketed production of talc and soapstone in the United States during 1913 was 175,833 short tons, an increase of 10.4 per cent as compared with the production of 1912. In the following table this production, with the percentage of increase or decrease with reference to 1912, and its value are shown by States. The succeeding table shows the production in marketed forms from 1910 to 1913. Rhode Island and Maryland in 1913 produced soapstone alone. The other States, except North Carolina, Vermont, and Virginia, produce talc only.

Marketed production of talc and soapstone in the United States, 1912–13, with increase and decrease in 1913, in short tons.

State.	1912		1913		Increase (+) or decrease (−) in quantity, 1913.	Percentage of increase (+) or decrease (−) in quantity.	Increase (+) or decrease (−) in value, 1913.	Percentage of increase (+) or decrease (−) in value.

Total	159,270	1,706,963	10.72	175,833	1,908,097	10.85

[a] Includes bath and laundry tubs; fire brick for stoves, heaters, etc.; hearthstones, mantels, sinks, griddles, slate pencils, gas tips, burner blanks, crayons, and numerous other articles for everyday use.
[b] For foundry facings, paper making, lubricators for dressing skins and leather, etc.

The importance of the talc and soapstone industry of the United States as compared with that of other countries is illustrated by the following table of the world's production. The figures for 1912 are not yet complete, but it will be noted that the United States contributes more than all the other countries combined.

Production of talc and soapstone in the principal producing countries, 1905–1912, in short tons.

Country.	1905 [a]	1906 [a]	1907 [a]	1908 [a]	1909 [a]	1910 [a]	1911 [a]	1912 [b]

[f] Soapstone.
[g] Statistics not available.

This large production accounts for a considerable export trade, especially in grades suitable for the manufacture of paper.

The production in the United States of the best grades of talc, however, such as are used for toilet powders, electric insulators, gas tips, and the like, is not equal to the demand, which is supplied chiefly by importations from Italy and France.

DISTRIBUTION OF TALC AND SOAPSTONE IN THE UNITED STATES.

The distribution and character of the talc mines and the soapstone quarries of the United States was shown on maps and tables in this report for 1912. As there has been no change of importance during the year the maps and tables need not be repeated here.

The crystalline character of talc and soapstone limits their occurrence to areas of crystalline rocks. By far the larger portion of the known occurrences and producing localities are in the Blue Mountain region of the Atlantic States from New England and New York to Georgia, although in recent years attention has been attracted to deposits in southeastern California.

Talc is a definite mineral of which soapstone, as the term is generally used, is only an impure massive form.

Talc is generally mined in small fragments by underground methods. On the other hand, soapstone is quarried in large blocks in open pits. Commercial talc and soapstone are not generally found together nor produced by the same company. Prior to 1912 talc and soapstone have been considered together in the United States Geological Survey reports, but in that year they were also considered separately, a practice which is followed in this report for 1913.

TALC.

PRODUCTION.

The total marketed production of talc for 1913 was 149,271 short tons, valued at $1,280,020, a decided increase as compared with the production of 1912, which was 133,289 short tons, valued at $1,097,483.

The relative rank of the producing States as to quantity and value of the production in 1913 is given in the following table. The production of Pennsylvania and New Jersey and also that of Georgia and Massachusetts are combined to conceal the output of individual producers.

Quantity and value of the talc marketed in the various States in 1912 and 1913, in short tons.

Rank and State.	1912		1913	
	Quantity.	Value.	Quantity.	Value.
1. New York	66,867	$656,270	81,705	$788,500
2. Vermont	41,270	245,679	44,447	302,375
3. Pennsylvania and New Jersey	10,400	50,519	11,308	80,780
4. North Carolina	3,492	63,004	4,576	48,317
5. Georgia and Massachusetts	[a] 6,836	[a] 49,172	3,309	35,416
6. Virginia	3,255	17,186	2,974	18,632
7. California	1,169	15,653	952	6,000
Total	133,289	1,097,483	149,271	1,280,020

[a] Includes also Maryland.

New York continues to be the leading producer, with an output of more than 54 per cent of the total production of the United States, and far outranking all other States except Vermont, which has in recent years so greatly increased its production that in 1912 and 1913 it was more than half that of New York.

Of the total output in 1913, by far the greater portion, 147,529 short tons, was sold as ground talc; 238 tons was sold as pencils or blanks for making gas tips, etc.; and 1,504 tons was sold rough as it came from the mine.

The variation in the annual production of the different States, although due in part to irregularities in the available deposits, which are in most States large, depends also on the market demand.

IMPORTS.

The total imports of talc for consumption in 1913 were 13,770 short tons, valued at $137,680, an increase of 25.3 per cent in quantity and of nearly 12 per cent in value as compared with the corresponding imports for 1912.

Talc imported for consumption into the United States, 1905 and 1909–1913, in short tons.

Year.	Quantity.	Value.	Average price per ton.	Year.	Quantity.	Value.	Average price per ton.
1905	4,000	$48,225	$12.05	1911	7,113	$88,050	$12.38
1908	7,429	97,096	13.07	1912	10,989	122,956	11.19
1909	4,417	56,287	12.74	1913	13,770	137,680	10.00
1910	8,378	106,460	12.71				

As shown by the accompanying table, 33 per cent of the imported talc came from Italy, nearly 40 per cent from France, and 24 per cent from Canada.

Imports of talc, ground or manufactured, into the United States, 1912 and 1913, by countries, in short tons.

Country.	1912			1913		
	Quantity.	Value.	Average price per ton.	Quantity.	Value.	Average price per ton.
Argentina	1	$25	$25.00			
Austria-Hungary	774	18,224	23.55	391	$9,137	$23.37
Belgium	7	133	19.00	8	209	26.13
Canada	1,974	21,045	10.66	3,348	33,107	9.89
England	101	1,368	13.54	34	d 57	16.38
France	3,941	20,260	5.14	5,466	25,242	5.17
Germany	7	261	37.29	15	1,846	123.07
Italy	4,184	61,640	14.73	4,510	65,163	14.45
Netherlands				2	52	26.00
Total	10,989	122,956	11.19	13,774	138,313	10.04

The production of talc in Canada in 1913 was 12,250 [1] short tons, of which nearly 27 per cent, 3,348 tons, came to the United States, as compared with 1,974 tons imported from Canada in 1912.

The imported talc is chiefly of the higher grades, such as is used for making toilet powder, gas tips, etc., for which purposes the supply in the United States is not equal to the demand.

[1] Preliminary report on the mineral production of Canada during the calendar year of 1913 (subject to revision): Canada Dept. Mines.

PRICES.

The prices depend on the grade of talc, which determines the purpose for which it is used. The average price in the rough as it came from the mine in 1913 was, for the whole United States, $3.77 a ton. Some of it sold in 1913 as low as $3 a ton, while material from the same mine worked up into crayons, pencils, etc., sold at the rate of $339 a ton. Ground pyrophyllite ranged in price from $2 a ton in the rough to $10 a ton ground, which is generally the selling price of New York talc. Lower grades of ground talc sell for $5 a ton; more of it sells for $6 and $7 a ton. The average price for manufactured talc in 1913 was $28.99 a short ton. The prices of imports ranged in 1913 from $123.07 for German talc to $5.17 for French ground talc.

The uses of talc, its modes of occurrence, and its preparation for market were discussed in the report for 1912, and as copies of that report are yet available these matters need not be taken up again at this time.

TALC INDUSTRY BY STATES.

CALIFORNIA.

The sudden expansion of the talc industry in California in 1911 and 1912 encouraged the hope that an important industry was developing on the Pacific coast comparable with that of the Atlantic States. A visit was made to Los Angeles and also to a district just east of the Death Valley region of San Bernardino and Inyo counties, where the activity centered. The Tonopah & Tidewater Railroad, connecting with the San Pedro, Los Angeles & Salt Lake Railroad as well as with the main line of the Santa Fe, affords convenient transportation.

The talc of the region is in general remarkable for its whiteness, its mode of occurrence, and its origin. It has been developed and mined at three localities—Zabriskie and Tecopa in Inyo County, and Riggs in San Bernardino County; but all three are within a region about 40 miles long north and south and 20 miles wide east and west. In the southern portion of the region are a number of other prospects, especially on Sheep Creek, about 20 miles northwest of Silver Lake, and at another point 7 miles east of Riggs. The localities at Sheep Creek, Riggs, and Tecopa were the only ones examined, although that west of Zabriskie was seen at a distance. The occurrence is essentially the same at all points. The similarity of the material is evident from the comparison in the accompanying table of the chemical analysis, No. 1, made of the talc at Sheep Creek and kindly furnished by Mr. H. H. Kerchoff, president of the Avawatz Salt & Gypsum Co., of Los Angeles, with analyses Nos. 2 and 3, made by the United States Geological Survey, of the talc mined near Riggs Station and of a sample kindly furnished by Mr. Frank Riggs, of Silver Lake, from a prospect 7 miles southeast of Riggs. The material of analyses Nos. 1, 2, and 3 is evidently a hydrous silicate of magnesia and compares favorably with the fibrous talc so extensively mined in the Gouverneur region of New York.

Analyses of talc.

1. Sheep Creek, 20 miles northwest of Silver Lake, San Bernardino County, Cal. Analyst, R. A. Percy.
2. One mile north of Riggs station, 9 miles north of Silver Lake, San Bernardino County, Cal. Analyst, R. C. Wells, U. S. Geol. Survey.
3. Seven miles southeast of Riggs station, San Bernardino County, Cal. Analyst, R. C. Wells, U. S. Geol. Survey.
4. Fibrous talc near Gouverneur, N. Y. Analyst, E. S. Sperry, Dana's System of mineralogy, 6th ed., p. 679, 1911.
5. Fibrous talc, St. Gothard. Analyst, Scheerer. Dana's System of mineralogy, 6th ed., p. 679, 1911.
6. Theoretical composition of pure talc.
7. Theoretical composition of pure tremolite.

Analysis No. 4 from New York, which contains 2.15 per cent oxide of manganese instead of lime, is probably exceptional. C. H. Smyth has shown the derivation of the New York talc from tremolite schist associated with limestone. As the alteration is rarely complete the commercial talc of New York must generally contain a considerable percentage of lime. The fibrous talc of the Alps (St. Gothard) contains an amount of lime to be expected in talc derived from tremolite. The material of analysis No. 3 is well-marked foliated slippery talc, but thin sections of it show remnants of tremolite partly altered to talc. The material of analysis No. 2 is compact and so fine grained that distinct remnants, if any, of tremolite are not determinable. This material is remarkable for its smooth porcelain aspect on slip and fractured surfaces. It is considerably harder than ordinary talc and has hardened somewhat since its removal from the mine. It contains a small quantity of alumina and is therein similar to the fibrous talc so extensively mined at Gouverneur, N. Y. (analysis No. 4), and to that of the Alps (analysis No. 5).

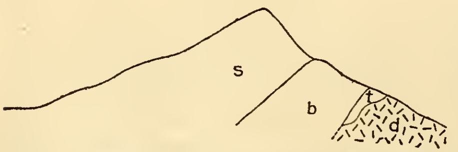

FIGURE 4.—Section of talc deposit 10 miles southeast of Tecopa, Cal. t, Talc, with some limestone, tremolite schist, and serpentine; b, banded, somewhat cherty limestone, 125 feet; s, lighter colored, less ferruginous, and apparently dolomitic limestone; d, diorite.

The mode of occurrence is essentially the same everywhere in the region and may be illustrated by a section of the deposit about 10 miles southeast of Tecopa, at an elevation of 1,000 feet above Tecopa and of 2,500 feet above sea level. (See fig. 4.)

The talc is for the most part very white and lies generally on the contact between diorite and banded limestone on the steep southwest slope of a ridge into which the formations dip. The deposit is irregular and varies somewhat abruptly in thickness from 12 feet or more to a mere film, both vertically and horizontally, but it can be readily traced by the white soil at the surface for a mile to the southeast. Several tunnels have been run into the deposit on the surface, where it has a thickness of about 12 feet. The talc is beautifully white, soft and slippery, and under the microscope finely fibrous; but it needs to be carefully separated from the harder and harsher white accompanying material, which is apparently fibrous tremolite. The deposit has been much squeezed and sheared, developing slickensides like plastic clay, which are generally parallel to the dip. On the side toward the diorite there is much faulting, and masses of tremolite rock are caught in the talc. Nodules of serpentine, and also of calcite and tremolite, from the size of a nut up to sheets a foot in extent, occur in the talc, and they have to be carefully removed. The sheets of calcite are usually bent or crumpled, as in highly crystalline rocks, and many of them have a decided tendency to cross-fiber structure.

This deposit occurs in an arid, treeless country at an altitude of 2,300 feet—about 1,000 feet above the railroad, to which there is a 7-mile wagon haul; and more than 2,000 tons of talc have been removed within the last few years.

The occurrence of talc on Sheep Creek 20 miles northwest of Silver Lake is illustrated in figure 5. The irregularity of the contact

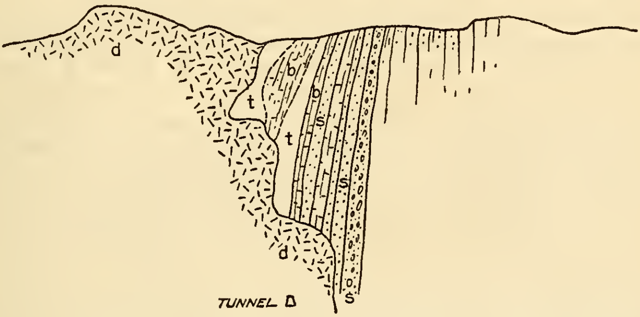

FIGURE 5.—Section of talc deposit and adjacent rocks on Sheep Creek, 20 miles northwest of Silver Lake, Cal. t, Talc; b, banded limestone; s, sedimentary rocks, inlcuding crystalline limestone, quartzite, and hornfels, the result of contact metamorphism; d, diorite.

between the diorite and the sedimentary rocks, as well as the contact metamorphism apparent in the hornfels, indicate that the diorite is later than the sedimentary rocks and may have been a factor in the genesis of the talc, which follows the contact between the diorite and the limestone. Grayish limestone occurs more or less abundantly in the talc—to an irregular thickness of nearly 30 feet. The strike of the deposit is northwest and southeast, and prospects have been opened along the outcrop for half a mile. Other prospects are reported on the same strike 6 miles farther to the northwest. At all the prospects seen the workings run into the talc horizontally. No evidence was seen to prove the continuity of the talc in depth, and the general form of the deposit suggests that it may be limited to near the surface.

The talc deposit near Riggs station on the Tonopah & Tidewater Railroad, 10 miles north of Silver Lake, has been traced northwest and southeast nearly a mile and opened at several points. As elsewhere in the region it lies between limestone and diorite, although there is much red granitic and aplitic intrusive as well as mica schist and other metamorphic rocks near by. This talc body has a thickness of 5 feet and is well banded, as if stratified parallel to the overlying limestone. The best talc is near the bottom, where the material was obtained for analysis No. 2 in the table of analyses. In thin section under the microscope it appears to be made up of fibrous and nonfibrous material, apparently talc and tremolite, a mixture that if chiefly talc would have the composition shown in analyses No. 2. The upper portion of the deposit contains nodules of serpentine, which a thin section shows to be inclosed in the tremolite from which the talc is apparently derived.

The most typical tremolite schist of the region, and very similar indeed to that of the talc region at Gouverneur, N. Y., occurs in a talc prospect 7 miles southeast of Riggs, where it is associated with very slippery foliated talc. A microscopic examination of a thin section of the latter shows clearly remnants of the tremolite from which the talc has been derived. The material from this locality is more decidedly slippery and normally talcose than any other observed in the region. Its derivation from typical tremolite schist suggests that, as in New York, the talc may be expected to persist in depth; but the California deposit has not yet been investigated with reference to depth. Its fibrous character, like that of the New York material, suggests its use in the manufacture of paper.

Talc is used in the manufacture of paper as a filler to produce a softer sheet, to improve the finish of the paper, and to give it a better surface for printing. It is not necessary to have a fibrous talc. "The principal requirements," according to information from the Everett Pulp & Paper Co., of Everett, Wash., are "smoothness, color, and freedom from grit, but of course a fibrous talc combined with the above would be preferable." The chief difficulty in the use of fibrous talc derived from tremolite in the manufacture of paper is the grit it contains. The grit may be lessened if not wholly avoided by a careful selection of material before milling and by including in the milling process properly regulated air-current separation. Complaint has been made also by paper manufacturers that the talc associated with limestone contains too much carbonate of lime, but the carbonate of lime also may be avoided by a careful selection of material at the mine.

The California material is used chiefly in the manufacture of tiles. The production reported for 1913 is less than that for 1912, but whether this was caused by the lack of demand, the high cost of production, or the condition of the deposits is not evident.

The output of talc in California declined 18.56 per cent in quantity in 1913 as compared with 1912. The only other point of production besides those in San Bernardino and Inyo counties is near Lindsay, in Tulare County.

GEORGIA.

Chatsworth, in Murray County, is the center of the talc industry of Georgia. The greater value of its output is in the higher grade of talc used for pencils, crayons, and other forms, although the greater volume of the output is in ground talc. The output decreased in quantity, but increased in value in 1913. As there were only two producers in the State in 1913 the total output can not be given without divulging confidential information.

The talc deposits of Georgia have recently been described by Otto Veatch in Bulletin 23 of the Georgia Geological Survey.

MASSACHUSETTS.

The great talc belt of Vermont extends into Massachusetts and is worked at one point (Franklin County) in the northwest portion of the State. There was only one producer in 1913, but the output of the company increased 14 per cent. The mill burned at Zoar in 1911 has not yet been rebuilt.

NEW JERSEY AND PENNSYLVANIA.

The vicinity of Easton in both Pennsylvania and New Jersey has long been known for its production of mineral pulp verdolite, the various grades of which are made up of several minerals, including talc associated with serpentine. The total production of 3 producers, 2 in Pennsylvania and 1 in New Jersey, in that region in 1913 was 11,308 tons, an increase of 8.73 per cent over the output of 1912. The value of the output increased from $50,519 to $80,780, nearly 60 per cent.

This talc region of Pennsylvania and New Jersey has been fully described by F. B. Peck in recent reports of the geological surveys of the two States, respectively.

Most of the product is ground for paint, plaster, paper, soap, and rubber goods, but some of it is sold in blocks as ornamental stone.

NEW YORK.

New York has been for many years the premier producer of talc in the United States, and that supremacy was maintained in 1913, when it produced nearly 55 per cent of the total output of the United States. It exceeded the production of all the other States combined by 14,139 tons, and it exceeded by practically 10,000 tons its own largest previous annual output, that of 1910. The production in 1913 amounted to 81,705 short tons, valued at $788,500, an increase of 22.19 per cent in quantity and of 20.15 per cent in value as compared with 1912, when the production was 66,867 short tons, valued at $656,270.

There were 5 important producing companies, 4 in the vicinity of Gouverneur and 1 near Natural Bridge. An account of each was given in the report for 1912.

Production and value of the talc of New York, 1880-1913, as compared with that of talc and soapstone in all the other States combined, in short tons.

Year.	New York.			All other States.	
	Quantity.	Value.	Price per ton.	Quantity.	Value.
1880-1900	629,925	$5,933,501	$9.42	340,003	$5,291,151
1901	69,200	483,600	6.99	28,643	424,888
1902	71,100	615,350	8.65	26,854	525,157
1903	60,230	421,600	7.00	26,671	418,460
1904	64,005	507,400	7.93	27,184	433,331
1905	56,500	445,000	7.88	40,134	637,062
1906	61,672	557,200	9.03	58,972	874,356
1907	67,800	626,000	9.23	72,010	905,047
1908	70,739	697,390	9.86	46,615	703,832
1909	48,536	359,957	7.42	81,802	862,002
1910	71,710	728,180	10.15	79,006	864,213
1911	62,030	613,286	9.89	81,521	1,032,732
1912	66,867	656,270	9.81	93,413	1,050,693
1913	81,705	788,500	9.65	94,128	1,119,597
Total	1,482,019	13,433,234	9.06	1,096,956	15,142,521

The most important papers published in the last few years concerning the talc deposits and industry of New York are by D. H. Newland in the New York State Museum Bulletin 161, pages 91–100, July 1, 1912, and by P. B. McDonald, in the Engineering and Mining Journal, April 5, 1913.

NORTH CAROLINA.

The total production of talc and pyrophyllite in North Carolina in 1913 was 4,576 short tons, valued at $48,317, an increase of 31.04 per cent in quantity and a decrease of 23.31 per cent in value, as compared with 1912. There was one producer of talc in Swain County and one in Jackson County, with two producers of pyrophyllite in Moore County; hence the production can not be stated separately without publishing confidential information.

North Carolina contains some high-grade talc for pencils, crayons, and gas tips, competing with that from Georgia. It is, however, the only State producing pyrophyllite. An article on the pyrophyllite of North Carolina by Claud Hafer appeared in the Engineering and Mining Journal for October 4, 1913.

VERMONT.

Vermont produces both talc and soapstone, but the output of the latter was relatively small. In 1913 its production of talc was 44,447 short tons, valued at $302,375, a decided gain over the output of 1912. There were six points of production, three of them operated by one company, the State ranking second in the United States in the production of talc. The new mill at Stockbridge and 4 miles of railroad were completed during 1913 and will contribute largely to increase the output of the State.

VIRGINIA.

Virginia, like Vermont, produces both talc and soapstone, but in this case the production of talc is relatively small. There are four producers of talc, whose output was 2,974 short tons, valued at $18,632. The production was 281 tons less than in 1912, but its value was $1,446 greater, owing to the fact that a new company began the production at Verdierville of a grade of talc that is used in the manufacture of pencils and gas tips. All the talc producers are in the northern portion of the State.

SOAPSTONE.

PRODUCTION.

The production of soapstone in the United States in 1912 and 1913 was not only greater than that of any other country but greater than that of all other countries combined. The total production of soapstone in the United States in 1913 was 26,562 short tons, valued at $628,077, a decided gain both in quantity and in value as compared with the production of 1912. There were five producing States, Maryland, North Carolina, Rhode Island, Vermont, and Virginia, but the output of Virginia exceeded by far the combined output of all the other States. Furthermore, the resources of Virginia are such that its large production may be expected to continue long.

As shown in the following table the total production of soapstone in Maryland, North Carolina, Rhode Island, and Vermont was 3,049 short tons, valued at $31,151, a decrease of 22.3 per cent in quantity and of nearly 38 per cent in value as compared with their output in 1912. On the other hand, the output of Virginia increased nearly 7 per cent in both quantity and value.

There is 1 producer in each of the three States, Maryland, North Carolina, and Rhode Island; 2 in Vermont; and 6 in Virginia—all 6 in essentially the same belt stretching northeast through Nelson, Albermarle, and Orange counties, a distance of nearly 75 miles. The talc producers of Virginia lie farther northeast. One company west of Fredericksburg produces both talc and soapstone, a combination that should enable the company to use nearly all the quarry products advantageously.

Talc and soapstone in Virginia is the subject of an article in The Tradesman for April 10, 1913, by Thomas L. Watson. It gives details of the distribution and points of production of soapstone in Virginia.

Marketed production of soapstone in 1912 and 1913, by States, in short tons.

State.	1912		1913	
	Quantity.	Value.	Quantity.	Value.
Maryland North Carolina Rhode Island Vermont	3,923	$50,193	3,049	$31,151
Virginia	22,058	559,287	23,513	596,926
Total	25,981	609,480	26,562	628,077

PRICES.

The prices of soapstone vary greatly, not only with the form in which it is sold, but also with the size and quality of the stone which determine the purpose to which it can be applied.

In the rough, as quarried, soapstone is reported as valued at $2 a ton; when sawed into slabs its value is increased to more than $15 a ton; and when manufactured into laundry tubs its average value is about $30 a ton.

BARYTES.

By James M. Hill.

PRODUCTION.

The production of crude barytes in the United States in 1913 was 45,298 short tons, valued at $156,275. Compared with the production of the preceding year, which was 37,478 short tons, valued at $153,313, this was an increase of 7,820 tons in quantity and of $2,962 in value.

The average price per ton was $3.19 in 1911, $4.09 in 1912, and $3.45 in 1913. The price given is that paid to the miner for his crude ore, hand cobbed, sorted, and ready for shipment to the mills. This price is not supposed to include the cost of haulage by wagon, boat, or railway, and it is believed that the cost of haulage is not included in the values reported. The price of the crude material f. o. b. mines reported by most of the principal producers in 1913 was lower than in 1912. The average price for the State of Missouri was $3.78 a ton, which was substantially the average price in Washington County, Mo., the principal producing county in the State.

At the close of 1913, 9,181 short tons of crude domestic barytes remained unsold at the mines, according to reports from the producing districts, as compared with 7,606 tons in 1912. From Missouri 60 producers reported an output of crude barytes, but the production of most of them was small. There were 4 producers in Tennessee, 2 producers each in North Carolina and Virginia, and 1 producer each in Georgia and South Carolina.

The total quantity of refined barytes reported as sold by mills in 1913 was 37,033 short tons, valued at $525,300. As compared with the production in 1912, which was 38,225 short tons, valued at $495,895, this was a decrease of 1,192 tons in quantity, but an increase of $29,405 in value. The average price per ton reported as received for refined barytes was $12.72 in 1911, $12.97 in 1912, and $14.18 in 1913.

At the close of 1913 there were 3,380 tons of refined barytes still in the hands of the various refiners. Six firms reported production of refined barytes, their plants being located in Missouri, North Carolina, South Carolina, Tennessee, and Virginia.

The following table shows the production, total value, and average price per ton of crude barytes mined in the United States from 1911 to 1913, inclusive:

Production of crude barytes in the United States, 1911–1913, by States, in short tons.

State.	1911			1912			1913		
	Quantity.	Value.	Average price per ton.	Quantity.	Value.	Average price per ton.	Quantity.	Value.	Average price per ton.
Missouri	21,500	$81,380	$3.79	24,530	$117,035	$4.77	31,131	$117,638	$3.78
Tennessee and Kentucky	8,819	20,053	2.27	[a] 3,718	8,682	2.34	[a] 2,098	3,568	1.70
Other States [b]	8,126	21,359	2.63	9,230	27,596	2.99	12,069	35,069	2.91
Total	38,445	122,792	3.19	37,478	153,313	4.09	45,298	156,275	3.45

[a] Production of Tennessee; no production of barytes reported for Kentucky in 1912 and 1913.
[b] Includes, 1911: Georgia, North Carolina, South Carolina, and Virginia; 1912: Georgia, North Carolina and Virginia; 1913: Georgia, North Carolina, South Carolina, and Virginia.

The following table gives the domestic production of crude barytes in short tons from 1883 to 1913, inclusive:

Production of crude barytes, 1883–1913.

Year	Short tons.	Year	Short tons.	Year	Short tons.
1883	30,240	1894	23,335	1905	48,235
1884	28,000	1895	21,529	1906	50,231
1885	16,800	1896	17,068	1907	89,621
1886	11,200	1897	26,042	1908	38,527
1887	16,800	1898	31,306	1909	61,945
1888	22,400	1899	41,894	1910	42,975
1889	21,460	1900	67,680	1911	38,445
1890	21,911	1901	49,070	1912	37,478
1891	31,069	1902	61,668	1913	45,298
1892	32,108	1903	50,397		
1893	28,970	1904	65,727		

IMPORTS.

The imports of barytes for consumption during the last five years and the value of imported barium compounds, from 1909 to 1913, are given in the following two tables:

Barytes imported and entered for consumption in the United States, 1909–1913, in short tons.

Year.	Manufactured.		Unmanufactured.	
	Quantity.	Value.	Quantity.	Value.
1909	3,016	$25,679	11,647	$29,028
1910	3,565	29,782	21,270	48,457
1911	3,147	22,083	20,214	36,643
1912	3,679	26,848	26,186	52,467
1913	5,463	38,155	35,840	61,409

Under the Payne-Aldrich tariff natural barytes was dutiable at $1.50 a ton, and blanc-fixe was admitted under a duty of one-half cent a pound. Under the present tariff of October 3, 1913, natural barytes is dutiable at 15 per cent ad valorem and manufactured barium sulphate, including blanc-fixe and satin white ($CaSO_4$), is dutiable at 20 per cent ad valorem.

Value of the imports of barium compounds, 1909–1913.

Barium compounds.		1909	1910	1911	1912	1913
Barium carbonate	natural	$31,584	$25,229	$27,351	$15,777	$13,116
	manufactured				9,938	38,949
Barium binoxide		255,013	341,631	270,917	252,320	239,000
Barium chloride		47,352	35,614	28,896	27,655	37,620
Blanc-fixe, or artificial barium sulphate		65,427	67,975	71,049	70,327	62,785
Total		399,376	470,449	398,213	376,017	391,470

The imports of barium chemicals or compounds were greater in 1913 than in 1912. Witherite, the mineral form of barium carbonate, was admitted free of duty under the Payne-Aldrich tariff and has so continued under the Underwood tariff. On manufactured barium carbonate there was a duty of 25 per cent ad valorem, amounting to about $4.37 per ton in 1912, but under the Underwood tariff it is dutiable at 15 per cent ad valorem. Barium binoxide is dutiable at 1½ cents per pound and barium chloride at one-fourth cent a pound under the present law.

In 1912 the Bureau of Foreign and Domestic Commerce, Department of Commerce, first attempted to separate the imports of natural and manufactured barium carbonate. It is thought that much manufactured barium carbonate was imported "duty free" prior to 1912 under the supposition that it was ground natural barium carbonate, witherite. In the table the imports of natural and manufactured barium carbonate have been separated for 1912 and 1913 since it appears that it is now possible to do so safely.

BARYTES IN CANADA.

PRODUCTION.

The following table gives the production of barytes in Canada in 1912 and 1913, the figures for 1913 being subject to revision:

Production of barytes in Canada, 1912–13, in short tons.

Year.	Quantity.	Value.
1912	464	$5,104
1913	641	6,410

OCCURRENCE OF BARYTES IN CANADA.

The entire production of barytes in Canada for 1913 was reported from the deposits at Lake Ainslie, Nova Scotia, which have been worked since 1890. The barite is found in veins, cutting pre-Cambrian felsites, which, though showing many irregularities in size, are fairly persistent, varying from 7 to 14 feet in width.[1]

Other commercial deposits in northeastern Nova Scotia are known at North Cheticamp, Inverness County; at Five Islands and Stewacke, Colchester County; and near River John, Pictou County. Barite deposits are known also in Hull township, Quebec; in Bathurst, North Burgess, McNab, Drummer, Galway, and Summerville townships, Ontario; and on Jarvis, McKellars, and Pie Islands in Lake Superior.

[1] Economic minerals and mining industry of Canada: Canada Dept. Mines, Mines Branch, p. 50, 1914.

CHARACTER OF BARYTES.

Barytes, or heavy spar ($BaSO_4$), is composed of 65.7 per cent barium oxide (BaO) and 34.3 per cent of sulphur trioxide (SO_3). The specific gravity of the mineral ranges from 4.3 to 4.6; its hardness varies from 2.5 to 3.5. It is usually a white opaque to translucent crystalline mineral about as hard as calcite, but it differs from calcite in its greater specific gravity and in the fact that it is perfectly inert when treated with acids. Some barytes is stained reddish pink or yellow by iron oxide. In its common form it is an aggregate of straight or slightly curved cleavable plates, but it occurs also in granular, fibrous, and earthy masses, and in the form of stalactites, as well as in single and clustered crystals. Natural barytes is rarely pure, its most common impurities being silica, lime, magnesia, and the oxides of iron and aluminum. Fine particles of galena are disseminated through many of the deposits in the United States. The commercial grades of the mineral as mined carry 95 to 98 per cent barium sulphate and 1 to 3 per cent of silica.

USES OF BARYTES.

Barytes is used principally as a pigment in mixed paints, in the manufacture of lithopone—a chemically prepared white pigment consisting of zinc sulphide and barium sulphate—and as a base in the manufacture of lake pigments. It is also used in the manufacture of white rubber goods, but it is said that lithopone has lately replaced barytes to some extent for this use. Wall-paper manufacturers are said to use some barytes for giving weight to their products. Barytes is used in the manufacture of asbestos cement, artificial ivory, and in the preparation of fertilizers, boiler compounds, insecticides, peroxide of hydrogen, and artificial driftwood salts. Barium carbonate and some barium chloride are used to prevent efflorescence on bricks. According to Heinrich Ries,[1] the efflorescence is due to soluble salts, especially sulphates, which on evaporation leave a white coating on the surface of the bricks. To prevent the formation of these salts a quantity of barium carbonate or chloride is added to the clay mixture which forms with sulphuric acid the practically insoluble barium sulphate. According to the United States consul at Chemnitz, Germany,[2] barium hydrate, which is considered to be a most satisfactory reagent in the refining of sugar, can probably be more widely used than heretofore owing to a recent German patent, No. 149803, secured by W. Feld for the regeneration of caustic barytes from the barium carbonate which is formed in the refining process.

Barium carbonate, sulphate, or nitrate is used in the manufacture of some glass. The barium oxide is said[3] to increase the specific gravity, refractive index, elasticity, and tenacity, and to impart an attractive surface to glass. It, however, makes the melt harder to work. Barium finds its chief application in rolled glass, hollow ware, crystal and table glass, and in special glasses such as the Jena phosphate crown glass, which contains 28 per cent BaO and 60 per cent P_2O_5.

OCCURRENCE OF BARYTES IN THE UNITED STATES.

Barytes occurs in veins as a gangue of metallic ores and also in veins in sandstone and limestone, or as a replacement of limestone. Differential weathering of the limestone and the barytes has produced deposits of the mineral embedded in residual clay. The mineral has a wide range in geologic age and in geographic distribution, but in the United States the principal sources of supply are the Missouri and the Appalachian districts. In 1913 the Missouri district furnished between 68 and 69 per cent of the total production of the United States. Almost the entire output of Missouri came from Cole, Franklin, Jefferson, Miller, Morgan, St. Francois, and Washington counties, the county last named producing more than 78 per cent of the entire output reported for the State. Among the Appalachian States, Georgia, North Carolina, Tennessee, South Carolina, and Virginia, named in the order of production, reported an output of crude barytes in 1913. The Kentucky fields remained idle during 1913.

As many inquiries are received by the Survey relative to the occurrence of barytes, it is thought best to include in this report brief notes on the more important barytes deposits of the United States and references to a few undeveloped occurrences. The more important districts are shown on the accompanying map, figure 6.

The Survey has not made a detailed study of the various barytes-producing districts, although a number of them have been visited incidentally to other work.

Alabama.—So far as known, no barytes has been produced from Alabama mines since 1906. There are some deposits which probably could be worked in Calhoun, Etowah, and St. Clair counties, in the northeastern part of the State, and in Bibb County, near the center. The residual deposits so far worked are associated with the Chickamauga ("Pelham") limestone, of Ordovician age, and the Knox dolomite, of Cambrian and Ordovician age. They seem to be localized along lines of folding and faulting of the rocks, particularly along the eastern side of the Appalachian fold. The barytes probably occurred originally as veins and replacements along fissured or fractured dolomite. Solution of the dolomite has left the insoluble barium sulphate in nodules and bowlders in the residual clay.

Georgia.—Within a radius of about 15 miles centered about Cartersville, Bartow County, Ga., considerable iron ore, ocher, and barite are mined from residual clays derived from Cambrian and Ordovician rocks. The deposits are on the eastern side of the Appalachian fold, where the sedimentary beds are fractured and fissured, and is a northward continuation of the Alabama field. The barite deposits are most closely associated with the Weisner quartzite and Beaver limestone, though some barite has been found with the Knox dolomite. Barytes, ocher, and iron ore are found in the same pits, and are usually found near the contact of the quartzite and limestone. The iron-bearing materials are most often found near the contact, while the barite is usually some distance from the contact, particularly in deposits on hillsides.

Kentucky.—In Kentucky barite deposits are known in the central (Blue Grass) and western portions of the State. Barite has been mined in Boyle, Fayette, and Garrard counties south of Lexington, though deposits are known in 13 counties centered about the capital. In this region the deposits are associated with Ordovician sediments, particularly in the limestones of Stones River and Trenton age and in the Eden shale. The barite occurs in strong though some-

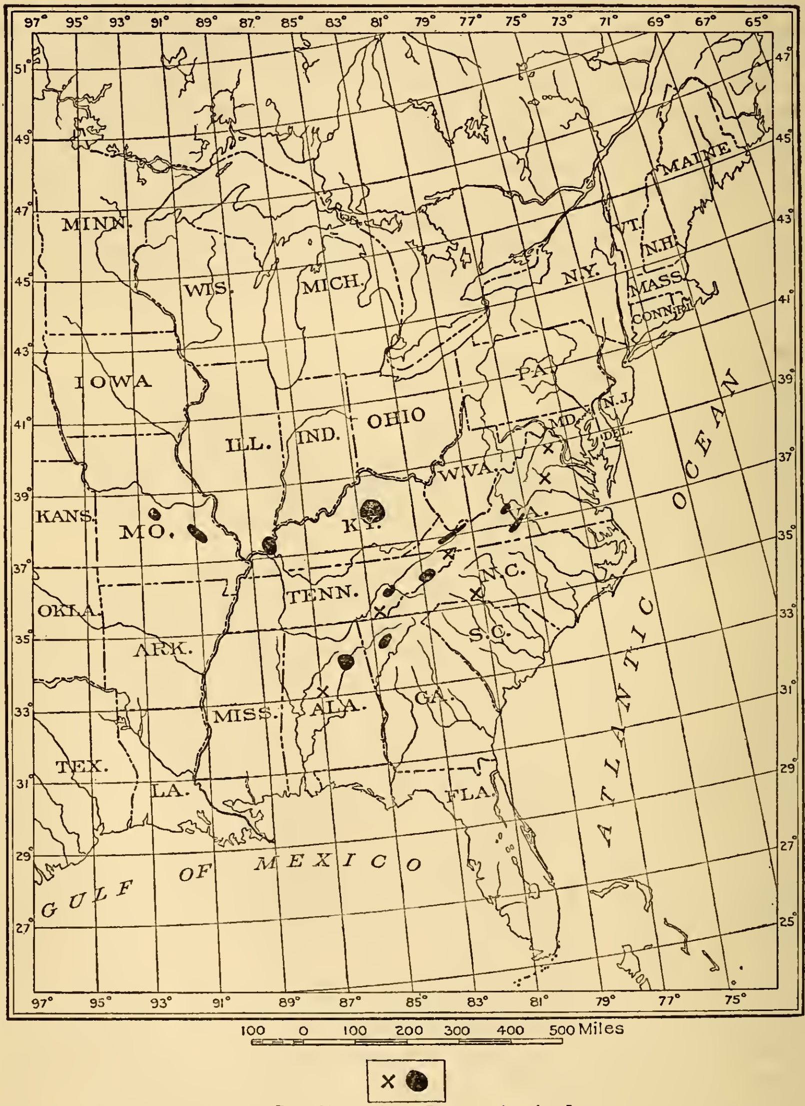

FIGURE 6.—Map of the eastern United States, showing the localities from which barytes has been produced.

what irregular veins inclined to the bedding of the formations, which are apt to become lean and barren of barite in the argillaceous beds, but are of good grade in the limestone layers. Some fluorite, galena, and sphalerite are associated with the barite.

In the western counties of Kentucky lying east of Tennessee River fluorite, barite, and lead and zinc deposits are found in faulted and somewhat folded Carboniferous limestone. The faults strike northeast, northwest, and east, though a few unimportant breaks have a northerly direction. Peridotite dikes cut the rocks and are believed to have been closely associated with the formations of the vein deposits. Barite is not particularly abundant, and most of the deposits have been worked for the metallic minerals or fluorite.

Missouri.—The greater part of the barytes produced in the United States is obtained from deposits in Washington, St. Francois, Franklin, and Jefferson counties of east central Missouri, and from Cole, Morgan, and Miller counties in the center of the State. The deposits are all in an area of Cambrian and Ordovician sediments lying to the northwest of the Ozark uplift. The barytes occur with chert in residual clays derived from the weathering of the dolomitic limestone of the Gasconade formation of Upper Cambrian age, or in the Bonneterre limestone, also of Upper Cambrian age, and as fissure fillings in the formations associated with quartz, pyrite, and galena. Practically all the barytes, locally known as "tiff," is mined from shallow shafts and open cuts in the residual clay by farmers or other people during periods of inactivity of other industries. The barytes is usually sold to local dealers and may pass through the hands of several middlemen before it reaches the refiners.

Tennessee.—Two districts in eastern Tennessee contain important deposits of barite. The French Broad district on the North Carolina line, south and a little east of Knoxville, includes parts of Cocke and Sevier counties. Owing to lack of transportation the veins in this region have not been extensively worked. In the Sweetwater district, including parts of Loudon, McMinn, and Monroe counties centering about Sweetwater, there has been extensive development and a considerable production of barytes in the past. The deposits are of the residual type, that is, pebbles and bowlders are found in the clay and sand derived from the weathering of folded and faulted rocks ranging in age from Cambrian to Ordovician. Most of the workable deposits are associated with the Knox dolomite.

Virginia.—In Virginia barytes occurs in three unlike areas: In the red sandstone-shale series of the Triassic; in the old crystalline metamorphic rocks, particularly in the Piedmont crystalline limestone area; and in the Valley region of faulted and folded Cambrian and Ordovician limestones. The deposits occur as veins and replacements in the limestone, though much of the barytes produced has been taken from residual clays derived from the weathering of the limestones.

The deposits in the Triassic red sandstones of Prince William County in the northeastern part of the State are of little importance at present, though they have been intermittently worked since 1845. The barite occurs as a filling or cement of brecciated impure limestones and red shales. The barite deposits of Bedford, Campbell, and Pittsylvania counties, in the south central part of the State centered about Evington and Toshes, are in highly altered crystalline rocks formed from old sedimentary and igneous rocks. Barite has been found associated with similar rocks in six other counties in the Piedmont region, but has not been mined to any considerable extent. The barite is found as irregular lenslike replacements of the crystalline limestone associated with the schists and gneisses and as lumps in the residual clay, which is often limonitic or manganiferous and has been used in the manufacture of natural mineral pigments.

In southwestern Virginia, in Tazewell, Wythe, Russell, and Smyth counties, barite occurs in the Cambrian and Ordovician limestones or their residual clay. The Knox dolomite and Chickamauga limestone are probably the chief sources of the barite. In the limestone it occurs as replacements and veins associated with sphalerite, galena, and some fluorite.

Other States.—Deposits of barytes are known in Mariposa County in California, in Clark, Elko, Mineral, and Nye counties in Nevada, in Blaine County in Idaho, and in Alaska. Most of the deposits in the Western States are undeveloped, as there has apparently been a limited market for this material in that region. It is, however, possible that the paint grinders on the Pacific coast could use a limited supply of the material.

About 10 miles northwest of Hailey, Idaho, at the head of the north fork of Deer Creek, there is an outcrop of white banded barite, apparently conformably bedded with sandstones and quartzites of Pennsylvanian age. It is said to be 50 feet thick and to have been followed for 1,000 feet.[1]

During 1913 E. F. Burchard, of the United States Geological Survey, discovered a considerable deposit of barite associated with quartzite schists, on Castle Island, in the Duncan Canal, 40 miles northwest of Wrangell in southeastern Alaska. The following notes are taken from his manuscript, which will be published during the year as part of "Mineral Resources of Alaska in 1913."

The barite outcrops as a roughly elliptical mass 75 feet wide by 250 feet long, and is exposed 35 feet above high-tide level on the second island of the group, beginning at the southeast. The barite is finely crystalline, grayish in color, and clouded and streaked with bluish-gray to black material that may be galena or sphalerite. Pyrite and magnetite are disseminated throughout the mass. The powdered material is grayish white in color, but can be cleaned by washing with weak sulphuric acid. Some of the material was submitted to chemical analysis, which showed that it contained about 89.16 per cent of barium sulphate and 5.05 per cent of silica, and that about 2.66 per cent of the remainder was metallic sulphides.

STRONTIUM.

By James M. Hill.

During 1913 no strontium was reported as mined in the United States, though strontium-bearing deposits are not unknown in this country. There is, however, a narrowly limited market for strontium compounds, as is shown by the import figures.

No strontium carbonate, oxide, or protoxide was imported in either 1911 or 1912, but in 1913 the total value of imports of these salts was $2,284. Probably some strontium nitrate was imported for use in "red fire," but it is not possible to obtain figures of the imports of any salts of strontia except those named above.

SILICA (QUARTZ).

By Frank J. Katz.

INTRODUCTION.

Silica, the oxide of silicon (SiO_2), heretofore treated in these reports under the heading "Quartz," is the most abundant of mineral substances. Its occurrences of commercial importance are in a great many different forms, such as vein quartz, as a constituent of pegmatites, as sand, sandstone, quartzite, or flint, as tripoli, and as diatomaceous (infusorial) earth. In some forms, such as rose, smoky, and amethystine quartz, it has a gem value. This chapter deals with silica from all sources exclusive of gem quartz, of all forms of silica used for making glass, and also of all silica used in the form of sand, gravel, and crushed material for building, for concrete and mortar, for foundry and furance work, and for cutting and grinding stone. Silica for such purposes is either gem material or sand, and it is commercially so designated. Such materials as are here excluded are separately considered in other chapters of Mineral Resources. Tripoli and diatomaceous (infusorial) earth have heretofore been dealt with as abrasive materials, and as they are to a large extent consumed as abrasives they are also treated in the chapter on abrasive materials.

USES.

Silica (quartz) as treated in this chapter is used for many purposes. The principal uses are in the manufacture of pottery, paints, scouring soaps, as a wood filler, and as a polisher. In pottery the use of silica, generally called flint in the pottery industry, diminishes the shrinkage in the body of the ware; it is also used in many glazes. Silica for use in pottery should contain less than 0.5 per cent of iron-bearing minerals. Considerable quantities of very finely ground silica are used in the manufacture of paint, as much as one-third of the total pigment used in some paints being this material. Finely ground crystalline material is superior to a natural silica sand for this purpose because of the angularity of the grains, which makes them adhere more firmly to the painted surface and after wear affords a good surface for repainting. The same property renders artificially comminuted crystalline quartz superior to natural sands in the manufacture of wood fillers. For soaps and polishing powders ground material is preferred to natural sands on account of its whiteness and angularity. For all these purposes large quantities of pure quartz sands and sandstones are finely ground and yield a product fully equal to that derived by grinding massive crystalline quartz.

The material known commercially in the United States as tripoli, which is the siliceous residue of decomposition of limestones, also yields an excellent grade of pulverized silica, which is used for the same purposes as silica powder obtained from massive crystalline quartz and from sands and sandstones. Diatomaceous (infusorial) earth is also used to make polishing powder for purposes similar to those for which quartz, sand, and tripoli powders are used, but the diatomaceous earth has somewhat different properties and finds for the most part different application.

Quartz crushed and graded to various sizes is used in the manufacture of sandpaper and sand belts, as a scouring agent, and for "frosting" glass with sand-blast apparatus, etc. Blocks of massive quartz and quartzite are used in the chemical industry as a filler for acid towers and as a flux in copper smelting. Ground quartz is also used in filters and in tooth powders and by dentists as a detergent.

Crystalline quartz and also sand have been used in the manufacture of silicon and of alloys of silicon with iron, copper, and other metals in the electric furnace. Quartz may be fused in the electric furnace to make chemical apparatus, such as tubes, crucibles, dishes, etc.

PRODUCTION.

The marketed production of silica in 1913 for the uses considered in this chapter, as reported to the United States Geological Survey, was 232,192 short tons, valued at $953,832. In the preparation of this report on silica in 1913 the attempt was made for the first time to collect statistics of production of silica of all kinds used as outlined above. Sources were considered that were not known when previous reports were compiled. It is not certain that the inquiries upon which this report is based reached all producers, nor that the returns were complete. But it is believed that the measure of incompleteness is well under 10 per cent of the actual total production. The author hopes that by the time the report for 1914 is in preparation he will have discovered all sources of silica and have secured complete returns from all producers. Although the total production is given without any great assurance of accuracy, it is offered as the best approximation that can at present be made. In the following sections silica from various sources is separately considered, and the reliability of the figures in each section is indicated.

Marketed production of silica for pottery, paints, fillers, polishers, abrasives, and other uses in 1913, in short tons.

Material.	Quantity.	Value.
Quartz (vein quartz,[a] pegmatite, and quartzite)	97,902	$201,488
Sand and sandstone [a]	106,857	466,523
Tripoli	20,831	216,517
Diatomaceous earth	6,602	69,304
Flint		
Total	232,192	953,832

[a] Includes only finely ground material. Figures probably incomplete.

QUARTZ.

PRODUCTION.

The marketed production of silica from vein and pegmatite quartz and from pegmatite in 1913 was 97,902 short tons, valued at $201,488 against 97,874 short tons, valued at $191,685 in 1912. This was an almost inappreciable increase in quantity and an increase of $9,803, or about 5 per cent, in value. The decrease in the quantity sold crude was 7,876 short tons, or about 11 per cent, with a decrease in value of $12,814, or about 24 per cent, whereas the quartz sold ground increased 8,057 short tons, or about 34 per cent, in quantity and $22,617, or about 15 per cent, in value. The average price per ton for crude in 1911 was 91 cents; in 1912 it was 82 cents, and in 1913 it was 73 cents. The average price per ton for ground quartz in 1911 was $8.32, in 1912 it was $7.94, and in 1913 it was $6.23. In 1913, of the total marketed output, 75.76 per cent was crude and 24.24 per cent was ground, and of the total value received, 27.02 per cent was for crude and 72.98 per cent was for ground. The figures of the production of quartz for 1913 and previous years are based on complete returns from all known producers.

The following tables show the marketed production of quartz in 1912 and 1913 classified as to crude and ground, by States, and from 1909 to 1913 classified as to crude and ground:

Marketed production of quartz in the United States, 1912–1913, by States, in short tons.

1912.

State.	Crude.		Ground.		Total.	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.

QUARTZ INDUSTRY BY STATES.

Arizona.—In Arizona only one firm reported production in 1913. The material was ground and was used for reverberatory bottoms. The production was many times larger than in 1912.

California.—No production of quartz from California was reported for 1913.

Connecticut.—Only one operator, the Bridgeport Wood Finishing Co., reported production of quartz in Connecticut in 1913. The material was derived from quartz veins and was used for soap, pottery, paint, and wood filler.

Maryland.—Maryland was second in output and first in value of quartz in 1913, reporting 7,858 short tons, valued at $55,442. This was a decrease of about 51 per cent in quantity and about 10 per cent in value as compared with 1912. There was very little quartz sold crude in 1913 against large sales of crude in 1912. On the other hand, over 30 per cent more was sold ground in 1913 than in 1912. There were 5 producers in Maryland in 1913—the Indian Rock Flint Co., at Castleton, the Husband Flint & Milling Co. at, Deercreek, and H. Clay Whiteford & Co., at Conowingo, in Harford County; the Maryland Flint Co., Glen Morris, Baltimore County; and Thomas & Son, at Marriottsville, Carroll County. The product was all derived from quartz veins, and was used for pottery, paint, soap, and scouring powder, and for chemical purposes.

Massachusetts.—The Enos Adams Co., with quarry and mill at Cheshire, Berkshire County, was the only Massachusetts producer of quartz for the purposes mentioned in this chapter. Part of the product of this company was ground and sold for use as abrasives; the remainder was used for building purposes, facing cement blocks, etc. The material quarried is a very pure quartzite.

Michigan.—In Michigan the only producer, as in previous years, was the Michigan Quartz Co., with mine and mill at Ishpeming and another mill at Milwaukee, Wis. Its product is derived from vein quartz and is used for paint and wood filler chiefly, and also for polisher.

New York.—P. H. Kinkel's Sons, at Bedford, Westchester County, N. Y., were the only producers in New York in 1913. The production in 1913 was much larger than in 1912. Quartz is derived from pegmatite and is used for sandpaper, paint, and wood filler.

North Carolina.—The only producer of quartz in North Carolina in 1913 was F. Oliver, of Charlotte, who quarried quartzite at Mount Holly, Gaston County. The output was used for packing acid towers.

Pennsylvania.—Two operators reported production of quartz in Pennsylvania in 1913, the Columbia Flint Co., with quarry near Bendersville, Adams County, and H. T. A. Rhodewalt, with quarry at Comog station, Chester County. The output was less than in 1912.

Tennessee.—In 1913 Tennessee produced more quartz than all the other States combined, but the output was of comparatively low grade and of small value. The Tennessee Copper Co. was the only producer and reported a larger production than in 1912. The product was quarried from quartzite and was used as flux in copper smelting

Wisconsin.—The Wausau Quartz Co. was the only producer in Wisconsin in 1913. This company quarries a very pure quartzite in the town of Fleith, Marathon County, and mills the product in Wausau. It is used for filter beds, for roofing and concrete work, for chicken grits, and for sandpaper.

PRODUCTION IN PRINCIPAL COUNTRIES.

The production of quartz in the United States and other countries for the years 1909 to 1913, inclusive, is given in the following table:

Production of quartz in the principal producing countries, 1909–1913, in short tons.

Country.	1909 [a]		1910 [a]	
	Quantity.	Value.	Quantity.	Value.
United States	135,469	$249,466	63,577	$193,757
Canada	56,924	71,284	88,205	91,947

FLINT OR CHERT.

PRODUCTION.

So far as can be learned no flint (proper) or chert was produced for consumption as silica or for use as pebbles in grinding mills in the United States in 1913.

IMPORTS.

The imports for consumption of flint pebbles into the United States in 1913 were valued at $319,509, as compared with $292,052 in 1912, $236,158 in 1911, $307,286 in 1910, and $301,547 in 1909:

The following table shows the value of imports of flint pebbles in 1913 by country of origin:

Imports of flint pebbles, unground, into the United States, 1913, by countries.

Belgium	$40,947	Germany	$2
Canada	8,599	Newfoundland	10,800
Denmark	134,625	Sweden	56
England	2,626		
France	121,854	Total	319,509

SAND AND SANDSTONE.

Under this heading are presented statistics only of that part of the sand and sandstone production which is finely crushed or ground for the uses previously enumerated in this chapter. Reports of such production in 1913 were made to the Survey by producers in Illinois, Ohio, Pennsylvania, and West Virginia. The data secured indicate a total production of 106,857 short tons, valued at $466,523, but it is not certain that reports were obtained from all producers. Prices per ton ranged from $3.25 to $5.25. The following table summarizes quantity and value of ground sand and sandstone produced in 1913:

Marketed production of ground sand and sandstone in the United States in 1913, by States, in short tons.

State.	Quantity.	Value.
Illinois	38,755	$135,813
Ohio, Pennsylvania, and West Virginia	68,102	330,710
Total	106,857	466,523

TRIPOLI.

The material commercially called tripoli in the United States is a residue from siliceous limestones which have been leached of their carbonate content. This material is nearly pure silica of very fine grain and may be either coherent or pulverulent. Tripoli is also used as an abrasive material and is therefore included in the chapter on abrasive materials. The statistics of tripoli production in 1913 are here repeated because much of the output is used for the same purposes as the other forms of silica treated in this chapter. The following table summarizes the production of tripoli in the United States in 1913:

Production of tripoli in the United States in 1913, by States, in short tons.

State.	Quantity.	Value.
Illinois	12,994	$128,892
Missouri, Pennsylvania, and Tennessee	7,837	86,725
Total	20,831	215,617

DIATOMACEOUS EARTH.

Diatomaceous earth is largely made up of silica. It is a variety of opal—that is, amorphous silica combined with a small quantity of water. It represents the remains of aquatic plants known as diatoms. Diatomaceous earth, which is also commercially called infusorial earth, kieselguhr, and rarely in the United States, although properly, tripoli, is largely used as an abrasive material and is treated in the chapter on abrasive materials. The statistics of production are repeated here because the composition and character of the material are to some extent similar to the other materials here considered and because it is in part put to the same uses.

Production of diatomaceous earth in the United States in 1913, by States, in short tons.

State.	Quantity.	Value.
California, Nevada, and Washington	6,035	$55,056
Connecticut, New York, and Maryland	328	8,065
Virginia, Georgia, and Florida	239	6,183
Total	6,602	69,304

GRAPHITE.

By Edson S. Bastin.

INTRODUCTION.

In the present report there is republished in full or in abstract all of the information on graphite that has appeared in previous Survey reports. This information has been amplified in some particulars and brought up to date whenever possible. It will be unnecessary therefore for readers to refer to any earlier Survey reports dealing with this mineral.

The production of natural graphite in the United States is sporadic, because the milling of disseminated flake graphite is still in the experimental stage and the product is of uneven grade. Because of this unreliability of the domestic supply most of the large consumers prefer to depend on imported material.

In 1913 the quantity of graphite imported into the United States for consumption was 28,879 short tons, valued at $2,109,791. In contrast to this the total domestic production was 4,775 short tons of natural graphite, valued at $293,756, and 6,817 short tons of manufactured graphite, valued at $973,397.

The cause of the unsatisfactory condition of the domestic industry is to be found in (1) the superiority of much of the Ceylon graphite to any graphite that is mined in this country; (2) the low cost of labor in Ceylon, which permits cheap mining, careful sorting, rubbing up, and blending of the product; (3) the facts that the largest domestic deposits are schists which carry small flakes of graphite disseminated through them and that the separation of the graphite from the accompanying minerals, especially mica, in such rocks is a problem of unusual difficulty. The one firm which can be said to have become firmly established in the treatment of such graphite rocks, the Joseph Dixon Crucible Co., possesses important advantage over other firms in that it manufactures much of its product into graphite paints, graphite grease, etc., before placing it on the market. When the margin of profit is small, such control of markets becomes of vital importance.

To-day there are more abandoned graphite mines and mills in the United States than the number in operation. The number of times that some of these properties have changed hands in the course of a few years evinces a record of misrepresentation and disappointment that can hardly be equaled in any other branch of mining, and many properties have been notoriously associated with stock manipulations of doubtful character. It should be clearly understood by anyone who contemplates the development of one of the flake-graphite deposits that the technology of concentrating such materials is yet in its infancy; that there are no well-established systems of treating the materials, such as exist, for example, for the treatment of gold or copper ores; and that the product obtained is variable in quality and in market value and subject to severe competition with foreign graphite. The largest part of the foreign graphite that comes into this country is brought in by American firms who either control or own the foreign mines or have purchasing agents abroad, and are, therefore, in a position to take immediate advantage of any change in the markets at home or abroad. In general, the cost of producing flake graphite is so high and the price at which it is sold so low that even under the most economic conditions the margin of profit is small. Moreover, certain rocks that carry graphite contain other minerals in such intimate association with the graphite as to preclude any possibility of successful concentration—such, for example, are rocks in which graphite flakes are interleaved with mica—and a careful study of the material by an expert should precede any attempt at development.

In a later paragraph the uses of graphite are discussed. These uses are manifold, but it should be remembered that graphite from any one property will be adapted for only certain of these uses, and that not only the purity of the graphite but its physical properties are of importance in determining the purposes for which it is suited. Crucible manufacture, for example, demands a flaky graphite high in carbon, and Ceylon lump, which retains its flaky character after grinding, is excellently adapted to this use. For foundry facings, on the other hand, an earthy, impure graphite is usually adequate. For many purposes—as for the manufacture of pencils—the best result can be obtained only by a careful blending of graphite of several different kinds. The blending in various proportions of slightly different grades of graphite from different mines to obtain products which meet the varied requirements of purchasers is one of the steps in preparing the Ceylon graphite for the market. To a certain extent blending is practiced by some American dealers, especially in marketing the amorphous forms.

PHYSICAL AND CHEMICAL PROPERTIES.

Chemically, the purest graphite is carbon with a fraction of 1 per cent of ash and volatile matter. In the trade graphite is frequently referred to as plumbago, or black lead. The graphites of commerce contain various impurities, sometimes in large quantities. Graphites showing 80 to 95 per cent graphitic carbon are pure enough for the requirements of the general trade, and for many uses, such as paint making, graphites with as low as 30 to 35 per cent of graphitic carbon are employed. The mineral possesses certain physical characteristics which usually enable it to be easily recognized. These are its steel-gray to blue-black color, extreme softness (1 to 2 in the scale of hardness), greasy feel, and the property of making a black metallic mark on paper. It is opaque in even the thinnest flakes, and the flakes, though flexible, are not elastic. Its temperature of fusion or volatilization is unknown, but is probably above 3,000° C. It is combustible at temperatures between 650° and 700° C. The specific gravity generally lies between 2.20 and 2.27. The only mineral with which graphite is likely to be confused is molybdenite, from which it differs slightly in color, the molybdenite having a somewhat bluish or greenish tinge. The two minerals may be distinguished by simple blowpipe tests. Graphite is in general a better conductor of electricity than most of the amorphous forms of carbon. Tests by P. M. Lincoln, of the Niagara Falls Power Co., showed a specific resistance of 0.00032 ohm in an artificial graphite electrode, and an amorphous carbon electrode of the same size showed a resistance of 0.00124 ohm.

In the trade two principal varieties of graphite are generally recognized. The graphite that possesses a lamellar, scaly, flaky, or fibrous structure is classed as crystalline. The other forms of graphite, of whatever occurrence or appearance, are classed as amorphous. The two varieties are not sharply differentiated, and the distinction appears to be largely in the size of the graphite particles. Much of the so-called amorphous graphite mined in the United States is shale or slate containing varying percentages of carbonaceous material, and it is often impossible, even with chemical tests, to tell whether the carbon in such rocks is graphite or ordinary carbon.

The physical character of graphite is usually of the utmost commercial importance, as will be further discussed in the section on uses.

ORIGIN.

Graphite occurs in nature in each of the three great groups of rocks — igneous, sedimentary, and metamorphic. It also occurs as veins, which may traverse rocks belonging to one or all of these groups.

Graphite has been observed in numerous places in igneous rocks, especially granite-pegmatites, so intercrystallized with the other rock minerals as to leave no doubt that it formed a part of the molten magma from which the rock crystallized. In some such occurrences, where the igneous rock is associated with carbonaceous sediments, it is probable that the magma absorbed carbon from these sediments, but in others it is equally probable that the graphite is of inorganic origin, or at least came up from great depths as an integral part of the igneous magma. The frequent occurrence of graphite in meteorites also indicates that it can be of inorganic origin. Except where igneous rocks are associated with carbonaceous sediments, the amount of graphite in them is usually small and of no commercial importance.

Graphite has been found in unaltered sedimentary rocks, but in all such rocks it is present in small amounts and has not been formed in place, but has been washed or weathered out of older igneous or metamorphic rocks.

The deposits of crystalline graphite which are of greatest commercial importance are veinlike in form and have apparently been deposited along fractures in the rocks. Foremost among these in size and importance are the famous Ceylon deposits, which are described further on in this report. The deposits near Dillon, Mont., also described in this report, and certain deposits in the counties of Ottawa and Argenteuil, Quebec, belong to this type. Very little is definitely known in regard to the origin of such vein deposits, although numerous theories have been proposed. It is certain that they were deposited along fracture planes in the rocks, and they were probably formed at considerable depths, but at temperatures which in some cases at least did not exceed 575° C.[1] In some localities they are associated with graphite deposits of contact metamorphic origin and were probably formed during the later stages of such metamorphism.

Many of the commercially important amorphous graphite deposits were coal beds which have been partly or wholly converted into graphite by the metamorphic effect of intrusive igneous rock magmas. Such is probably the origin of the important deposits of Sonora, Mexico, and of the deposit of Turret, Colo.

The large group of so-called disseminated deposits in which the graphite occurs in small flakes disseminated through a foliated rock, usually a crystalline limestone or a schist, is of great importance in the United States, Canada, and Germany. Such deposits have probably been formed by the dynamic metamorphism of sediments which carried carbon in some form scattered through them. Metamorphism by igneous rocks has also played a part in the formation of some of the deposits of this type.

MANUFACTURED GRAPHITE.

The manufacture of graphite on a commercial scale from various forms of amorphous carbon is conducted by the International Acheson Graphite Co., of Niagara Falls, which utilizes electric power generated at the Falls. Dr. Acheson patented the process for the manufacture of graphite by the electric furnace in 1896, and its commercial development has been so rapid that at present the output of artificial graphite is greater than the whole production of natural crystalline graphite in the United States.

The conversion appears to take place on a commercial scale only when certain impurities, usually siliceous, aluminous, or ferruginous, are present. These need not form more than 3 per cent of the total, but to obtain the best results should be evenly disseminated through the mass. The explanation of the conversion which has been advanced by Dr. Acheson supposes that the amorphous carbon first unites with the siliceous, ferruginous, or other impurities present to form carbides, which are later decomposed with the formation of graphite and the volatilization of the other constituents. The small amount of impurity required to effect the change is explained by supposing that the transfer becomes progressive, vapors of iron or silicon traversing the entire charge, combining with molecules of amorphous carbon, and then abandoning them in a graphitic state. This explanation is not, however, accepted by all investigators, and recent investigations appear to show that the product obtained in the electric furnace depends fully as much upon the nature of the original carbon used as upon the impurities present.

Anthracite coal carrying small amounts of evenly distributed impurities is used in the manufacture of the ordinary grades. An anthracite with 5.78 per cent ash is said to have yielded a graphite, with only 0.03 per cent of ash, the siliceous impurities being volatilized in the process. For obtaining the purest grades of graphite, petroleum coke is substituted for anthracite. An important part of the industry at Niagara Falls is the graphitization of rods and bars

[1] Bastin, E. S., Origin of certain Adirondack graphite deposits: Econ. Geology, vol. 5, pp. 152–155, 1910.

of amorphous nongraphitic carbon for use mainly as electrodes in electrochemical industries. These bars are made by pressing hot through a die in a hydraulic press a mixture of tar and ground petroleum coke. They suffer very little change in size or form in the process of graphitization. The Acheson furnaces have permanent heads for conducting the current. The walls are of loose brick construction, designed to retain the materials in place while the furnace is in operation; when the furnace is about to be unloaded the walls are easily torn down. Coke and sand are used for insulating. Although several furnaces connect with each electric unit, only one is fired at a time, the others being in process of loading, unloading, cooling, or repair. Furnaces for the production of ordinary bulk graphite are run for 12 to 24 hours and are allowed to cool for about four days, reloading taking place about every five days. The carbon rods and bars for electrodes must be fired much longer.

Prices for powdered graphite range from 4 cents to as much as 28 cents a pound, according to grade, and for the electrodes from 10 to 12 cents a pound. Much of the powdered graphite is mixed in proportions varying from 1 to 10 per cent with greases of several degrees of stiffness. A specially treated graphite which will remain suspended in oil is marketed in a concentrated form in gallon equivalents. When 1 gallon equivalent is mixed with oil to make 1 gallon of material the mixture contains 0.25 per cent of graphite.

In spite of the development of the manufacture of graphite by the electric furnace, the demand for the natural product has increased very largely in recent years because of the growth of the iron and steel industry, the largely increased use of copper and its alloys, the increased need for lubricants, and the development of electric machinery which calls for graphitized products.

USES.

The characteristics possessed by graphite and already mentioned make it a mineral of great and increasing industrial importance, but also, as already stated, graphite from any one property is never adapted to all of these uses, its purity and physical character determining its industrial application. One of the oldest and most important applications is in the manufacture of crucibles for use in the steel, brass, and bronze industries. Because graphite is nearly pure carbon, is relatively inert chemically, and volatilizes only at high temperatures it has exceptional value for this purpose. Such crucibles must have good tensile strength, and the poorer the binding quality of the graphite used the larger the quantity of less refractory binding material which must be added to hold the mass together, thus increasing the more fusible constituents of the crucible at the expense of the more refractory and materially decreasing its life. It is for this reason that a flaky graphite is used in crucibles, for the interlocking and overlapping of these flakes adds to the tensile strength. Ground Ceylon lump graphite is the material most in favor in the United States for making crucibles, although small amounts of American and Madagascar flake graphite are also used. Amorphous graphite has never been successfully utilized in crucible manufacture with the single exception of very small crucibles machined out from manufactured graphite rods or blocks.

As pointed out by Miller:[1]

In the manufacture of crucibles the graphite owes its value to the fact that it does not fuse at the temperature at which most metals and alloys melt and also is a good conductor of heat. By experiment it has been shown that due to the ease with which the graphite conducts the heat from without the crucible to the metal within less fuel is consumed when graphite crucibles are used than when clay crucibles are employed. Time is also gained because the metal melts more quickly. Further, graphite crucibles can withstand sudden changes in temperature much better than clay crucibles.

Other refractory products, such as muffles, stirring rods, dipping cups, skimmers, and nozzles, are usually made from materials similar to those used in crucibles, although manufactured graphite products are also on the market for many of these uses and for the preparation of molds for metal casting. Manufactured graphite for such uses is made by treating in the electric furnace amorphous carbon articles previously made up into the desired form. The main use of such graphitized carbon rods and plates is as electrodes in electrochemical industries. They can be machined, threaded, and cut with ease.

One of the most important uses of graphite is for lubricating. The addition of graphite to oil results in a lower frictional resistance than would be obtained by the use of oil alone. The quantity of oil required for a given service is also reduced and a lighter grade of oil may be employed without decreasing the quality of the lubrication. Only a small quantity of graphite is required, and the benefits derived from its use persist long after the application has ceased. In light bearings of machinery, where oil can not be used on account of the danger of soiling delicate textiles, graphite can be used alone as a lubricant. Both the amorphous and the crystalline varieties of natural graphite are extensively employed for lubrication, and when used for this purpose should be free from gritty impurities. The purity of the better grades of lubricating graphite usually exceeds 90 per cent. Lubricating graphite is sometimes marketed as dry flake or powder but usually as a mixture with oil or grease.

The use of graphite in the manufacture of pencils is probably both its oldest and its best-known application. This industry in Germany and England is several centuries old, and many of the modern factories manufacture hundreds of varieties of pencils, yet the percentage of graphite used for this purpose is not large, being undoubtedly less than 10 per cent of the world's production, and one authority estimates it as low as 4 per cent. In this industry the physical character of the graphite is of great importance. Crystalline graphite, however pure, would, if used alone, yield a "lead" that would slip over the paper without leaving more than a faint streak. Furthermore, it is almost impossible to grind the easily cleavable flake graphite into a powder of the fineness and evenness of grain requisite for the better grades of pencils. The better grades of amorphous graphite constitute the bulk of the material used in pencil manufacture. For some of the cheaper pencils only one kind of graphite is used, but the graphite for pencils of the better grades is a careful blend of several kinds. One blend, for example, contains about one-third Ceylon crystalline graphite, one-third Bohemian amorphous graphite, and one-third Mexican amorphous graphite. The Ceylon graphite adds to the smoothness of the "lead"; the Bohemian graphite

[1] Miller, B. L., Graphite deposits of Pennsylvania: Pennsylvania Topog. and Geol. Survey Comm. Rept. 6, p. 28, 1912.

adds blackness. Graphite used for pencils is mixed with carefully refined clay, which is usually imported from Germany, no domestic clay having been found entirely suitable for pencil manufacture. The more graphite and the less clay the softer the pencil; the less graphite and the more clay the harder the pencil. The cores of softer pencils are usually made larger than those of the harder ones in order to give them equal tensile strength. For a pencil of medium hardness about one-third clay is commonly used. The wet mixture of clay and graphite is worked and reworked until it is so pliable that it can be looped in coils and even tied in loose knots.

Up to a few years ago every American pencil manufacturer had to import his amorphous graphite from Bohemia or Bavaria. About 14 years ago a large deposit of amorphous graphite was discovered in Sonora, Mexico. This proved to be of excellent quality for pencil making and many other uses, and the American pencil trade now derives its supply mainly from this source. Mexican graphite is also exported to European pencil manufacturers.

A use which has increased rapidly in importance within the last few years is the manufacture of graphite paint, especially for structural iron and steel work. Much of the graphite used for this purpose is rather impure, the specifications frequently requiring not more than 35 or 40 per cent of graphite in the paint pigment, the remainder being generally siliceous, aluminous, or ferruginous material. Most of the graphite used in paints is of the amorphous variety, but some very fine-grained crystalline material is also employed. Six graphite paints used in tests on the Pennsylvania Railroad bridge at Havre de Grace, Md., showed from 19.16 to 97.80 per cent of graphite in the pigment. Recent tests made in cooperation between the Office of Public Roads of the Department of Agriculture and the Paint Manufacturers' Association, for the purpose of determining the relative merits of various paint pigments as preservative coatings for iron and steel, have yielded results of importance, with which makers and users of graphite paint should be familiar.[1]

Large quantities of amorphous graphite and of finely ground crystalline graphite are used for coating molds in foundries. A high degree of purity, though essential for the finest castings, is not necessary in all graphites used for this purpose; in fact, the presence of siliceous material may sometimes be of positive benefit by causing the graphite to cling or spread better on the face of the mold. Considerable amounts both of amorphous graphite and of finely ground crystalline graphite are used in the manufacture of stove-polishing powders and pastes. Another use of crystalline graphite is as a protective polish for gunpowder and as a packing material for the delicate electric-lamp filaments; it is also used in electrotyping and as a filler for dry batteries. Within recent years a considerable market has been built up both for amorphous graphite and for fine flake graphite as a boiler compound. Its presence in the boiler prevents the scale from adhering strongly to the iron.

The proportions of the world's supply of graphite used for various purposes can only be approximately estimated. The following table furnished by Mr. Harry Dailey, of the Joseph Dixon Crucible Co., is in agreement with one published by Miller.[2]

[1] Cushman, A. S., The preservation of iron and steel: U. S. Dept. Agr., Office Pub. Roads, Bull. 35, 1909.
[2] Miller, B. L., op. cit., p. 27.

Estimated percentage (by quantity) of the world's graphite consumption used for various purposes.

	Percentage.
Crucibles	55
Stove polish	15
Foundry facings	10
Lead pencils	5
Paint	5
Lubricants	5
All other uses	5
Total	100

If the value rather than the quantity be considered, about 75 per cent of the world's consumption should be credited to crucibles.

PRODUCTION AND IMPORTS.

NATURAL GRAPHITE.

PRODUCTION.

In 1913, as in 1912 and 1911, the total production of crystalline graphite came from Alabama, New York, and Pennsylvania. All of this crystalline graphite was of the variety known in the trade as "flake" graphite, that occurs as small flakes disseminated through crystalline schists, from which it is separated by more or less complicated milling processes. The production of crystalline graphite, which showed a continuous decrease from 1909 to 1911, increased slightly during 1912 and 1913. This increase was mainly due to increased production in New York and Alabama, the Pennsylvania output being relatively small and much the same.

Amorphous graphite was produced during the year by five different firms, located in Rhode Island, Colorado, Wisconsin, Nevada, and California. Nearly all of this material was of low grade and suited only for paint pigment and foundry facings.

Further details in regard to various properties are given in the summary by States and Territories.

Production of natural graphite, 1909–1913.

Years.	Amorphous.		Crystalline.		Total.	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
	Short tons.		*Pounds.*		*Short tons.*	
1909	[a] 5,096	$32,238	6,294,400	$313,271	8,243	$345,509
1910	1,407	39,710	5,590,592	295,733	4,202	335,443
1911	1,223	32,415	4,790,000	256,050	3,618	288,465
1912	2,063	32,894	3,543,771	187,689	3,835	220,583
1913	2,243	39,428	5,064,727	254,328	4,775	293,756

[a] Includes Georgia graphitic slate.

On account of the small number of producers, figures of production by States, except for Alabama, can not be published without revealing individual productions. The production of Alabama amounted to 2,020,910 pounds of crystalline graphite, valued at $87,336.

IMPORTS.

The imports for consumption of graphite into the United States in 1911, 1912, and 1913, by countries, are shown in the following table:

Imports of graphite for consumption into the United States, 1911, 1912, and 1913, by countries, in short tons.

Country.	1911		1912		1913	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
Ceylon	13,119	$1,132,678	16,791	$1,379,587	16,996	$1,674,764
Mexico	3,368	254,060	3,518	163,107	4,435	198,000

MANUFACTURED GRAPHITE.

The following table shows the production of manufactured graphite by the International Acheson Graphite Co., at Niagara Falls, N. Y., for the years 1909–1913, inclusive. The diagram (fig. 7) shows the production from the commercial inception of the industry in 1897.

Production and value of manufactured graphite, 1909–1913.

Years.	Quantity.	Value.	Average price per pound.
	Pounds.		*Cents.*
1909	6,664,017	$480,000	7.20
1910	13,149,100	945,000	7.20
1911	10,144,000	664,000	6.55
1912	12,896,347	830,193	6.44
1913	13,633,342	973,397	7.14

INDUSTRY BY STATES AND TERRITORIES.

ALABAMA.

Graphite is widely distributed among the metamorphic rocks of Alabama,[1] in which it occurs in two forms: (1) In the feebly crystalline schists which have been called the Talladega slates,[2] and which in part at least are Paleozoic sediments of as late age as the "Coal Measures," graphite is often found as a black graphitic clay free from grit. In this condition the graphite is difficult to separate from the other matter with which it is mixed, and the material has not yet been utilized commercially to any great extent. Examples of this mode of occurrence may be seen near Millerville, in Clay County, and

[1] Smith, E. A., Min. Industry, vol. 16, p. 568, 1907.
[2] McCalley, H., Alabama Geol. Survey Rept. valley regions, pt. 2, pp. 36–38, 1897.

about Blue Hill, in Tallapoosa County. (2) In the mica schists and other highly crystalline rocks graphite is found in the form of thin crystalline flakes, which may be separated from the associated minerals. Graphitic schists of this type are now being worked at three localities and have in the past been worked at several others.

Three graphite companies were active in Alabama during 1913. One of these, the Alabama Graphite Co., with mine and mill 6 miles west of Ashland, Clay County, reported a notable increase in production as compared with 1912. The other, the Quenelda Graphite Co. (formerly the Allen Graphite Co.), at Quenelda, Clay County, has completed a new mill to replace the one destroyed by fire in 1911. This mill was put in operation November 1, 1913, and an important quantity of flake graphite was marketed during the year. The mine and mill 4½ miles west of Ashland, formerly operated by the Ashland Graphite Co., have not been in operation since 1911, and it is reported that the company has dissolved. The Flaketown Graphite Co., near Mountain Creek, in Chilton County, reported an important production.

The properties of the Quenelda Graphite Co. and that formerly operated by the Ashland Graphite Co. and a few other Alabama graphite properties were visited by the writer in 1911. The original reports upon them being exhausted, his observations are reprinted below. The property of the Alabama Graphite Co. was not developed at that time and has not since been visited.

CLAY COUNTY.

Ashland, the shipping point of the Clay County graphite properties, is the terminus of a short branch of the Atlanta, Birmingham & Atlantic Railroad. This branch is 7 miles long and joins the main line at Pyriton. The freight rate on refined graphite from Ashland to New York City is about $7 a long ton.

QUENELDA GRAPHITE CO. (FORMERLY THE ALLEN GRAPHITE CO.)

The quarry and mill of this company are located a little over 8 miles west of Ashland, at a settlement shown on the United States Geological Survey's map of the Ashland quadrangle under the name "Graphite." The mine is about half a mile from the mill, with which it is connected by a tramway. The concentrate is hauled over a fairly good road to Ashland for shipment. The mining is entirely from open pits, and because of the decomposed character of the rock can be accomplished largely with the aid of pick, shovel, and crowbar, without much drilling and blasting.

The main pit is about 450 feet in length, 100 feet in average width, and about 60 feet in maximum depth. A small pit just east of the main pit and on the same graphitic band is about 100 feet long, 90 feet wide, and 25 feet deep. A third pit has been opened on the same band of graphitic schist about 1,000 feet east of the main pit on the west face of another hill. This is about 90 feet wide, about 200 feet long, and about 40 feet deep. The strike of the schist at the north end of the main pit is N. 80° E., with a dip of 75° S. This is fairly typical for the deposit as a whole.

The rock mined is highly schistose and is composed largely of quartz and graphite. A white, fibrous mineral, probably sillimanite, is also abundant. Feldspar and mica are rare. Few of the thin graphite flakes so far seen by the writer exceed 2 millimeters across and most of them are under 1½ millimeters. They are arranged subparallel to one another, and to this arrangement and a similar orientation of the sillimanite (?) prisms is largely due the schistosity of the rock. At the west end of the main pit a dike of coarse granite, 1 to 1½ feet wide, parallels the foliation of the schist, and in the easternmost pit the graphitic schist has also been intruded by an irregular body of coarse

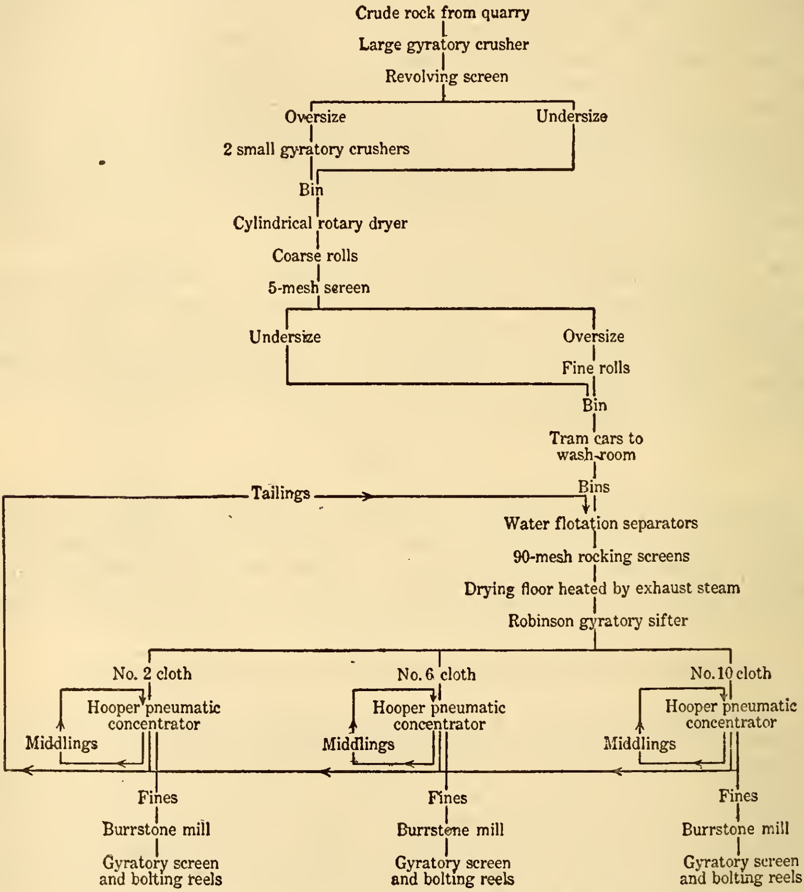

FIGURE 8.—Diagram showing milling processes at Allen graphite mill, Graphite, Ala.

granite pegmatite carrying muscovite crystals up to 3 inches across. The graphitic beds here are also disturbed by faulting. The contact metamorphic effects of these small intrusions on the graphitic schist appear to be slight.

The mill which was in operation at the time of the writer's visit has since been destroyed by fire and replaced by a new one, but as the old mill was studied in some detail a description of the process may still be of value.

The milling process in the old mill was divided into three principal stages—(1) crushing and drying; (2) preliminary wet concentration; and (3) final dry concentration. The details are shown in figure 8.

The most important step in the milling process was the preliminary concentration by water flotation. In these concentrators the dry crushed rock was spread in a thin stream upon the surface of slowly flowing water. The graphite being flaky was supported by the surface tension of the water and floated off, while the granular gangue, mainly quartz, sank and was sent to the dump. The process is cheap where water is plentiful. The tailings seen on the dump carried surprisingly little graphite; that which was present was usually attached to other minerals. Much fine grit, of course, floated off with the graphite but was removed in the final dry concentration.

The crude rock was said by the operators to average about 5 per cent graphite. For two successive years (September, 1908, to September, 1910) the finished product formed, respectively, 2.95 and 2.7 per cent by weight of the crude rock treated. Four principal grades were produced, whose relative proportions were about as follows:

Grades of flake graphite produced by Allen Graphite Co., Clay County, Ala.

	Per cent.
Grade C. Crucible flake	36
Grade 1. Lubricating flake (coarse)	11
Grade 2. Lubricating flake (fine)	18
Grade D. Dust for foundry facings, etc	35
	100

The highest grade averaged over 90 per cent graphite; the dust averaged about 50 per cent graphite. The average prices f. o. b. New York in 1911 were: Grade C, 6½ cents per pound; grade 1, 5½ cents per pound; grade 2, 4½ cents per pound; and grade D, 1 cent per pound.

ASHLAND GRAPHITE CO.

The quarry and mill of the Ashland Graphite Co., which has not been a producer since 1911, are located about 4½ miles west of Ashland. The company was the successor to the Enitachopco Graphite Co. The product of the plant was hauled by team to Ashland. The workings at this property consist of two open pits located in the same belt of graphite schist. The two pits are on neighboring knolls, and the mill is in the small valley between them. The largest or eastern pit is about 400 feet long, 30 to 50 feet wide, and 50 feet deep. It follows along the strike of a band of graphitic schist which averages about 30 feet in width, though broadening locally to about 50 feet. The strike is about N. 55° E. and the average dip is about 45° E. The second pit, located west of the mill, is about 150 feet long, 20 feet wide, and about 20 feet deep. The trend of the schists is similar to that at the larger pit.

The graphitic rock at this quarry is similar in general to that at the Quenelda quarry. The schist is too much decomposed for the complete identification of all the minerals, but quartz is the principal component. As a rule mica is rare, but the brown mica biotite is common in a few places. The graphite forms thin flakes, mostly under 1 millimeter in diameter, although some reach 2 millimeters. No igneous rocks were seen in association with the graphitic schist at this property. The rock being more or less decomposed, can be excavated with pick and crowbar with occasional blasting. It is loaded into tramcars and hauled to the mill.

The mill has a capacity of about 50 to 60 tons a day of 12 hours. The milling process was in general similar to that at the old Allen mill, though differing in details. A dry pan was used in preliminary crushing. The water flotation separators were similar to those at the Allen plant. The final dry concentration was accomplished by screens and burrstone mills.

CHILTON COUNTY.

DIXIE GRAPHITE CO.

The property of the Dixie Graphite Co., is about 6 miles northeast of Mountain Creek, the shipping point, a small station on the Louisville & Nashville Railroad. The company has been out of business for many years and the mill is partly ruined. Two Jeffrey vibratory screens and a rotary drier are all that remain of the milling machinery. The graphitic rock was taken from several small open pits and a short tunnel on the slopes of a small creek valley. The creek is of sufficient size to furnish water for wet concentration but not for power. The tunnel is about 50 feet long and is enlarged at its end to a room about 50 by 50 feet and 15 feet high. The rock is a graphitic quartz schist interbanded with schist rich in muscovite. The general strike is about N. 70° W., and the dip is about 60° N. Quartz lenses are abundant. The graphitic portions are pockety in their distribution, and the flakes are small. For these reasons and because of its distance from the railroad the property is much less promising commercially than others in the State.

FLAKETOWN GRAPHITE CO.

The Flaketown Graphite Co. operates a quarry and mill in the valley of Chestnut Creek, about 3½ miles northeast of Mountain Creek station. The property is about 3 miles west of that of the Dixie Graphite Co. The graphitic rocks lie in the west valley slope and have been developed by a small open pit. South of this pit sufficient prospecting has been done to show that the deposit is of very considerable size. The rock is a graphitic quartz schist very similar to those worked in Clay County. On account of its situation on a steep valley slope, which favors relatively rapid removal of weathered material, the remaining material is not so much decomposed as the deposits west of Ashland, in Clay County.

Small quantities of green micaceous mineral, probably muscovite, are present in some specimens, but in general, mica is rare. The strike of the schist folia at the main pit is N. 35° W., with a dip of 45° SW. A few hundred yards farther south the strike shifts to N. 20° W. and N. 15° W. A dike of granite pegmatite 1 foot wide intrudes the graphitic schist at the main pit. It parallels the foliation, and within 1 to 2 inches of the schist carries graphite in scattered flakes up to one-eighth of an inch in diameter.

An analysis made by the United States Geological Survey of a composite sample of graphitic schist, collected from a number of different exposures on this property, showed 4.63 per cent of graphite.

The mill is located at the quarry, and during part of the year electric power for its operation is generated by water power from a 20-foot dam on Chestnut Creek. Auxiliary steam power is also installed. The details of the concentrating process were not observed. Mountain Creek is the nearest shipping point.

COOSA COUNTY.

A graphite prospect is located about 2 miles northwest of Goodwater, a station on the Central of Georgia Railway. At this locality a large number of small prospect pits are scattered over an area of several acres, and nearly all show graphitic quartz schist. The prospects are on a steep southwest hillside overlooking the iron bridge where the wagon road from Goodwater to Pine Grove crosses Hatchet Creek. The rock is gray when fresh and highly schistose and strikes nearly east and west, with a dip of about 45° S. It is almost identical in character with the graphitic schist worked in Clay County and consists largely of quartz and graphite, the latter in flakes mostly under 1 millimeter in diameter. Very little mica is present. An analysis of a composite sample of graphitic schist collected from a large number of pits on this property showed 2 per cent of graphite, but in certain portions the percentage will undoubtedly be greater. The deposit is unquestionably a large one and its situation on a steep hillside would afford opportunity to work to a considerable depth by open-pit methods. The neighboring Hatchet Creek could furnish abundant water for wet concentration of the graphite.

A second deposit, probably of similar character, has been prospected between Mount Olive and Hollins. It was not visited by the writer, but is said to be of considerable size.

ALASKA.

Graphite mining in Alaska has not yet attained the status of an established industry. During the last six or seven years development work has been in progress at several properties near the Imuruk Basin on Seward Peninsula, and small trial shipments have been made to the United States.

In 1913 a small quantity of hand-picked crystalline graphite was brought into the United States by the Uncle Sam Alaska Mining Syndicate and was treated in an experimental mill at Everett, Wash., to determine its value for the various purposes for which graphite is commonly applied. It is said that about 200 tons of crystalline graphite, averaging 80 per cent carbon, is sacked at the mines ready for shipment in the summer of 1914, and that it is planned to erect a mill at Seattle for its treatment.

The Alaska Graphite Co. did not market any graphite during 1913, but expects to renew operations in 1914.

The following descriptions are in the main abbreviated from the reports of F. H. Moffit and P. S. Smith, of this Survey:

Extensive graphite deposits occur in Alaska on both the northern and the southern slopes of the Kigluaik Mountains in the southern part of Seward Peninsula. On the south side of the range between Grand Central and Windy Creeks [1] a sharp ridge is made up of biotite schists striking east and west intruded by dikes and sills of granite and pegmatite. Some of the schists are highly graphitic, the graphite occurring as abundant small flakes, much of it not distinguishable on casual examination from biotite. Locally graphite is segregated in beds of much flattened lenticular form lying in the cleavage of the schist and

[1] Moffit, Fred. H., The Nome region: U. S. Geol. Survey Bull. 314, pp. 139-140, 1907.

reaching thicknesses of 6, 8, or even 18 inches. Thin beds of schist with numerous large garnets are included, and quartz is nearly everywhere present.

The sills and dikes of pegmatite which cut the graphitic schists also contain graphite. The graphite in these appears to have crystallized at the same time as the other pegmatite minerals. At one place about 8 inches of solid graphite is included between a pegmatite sill and the overlying schist. The steep slopes of the mountains are strewn with loose fragments. One block approximately 7 feet by 6 feet by 30 inches consisted of about equal amounts of schist and apparently almost pure graphite. These deposits are on the south side of the range and have not been developed.

On the north side of the Kigluaik Mountains,[1] near the Imuruk Basin, deposits of graphite occur, upon which some development work has been done. One firm—the Alaska Graphite Co., of San Francisco—has shipped small quantities from this locality to the United States. At the mine of this company graphitic schists are interlaminated with more quartzose biotite schists, and both are intruded by granitic rocks. Much of the graphite is obtained in "blocks" up to 2 feet in length and 1 foot in thickness, practically unmixed with foreign material. Dislocations and fractures make the stoping out of the ore more or less dangerous. After the ore is broken from the ledge it is cobbed and hand sorted. In this sorting less than 25 per cent of the material is retained. This is sacked and hauled down the steep slope of the mountains on sleds to the flats surrounding Imuruk Basin. The sacks are then transported by horses to the shore, where they are put aboard a boat and taken to Teller for shipment. The work thus far has been mainly of a development nature. The small quantity brought to the United States was ground in San Francisco and sold principally for foundry facings. All of the material shipped was crystalline so far as known. It is said to average from 50 to 75 per cent graphite.

During 1912 the Uncle Sam Alaska Mining Syndicate opened a new property on the north side of the Kigluaik Mountains. According to a description obtained through the courtesy of the manager of this company the property comprises nine locations of claims and two mill site locations, nearly 2 miles (10,168 feet) south of Graphite Bay, a branch of the Imuruk Basin. The elevation is about 500 feet above sea level. The graphite occurs associated with schists and gneisses which strike east and west and have steep dips. The richer graphitic portions can, it is claimed, be readily separated by hand sorting.

ARKANSAS.

Graphite has been reported from a locality 2 miles north of Mountainburg, Crawford County. This property was examined by the writer in 1912, and the deposit was found to be a thin bed of sheared carbonaceous shale and not graphite.

CALIFORNIA.

Graphite is known to occur in a number of localities in California and serious attempts have recently been made to develop some of these.

---

[1] Smith, Philip S., Investigations of the mineral deposits in Seward Peninsula: U. S. Geol. Survey Bull. 345, p. 250, 1908; also, Recent developments in southern Seward Peninsula: U. S. Geol. Survey Bull. 379, pp. 300-301, 1909.

Calaveras County.—A small amount of material said to carry about 10 per cent of graphite was mined in 1913 near Campo Seco in Calaveras County, and ground with iron oxide at Stockton for use as a paint pigment.

Mendocino County.—In 1909 some graphite was mined near Point Arena by a company known as the Dixon Graphite & Milling Co. The material was said to carry 8 to 10 per cent of graphite. Samples sent to the Survey for examination were graphitic schist, somewhat decomposed, in which the graphite occurs as small flakes. The material is similar in general to some of the graphitic schists of the eastern United States. In 1911 the company was reported to be out of business.

Los Angeles County.—The California Graphite Co., with office in Los Angeles, was incorporated in January, 1913, to develop a graphite deposit near Saugus. It is reported that important development work has been done during the year. Samples forwarded to the Survey for examination show that the material mined is a decomposed fine-grained graphitic schist. The graphite is of the crystalline variety and occurs in small flakes mostly under 0.5 millimeter in diameter. The matrix is quartz and decomposed feldspar. In the samples forwarded little or no mica was observed either in the crude material or in the concentrate. An analysis made in the Survey laboratory of a composite sample obtained by clipping small pieces from 6 larger samples showed 10.4 per cent of graphitic carbon. The writer is not informed in regard to the concentrating process, but the samples of concentrate forwarded were exceptionally clean and after "finishing" should make a high grade of lubricating stock.

COLORADO.

Chaffee County.—Amorphous graphite is mined in Colorado by the Federal Graphite Co., about 2 miles northeast of Turret in Chaffee County. The mine is situated on the west slope of Graphite Hill, within about a mile of the stage road from Salida to Turret (14 miles), and was visited by the writer in the summer of 1909.

The workings at that time consisted of two inclined shafts located about 100 feet apart on the same lode. These shafts had been sunk to a depth of 40 to 50 feet and some drifting and stoping had been done. A tunnel was being driven about 125 feet below the mouths of the inclines, from which a raise could be opened to the graphite bed.

The graphite occurs in one principal and a number of subordinate beds interbedded with white to gray crystalline limestone, buff-colored quartzite, and dark-gray to purplish quartzitic schist. The sediments and associated graphite beds strike about north and dip to the east at 30° to 40°.

The hill slope above the graphite beds is occupied by a gray to purplish quartz schist, but just over the crest of the hill and not more than 500 or 600 feet east of the graphite is a large area of gneissic biotite granite. Fine-grained granite occurs as a dike cutting the sediments within a few feet of the main graphite bed at the mouth of both of the inclines, and a tongue of graphic granite a few inches wide was observed penetrating slightly graphitic material just beneath the productive graphite bed.

The main productive bed as exposed in 1909 varied from 3 to 4 feet in thickness, somewhat more than half of this thickness consisting of the second grade of ore, which is lower in graphite than the first grade, higher in clayey material, and of a grayish or purplish tint. The first grade of graphite is dull black and very pure, the purest portions showing a somewhat foliated structure. Both grades are very fine grained and earthy and are properly classed as amorphous. In the northern incline a second bed 1 foot thick of first-grade ore was exposed about 4 feet above the main bed. What appears to be the same graphite bed had been prospected north and south along the slope of Graphite Hill for about a mile. In the southern incline graphitic beds are separated by a bed of crystalline limestone, tapering from a thickness of 2½ feet to 8 inches in a distance of about 20 feet.

It is evident that this graphite was originally coal and highly carbonaceous shale interbedded with sedimentary rocks. The coal has been converted into graphite and its inclosing sandstone and limestone into quartzite, quartzitic schist, and crystalline limestone through the heating and other contact metamorphic effects of large masses of granite which have been intruded into the sediments. The granite and granite gneiss occupy most of the country between this mine and Turret and form large areas south and east of the mine.

The first-grade graphite is packed in bags; the second grade is shipped in bulk. It is hauled 5 miles, mostly downhill, to a siding on the Denver & Rio Grande Railroad and shipped to the mill of the company at Warren, Ohio. There it is pulverized and air floated and is marketed mainly for paint pigment and foundry facings.

Gunnison County.—Some development work was in progress during 1912 on a new graphite property near the summit of Italian Mountains, in Gunnison County, Colo. The deposits are near the head of Cement Creek and are about 10 miles from the railroad. A company formed for their development is known as the Colorado Graphite Mining & Manufacturing Co., with office in Denver. According to a private report made to this company by S. C. Robinson, mining engineer, there appear to be three parallel "veins" of graphite about 50 feet apart, lying parallel to the inclosing beds of stratified rock, which here stand nearly vertical. The middle "vein" is the largest and has a width of 4 to 6 feet. All development has thus far consisted in open-cut mining. This locality lies either within or just east of the area covered by the Anthracite-Crested Butte folio (No. 9) of the Geologic Atlas of the United States. Within this area coal occurs in the Cretaceous formations. Though normally bituminous, it has locally been altered to anthracite as a result of dynamic metamorphism or of the proximity of igneous rocks. The occurrence of graphite as a result of still more intense alteration is therefore not at all surprising.

GEORGIA.

Georgia produces no material which can properly be described as graphite, but a large quantity of slate containing 2 to 15 per cent of carbon was quarried near Cartersville, in Bartow County, and ground for use as a filler and drier in fertilizers. It is doubtful whether the carbon of this rock is graphite or amorphous carbon. In previous years the production of this material has been included under the heading of amorphous graphite, but as it is not adapted for any of the purposes for which higher grades of amorphous graphite are used, and as these higher grades are never used as fertilizer filler, it is thought best not to include this material under the name of graphite.

The material is simply crushed and ground and then sells for $1.25 to $1.50 a short ton f. o. b. mills. These deposits have been described by Hayes and Phalen.[1]

IDAHO.

In 1908 a graphite mine was opened near Ketchum, in Blaine County, by Messrs. Hampton & Griffith. Some production was reported in 1909, but none has been reported since then. The material is said to be amorphous.

Graphitic schists are known to occur on Salmon River, near Grangeville, Idaho, and analysis of a specimen showed 7.6 per cent of fixed carbon.

MAINE.

Graphite is known to occur at several localities in Maine and in 1905 an unsuccessful attempt was made to mine it near Madrid, in Franklin County. The deposits have been fully described by George Otis Smith,[2] from whose report the following information is taken.

At Madrid the graphite occurs locally in a schist near its contact with granite-pegmatite. In some of the schist the graphite is in particles of microscopic size, but in the best grade of graphite rock it occurs in flakes averaging 0.04 millimeter (range 0.01 to 0.20 millimeter) in diameter. The graphite flakes are fairly evenly distributed and in the sample analyzed constituted 8.5 per cent by weight of the rock. In some specimens the graphite is intimately associated with muscovite flakes, but in others quartz is the chief matrix. In view of the small size of the graphite grains, their separation from the mica and quartz with which they are intergrown would not be economically practicable by any methods now known. Without concentration, the material on account of its small percentage of carbon, would have no present commercial value.

About 1½ miles northwest of Yarmouth village in Cumberland County graphite occurs in flakes disseminated through a dike of granite-pegmatite. In the sample analyzed 9 per cent by weight of graphite was present. As the graphite-bearing dike has an average width of only 1 foot, the deposit can not be considered to have commercial importance.

MASSACHUSETTS.

A graphite deposit occurs near Sturbridge, a small village on the trolley line between Worcester and Springfield, not far from the Connecticut boundary. (See fig. 10, p. 205.) The mine is 3 miles southwest of Sturbridge as the crow flies, but about 6 miles by road, and lies just west of Lead Mine Pond. Although it has not been worked for many years it is of unusual historic interest and forms the subject of a historical paper by G. H. Haynes,[3] from which the following extracts are taken:

The mine was not only the first graphite mine worked in the United States, but one of the first mining adventures of any kind in America. In 1644 there was granted to John Winthrop, jr., son of Gov. Win-

throp, of Massachusetts, "Ye hill at Tantousq, about 60 miles westward (from Boston), in which the black leade is, and liberty to purchase some land there of the Indians." He made the acquisition doubly sure by purchasing the tract from the Indian inhabitants. Development was not begun until 1658, after Winthrop had interested some Boston men in the project. How long this work was continued or how much graphite was obtained is not known, but several letters to Winthrop from his miners are on record in which they complain of the cost and difficulties of mining, and the work seems to have been soon abandoned. Nothing further was done at the property until 1738, when John Winthrop, nephew of the original owner, again started mining and shipped some of the graphite to England, where it brought about 4 pence a pound. A little mining was done in the summer of 1740, when less than a ton was extracted. Discouraged at the small price received for the material, mining was again abandoned, and there is no record of further development while the property belonged to the Winthrop family. It remained idle until 1828–29, when Frederick Tudor, of Boston, secured possession of the mine and operated it as an adjunct to the manufacture of crucibles. After Mr. Tudor's death the property remained idle until sold to the Massachusetts Graphite Co. in 1902. It has remained in the possession of this company up to the present time and has been operated occasionally.

According to B. K. Emerson [1]—

> The deposit is a series of flat pockets reaching 3 to 4 inches in thickness, placed with the bedding, but not very extensive in this plane. The bed is near the base of the Brimfield (carboniferous) and in the zone of strong influence of the granite.

The mine was visited by the writer in the summer of 1912. In the caved and water-filled workings no graphite could be seen in place; it was evident, however, from the form of the workings that the graphite masses lay parallel to the trend of somewhat quartzose mica schists whose strike varies from N. 20° E. to N. 30° E. and whose dip is to the northwest at 70°–80°. Pillars of schist left between some of the pits show no trace of graphite and from this it is inferred that the graphite formed a series of lenses and not a simple continuous vein. None of the schist was observed to be graphitic; it has been intruded by small masses of granitic rock.

The workings begin on the northeast with a drift tunnel whose portal is near the shore of Lead Hill Pond. From this point southwestward for about one-half mile the main graphite-bearing zone has been prospected and locally there has been extensive excavation through shafts or from open pits. Two shafts are each about 100 feet deep. On one of the shaft dumps massive pyroxenite with pyroxene crystals one-half inch in diameter was noted, but the rock was not seen in place. A block of solid graphite from this mine 7 inches across was seen in the Elms Hotel in Sturbridge. It closely resembled the Ceylon graphite and showed bladelike crystals 2 inches in length. It is reported that one lump of solid graphite taken out in 1904 weighed 510 pounds.

It is evident that the deposit belongs to the vein type represented by the occurrences in Ceylon, at Dillon, Mont., and at certain places

[1] Emerson, B. K., The geology of Massachusetts and Rhode Island: U. S. Geol. Survey Bull. (in preparation).

in Canada, but the exposures were too poor to throw much light upon its origin.

Water entering apparently from Lead Hill Pond along the vein is said to have been a considerable handicap to mining in the deeper workings.

MICHIGAN.

Graphitic rock is obtained from Baraga County, in northern Michigan, by the Detroit Graphite Co., and shipped by rail to its mill at Detroit. The mine is located 7 miles south of L'Anse, a station on the Duluth, South Shore & Atlantic Railway. The mine is worked intermittently, most of the rock being hauled to the railroad in the winter over the snow.

The rock mined is a dark reddish-brown graphitic and ferruginous slate which is said to average about 33 to 35 per cent of graphitic carbon. The latter is so finely divided that it should be classed as amorphous. An analysis of this rock, made by the late Prof. A. B. Prescott, of the University of Michigan, and furnished to the writer by the company, is as follows:

Analysis of graphitic rock from Baraga County, Mich.

Carbon, graphitic (C)	28.39
Silica (SiO_2)	46.97
Alumina (Al_2O_3)	16.90
Iron, soluble, as Fe_2O_3	.41
Iron, insoluble, as Fe_2O_3	3.81
Lime (CaO)	.47
Magnesia (MgO)	.52
Water, uncombined (H_2O)	.13
	97.60
Carbon dioxide, combined water, sodium compounds, loss, and undetermined matter	2.40
	100.00

The rock is too fine grained to permit of any concentration of the graphite and is ground just as it comes from the mine and used only as a paint pigment, for which it appears to be well adapted. The lumps of rock are first reduced in a jaw crusher, then dried and pulverized in a continuous feed tube mill. Finally it is air floated, so that an exceedingly fine-grained powder is obtained. The black pigment thus obtained is used not only in the manufacture of black paints, but is mixed with other pigments to yield gray, dark-green, and dark-red paints. A reserve having accumulated, no mining was done during 1913.

Similar material is also mined by the Northern Graphite Works, with mill at L'Anse and mine 9 miles from L'Anse. This company has taken over the mill formerly used by the Hathaway Graphite Co. The material is picked, crushed, ground, air floated, and bolted through silk to a fineness of about 200 mesh. The plant was operated during 1911 and 1912, but was idle in 1913.

The plant of the United States Graphite Co. for the treatment of amorphous graphite imported from the State of Sonora, Mexico, is located at Saginaw.

MONTANA.

The only graphite property operated in Montana is that of the Crystal Graphite Co., near Dillon, whose principal mine was visited by the writer in June, 1911, and is described below in detail. Considerable development work has been in progress there for several years, and it is expected that shipment of the product to eastern markets will soon begin.

The mine of the Crystal Graphite Co., near Dillon, is of more than ordinary interest because in its geologic relations and in the character of its graphite it shows some similarities to the famous deposits of Ceylon. Unfortunately, the quantity of high-grade graphite yet discovered is too small to form the basis of an industry like that of Ceylon, but there seems good prospect of the development of one

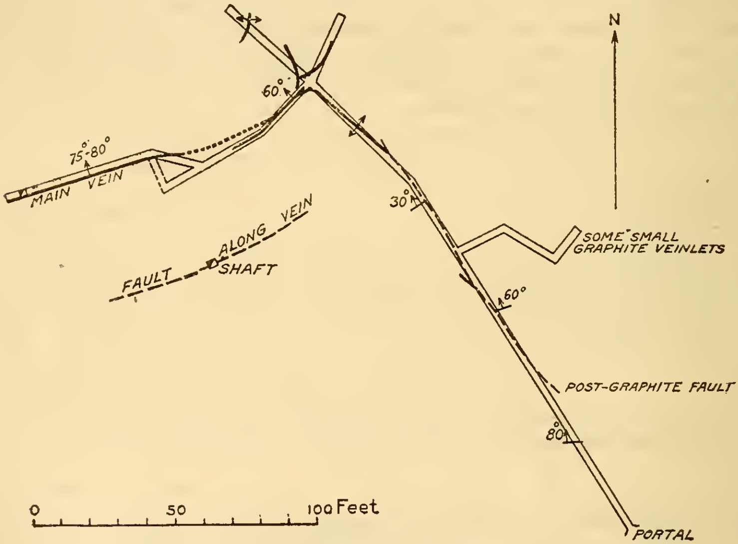

FIGURE 9.—Plan of main workings, Crystal Graphite Co., near Dillon, Mont.

paying mine. The principal workings on the property are located about 9 miles southeast of Dillon (16 miles by road), at the south end of the Ruby Range. The property is within the area of the Dillon topographic sheet of the United States Geological Survey. The mine occupies what is known as Crown Point at an elevation of 9,000 feet, and a good wagon road leads to the mine cabins, within a mile of the mine. From there to the mine the steep mountains must be climbed on foot. Without great expense a wagon road could be constructed to the mine, or the graphite could be transported on pack animals over the steeper part of the trail. The mine is located on the ridge between Timber and Van Camp gulches.

According to Winchell,[1] the rocks exposed in the Ruby Range are chiefly the thick limestone series of the Paleozoic in Montana. The rocks immediately associated with the graphite deposits are limestones and quartzites, apparently of Paleozoic age, which overlie quartz schists and slates that are probably pre-Cambrian. All are

[1] Winchell, A. V., Graphite near Dillon, Mont.: U. S. Geol. Survey Bull. 470, pp. 528–532, 1911.

intruded by granite and pegmatite, and certain rocks of contact-metamorphic origin are developed as a result of this intrusion.

The principal workings are shown in figure 9, the graphite veins being indicated in heavy, solid black lines. The strike of the rocks near the tunnel is variable from N. 5° E. to N. 60° E., with dips of 30° to 60° NW. The first 160 feet of the tunnel may be regarded as crosscut, but the workings beyond follow in part graphite veins. The wall rocks where exposed are pegmatite, quartz schist, and garnetiferous mica schist. As shown in figure 9, in the first 160 feet the tunnel encounters several small graphite veins, but the maximum width of graphite exposed in any of them is only 2 inches, so that they are not workable. The noteworthy feature of this part of the tunnel is the fault plane shown on the map by a broken line. This was formed later than the graphite, for it cuts the graphite veinlets. It carries much gouge but no graphite, except the little that has been dragged out from the veins. At 160 feet from the portal one of the main graphite veins of the mine is encountered and is followed by the tunnel for 30 feet to a point where it turns sharply west. This vein is commonly vertical, but where it turns the dip shifts to 60° N. In places it shows 4 inches of very pure graphite, and in one place the graphite is reported to be 6 inches wide. Beyond the turn this vein merges with the main vein of the mine which is developed by the 120-foot northeast to southwest drift shown on the map.

The main vein shows from 2 to 8 inches of very pure graphite. It dips from 60° to 80° N. Near the main tunnel where it shows 4 inches of pure graphite it is in sharp contact with walls of granite-pegmatite which near the vein contain scattered graphite flakes up to one-fourth of an inch in size. The graphite has been fractured by postmineral movements along the vein and slickensides are developed in both the graphite and the wall rocks.

One of the best exposures in the mine is 10 feet from the face of the main tunnel where a graphite vein is shown in cross section. The wall rock there is altered quartz schist, in places becoming micaceous, and is traversed by a nearly vertical fracture zone along which graphite has been deposited. The vein is about 2 feet wide and consists of an irregular network of graphite veinlets inclosing many sharp-walled schist fragments. The graphite forms about half of the vein material and the veinlets locally unite to form irregular bunches. The south wall is fairly regular, but the north wall is ragged and is penetrated by irregular apophyses from the main graphite mass.

It is evident from this description that the graphite of this mine forms rather irregular veins deposited along fracture planes and more or less broken up by later fracturing.

In comparing the graphite from these veins with that from Ceylon it must be remembered that the workings are shallow and that surface alteration has produced certain changes which will be less noticeable when greater depths have been reached. For example, (1) the luster of this graphite, even when the lumps have been polished or rubbed up, is much less brilliant than that of most of the Ceylon material; (2) thin films of iron oxide occur along parting planes between some of the graphite plates; and (3) the graphite is softer than that from Ceylon and grinds up more readily, though still yielding a flaky product. These differences will probably decrease with depth.

When broken between the fingers the graphite separates into splinters which are roughly spearhead shaped. Truly fibrous varieties, such as the "needle lump" which occasionally occur in Ceylon, were also noted at Dillon.

The absence of the cheap labor available in Ceylon for sorting, rubbing up, etc., is in Montana a handicap which may be offset in a measure by the employment of modern and expeditious methods of mining. If the graphite is steadily produced, a market for use in crucibles might be built up, and it should be excellently adapted for lubricating.

There are numerous other prospect tunnels in this vicinity which show more or less graphite, but none of them are of any commercial promise.

NEVADA.

For a number of years a small amount of graphite has been mined by the Black Lead Mining Co., 3 miles from Carson City, in Ormsby County. The material, which is amorphous, is said to carry from 30 to 50 per cent of graphitic carbon. It is crushed, ground, and bolted, and sold mainly as a paint pigment and for foundry facings.

In 1912 E. Edwin, of Ludwig, Lyon County, reported the discovery of a graphite deposit in that county. He states that the graphite deposit is between 4 and 5 feet thick and is traceable on the surface for several hundred feet. A specimen sent to the Survey was an amorphous graphite of good quality.

NEW JERSEY.

Graphite is known to occur in disseminated flakes in the crystalline rocks of the highlands of northern New Jersey at a number of localities. (See fig. 10.) Several attempts to mine and concentrate the material have been made in the past but have not proved successful, and the State is not now a graphite producer.

The following data regarding the property of the Raritan Graphite Co., of High Bridge, N. J., was furnished by Henry B. Kümmel, State geologist, under date of August 31, 1908:

> The plant consists of a 2-story building with machinery, including two 80-horsepower boilers, two 65-horsepower Atlas engines, one 4-drill air compressor, 1 small hoist, and about 7 dump cars. The graphite-bearing rock forms a bed 30 to 50 feet wide, dipping 70° to the west with a north-northwest strike. It is covered by 6 feet of soil and disintegrated rock. The graphitic bed is considerably decomposed to a depth of 30 feet. The plant was erected in 1906 and up to the middle of November, 1907, they had worked intermittently about seven months. A tunnel was driven into the hill along the strike of the graphite-bearing rock for a distance of about 400 feet, and a pit sunk on top of the hill to a depth of 40 feet to the tunnel. The only ore treated was taken out in driving the tunnel, which was driven in the best part of the bed. The rock is supposed to contain from 4 to 8 per cent of graphite, and the mill test was said to have given about 4 per cent extraction. It is reported that during the seven months of work, 3½ carloads (25 to 30 ton cars) of rock were mined and shipped. The plant is still idle.

The geological occurrence of graphite in this district has been more fully described by Bayley and Stewart.[1] According to these writers the graphite occurs in several ways—(1) as a component of Franklin limestone; (2) in gneisses, which may be in part altered sediments, but in places are certainly mashed pegmatites; (3) in coarse granite

[1] Bayley, W. S., and Stewart, C. A., Note on the occurrence of graphite schist in Tuxedo Park, N. Y. Econ. Geology, vol. 3, pp. 535-538, 1908.

dikes and pegmatites; and (4) in fine-grained quartzitic micaceous schists, especially where they are associated with pegmatites. The last-named mode of occurrence is the most important. Concentrating works at Bloomingdale, at High Bridge, and near Brookside have all failed. In the graphitic schists at Tuxedo Park the graphite plates are usually in parallel intergrowth with biotite plates. The graphitic schist is believed to be the product of the metamorphism of a sediment rich in organic matter. The pegmatites are graphitic only close to the schist or where they carry fragments of this rock.

The following description of the old graphite mine near Bloomingdale is quoted from a report by Cook, published in 1879:[1]

The mine is about a mile south of the village, in Morris County. There are three openings on a northeast and southwest line, on the strike of the gneiss rock. The main one is said to be about 60 feet deep. It is now full of water. The rock, which crops out on the surface on both the northwest and the southeast of the opening, is a micaceous gneiss. From an examination of the material thrown out of this opening and lying about it, the graphite appears as a constituent mineral of the gneiss and of the coarse crystalline rock which is associated with it. The next opening toward the northeast is 80 yards distant. It is a shallow cut across the strata. The gneiss there dips 50° S. 80° E. The northeast opening is about 50 yards from the latter, and is 18 to 20 feet deep. The rock dips 70° SSE. It is here also a micaceous gneiss, which is traversed by a coarse crystalline, feldspathic rock, and the graphite is found in them both. A brown mica, in large plates, and pyrite occur in scattered bunches in the vein mass at all of the openings. The sample selected for examination represents the heaps at the mine. These appear to have been sorted for working. Analysis shows the sample to contain 11.2 per cent of graphite.

The works are about 300 yards southeast of the mine and on the west side of a small stream, which furnishes water power. They contain the necessary stamps for crushing the ore and other machinery for separating the plumbago from the rock, and with very little work they could be put in running order. The stream affords 130 feet head of running water, but the volume is insufficient for steady work and the flume is out of repair. The present location is not as good as could be had on Pequannock River, less than a mile from the mine, and the changes needed in the introduction of new methods of working could be as economically made at another location as in the present mill.

The locations of the principal graphite deposits that have been worked in New Jersey are shown on figure 10.

NEW MEXICO.

Small quantities of graphite have been mined in the past near Raton, Colfax County. The deposits have been examined by Willis T. Lee,[2] of this Survey, and the following extracts are taken from his report:

A large body of amorphous graphite occurs in the canyon of Canadian River, about 7 miles southwest of Raton, in Colfax County, N. Mex. The bed lies practically horizontal and has been prospected for a distance of several miles along the outcrop in the Canadian and its tributary canyons and traced laterally into the principal coal bed of the Raton field, which contains bituminous coking coal. Igneous material was forced into the coal-bearing sedimentary rocks in many places in this field and usually formed coke where it came into contact with the coal, but in the Canadian Canyon the intrusive mass took the form of many sills above, below, and in the coal bed and apparently heated the sedimentary rocks through a considerable thickness. The coal has been most completely graphitized where the bed was fractured and diabase forced into it. The graphite occurs in "pockets" or irregular masses in the diabase and is more or less columnar, the columns usually standing normal to the faces of the

[1] George H. Cook, New Jersey State Geologist, Ann. Rept. 1879, p. 154.
[2] Lee, W. T., Graphite near Raton, N. Mex.: U. S. Geol. Survey Bull. 530, pp. 371-374, 1913.

igneous rock. The columnar parts are relatively pure, but the noncolumnar parts seem to have resulted from what was originally bony coal or carbonaceous shale.

The writer collected a sample of the graphite for analysis 160 feet from the mouth of an old opening, at a point where the bed was about 3 feet thick. In order to obtain a representative sample, the weathered material was cleared from the exposed face of the bed. The sample represents the entire thickness of the graphite at this point, and therefore the analysis shows a greater percentage of impurity than would be found in pieces selected from the best material.

The prospect from which this sample was taken was opened in 1889 by the Standard Graphite Co., of New York, and 250 tons of graphite was shipped from it to Moosic, Pa., where the ore was tested as to its availability in the manufacture of paint. One of the objects of the company was to ascertain whether the graphite could be handled profitably, and careful accounts were kept. According to the statement of one member of the company it was ascertained that the graphite could be placed in the bins at Moosic for $17.50 a ton, the greater part of the cost being shipping charges. At Moosic, at an additional cost of 90 cents a ton, it was ground and separated from some of its impurities by means of air blasts. The refined product contained 80 per cent of carbon, the 20 per cent impurity being mostly silica, which was not regarded as objectionable in the manufacture of paint. The tests were satisfactory to the company and the mill was being taken apart for shipment to Raton when it was destroyed by fire. Nothing has since been done toward developing the graphite.

The sample was analyzed as coal in the laboratory of the United States Geological Survey at Pittsburgh and showed fixed carbon, 76.11 per cent; volatile matter, 6.07 per cent; ash, 16.51 per cent; and moisture, 1.31 per cent. The sulphur was separately determined as 0.177 per cent.

NEW YORK.

The Adirondack region has for some time been the leading and most regularly producing district in the country, largely because of the steady production of one mine at Graphite, operated by Dixon's American Graphite Co. Many other properties which have thus far produced little are of very considerable scientific interest and some are of economic promise. Nearly all of the New York deposits that have been worked are located in the eastern and southeastern Adirondack region, in Essex, Warren, and Saratoga counties, and the northern part of Washington County. (See fig. 10.) West of the Adirondacks some prospecting and development work has been done in St. Lawrence County. All the deposits are located within the area of pre-Cambrian metamorphic rocks. The more important localities are described below. In 1913 the only producers of natural graphite in New York were Dixon's American Graphite Co. and the Graphite Products Corporation, of Saratoga.

ESSEX COUNTY.

CROWN POINT MINE.

A graphite mine formerly operated by the Crown Point Graphite Co. has been idle since the fall of 1910. It is situated about 7½ miles southwest of Crown Point Center, 11 miles from Crown Point Station, and about 10 miles from the railroad at Ticonderoga. A concentrating mill is located at the mine and a finishing mill at Crown Point Center.

The mine is located on the northern slope of the low ridge north of Chilson Lake. The ore is a graphite-bearing crystalline limestone, and the single bed worked strikes about N. 65° to 70° E. and dips

55° to 60° S. The width of the limestone bed varies from 3 to 7 feet and it is traceable along its strike for over 1,000 feet, east-northeast from the shaft. A second bed of graphitic limestone occurs about 375 feet south of the main bed, but is apparently narrower and not traceable far along its trend. Other bands and lenses of graphitic limestone thus far discovered in the vicinity appear to be small and probably are not of much commercial importance.

The best ore from this mine is light gray in color and is made up almost entirely of calcite grains and plates of graphite, with a few scattered grains of pyroxene. Much of the ore, however, is a darker gray in color, owing to a greater abundance of pyroxene. Under the microscope this type of ore is found to consist of interlocking grains of calcite averaging about 2 millimeters in diameter, of pyroxene largely altered to chlorite, and of graphite plates. Most of the latter range from 0.9 to 3 millimeters in length and from 0.15 to 0.3 millimeter in thickness. The rock shows very little tendency toward a schistose structure and the graphite plates are oriented in every direction. A faint banding is due to the greater abundance of pyroxene (green to the naked eye) in certain layers than in others. Little or no mica is present.

A composite sample of the ore selected by the writer so as to represent approximately the run of the mine was analyzed in the laboratory of the United States Geological Survey and showed 2.97 per cent of graphitic carbon.

Granite occurs near the ore body in dikes which are mainly parallel to the limestone in trend, but which here and there cut across the trend of the limestone and the associated schists and are therefore distinctly intrusive in them. At several points typical granite occurs within a few feet of the ore bed. Rocks in which gray bands alternate with bands which are dark green to brownish black are interbanded with the ore; they consist largely of pyroxene, some biotite, quartz, and feldspar, with occasionally some calcite and pyroxene grains. Certain phases of the schist associated with the ore are coarsely crystalline, showing dark-brown pyroxene crystals over 1 inch in length, crystals of calcite one-half inch to 1 inch across, pyrite grains one-half inch or so in diameter, and graphite plates up to one-half inch across.

This locality lies near the border of a large area of granite of pre-Cambrian age. The even distribution of the graphite through the crystalline limestone renders it probable that the carbon formed an original constituent of the limestone. Its conversion to the graphitic state, the recrystallization of the limestone, and the development in it of the mineral pyroxene are the result of metamorphism, possibly in part dynamic, but due to some extent to the contact effect of the neighboring masses of granite rock, as shown by the development of pyroxene schists and coarse crystalline aggregates of pyroxene, calcite, pyrite, and graphite. As already stated, the ore bed persists laterally with fairly uniform width and values for over 1,000 feet. There is no evidence that it may not also persist to a considerable depth, although the proximity of intrusive granite renders it liable to be cut off at any point by that rock.

The development work, aside from shallow surface pits, consisted in the spring of 1909 of an inclined shaft about 72 feet in depth, from which the miners have drifted eastward along the ore bed, removing a considerable amount of ore by stoping, and finally reaching the surface again about 150 feet east-northeast of the shaft. From the shaft the ore was hoisted direct to storage floors at the mill and after preliminary crushing and drying was concentrated by dry processes which were not made public. The mill is said to have a capacity of 30 to 50 tons per 10-hour day. From this mill the concentrates were hauled by teams 7½ miles to a finishing mill at Crown Point Center. The finished product was bagged and hauled 2½ miles to the railroad at Crown Point. The ore, being calcareous is soft and easy milling.

BLY OR JUMBO GRAPHITE PROSPECT.

This prospect is located on Bear Pond Mountain, in the town of Ticonderoga, and is reached by an 11-mile drive from Crown Point. Only prospecting work has been done at this locality, but it has extended over a large area, so that a very good idea can be obtained as to the extent of the ore. At a test pit dug across the trend of the schist on the northeast slope of Bear Pond Mountain the schists strike about N. 65° W., and are nearly vertical. Farther west strikes of N. 80° E. and N. 85° W. were observed; and at the upper pit, high up on the northwestern slope of the mountain, the strike was nearly 70° E. and the dip vertical. This latter hillside pit is 15 feet in maximum depth and 15 feet wide, and exposes 20 feet of graphitic, schist at right angles to the strike. Strippings above the pit raise the known thickness of graphitic rock to about 100 feet. At another small pit about 10 by 12 feet and only 5 feet in depth, at the extreme western part of the summit of the mountain, the schists are vertical and strike about east and west. They are also more quartzose and more contorted than at the other pits. The first pit which was opened is on the south side of the summit and is about 20 by 20 feet and 15 feet in depth. Exposures in the pit and strippings above the pit show about 40 feet of graphitic schist measured at right angles to the trend. The pits on the south side of the mountain are plainly in a separate graphite bed from those on the north side of the mountain.

Exposures in these pits and the natural outcrops show that almost the whole mountain is composed of quartz-mica schists, locally becoming very highly quartzose, which have a fairly regular strike of about east and west and are about vertical in dip. Within these masses occur at least two broad bands of graphitic schist, one on the north side of the mountain which locally attains a width of at least 100 feet, and another on the south side of the mountain locally at least 40 feet wide. Both of these, and especially the northern one, have been traced for considerable distances parallel to the trend of the schist. The supply of graphitic rock is unquestionably large, probably larger than at any other locality thus far prospected in the State. The ore is typically a dark gray, rather coarse and even-grained schist, containing locally small lenses of quartz and feldspar which are much coarser and are pegmatitic in their texture. These may represent small intrusions of granite pegmatite, but the apparent lack of connection between them and any larger masses of granite favors the idea that they are portions of the schists which crystallized more coarsely in the metamorphism that has affected all the rocks in the mountain. At some of the shallow openings on the northeast slope of the mountain the rock is much decomposed, and the graphite, instead of being evenly distributed, is most abundant in small lens-shaped masses which constitute what is called by the owner of this property the "soft ore." Careful examination shows this to be graphitic schist similar to the hard ore but much more decomposed.

Three samples of ore from different prospect pits on this property were examined under the microscope and were found to be composed of interlocking grains of quartz and feldspar in nearly equal abundance, with much biotite (brown mica) and an occasional grain of epidote. Nearly all of the graphite present is either intergrown with the biotite or closely associated with it. Most of the graphite plates are bordered on both sides by biotite and lie between the biotite laminæ as between leaves of a book. Thus biotite crystals 0.15 to 0.45 millimeter thick may inclose graphite flakes of about one-tenth this thickness. The fairly well-developed schistose structure is due to the fact that most of the biotite and graphite plates are oriented in a common direction.

The parallel intergrowth of much of the graphite with brown mica in this ore would unquestionably increase the difficulty of the separation of these two minerals in the milling processes. Fine grinding of some of the ore by the writer shows, however, that a partial separation can be effected in this manner, and portions of the deposit may be found which are sufficiently free from biotite so that this difficulty need not be reckoned with.

Analyses of four samples of ore from various pits at this property made for the owners are reported to run 6.4, 6.6, 6.2, and 8.8 per cent of graphitic carbon. An analysis of a composite sample selected in 1904 to represent as nearly as might be the general run of the mine showed about 5 per cent of graphitic carbon. So far as known, no development work has been done at this prospect since the writer's visit in April, 1909.

TICONDEROGA GRAPHITE MINE.

This mine is located on the eastern slope of Chilson, or Lead Hill, about 3 miles northwest of Ticonderoga, and was worked for many years by Dixon's American Graphite Co. It has now been idle for a number of years, but the supply of graphite ore is not exhausted, and it is possible that the property will be worked again in the future.

The workings consist of a large number of small open pits and several of larger size scattered over an area of several acres in extent. One of the largest of the open pits is about 20 by 40 feet and 20 feet deep, and two short tunnels have been driven from it. The workings first reached in approaching this property along the wagon road are underground and are said to be quite extensive. At the time of the writer's visit they were partly filled with water and could not be entered for any great distance.

Geologically this is one of the most interesting localities with which the writer is familiar. The rocks are of three types: (1) Intrusive igneous rocks, including granite gneiss, pegmatitic granites, and coarse granite pegmatite; (2) crystalline limestone, mica schists, and quartzitic schist that are all probably regionally metamorphosed sediments; and (3) certain unusual rocks characterized by a typical assemblage of contact-metamorphic minerals. These are believed to have been formed through the contact metamorphic effects of the igneous rocks on limestone and in them most of the graphite is found.

Where the granite gneisses are exposed they strike about east and west, nearly parallel to the trend of the associated schists. The gneissic phases of the granite grade into others which are somewhat pegmatitic, although their feldspar crystals seldom exceed 2 inches in diameter. The only coarse pegmatite exposed at this locality is a highly quartzose mass exposed at one of the larger pits. The quartz of this mass is white to dark gray, feldspar is absent from most of the rock, but is present with pyroxene and an occasional black tourmaline in some of the apophyses. This quartz pegmatite is largely barren of graphite, though carrying an occasional isolated plate near its border. In the finer-grained pegmatites and the granite gneiss practically no graphite occurs, except close to the contact with other graphite rocks. The schists intruded by the pegmatite trend at one place east and west, with a dip of about 55° S. Crystalline limestone at one place shows a trend of about N. 70° W., and a dip of 30° S. Much of the schist is highly quartzose and was probably originally an impure sandstone. The beds of crystalline limestone pinch and swell and are sometimes cut off by the granitic rocks. None were observed which were over 3 to 4 feet in thickness. Occasional schist fragments are inclosed in the pegmatitic granite, and, although more or less recrystallized, still preserve their angular outlines and schistose structure.

Most of the graphite occurs irregularly distributed through the contact metamorphic rocks above referred to. In these it forms plates usually less than one-half inch across, but locally over 1½ inches, oriented in every direction, the interspaces being occupied sometimes by scapolite, which superficially resembles light-gray feldspar, sometimes by pinkish to green pyroxene, and sometimes by an association of both these minerals. Some aggregates, several inches across, are composed almost wholly of graphite plates, and constitute one of the principal types of rich ore. Masses several feet across associated with the graphite consist of a granular aggregate of dark-green or pinkish pyroxene grains averaging about 2 millimeters in diameter, with only an occasional crystal of calcite, scapolite, or graphite. Between this and the rich graphite ore there is every possible gradation. Aggregates of coarsely crystalline graphite and scapolite sometimes traverse the fine-grained granular pyroxene aggregates in a more or less veinlike, though irregular manner. Near the contact between the pegmatitic granite and the crystalline limestone, as exposed at the most extensive of the underground workings, the graphite is associated with large crystals of dark-green pyroxene 6 inches across, crystals of calcite of equal size, and large crystals of quartz, scapolite, and biotite. Weathering away of the calcite in some cases shows the pyroxene with very perfect crystal forms. Vesuvianite was observed in crystals about one-half inch in diameter, associated with the pyroxene at this working.

A second mode of occurrence of the graphite at this locality is in narrow veins from 1 to 2 inches wide, most of which are vertical and trend nearly north and south. They cut indiscriminately across the schists and pegmatitic granite, but in a number of cases terminate abruptly when crystalline limestone is reached. In them graphite is usually the only mineral recognizable and forms aggregates of nearly parallel blades arranged about at right angles to the walls of the vein and closely resembling certain of the Ceylon occurrences. In most places the walls of the veins are sharp, and the pegmatitic granite shows no change of texture next to the vein. In a few places, however, the pegmatite becomes pyroxenic, finer grained, and somewhat graphitic next to the vein.

In conclusion, the field evidence seems to indicate a contact metamorphic origin for the graphite of this locality and its associated pyroxene, scapolite, vesuvianite, coarsely crystalline calcite, quartz, etc. In less technical language, these minerals appear to have been formed through the alterations produced in masses of limestone of varying purity by masses of pegmatite and pegmatitic granite which were forced into them in a hot and somewhat fluid condition. Since graphite is not observed in the granitic rocks at a distance of more than a few feet from the sedimentary rocks, it was probably not derived from these igneous rocks, but, on the contrary, was an original carbonaceous constituent of the sedimentary rocks, and has been recrystallized in the contact metamorphism. The vein occurrences of graphite appear to have been formed in the later stages of this metamorphism.

SARATOGA COUNTY.

SACANDAGA GRAPHITE CO.'S MINE (FORMERLY THE GLENS FALLS GRAPHITE CO.

The mine of the Sacandaga Graphite Co. is in the town of Day, Saratoga County. It is about 1¼ miles due west of Conklingville in the Sacandaga Valley, and may be reached by an 8-mile drive from Hadley, on the Adirondack branch of the Delaware & Hudson Railroad. The mine was opened in the spring of 1906. It consists of a single open pit on a southwest hill slope at an altitude of about 1,000 feet. The excavations had in April, 1909, extended to a depth of about 20 feet and covered an area of about 1 acre. The rocks are gneisses, whose strike varies from about N. 70° W. to east and west, with an average dip of about 30° N. The gneiss is coarsely banded and shows notable variation in composition from layer to layer. Some bands are light gray and are composed mainly of interlocking quartz and feldspar grains; other layers are highly garnetiferous. These barren portions of the gneiss alternate with bands which are graphitic.

Much of the graphitic gneiss at this locality is dark silvery gray in color and shows an alternation of thin layers which are highly micaceous and graphitic with other layers from one-eighth to one-fourth of an inch across, which are largely composed of feldspar or quartz. Under the microscope finer-grained bands are seen to consist of a granular aggregate of quartz, orthoclase, and biotite, with some graphite flakes. Other layers are rich in epidote. The graphite plates are not so evenly distributed as in the schist at the American Graphite Co.'s mine, but usually occur in very irregular aggregates, and some of the plates have a length of 3 or 4 millimeters.

Only the more highly graphitic portions of the gneiss were saved in the mining. These usually form more or less lens-shaped masses from a few inches to a foot or more in length, inclosed by the less graphitic rock. Much of the ore mined in 1909 was partly decomposed and rather soft. Although the percentage of graphite is locally much higher than in deposits like those at Greenfield and Graphite, where the flakes are more evenly disseminated, the graphite is much less regular in its distribution, and it is difficult to predict the probable extent of the ore laterally beyond the present exposures, or in depth. The origin of the graphite-bearing gneiss is not entirely clear. It probably represents, in part at least, sediments which have been severely metamorphosed, but there is some indication in their highly feldspathic character that they may, previous to the metamorphism, have been more or less injected by granitic material.

The mill of this company is located about 1,700 feet southwest of the mine and is operated by the water power of a small creek. Its equipment in 1909 included a Sturdevant crusher, Sturdevant rolls, hexagonal revolving screen, wet screens, a drier of special pattern, burrstone mill, and equipment for bolting and grading. In 1912 the following grades were produced:

Grades of graphite produced by Sacandaga Graphite Co. in 1912.

Grade.	Percentage of carbon.	Average price per pound.
		Cents.
Pulverized flake	92	15
No. 1 flake	90	9
Stove-polish grade	80	6
Foundry facings grade	60	3½

The property was not in operation during 1913.

EMPIRE GRAPHITE CO.'S MINE.

A graphite mine worked by the Empire Graphite Co. is located about 2¼ miles west of Porter Corners in the town of Greenfield, Saratoga County. The property was visited by the writer in April, 1909, and its appearance at that time was as follows: The excavations covered about 2 acres along a small ravine on an eastern hill slope, but were only about 25 feet in maximum depth. One tunnel 100 feet long and another about 50 feet long had been driven. The rocks are schists which strike about N. 80° W., and dip about 25° S. They were observed to be graphitic for a thickness of at least 25 feet.

In general appearance the ore is similar to that of the Dixon mine at Graphite, though the graphite flakes seem to be somewhat smaller. The schist is pure silver gray in color when fresh, but weathers to rusty brown and yellow. Certain layers interbedded with the highly graphitic portions are coarser grained and contain only occasional graphite plates, being composed largely of quartz, altered feldspar, and some biotite.

A sample of the best ore when examined under the microscope showed quartz in interlocking grains as its principal mineral; feldspar, in part plagioclase and in part orthoclase, nearly as abundant as quartz; brown biotite present in small quantities; and occasional small apatite prisms. Graphite occurs in plates about 0.8 millimeter in average length and 0.09 millimeter in average thickness, though few attain a length of over a millimeter. A considerable quantity of pyrite is also present, the grains usually being in contact with or closely adjacent to the graphite plates.

Outcrops are scarce in the immediate vicinity of the mine, but the graphitic schists have been traced by test pits for over 1,000 feet along their strike. At a locality about half a mile north of this mine on the Nathan Towne farm graphitic schists similar to those at the Empire mine are interbedded with granite gneiss like that associated with the ore at Graphite, and with thick beds of quartzite bearing occasional mica plates from one-eighth to one-quarter of an inch in diameter. These quartzite beds grade gradually into layers of graphitic schist. They furnish good evidence of the sedimentary origin of the rocks of this vicinity, the original beds being in all probability an alternation of beds of sandstone and shale. These have been brought to their present form of quartzites and graphite schists and garnet schists through regional metamorphism.

A mill has been erected at the mine and the process of concentration there employed has been described by F. C. Nicholas,[1] as follows:

The mill is arranged on the gravity principle and has a capacity of 200 tons every 24 hours.

The material taken from the mine or quarry is delivered to a rock breaker and is reduced to 1½ to 3 inches in size. From the breaker the rock drops to a set of heavy rolls, some 20 feet long by 2½ feet in diameter. In these rolls the material is crushed to a fine sand and drops to a bin, where it is held in check and delivered evenly as required over a second set of rolls the same size as the first, but closely set. In these rolls the material is ground to a fine powder, which is then delivered on an incline and discharged into two great buddles, the tanks of which are 4 feet high and 18 feet in diameter.

The buddles are built of cement and have a steel lining. In the center is an axle and hub, from which long arms and paddles protrude to within about ½ inch from the steel casing. Water and pulverized material fill the tanks and the hubs are set in motion turning the paddles with great rapidity. By this action the material is vigorously agitated, stirred, and turned over for about two hours, every particle having become thoroughly separated and brought under the influence of the water.

In this state the pulp is run to a second set of buddles and is agitated again. The lighter graphite as it rises to the surface of the buddles being completely isolated from the grit is allowed to flow over the top, while the waste is from time to time sluiced into a pit by opening gates in the buddles. The graphite which is run over an outlet at the top of the buddles is then delivered to a set of wet screens and is separated into two sizes. During this separation any remaining grit is disposed of, this operation being simply to allow the water to act on any grit which may remain.

After the separation is completed and all remaining traces of grit have been removed, the graphite is passed to a steam drying cylinder, which weighs about 15 tons. This cylinder revolves till the graphite is thoroughly dried, after which it is passed over silk cloth screens, separated to four sizes, and the process is completed.

The milling process appears to be successful in separating the quartz, feldspar, and other granular constituents, but does not effect a separation of the foliated minerals, biotite (brown mica), and chlorite. Fortunately, in much of the ore these foliated minerals are rare. Some of the ore is said to analyze as high as 12 per cent graphitic carbon, though the average would probably not exceed 7 per cent. The actual percentage saved in milling would probably be considerably lower. The output is hauled 4 miles to the Delaware & Hudson Railroad at Kings station.

The appearance of the property in 1911 has been described as follows by Newland:[2]

The work in 1911 consisted mainly of development incident to a change from surface to underground methods of mining. The deposit along the outcrop has been decomposed with the formation of clayey matter which complicated the separation of the graphite. The matrix is a feldspathic quartzite resembling that at the American

---

[2] Newland, D. H., Mining and quarry industry of New York: New York State Mus. Bull. 161, p. 34, 1912.

(Dixon's) mine, but the flake averages a little smaller in size. Two distinct beds are in evidence, separated by 4 feet of limestone and barren quartzite. The upper bed has a thickness of from 10 to 14 feet and the lower of from 4 to 5 feet. The immediate walls consist of mica schist, carrying pyrite, but thick-bedded garnetiferous gneisses occur in the upper part of the series, south of the workings. The outcrop of the beds strikes nearly east and west and is marked by a slight depression in the easterly sloping ridge. It is traceable for 1,500 feet or more from the present mine openings which are at the eastern end of the outcrop. The dip is about 30° S. The principal development aside from the open cuts, consists of an adit driven in the side hill along the course of the upper seam for a distance of about 125 feet. Additional workings will be necessary before the mill can be maintained in steady operation.

In 1912 the company reported that the following grades were produced:

Grades of graphite produced by Empire Graphite Co.

Grade.	Percentage of carbon.	Average price per pound f. o. b. mill.
		Cents.
Large flake	90	8½
Medium flake	87	7¼
Small flake	85	5

The property was not operated in 1913.

GRAPHITE PRODUCTS CORPORATION'S MINE.

This mine, near Kings Station north of Saratoga Springs, was first opened in 1912 under the name of the Saratoga Graphite Co. The property is described as follows by D. H. Newland:[1]

The mines are open cuts along the outcropping edges of a quartz-graphite schist which occurs in broken areas within the pre-Cambric formations that are otherwise represented by crystalline limestone, quartzite, amphibolite, and gneissoid eruptives of granitic and basic character. They lie about one-half mile west of the Saratoga-Mount McGregor highway on the side and top of the ridge that marks the eastern boundary of the pre-Cambrics as they fall off and disappear below the Paleozoic strata which border the Adirondack area. The first outcrop of the graphite rock on the north side of the ravine in which the mill is located shows from 10 to 12 feet in a single bed. The outcrop is much softened and iron stained through the decomposition of pyrite that is present in the fresh rock. This soft clayey material is of little value for milling purposes. The bed dips 30° southeast, nearly parallel with the hill slope. The open cut is 50 feet long and 25 feet in width. Specimens of the less altered schist show an abundance of graphite, but in finely divided condition, most of the scales being less than 1 millimeter diameter. There is some brown mica present. About one-fourth mile farther west and higher up a second area of the schist appears and has been opened by a pit, which is 75 feet long by 30 feet in width. The schist here is not so thinly laminated and contains knots and stringers of feldspar. The beds dip to the southeast at a lower angle than in the easterly pit; they have a pitch to the northwest. The graphite here is somewhat coarser, the diameter of the flakes running up to 2 or 3 millimeters. The two areas are separated by a rather massive, dark hornblende gneiss that appears to be a metamorphosed gabbro. The output of refined graphite thus far has been small. The mill has the usual equipment of the Adirondack graphite mills. Stamps are used for final crushing and the separation is effected mainly by buddles, supplemented by air jigs and revolving screens for the final treatment.

ST. LAWRENCE COUNTY.

The Macomb Graphite Co., in 1911, reported a small production of crystalline graphite from its mine near Pope's Mill. The property was idle in 1912 and 1913.

[1] Newland, D. H., The Mining and quarry industry of New York State: New York State Mus. Bull. 166, p. 32, 1913.

WARREN COUNTY.

AMERICAN GRAPHITE CO.'S MINE (DIXON'S MINE).

The American Graphite Co.'s mine is located in the northeastern part of Warren County, about 3 miles west of Lake George in the town of Hague, at a small settlement known as Graphite. The mine is owned by the Joseph Dixon Crucible Co. and has been operated by that company for over 30 years. It is by far the largest producing graphite mine in the United States. The ore is a medium-grained quartz-graphite schist, dark silver-gray when fresh, but becoming stained yellow and brown upon weathering. This rusty weathering is of assistance in tracing the outcrops of the ore bed. A composite sample of ore taken from the bins at the mill, selected so as to be somewhat representative of the run of the mine, was analyzed in the laboratory of the United States Geological Survey and showed 6.25 per cent of graphitic carbon.

A sample of this ore when examined under the microscope showed quartz in irregular grains as its dominant mineral. Muscovite occurs as aggregates of small shreds forming irregular bands and patches. Some of these probably represent decomposed and altered feldspar grains. Apatite is abundant in small prisms with more or less rounded outlines. There is an occasional small plate of biotite. The graphite forms flakes of an average length of about 0.9 millimeter and an average thickness of about 0.09 millimeter. The longest flake in the section was 2.8 millimeters, and a few were as much as 0.2 millimeter in thickness. Cross sections of the plates show them to possess very ragged and irregular borders.

The texture of the rock is decidedly schistose, due to a tendency for the quartz grains to be more or less elongate in the same direction and for many of the graphite plates to be oriented parallel.

The rock overlying the ore bed is in most cases a gneiss with pink garnets up to half an inch in diameter in a matrix composed of interlocking grains of brown biotite, feldspar, and quartz, with a few scattered plates of graphite. Another dark-gray schistose rock which is locally interbedded with the ore, but which is discarded in the mining, is shown under the microscope to consist wholly of quartz, plagioclase feldspar, and greenish-brown biotite, with no graphite. Evidence of sedimentary origin of the rocks of this locality is found in (1) the highly quartzose, nonfeldspathic character of much of the ore; (2) the highly and evenly garnetiferous character of much of the wall rock; (3) the even dissemination of the graphite in the schist which forms the ore; (4) the persistence of ore beds and garnetiferous gneisses with fairly uniform trend, width, and character for considerable distances, and (5) the presence locally of interbanded masses of crystalline limestone. They probably represent carbonaceous quartzites alternating with beds which were less carbonaceous and with thin masses of crystalline limestone, all of which have been wholly recrystallized with the development of a schistose structure and the conversion of the original carbonaceous material into graphite through the processes of dynamic metamorphism.

The general strike of the schist at this locality is nearly N. 45° E. and the dips are from 20° to 25° SE. Ore has been mined from two beds several hundred yards apart. The southeastern of these beds is not now worked, but was excavated several years ago at what is known as the "summer pit," the workings being shallow and operated only during the summer season. The ore bed here strikes about N. 50° E. and dips 20° SE. The thickness at the mouth of the pit is from 6 to 10 feet. The workings extend at least 600 feet along the strike, but were not carried to great depth along the dip. This pit was opened about 1890 and operated for two or three summers after that. The ore is similar to that of the bed now being worked, and a large supply is apparently still untouched. It is not improbable that this bed represents a repetition by faulting of the bed exposed in the main workings.

The main or northwestern bed (which is the one now being worked) is parallel to that at the "summer pit" in strike and dip. Its outcrop is visible at a number of old workings near the mine. All of the present work is underground, and excavations have extended for about 2,000 feet along the dip of the ore bed, the deepest parts of the mine being about 200 or 250 feet below the surface. The thickness of the productive bed varies from 3 to 20 feet, the average being much nearer the larger limit than the smaller. Occasional lens-shaped enlargements of the productive bed occur, and one of these is being mined at the present time in what is known as the "sink." At one of the outcrops a strike of nearly N. 60° E. and a dip of 25° SE. was observed; at another the dip was similar, but the strike nearly N. 45° E., and the thickness about 10 feet. Because of the gentle inclination of the ore bed no tunnels or shafts need be driven through barren rock, and practically all of the excavation is within the ore bed itself, the wall being supported by timbering and by occasional pillars of ore. The excavating is accomplished by compressed-air drills and blasting, and the ore is broken with sledges into pieces under 8 or 10 inches in diameter, loaded upon cars, and hauled by electric locomotives to the mill. The latter is located at the mine, but was not visited by the writer, the processes of treatment being at that time kept secret.

In a communication from the company received in February, 1912, the milling process is briefly described as "crushing, rolling, and buddling to a 70 per cent concentrate." The concentrates obtained are said to average about 3 per cent by weight of the ore mined. From this mill the concentrates are hauled by teams 11 miles to Ticonderoga where they receive final treatment in the finishing mill, the process consisting in grinding between burrstones and bolting. The finished graphite is then shipped by rail to the factory of the Joseph Dixon Crucible Co., in Jersey City, N. J., where it enters into various graphite products.

What was known as the Lake Shore mine, worked by this company at Hague several years ago, has been abandoned and the mill at Hague demolished.

FAXON'S MINE.

The property adjoining the American Graphite Co.'s land on the southwest is owned by William H. Faxon, of Chester, N. Y. Considerable excavating and drilling have been done, but no ore has been shipped. The principal workings are located about a mile southwest of the mill of the American Graphite Co. Here the ore bed shows in a natural exposure on the side of a small creek valley, and a tunnel about 40 feet long has been driven horizontally along the strike of the ore bed. The ore and associated rocks here strike N. 50° E. and dip about 20° SE. In general appearance the ore is practically identical with that at the Dixon mine. The microscopic appearance of the sample is as follows:

Under the microscope quartz in irregular interlocking grains is seen to be the most abundant mineral. Feldspar, in part plagioclase and in part microcline, also occurs, but has suffered considerable alteration. Brown biotite is present in small quantities, as are also small rounded prisms of apatite. Graphite occurs in plates averaging about 0.45 millimeter in length and about 0.075 millimeter in thickness, though a few plates are 0.75 millimeter long. The schistose structure, which is quite marked in this rock, is due to the parallel elongation of many of the graphite and biotite plates and a slight tendency for the quartz grains to be elongate in the same direction.

The ore bed here has a thickness of about 25 feet, though the percentage of graphite varies somewhat from layer to layer. The rock overlying the ore bed is in part a gneiss studded with pink garnets similar in every way to that overlying the ore at the Dixon workings. This gneiss contains a few graphite flakes. Interbedded with the gneiss occurs crystalline limestone, light gray in color and fine-grained, which under the microscope shows scattered pyroxene grains and a few quartz grains and graphite plates. There is evidence of shearing movement in the beds overlying the ore, lenses of quartz schist surrounded by crystalline limestone having been broken in several instances and the fragments dragged apart, though still preserving their angular outlines. There is also some crumpling in the more quartzose layers.

It is possible that the ore bed at the Faxon mine is the continuation of one or the other of the beds worked by the American Graphite Co., though their continuity has not been certainly traced. The ore is similar in quality, and there seems to be no reason why this property should not in the future be worked as successfully as the adjoining one.

The following more recent information in regard to the Faxon mine is quoted from reports by D. H. Newland:[1]

Adjoining the American mine on the southwest, the property of W. H. Faxon, of Chester, N. Y., has been explored recently with promising results. The same series of quartzites, limestones, and gneisses are in evidence, though the graphite deposits appear to occupy a higher position than those of the American (Dixon's) mine.

This property has been explored recently with considerable thoroughness by test pits and diamond drilling, but still awaits active development. The exploration has demonstrated the continuity of the graphite beds over a distance of fully 4,000 feet along their course to the southwest and, with some interruptions, for several hundred feet on the dip, which follows a low angle to the southeast. The same series of gneisses, limestones, and graphitic quartzites is found here as in the area under exploitation. The graphitic quartzite that constitutes the principal ore body has a thickness ranging from 5 or 6 to 25 feet, showing local pinches and bulges as is usual in the Adirondack deposits. There is considerable variation in the size and abundance of the flake, but as a whole the character of the quartzite is quite like that in the American mine. Near the southwestern end of the property the graphite series outcrops in a little ravine where a short drift has been extended into the north bank; two distinct beds are found here separated by a band of garnetiferous gneiss. In a drill hole (No. 2) 300 feet or so northeast of the drift a similar relation holds, the upper bed measuring about 4 feet and the lower 18 feet thick with 26 feet of gneiss between them. The two beds appear to merge a little farther northeast, for in No. 3 drill hole just east of a camp a single seam over 20 feet thick was encountered and this apparently con-

[1] Newland, D. H., The mining and quarry industry of New York State: New York State Mus. Bull. 142, pp. 37–38, 1910, and Bull. 161, pp. 32–33, 1912.

tinues with local variations as to thickness to the northeastern limits of the property, except in one place where the series is invaded by a gabbro intrusion. The deepest hole, No. 7, was put down in the flat about 600 feet east of No. 3 and twice that distance from the outcrop of the graphite bed on the ridge to the northwest. The data for this boring have been kindly supplied by Mr. Faxon and are illustrative of the general conditions under which the graphite occurs.

In hole No. 1 on the northeast, next to the American property, the graphite bed measured 20 feet thick.

ROWLAND GRAPHITE CO.

This company reported a small production in 1909 from their property near Johnsburg, but has since been idle.

WASHINGTON COUNTY.

In October, 1909, the writer paid a very brief visit to the idle graphite properties situated in the town of Dresden, Washington County. They lie northwest of South Bay, an arm of Lake Champlain. The mine and mill of the Champlain Graphite Co. are within a few rods of the shore of the bay near a prominent bluff known as the "Diameter." The mine and mill of the Adirondack Graphite Co. are also located near the bay about 1 mile farther northeast. The properties may be reached by team and ferry from Whitehall (4–5 miles) or by boat from Whitehall (5–6 miles). The third mine, that of the Silver Leaf Graphite Co., is little more than a prospect pit and is situated in the woods about 1 mile northwest of the Champlain Graphite Co.'s plant. All three mines were opened about 1904.

The mine of the Champlain Graphite Co. is an open pit about 100 feet in length, and 25 feet in maximum depth, on a steep eastern hill slope. The rock is a quartz schist of rather variable character and not very regular foliation. The general strike is about N. 10° E. Some of the more massive layers which are dark gray and fine grained are seen under the microscope to be a granular association of greenish-brown hornblende, feldspar (labradorite), and magnetite, with a little biotite and quartz, but no graphite. They may represent dikes of diabasic rock which have later been metamorphosed to hornblende diorite. The rock in which these dioritic layers occur is schistose and graphitic. Some phases are finely and others coarsely foliated. A specimen typical of most of the material which has been milled when examined under the microscope was found to consist of quartz, muscovite aggregates, which probably represent decomposed feldspars, somewhat altered biotite, and graphite. The latter occurs in flakes which in the thin sections examined varied from 0.015 millimeter to 0.25 millimeter in thickness and up to 1.3 millimeter in length. The average length does not exceed 0.75 millimeter. The graphite is usually closely associated with the biotite, the two being interleaved in some places, as at the Bly mine in Ticonderoga. The schist contains small isolated lenticles up to 2 inches wide of coarsely crystalline calcite, feldspar, quartz, and some garnet.

The mill at this mine had not been running for some time and the milling process could not be studied in detail. The equipment includes a jaw crusher, 12-inch rolls, broken-screw agitators, 3 buddles, drying floor, bolting machines, tube mill, etc.

A prospect opened by the Silver Leaf Graphite Co. is situated in the woods about 1 mile west of the Champlain Co.'s mine. It consists of one pit 15 feet wide, 40 feet long, and 5 or 6 feet deep. The ore is similar to that at the Champlain Co.'s mine. The graphitic schists strike N. 10° W. and dip 25° E. More quartzose layers alternate with others which are more argillaceous and more graphitic. The company has no mill.

The mine and mill of the Adirondack Graphite Co. are about a mile northeast of the Champlain Graphite Co.'s plant, near the wagon road which skirts the South Bay shore. The hillside quarry is about 100 by 100 feet and 30 feet in maximum depth, and all the rock exposed is more or less graphitic. The ore is a dark-gray, readily cleavable schist, which is much more uniform in character than that at the Champlain mine. The strike is quite regular and averages about N. 80° W. The dip is about 30° S. A thickness of 25 feet of graphitic schist is exposed. A thin section of typical ore when examined under the microscope shows quartz as the most abundant mineral with sharply bounded muscovite aggregates, which probably represent altered feldspar grains, and abundant brown biotite. Associated with the last and for the most part interleaved with it occurs the graphite, which according to an analysis made in the laboratory of the United States Geological Survey,[1] constitutes 5.29 per cent of the rock. The sample analyzed was a composite one collected by the writer from various parts of the quarry and probably approaches closely the average run of the mine. Some chlorite and zoisite occur, and certain bands parallel to the schistosity are very rich in pyrite. The rock owes its foliated structure to subparallel arrangement of the graphite and the biotite flakes. The graphite flakes in the thin section studied vary from 0.02 millimeter to 0.15 millimeter wide and range up to 0.9 millimeter in length. The average length is not over 0.05 millimeter.

The mill of this company was situated at the quarry, but at the time of the writer's visit had not been running for many years. The equipment includes a jaw crusher, crushing rolls, a stamp mill with two batteries of 5 stamps each, an inclined screw washer, Wilfley table, 2 buddles, and a flotation separator of special design.

NORTH CAROLINA.

Graphite is known to occur at many localities within the area of crystalline rocks in the central and western parts of the State.

A number of years ago an unsuccessful attempt was made by the Southern Graphite Co. to work a graphite deposit near Graphiteville,

[1] George Steiger, analyst.

McDowell County. According to an article by F. W. Ihne,[1] the graphite is of the flake variety and occurs in a graphitic mica schist. The belt of graphitic schist is in places 300 feet in width, and the percentage of graphite as determined by assays on hundreds of samples is commonly between 3½ and 9 per cent, though in places as high as 18 or even 27 per cent. Some lean bands or lenses occur within the graphitic zone. The milling process, which was complicated and included some processes devised particularly for this mill, is briefly described in the article referred to.

In 1911 Charles Rennie, of Franklin, N. C., reported the occurrence of flake graphite 4 miles west of Franklin. A few tons were shipped for treatment to the Federal Graphite Co., at Warren, Ohio.

In 1912 a few tons of graphitic schist were mined at Barretts Mountain, in Alexander County, but none was refined or shipped.

PENNSYLVANIA.

DEPOSITS.

Graphite occurs at many places in the area of old crystalline rocks in the southeastern part of the State, and has been mined in Chester, Berks, Bucks, and Lehigh counties. The most important deposits are in the Pickering Valley, in Chester County.

The graphite deposits of Pennsylvania have recently been made the subject of a special report prepared by B. L. Miller, for the State of Pennsylvania.[2]

This report may be procured by addressing Richard R. Hice, State geologist, Beaver, Pa., and to it the reader is referred for fuller details. The observations given below were made by the writer in 1909, and supplement to some extent those given by Dr. Miller in the report just cited. The location of the principal mines is shown on the map (fig. 10, p. 205).

CONDITION OF INDUSTRY IN 1913.

The only graphite producers operating in Pennsylvania in 1913 were the Graphite Products Co. and Pettinos Bros., near Byers, and the Rock Graphite Mining & Manufacturing Co., near Chester Springs, all in the Pickering Valley in Chester County. Pettinos Bros. operated only part of the year, their plant having burned to the ground on August 2, 1913. The Graphite Products Co., on June 1, 1913, leased the plant of the Pennsylvania Graphite Co., and during the remainder of the year scored an important production.

CHESTER COUNTY.

Chester County has for many years been the center of the graphite industry of Pennsylvania, and within the last 10 years has been the sole productive district. A single mine is located near Coventryville, in the valley of French Creek, but most of the mines are in the Pickering Valley, which is served by a branch of the Philadelphia &

[1] Ihne, F. W., Graphite in the South: Manufacturers' Record, vol. 54, p. 138, 1909.
[2] Miller, B. L., Graphite deposits of Pennsylvania: Pennsylvania Top and Geol. Survey Comm. Rept. 6, 1912.

Reading Railway, running from Phoenixville to Byers, a distance of 11 miles. Ten different mines with extensive equipment have from time to time been operated in this valley.

UWCHLAND OR BYERS GROUP OF GRAPHITE MINES.

A group of three graphite mines probably situated along the same belt of graphite-bearing rocks near Byers station (Uwchland post office), in Chester County, are similar in the character of the material mined.

The mine and mill of the Acme Graphite Manufacturing Co. are about three-quarters of a mile west-southwest of Byers station. The mine was operated in 1907 by the Continental Graphite Co. The present company began operations in 1909, rebuilding the mill, and continued work until December, 1910. Since then the property has been idle.

The graphite-bearing rocks strike nearly east and west (N. 85° E.) and dip about 45° S. They have been developed by an inclined shaft descending along the dip of the graphitic beds (45° S.). From the bottom of this shaft drifts have been driven eastward for about 150 feet and westward about 20 feet along the graphitic beds. An older level, now in part abandoned, is cut by the shaft at about 70 feet below the surface. A part of this drift was caved, but it was open for about 70 feet east and 30 feet west of the shaft. The mill is close to the mine.

The mine and the mill of the Pennsylvania Graphite Co. are located about a quarter of a mile south of Byers station. They were in active operation at the time of the writer's visit in 1909. The workings are mainly underground, but some ore is "milled" down from open pits into cars in the drifts and thence hauled to the shaft for hoisting. The underground workings accessible aggregated over 900 feet in length to the east of the shaft; to the west of the shaft the drifts were said to extend for about 800 feet, but because of caving only 300 feet were accessible. Considerable stoping has been done above this level. Drifts driven many years ago at higher levels aggregate several hundred feet more, but for the most part were inaccessible. The graphitic beds have a general east and west strike, and dip about 35° S. The shaft descends along the dip to the 70-foot level and from there descends vertically to a depth of 154 feet. There are several open pits. The largest one, temporarily abandoned, is about 30 feet in maximum depth, 100 to 150 feet in width, and about 400 feet in length along the strike of the deposit. The main open pit which was worked in 1909 was 25 feet in maximum depth, 100 feet in width, and 150 feet in length along the strike of the deposit. The width of the underground excavations, though variable, is usually about 15 feet. The mill of the Pennsylvania Graphite Co. had up to 1909 handled only the softer types of graphitic rock available in this mine, the harder material being held in reserve pending the installation of new equipment. The mill was complicated in the arrangement of the machinery, though the types of machinery used are not very numerous. The concentration was accomplished by broken-screw log-washers and wet reels of various mesh. After passing through a rotary drier the concentrate was finished by repeated grinding in burrstone mills and screening, progressively finer screens being used after each grinding. The coarsest flake for crucible stock required grinding on three stones; the finest material passed over six or seven stones. This mill was destroyed by fire.

The graphite mine of Pettinos Bros. is situated about a quarter of a mile east of the Pennsylvania Graphite Co.'s plant on the same general belt of graphitic rock. The underground workings were not accessible at the time of the writer's visit (October, 1909). The shaft is said to be 98 feet deep and to connect with drifts aggregating several hundred feet in length. Graphitic rock has also been taken from several open pits, the largest of which is 25 feet in maximum depth, 100 to 150 feet in width, and 200 feet in length, parallel to the strike of the graphitic beds. Because of weathering and caving there are no good exposures of the graphitic rocks. The mill, which was located at the mine, was destroyed by fire in August, 1913, and has not been rebuilt.

As already stated, all three of these mines are located on the same low east-west ridge and probably on the same belt of graphitic rock. The graphitic rocks at the Acme and the Pennsylvania mines are similar, and those at the Pettinos mine, though not now exposed, probably belong to the same types. The freshest specimen of graphitic rock obtained was from the dump at the Pennsylvania mine. It is a gray, coarse, crystalline limestone containing graphite flakes oriented in every direction and ranging up to one-quarter of an inch in diameter, and plates of brown mica (biotite) up to one-eighth of an inch across. Rock of this freshness is rare, however, and a much commoner graphitic rock at both mines shows graphite flakes embedded in a dull white to greenish matrix which effervesces feebly or not at all with dilute hydrochloric acid. Under the microscope the whitish matrix in which the graphite flakes lie is found to consist of a finely granular aggregate of quartz and calcite (or dolomite) with some zoisite and epidote. Another type shows a more coarsely crystalline matrix consisting mainly of calcite with abundant chlorite (penninite) and an occasional crystal of tremolite and epidote. Most of the so-called "hard ore" at the Pennsylvania mine belongs to one of the types described above, characterized by a white, rather highly calcareous matrix inclosing the graphite flakes.

At both the Pennsylvania and the Acme mines much of the graphitic rock is characterized by a dark, greenish matrix. This type usually can be excavated by pick and shovel without drilling and is thus termed "soft ore." A specimen of this ore contained graphite flakes in a matrix which the microscope showed to be almost exclusively epidote. Much of the decomposed rock exposed in the open pits is a rather fine-grained quartz-feldspar-graphite schist carrying a little muscovite. The schists at all three mines show a fairly regular east and west trend and dip to the south at 35° to 45°. Interbanded nongraphitic talc schists are exposed in the upper level of the Acme mine, where they form the wall rock at several points, and occur as lenses in the graphitic portions.

The other abundant rocks at this group of mines are granitic, mostly fine-grained granite pegmatite. At one of the open pits these rocks make up about one-half of the total exposures. They are distinctly intrusive in the graphitic rocks, and vary in size from very narrow stringers to masses many yards across. The intrusions for the most part parallel the trend of the graphitic rocks, though frequently breaking across. The granitic rocks contain graphite only in the immediate vicinity of the highly graphitic schists and limestones. Even near such contacts there are only occasional flakes.

The excavations at the Pennsylvania mine show beyond question the presence of at least three adjacent belts of workable graphitic rock. These are in general parallel in trend, but mining experience has shown that they are frequently cut off or displaced by irregular intrusions of pegmatite and by numerous fault planes, some of the latter being nearly parallel to the trend of the graphitic beds and others nearly at right angles to them. The soft character of much of the graphitic rock is due to the disintegrating action of surface waters, and it is to be expected that at greater depths the rocks will become firmer. The amount of graphitic rock available, even of the soft types, is unquestionably large.

A graphite mine has been worked by the Eynon Graphite Co. in the town of Coventry, 12 miles from Byers station, but the output has been small and the property was not visited.

ANSELMA GRAPHITE MINE.

A graphite mine and mill which have been abandoned for many years are located about 1 mile southeast of Anselma station. The workings are mainly underground and are now filled with water. Where the graphitic rock outcrops it is a coarse-grained quartz-graphite schist showing graphite flakes up to half an inch across. The strike is N. 85° E. and the dip 40°. This trend, if continued westward, would connect this deposit with those at Byers, which exhibited similar strikes and dips, and it is possible that they lie in the same belt of graphitic rock. The mill located at the mouth of the shaft has been in part dismantled.

ROCK GRAPHITE MINING AND MANUFACTURING CO.

The mine and mill of the Rock Graphite Mining and Manufacturing Co., formerly the Sterling Graphite Co., are located about 1 mile northwest of Chester Springs station. The property was opened in 1904 and has been operated intermittently since then. The mine is an open pit, about 100 by 100 feet and 25 feet in maximum depth, and is located on a northeast hill slope. The rock as here exposed is dark-gray schist, striking north and south and dipping 35° E. Its character is quite uniform throughout its exposed thickness of 18 to 20 feet, if we except the presence of a few stringers of granite pegmatite. Some of the latter carry an occasional graphite flake up to one-fourth of an inch across. Under the microscope the texture is found to be granular. Quartz is the principal mineral, with abundant altered feldspar, biotite, and graphite. The biotite and graphite flakes are frequently attached to one another in parallel growth. The graphite flakes average about 0.6 millimeter in greatest dimension, though some reach 1.5 millimeters. The mine differs from all others in the district in the relatively hard and little weathered condition of most of the rock utilized. Only about 4 feet of weathered material occurs at the surface. In physical character the rock utilized is much like that mined by the Dixons at Graphite, N. Y.

The mill of this company is near the mine and is connected with it by a tramway. The schist is first crushed in a jaw crusher, then passed to a rotary drier, crushing rolls, pneumatic sizing machines, and flotation separators. The concentrates from these separators pass to a rotary drier and are finished in burrstone mills and classifiers. The capacity of the mill is 1,200 to 1,500 pounds of finished product in 10 hours, and the weight of the finished product is stated to be about 3 per cent of that of the rock as mined, about 35 tons of the rock yielding 1 ton of finished graphite. The percentage of graphite in the finished product varies from 42 per cent in the lower grades of dust to over 96 per cent in the high-grade crucible stock.

CRUCIBLE FLAKE GRAPHITE CO.

The mine and mill of the Crucible Flake Graphite Co. are located about 1 mile northwest of Chester Springs station. The mine is located at the summit of a small knoll only a few hundred yards from the mine of the former Sterling Graphite Co. It is a single open pit, about 100 feet by 100 feet and 20 feet in maximum depth. The graphitic rock is part of the same body worked at the Sterling mine and is of essentially the same character. A tramway, traversing a tunnel for part of its length, connects the mine with the mill. The types of machinery used were similar to those at the Sterling mill, though differently arranged. The power of the large Corliss engine is first used to drive a dynamo, and the electric power is then distributed to motors connected with the different parts of the milling machinery. This arrangement has certain advantages in permitting greater freedom in the arrangement of the machinery and in permitting the suspension of certain parts of the milling process while others are still going on.

The last mining done at this property was in 1909. In 1910 the company was reported to be out of business, and the mill has been partly dismantled.

CHESTER GRAPHITE CO.

The mine and the mill formerly worked by this company are located about 1 mile southeast of Chester Springs station and were in active operation at the time of the writer's visit (October, 1909). The graphitic rock was excavated from open pits and dumped down chutes leading to a tunnel about 400 feet in length. From the chutes it was drawn into cars and trammed to the mill. One of the open pits is about 300 feet long from east to west, 100 to 200 feet wide, and 50 feet in maximum depth; another is 100 feet along the strike of the rocks, 60 feet wide, and 50 feet deep.

The rocks exposed in the pits and tunnel are much weathered, and in most of the excavating only picks and shovels need be used. The commonest rocks are quartz-feldspar-graphite schists of medium coarseness, in part quite free from mica, but locally carrying it (muscovite variety) in abundance. Their general strike is about N. 25° E. with a dip of 35° SE. These schists have been extensively intruded by granitic rock (granite pegmatite), the injection locally being on such a small scale that the whole rock becomes a typical injection gneiss. Many of the smaller granitic stringers carry some graphite, The flow sheet for the mill of this company has been published with explanatory descriptions in Mines and Minerals.[1]

This property was last operated in 1910, and in 1913 the company was reported to be out of business.

FEDERAL CARBON CO.

The mine of the Federal Carbon Co. is located about half a mile northeast of that of the Chester Graphite Co. It has been idle for several years. The development includes both an open pit and underground workings. The open pit averages about 100 feet wide, with a maximum depth of about 30 feet; its length in a N. 50° E. direction parallel to the general trend of the graphitic schists is several hundred feet. From the open pit the graphitic rock, which is very soft, is "milled" down into the underground workings. The latter lie beneath the open pits in the same belt of graphitic rock, and the drifts, being for the most part parallel to the trend of the schists, are also parallel to the length of the open pit. The underground workings consist of a vertical shaft 143 feet deep, connecting with three levels at vertical depths, respectively, of 55, 80, and 143 feet. The tunnel of the upper or 55-foot level extends northeast for 500 or 600 feet from the shaft, with a tunnel entrance close to the mill. The graphitic rock of the open pit has been "milled" down into this tunnel, and the rock hoisted from the 80-foot and the 143-foot levels has also been transported to the mill via this level. The drifts on the 80-foot level aggregate about 500 feet in length. The mine below the 80-foot level was filled with water at the time of the writer's visit. The drifts on the 143-foot level are said to aggregate about 700 feet in length. Very little stoping has been done from the 80-foot to the 143-foot level, but the drifts are in graphitic rock for nearly all of their length.

The graphite-bearing rock at this mine is a weathered quartz-graphite schist practically identical with that at the Chester Graphite Co.'s mine. The strike varies from N. 30° E. to N. 55° E. and the dip from 30° to 35° SE. The workings all appear to lie in a single belt of graphitic schist, which varies from 6 to 30 feet in width. The hanging wall in one portion of the 80-foot level was pegmatite, and in a number of places dikes of aplitic granite were found cutting the graphitic schist. The quantity of graphitic rock blocked out by these workings is unquestionably very large.

The mill of this company is located close to the mine and about 1 mile from Pikeland, the nearest station on the railroad. A wet process of concentration was used, the equipment including jaw crusher, crushing rolls, log washers, revolving drier, hexagonal dry screens, burrstone mills, and bolting machines.

GIRARD GRAPHITE CO.

The mine and the mill of this company are located about 2 miles southwest of Kimberton. The first excavations here were for iron ore, but graphite was the mineral sought later. The large open pit about 400 by 300 feet was excavated principally in mining the iron ore. The pit and a 65-foot vertical shaft near by were filled with water at the time of the writer's visit (October, 1909). None

[1] Graphite: Mines and Minerals, vol. 30, pp. 394–395, 1910.

of the graphitic rock utilized could be seen, but the mill concentrates showed that some of it must have been quite coarse grained, some of the flakes of mica (muscovite) and graphite being one-fourth of an inch across. Some of the crushed material seen in the log washers was granite pegmatite. The mill equipment included log washers, drier, pneumatic separators, burrstone mills, and classifiers. The property has not been worked for many years, and in 1911 the machinery was entirely removed.

AMERICAN FLAKE GRAPHITE CO.

The mine and the mill of the American Flake Graphite Co. are located about 3 miles southwest of Phoenixville and 1½ miles southeast of Kimberton station. The shipping point is Harveyville on the Pennsylvania Railroad about midway between the mine and Phoenixville. The mine is a single pit on a southern hill slope. It is about 150 feet long from northwest to southeast, 40 feet wide, and 30 feet in maximum depth.

The rock is a decomposed quartz-graphite schist containing relatively little mica, and so soft that it can be mined with pick and shovel. Its general strike is N. 15° E. and dip 30° to 35° SE. The pit exposes a thickness of at least 20 feet of this graphitic schist. There are a few lenses and stringers of gray quartz up to 4 inches wide and of fine-grained, much decomposed granite-pegmatite up to 1½ feet across. The pegmatite dikes are largely quartz and feldspar; they carry little or no graphite, and were discarded in the mining.

The ore was loaded into a mine car, which was hauled by a mine cable up an inclined trestle to the upper floor of the mill. The concentration was accomplished by a combination of wet and dry processes. The equipment included crushing rolls, log washers, pneumatic separators, and flotation separators of special design. The finishing was accomplished in the usual manner with French burrstone mills and screens.

The company was an important producer for three years, from 1909 to 1912, but has since been idle and the mill has recently been dismantled.

BERKS COUNTY.

The graphite deposits of this county have been described in detail in the report by Miller, already referred to.[1]

In summary Miller says:

> Graphitic gneiss is widely distributed in the crystalline rocks of South Mountain, or Reading Hills, and several graphite mines and prospects have been worked in the county. All of them were unsuccessful, however, for one reason or another, and no graphite mines have been operated in this county for several years. The mines are located in two regions, near Boyertown and in the vicinity of Rittenhouse Gap.

LEHIGH COUNTY.

Some development work has been done on the graphitic gneisses of South Mountain, in the southeastern corner of the county, but so far as known no attempt has been made to concentrate the graphite.

---

[1] Miller, B. L., op. cit., pp. 111-115.

BUCKS COUNTY.

Several occurrences of graphitic schist in this county have been described in detail by Miller,[1] his summary being as follows:

Graphite occurs in several places in the narrow band of crystalline rocks that extends across the southern portion of the county from Morrisville through Langhorne to Trevose. The graphite is found in a graphitic gneiss mainly, but in one place it is present in the coarse-grained crystalline Franklin limestone.

Graphite has been mined at two places in Bucks County, in both places in the graphite gneiss.

RHODE ISLAND.

Graphite shales have been worked in Rhode Island for many years, and in 1913 a considerable tonnage from Fenner Ledge at Cranston was marketed crude for use in foundry facings and as paint pigment. The average value of the material was $6.75 a ton f. o. b. mines, and it is said to average about 50 per cent graphitic carbon.

The deposits occur in the vicinity of Providence and near Tiverton, in Newport County, and have been studied by Prof. C. W. Brown, of Brown University, who in 1908 kindly furnished the following descriptions of their mode of occurrence and development for use in these reports:

Graphite has been known in the State for more than twenty years, and during the excavation of the sandstone on the east side of Rocky Hill, in Cranston, about 1,000 tons of graphitic "waste" were dumped on the site of the present Narragansett brewery. No successful attempts at development were made, however, until about 1888. All of the graphite of the Narragansett basin region is similar in character and in mode of occurrence. The largest workings are located at Cranston, near Providence. Smaller deposits occur at Saunderstown, and at Pawtucket and Valley Falls. All the deposits thus far enumerated occur in the Kingstown series of Carboniferous rocks near the western border of the Narragansett basin. Graphite is found also at one locality on the eastern border of the Narragansett basin between Tiverton and Little Compton, and at two localities nearer the center of the basin at Portsmouth, and in the College Hill tunnel in Providence. At these localities it occurs in carbonaceous beds of the Aquidneck series.

PROVIDENCE COUNTY.

Cranston mines.—The largest of the Rhode Island mines is at Fenner Ledge, in Cranston, a suburb of Providence, and is typical of the mode of occurrence in the western portion of the Narragansett basin. This locality has in the past been worked by a number of companies, among others the Rhode Island Graphite Company. A stock company, capitalized at $50,000, was formed in 1898 by J. Mason Gross. The venture, however, was not a success, and for the last two years the property has been worked on a small scale by Mr. Fenner.

The section at Fenner Ledge, as exposed from west to east on a quarried face, is as follows:

Section at Fenner Ledge, Cranston, R. I.

	Feet.
Slightly sheared coarse sandy shale, with occasional pebbly beds	60
Darker, more carbonaceous shale, speckled with glistening plates of ottrelite	75
Graphitic shale, much crumpled and possibly faulted	20
Sandy shale	25
Highly contorted graphitic shales showing lustrous graphite on the sheared surfaces, with more clayey material between; some small quartz and pyrite veins (this is the principal portion which has been worked for graphite)	30
Somewhat carbonaceous shales, with a small bed which is quite graphitic	100+

[1] Miller, B. L., op. cit., pp. 117-118.

Just south of the cliff section described above, at the openings formerly worked by the Rhode Island Graphite Company, the most graphitic portions show close folding with westerly overturning and a gentle northerly pitch. The worked bed is 12 to 14 feet wide, and pinches out upward. The strike is north-northeast, with an easterly dip of 50°. A drift some 30 feet high has been carried along this bed for about 100 feet. As much as 15 tons was taken from this property per diem with a working force of 12 men. In all, about 30,000 tons must have been taken out during the intermittent operations of this property for the last ten years. The plant, which is now abandoned, consisted of a 50-horsepower hoisting engine, sheds for crushing, pulverizing, drying, bolting through silk or brass mesh (from 160 to 220 to the inch), and barreling. The product was shipped to eastern and western firms for foundry facings.

The present operations are confined to the open quarry face, whose detailed section is given above, and about 300 tons of crude material have been shipped in the last two years, at an average selling price of $6 per ton. The material is excavated cheaply by hand drilling and blasting, and shipments are made to the Springfield Facing Company, Springfield, Mass.; to Cincinnati; Detroit; Hamilton, Ontario; New York City; and to New Jersey firms.

NEWPORT COUNTY.

Tiverton quarry.—The graphitic schist worked between Tiverton and Little Compton is exposed in an open cut on the beach. It is exposed for a length of 70 feet and a width of 25 feet. Since it is located at tidewater, any downward development will have to take this factor into consideration. Henry Sisson has worked this occurrence on a lease for the last ten years, and in that period has extracted at a low cost per ton about 200 tons. After grinding by the Springfield Facing Company, it is sold for paint at about $100 per ton. Recently some contracts for painting bridges and gasometers with this paint have been made. The graphite at this locality appears to be more unctuous to the touch than that at other places. There has been more shearing and faulting, but less contortion, than to the westward. Underneath there are also some occurrences of crude hematite and larger quartz veins than at Cranston.

Other localities with shafts were filled with water, and no data could be secured.

All the evidence shows that the graphite represents an original carbonaceous constituent of these rocks, which has been converted into its present form by heat and pressure. The most highly graphitic portions of the graphite-bearing formations are the softest and the most crumpled.

In the following table analysis No. 1 shows the composition of an average specimen of the graphitic shale from the Cranston property, and analysis No. 2 shows the composition of a selected specimen:

Analysis of graphitic shale from Cranston mines, Rhode Island.

	1	2
Volatile	5.92	7.86
Graphitic carbon	40.76	25.27
Ash	53.32	66.87
	100.00	100.00

TEXAS.

The following description of occurrences of graphite in the Llano region of Texas was furnished by Sidney Paige, of the United States Geological Survey:

Graphite-bearing schists are widely distributed throughout the pre-Cambrian series, though the content of graphite is very variable. In most instances the graphite schists are associated with limestone or marble, a natural occurrence since carbonaceous shales are often associated with limestone strata. Often these schists can be traced for long distances.

Graphite-bearing schists were noted at many localities, but since only one of these is as yet considered of importance a description of the occurrence at this locality will serve as a measure of those left undescribed; for it may be said in general, that it would not be advisable to spend money upon prospecting or testing at other localities until the deposit in question is proved a commercial success. If any exception be made to this statement it would be that perhaps certain beds carry sufficient graphite to be of value as a paint pigment, in the industrial manufacture of which a very impure graphite can be used.

The locality which has received and warranted the most attention is 1⅞ miles due south of Lone Grove, is approximately 1,500 feet west of Little Llano River, and about 800 feet north of the Houston & Texas Central Railroad. The property is controlled by R. H. Downman, of New Orleans.

The graphite occurs in graphitic schists associated in this vicinity with considerable limestone. Granite and pegmatite intrusions have locally disrupted the beds, and at a first glance the impression might be formed that pegmatite had introduced the graphite. A careful examination of the graphite bunches in the pegmatite shows, however, that they represent broken fragments of schist. A specimen was polished and etched with hydrochloric acid, which in dissolvng out the calcite contained between the laminæ of the schist fragments showed clearly the schistose nature of the graphite.

The graphite-bearing schists can be traced with interruptions for half a mile northwestward from a point a little west of the railroad bridge, through the present workings, to a point where the series disappears beneath overlying Cambrian sandstones. Graphite is also reported across the river to the south in the same trend.

The deposit has been prospected by a shaft with underground workings and by a number of surface cuts, four or more, over a distance of about 500 feet.

A private report made in 1902 by William Young Westervelt and furnished by the courtesy of Mr. R. H. Downman contains much interesting data on this property, and the following notes re copied or abstracted from it.

An average sample taken over the length of a 72-foot prospect cut showed a carbon content of 11.45 per cent.

A number of tests were made with the following results:

A general sample was made up of all the samples secured underground and crushed to pass a 10-mesh sieve. It was assayed and found to contain 14.50 per cent graphite. * * * Further tests indicate that ore containing 14.50 per cent carbon (the assay of the made-up general sample) will yield from 1 to 4 per cent of its weight of flake graphite [1] containing from 56 to 40 per cent carbon, whose impurities contain less than 2 per cent each of iron (Fe) and lime (CaO), the most common of the objectionable impurities for crucible manufacture. Also * * * that fine graphite could be produced amounting to from 27 to 28 per cent of the original ore and containing from 29.75 to 25.80 per cent pure graphite, the total recovery of graphite in the form of flake and fines being 60 to 61 per cent of the total graphite in the original sample.

Other tests on specially selected samples were made, but need not be presented here.

Much of the territory included in this property has not been adequately tested by surface cuts, and it is believed that possibilities exist for the successful establishment of a graphite industry at this point.

---

[1] Too large to pass a 60-mesh sieve.

South of Llano, about 2 miles, graphite schists trending in a northwest-southeast direction toward Sharp Mountain may be observed. In this vicinity, perhaps, with the exception of the property already described, exists the most favorable opportunity to prospect, though graphite schists occur at many localities throughout the region. It must be borne in mind, however, when making an estimate of the graphite content of a given band of schist that appearances are very deceptive, a very little graphite making a very striking showing.

UTAH.

During 1909 a supposed graphite mine was opened near Brigham City, in Boxelder County, Utah, by the Homber Mining Co. of Salt Lake City. According to Hoyt S. Gale,[1] of the United States Geological Survey, the deposits are located on Three Mile Creek between Brigham and Perry. They are carbonaceous schists, which form part of an extensive series of altered sediments. The beds as exposed in the shallow prospects are at least 20 feet in thickness and appear to be persistent for considerable distances. The rock when rubbed takes on a black lustrous polish similar to that shown by certain slates carrying amorphous graphite. It has not a greasy feel, but is free from coarse grit. An analysis made in the laboratory of the United States Geological Survey of a composite sample showed 3.48 per cent of fixed carbon. A selected sample of the most carbonaceous-looking material showed 5.59 per cent of fixed carbon. All of this carbon burns off readily in the ordinary Bunsen flame, and is therefore not graphite. Though probably lacking some of the resistant qualities of slates containing amorphous graphite, the material has proved to be marketable after grinding as a paint pigment.

VIRGINIA.

Although no graphite is now produced in Virginia it is known to occur at a number of localities in the Piedmont region east of the Blue Ridge.[2] Near Somerset station in Orange County on the Somers place a large exposure of graphitic schist occurs, and at the same place much graphite is reported mixed with pyrite in a pyrite vein. In Louisa County, near Green Spring, specimens of graphite of considerable purity are found. Good specimens of the mineral have also been obtained on the road from Drakes Branch to Saxe in Charlotte County. It is reported from near Jefferson post office in Powhatan County.

A graphite mine was opened years ago about 2 miles west of Buck Mountain in the northern part of Albemarle County by the Naylor-Bruce Graphite Co. The mine has been idle for some years, and the openings were so covered at the time of the writer's visit in April, 1911, that very little could be seen of the geology of the deposit. The mine is on a northeast hillside on the farm of W. A. Naylor. A lower pit only 20 feet above the creek level is about 10 by 10 feet and 15 feet deep, and was water filled. The rock exposed near the pit is a mottled green and gray rock of somewhat gneissic texture, which is stated by T. L. Watson to be a pyroxene syenite.

---

[1] Gale, Hoyt S., Supposed deposits of graphite near Brigham, Utah: U. S. Geol. Survey Bull. 430, pp. 639–640, 1909.

[2] Watson, Thomas L., Mineral resources of Virginia, pp. 188–190, 1907. Published by Jamestown Exposition Commission.

The principal working is a short distance higher up in the hillside, and consists of an open pit 40 by 30 feet and 12 feet deep, and of a shallow shaft. A small shaft house has been erected. The principal wall rock is the pyroxene syenite, which strikes N. 60° E. and dips about 80° SE. This syenite is intruded by diabase dikes, one dike at this pit being 14 inches wide, and by a 3-inch dike of pegmatite much weathered but showing feldspar crystals up to three-fourths of an inch and quartz crystals up to one-half inch across.

Graphite is exposed only on the south wall of the open pit where the rocks are much weathered. Here there is a single vein cutting the pyroxene syenite and varying from 1 to 2 inches across. This sends off into the syenite numerous short branches up to three-fourths of an inch across. The vein is composed largely of graphite with little or no gangue material. The graphite is in part earthy in texture, but in other places is crystalline with a well-developed fibrous structure. Some hand specimens forwarded to the Survey show some of the graphite fibers oriented at right angles to the sharply defined walls of the vein, but in other specimens they curve through angles of over 90°, possibly as a result of movement along the vein. In some places the fibers even lie parallel to the vein walls. The property is said to have yielded single blocks of graphite weighing several hundred pounds. An analysis by Froehling and Robertson, of Richmond, gave 76.28 per cent of graphitic carbon.

In general the exposures were too poor to reveal much in regard to the origin or probable extent of the deposit.

WISCONSIN.

The only graphite company operating in Wisconsin during the year 1913 was the Wisconsin Graphite Co., having a mill near Stevens Point and a mine about 2 miles northwest of Junction City. The mine is a narrow open pit about 300 feet long from north to south, from the bottom of which a shaft inclined about 30° W. has been sunk. There are three levels in the underground workings. The underground workings were not accessible and little could be learned of the size or shape of the workable body of rock. It appears to strike nearly north and south and to dip gently to the west. The material mined is hauled to Junction City and transported by rail to the company's mill on Big Clover River south of Stevens Point. The product is crushed, dried, pulverized in tube mills, and air-floated. The pulverized product is said to bring from $25 to $35 per ton f. o. b. mills, according to fineness and percentage of carbon. The carbon is said to range from 30 to 40 per cent.

The mine of the Pioneer Graphite Co. is about one-eighth of a mile north of that of the Wisconsin Graphite Co. It has been idle since 1909, when the mill was destroyed by fire. An open pit 100 feet long from north to south and 40 feet wide is now filled with water. A shaft, said to be 86 feet deep, connects with several levels, and about 250 tons of material in all has been mined.

The rock mined at both of these properties is a black slate or shale of hackly fracture, which has in places been sheared with the development of a schistose structure and glossy slickensided surfaces. Occasional small seams of quartz and pyrite traverse this rock. A rock associated with the black rock is bright terra cotta colored and is evidently very rich in iron oxide. The carbon is in a very finely divided state so that concentration is impracticable and the whole rock must be utilized. It is uncertain whether the carbon is true graphite or merely amorphous carbon.

WYOMING.

The following paragraph in regard to the Wyoming graphite deposits is quoted from a recent bulletin by the State geologist:[1]

> This mineral [graphite] is found in Laramie, Albany, Carbon, and Fremont counties, the carbon content, as shown by analyses of samples, varying from 10 to 60 per cent. In Albany County there is a large district known as Plumbago Canyon, where there are a great many deposits of graphite. In Fremont County a deposit of graphite, which is said to be extensive and very pure, occurs near Miners Delight. The graphite found in the State is mostly of the amorphous variety and suitable for paint and foundry facings.

Graphite deposits in the Haystack Hills, Laramie County, have been described by Ball,[2] and the following data are taken from his report:

The graphite occurs as a constituent of a pre-Cambrian mica schist at and near its contact with granitic intrusive rocks. The schists at some distance from such contacts carry carbon but not as recognizable graphite flakes. The largest band of graphitic schist observed has a thickness of only 8 to 10 feet but can be traced along its strike for at least 1,000 feet. The richest material contains upward of 16 per cent of graphite, but estimates based on analyses indicate that the average would be from 6 to 8 per cent. The associated minerals are quartz and tourmaline with a little biotite, muscovite, and feldspar. The graphite flakes are very minute—from 0.04 to 0.15 millimeter in diameter. Profitable separation of such fine material from its matrix could probably not be accomplished by any methods now known, and the quantity of material available is small when compared with many of the flake graphite deposits of the Eastern States. The deposits were prospected as early as 1881, but have never been worked.

MARKETS AND PRICES.

The prices paid by crucible makers and others for Ceylon graphite during 1913 were approximately as follows:

Prices of Ceylon graphite at New York City in 1913.

	Cents per pound.		Cents per pound.
Ordinary lump:		Dust:	
Best	9½–11	Best	4 –5½
Medium	7½– 9	Medium	3 –4
Poor	6½– 8	Poor	2 –3
Chip:		Flying dust:	
Best	7½–10	Best	2½–3½
Medium	6½– 8½	Medium	2 –3
Poor	4 – 7	Poor	1½–2

The rise in prices of Ceylon graphite which began in the last half of 1912 continued in 1913, reaching its highest point in September or October. After this the prices receded somewhat, though still maintaining a very high level. The average prices for Ceylon gra-

[1] Jamison, C. E., Mineral resources of Wyoming: Wyoming State Geologist Bull. 1, ser. B, p. 34, 1911.
[2] Ball, S. H., Graphite in the Haystack Hills, Laramie County, Wyo.: U. S. Geol. Survey Bull. 315, pp. 426–428, 1907.

phite in 1913 were at least 30 per cent higher than for 1912. This notable increase appears to have been mainly a direct result of mining and trade conditions in Ceylon as is indicated by the following statement taken from a report by Chas. K. Moser, United States consul at Colombo:[1]

The surprising increase in the price of plumbago or graphite during the last year appears to have led to some misapprehension in the iron and steel trade throughout the world as to the real causes for it. In Ceylon especially the price has risen beyond all expectation, and European importers have been inclined to place the blame on local shippers. The three reasons assigned locally are the severe floods of 1913, the increased expense of mining as the mines increase in depth, and the shortage of labor.

The followiug comparative figures, taken from the books of one of the largest exporting firms in the island, show the rise in plumbago prices.

Quality.	January, 1912.	January, 1913.	October, 1913.
	Per ton.	*Per ton.*	*Per ton.*
Medium lump	$85.97	$123.27	$162.20
Superior flying dust	45.42	68.13	113.54
Common dust	*a* 25.95	26.76	*b* 66.50
Medium ordinary lump	97.32	134.63	197.88
Superior chip	94.08	131.38	194.64
Superior ordinary lump	154.09	178.42	235.18

a 58 to 60 per cent carbon test. *b* 56 to 57 carbon test.

Uncured plumbago that ordinarily commands about $88 per ton now brings $162 to $195.

* * * In the opinion of Colombo shippers the only solution of the difficulty is for all mine owners to abandon as far as possible the old methods and old machinery and equip their mines with modern machinery. The most necessary machine is a mine pump that will pump out 2,000 to 3,000 gallons per hour with an engine of 25 to 35 horsepower to run it. At present there is one American pump in the island of a type that gives entire satisfaction. * * * The supply of plumbago near the surface has been practically exhausted throughout the plumbago district and the mines in going deeper to get more material have naturally encountered more water. Buckets and hand pumps and coolie labor have been unable to cope with the inflow.

The average price for the best grades of Chosen (Korea) graphite during 1913 was about $25 a ton c. i. f. New York City, or about the same as in 1912. Poorer grades sold as low as $20 a ton.

The few American firms that produced flake graphite during the year reported a fair demand for their product. The prices were extremely variable, but in most cases from 6 to 7½ cents a pound f. o. b. cars was obtained for the better grades of finished crucible and lubricating flake. Some firms sold a part or all of their product as partly finished concentrates, which brought a somewhat lower price.

CEYLON.

The following account of the graphite deposits of Ceylon is condensed from a paper[2] by the writer published in 1911. Those desiring more complete information should consult the original paper and its accompanying bibliography.

The graphite deposits of Ceylon are of especial interest to Americans because most of the graphite used in this country comes from

[1] Daily Cons. and Trade Repts., Dec. 27, 1913.

[2] Bastin, E. S., The graphite deposits of Ceylon; a review of present knowledge with a description of a similar graphite deposit near Dillon, Mont.: Econ. Geology, vol. 7, pp. 419–433, 1912; also U. S. Geol. Survey Mineral Resources for 1911, pt. 2, pp. 1094–1103, 1912.

that island and because the United States has for many years been the largest consumer of the Ceylon material. Much has been printed in regard to these deposits, but it is widely scattered through publications in various languages which are not readily accessible to the American public. The writer has, therefore, summarized the more important facts which are on record, with apologies for any errors which may have crept in on account of his lack of personal knowledge of the island.

Although their existence was known in early times and mentioned in print as early as 1681, the graphite deposits of Ceylon were not

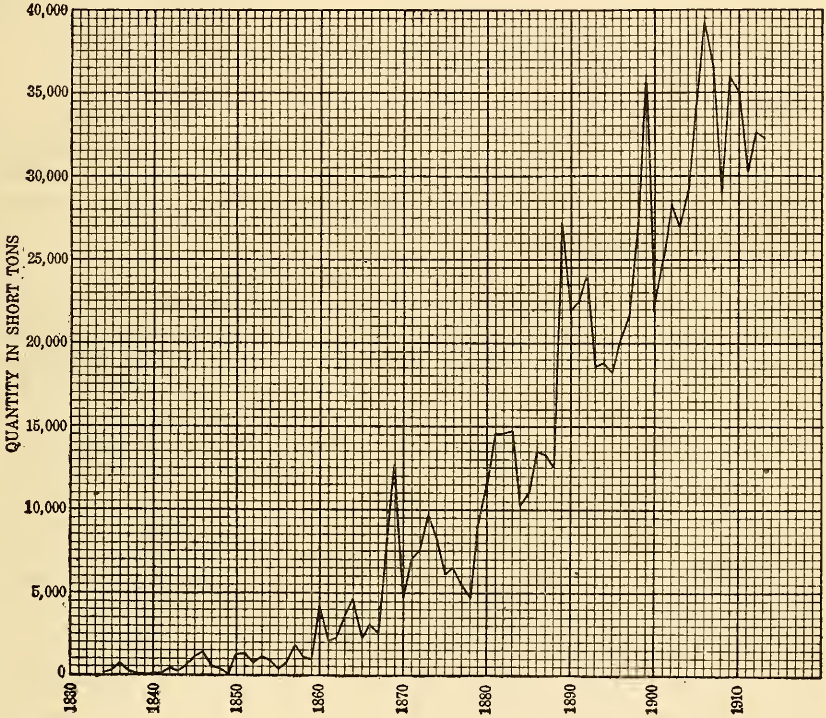

FIGURE 11.—Diagram showing quantity of graphite (plumbago) exported from Ceylon from 1834 to 1913.

exploited until some time between 1820 and 1830. Joseph Dixon is said to have imported a small quantity into the United States in 1829, but it was not until 1834 that the industry assumed any commercial importance. From that time to this, as a result of the growth of metallurgical industries and the resulting demand for refractory materials, the industry has developed rapidly, until at present graphite is subordinate in value only to tea and the products of the cocoanut palm among the exports from the island. Figure 11 shows the exports of graphite from Ceylon from 1834 to 1913.

From the early days of the industry up to 1901, Great Britain consumed more Ceylon graphite than any other country. Since 1901 the United States has assumed the first place, with Great Britain second until 1909, when Germany took second place. The distribution of graphite exports for one year in each of these trade periods is shown in the following table:

Exports of graphite from Ceylon, in short tons.

Destination.	1885 a	1902 a	1913 b
United Kingdom	7,670	7,586	5,995
United States	3,074	15,244	16,381
Germany	67	3,833	7,039
Belgium	....	1,096	2,216
Other countries	187	453	622
Total	10,998	28,212	32,253

a Figures from Ceylon Government Blue Book.
b Advance figures issued by the Ceylon Chamber of Commerce.

With the exception of a limited amount of graphite mining done on tea estates, the industry is in the hands of native Sinhalese. It has been estimated that the various processes of mining, sorting, "curing," packing, and shipping graphite, as well as the making of barrels in which it is exported, provide employment for about 50,000 men, women, and children.

The island of Ceylon is just off the southern point of the peninsula of British India, the channel between being nowhere deep enough for the passage of large ships. The island is more or less pear-shaped in form, and has a length from north to south of about 275 miles and a maximum width of about 135 miles. A railroad extends the entire length of the island, with branches into the central interior. Colombo, the capital and principal seaport, is on the western coast, and is the port from which nearly all of the graphite is shipped. A small quantity is shipped from Galle.

The island of Ceylon may be divided into two natural divisions—a mountainous region of crystalline rocks, which forms the southwestern part of the island, and a lowland area made up of coral limestones and marine sands of much later origin to the north and east. In the mountainous region there are 10 peaks which rise to elevations of over 7,000 feet, the highest being 8,296 feet. This region covers about one-fifth of the area of the island. The principal mines are in the south-central and southwestern parts of the island, and all are within the mountainous region.

The most abundant rocks of the mountainous crystalline area are gneisses of both light and dark varieties. Intimately interbanded with the commoner types of gneiss in bands varying from a few inches to hundreds of yards in width are crystalline limestones, many of which are dolomitic. The origin of the gneisses is not certainly known, but the presence of beds of crystalline limestone will be regarded by most geologists as proof that a part of them at least are metamorphosed sediments. Others are probably altered igneous rocks.

The groundmass of gneissic rocks has been intruded by several types of massive igneous rocks, among which granite pegmatites are conspicuous. The graphite is present locally in small amounts disseminated in the crystalline limestones and some of the gneisses. The commercially important deposits, however, are all veinlike in character and were deposited along fracture planes in the rocks. They were thus formed distinctly later than the rocks which they traverse. In most of the graphite districts the main veins parallel the foliation planes of the gneisses, thus striking northwest and southeast. In the Kurunegale district, on the other hand, the principal veins strike northeast and southwest parallel to a system of joint fractures. In any pit or series of pits there is usually a single main vein or several parallel veins following one of these directions of fracturing and sending off minor veins or stringers along the less prominent set of fractures. In some places the extent of the veins along their trend is so slight that they may be more correctly described as lenses. In other places veins of considerable width may contract to mere seams only to widen again when followed farther. The width of the veins varies from less than an eighth of an inch to several feet, and some as narrow as 2 or 3 inches are worked. The walls are usually sharply defined, and the bordering rock is not impregnated with graphite to a distance of more than half an inch from the veins.

In small veins the graphite usually forms an aggregate of parallel platy needles set at right angles to the vein wall. In the larger veins most of the graphite shows a coarse platy structure, though the needlelike structures may be developed in a band from a few millimeters to 2 or 3 centimeters across next the walls or next masses of wall rocks inclosed in the vein. The needlelike aggregates are in high favor commercially because of their highly fibrous structure and are known as "needle lump." Spherulitic aggregates of graphite plates are of occasional occurrence.

Usually the veins consist almost entirely of graphite, but sometimes other minerals occur in important amounts. Pyrite is almost always present either disseminated between the individual flakes or needles or concentrated in a more or less definite band in the central portion of the vein. Occasionally a pyrite crystal is penetrated by graphite flakes. Quartz, usually milky, often forms a part of the vein, sometimes occurring as a central band. In a few places rosettes of graphite flakes occur in the quartz, and in other places quartz grains lie between flakes of graphite. Quartz and pyrite are the only accessory minerals which are nearly always present, but occasional minerals are biotite, orthoclase feldspar, pyroxene (usually augite), apatite, allanite, and rutile; the last is sometimes developed along cleavage planes in the graphite crystals. In one mine a remarkable cavity or "vug" was encountered which was about 15 feet high, more than a yard wide, and oval in section. Its walls were lined with flaky graphite, and similar material filled its lower portion. In some of the graphite veins slight movements subsequent to their formation have bent the graphite flakes or crushed them to an earthy mass and developed slickensided fracture surfaces.

The graphite is mined either from open pits or through vertical shafts connecting with underground workings. The majority of mines are not deeper than 100 feet, though a few go as deep as 400 or 500 feet. On account of the heavy rainfall water is one of the chief obstacles in deep mining. In a few mines steam pumps and hoists are employed, but as a rule the mining methods are still crude, the acme of mechanical ingenuity being reached in a windlass operated by five or six men for hoisting the graphite in a sort of tub.

The workmen usually ascend and descend by means of rough wooden ladders, tied with jungle ropes and rendered exceedingly slippery by the graphite dust and water.

The mineral as it comes from the pits may contain as much as 50 per cent of impurities, mostly in the form of quartz and wall rock. It is conveyed in bags to a dressing shed, where it is picked over and the impurities reduced to 5 or 10 per cent. It is then packed in barrels for transportation to Colombo or Galle. At these ports it is unpacked and submitted to further treatment known as "curing." The graphite merchants have fenced yards or "compounds" for the final preparation of the graphite for the market. In the methods of "curing" there is some diversity, but the first step is usually to set aside the large lumps and to pass the remainder through stationary screens of several different sizes of mesh. The large lumps and the screened pieces are then broken with small hatchets by Sinhalese women to remove the coarser impurities, such as quartz, and are then rubbed up by hand on a piece of wet burlap and finally on a piece of screening to give them a polish. Finally, various grades coming from several mines or differing in size or texture are blended to meet the requirements of purchasers, a process requiring skill and long experience.

The poorer material is usually beaten to a powder with wooden mauls or with beaters shaped like a rolling pin, and is then sorted into different grades. In some establishments the impure grades are washed in a tub or pit. In this process the mineral is placed in saucer-shaped baskets and by a circular "panning" motion of the immersed baskets the graphite particles are thrown off into the pit, while the heavier impurities, especially pyrite, remain behind. To separate the very fine material, the powdered graphite is placed in a basket with somewhat the shape of a large dustpan. The contents of the basket are thrown into the air, and the heavier particles fall back into the basket, while the finer material is blown forward and falls on the floor.

CHOSEN (KOREA).

The following information in regard to the graphite deposits of Chosen (Korea) is taken from a private report prepared in 1909 and placed at the writer's disposal through the courtesy of Mr. Charles Pettinos:

The existence of large deposits of graphite in Chosen has long been known, but no attempt has been made to develop them until within the last few years, the first mention of graphite in the Chosen customs returns being in 1903, although sample shipments had been made before that time. Graphite is known to occur in all the Provinces, but appears to be most abundant in the Province of Kyeng-Sang, which is nearest to Japan, in Chung-Cheng, one of the western Provinces, and in the northern Province of Pyeng-an. In northern Kyeng-Sang the graphite is interbedded with gneiss. Up to June, 1909, 65 mining rights had been granted under the Chosen laws for the mining of graphite and over 40 more were pending.

In 1909 there were five producing mines in Chosen, all operated by Japanese firms. The first of these mines is situated in the northern part of Chung-Cheng Province, not far from Whang-gan station on the Seoul Fu-San Railway, over which the product is shipped to Fu-San.

The second mine is not far from the first in the northern part of the Province of Kyeng-Sang. The graphite from this mine is transported by river to another station on the Seoul Fu-San Railway. Both of these mines are controlled by the same company, which employs in them about 30 Japanese and 100 Koreans.

The other three productive mines are located in close proximity to one another in the northern customs district of Gen-San and employ about 345 Koreans and 32 Japanese. Transport is costly, being effected partly by oxcarts, partly by river boats, and partly by junks to the port of Gen-San.

An American firm of Seoul is investigating several graphite deposits and has done considerable development work on a property on the east coast about midway between Fu-San and Gen-San. The graphite can be transported by junks to Gen-San at small cost.

All the deposits mentioned above are amorphous graphite. Nothing is published concerning their geologic relations or origin, but a report on them by the Japanese Government is in process of preparation. Some of them are said, however, to be of large size and easily mined. The percentage of carbon in the material which has been shipped is said to vary from 60 to 85.

In December, 1913, six graphite mines were said to be active in Chosen.

Crystalline graphite is also known to occur in Chosen, and one property in Pyeng-an Province, northern Chosen, is being developed. Samples are similar to the graphite of Ceylon, but no information is available in regard to the size or extent of the deposits.

The exports of graphite from the ports of Fu-San and Gen-San, which includes practically the whole Chosen output, are as follows:

Exports of graphite from Chosen (Korea), 1906–1908.

	Long tons.
1906	733
1907	1,154
1908	6,455

Most of the Chosen graphite which has gone to Europe or America has been shipped from Japanese ports. It can be laid down at these ports at a cost of from $10 to $13 a long ton. Considerable quantities of Chosen graphite are now being utilized in the United States, where it comes into competition with the amorphous graphite imported from Mexico. It is used for paint pigment, foundry facings, and for powder glaze. In the latter utilization it is often mixed with Mexican amorphous graphite.

MADAGASCAR.

GENERAL CONDITIONS OF INDUSTRY.

Within the last two years increasing quantities of crystalline graphite have been brought into the United States from the French island of Madagascar, off the east coast of Africa. In general, this graphite is after concentration similar to the flake graphite obtained from New York, Pennsylvania, and Alabama, but in some lots certain of the flakes are bladelike and resemble Ceylon chip in form. The carbon in most of the concentrate thus far imported ranges from 80 to 85 per cent. It has been used in conjunction with Ceylon graphite in the manufacture of crucibles by several American firms, and has been otherwise applied as a substitute for Ceylon chip and American flake. The Morgan Crucible Co., of London, is a large buyer and has a plant at Tananarivo, in which the low-grade material is enriched. The opening for through service in March, 1913, of the new railroad between the port of Tamatave and Tananarivo in one of the graphite mining districts of the plateau should serve to stimulate the industry. A railroad which will traverse a graphite-bearing district is under construction from Tananarivo to Antsirabe, 107 miles farther south, and will probably be completed in 1917. According to one of the Madagascar graphite dealers, the Morgan company buys according to a graded scale of prices based upon size of flake and percentage of carbon, the prices in the latter part of 1913 varying from a little over 2 cents a pound for the smaller sizes (passing a No. 60 French standard screen), carrying 70 per cent carbon, to about 6½ cents a pound for the large sizes (between Nos. 30 and 40 French standard screen), carrying 97 per cent carbon. The prices paid for material carrying 85 per cent carbon vary from about 3½ cents to 5 cents according to size. The graphite for export is commonly packed in bags holding 80 to 100 kilograms. The freight rate from Tamatave to New York City is about $15 per 1,000 kilograms.

Up to December 31, 1911, the total number of claims taken up was 200; by the end of 1912, the number had increased to 942; and by April 1, 1913, to 1,392.

The graphite deposits are found to extend nearly the whole length of the island from near the Amber Mountains on the north to Ambalavao on the south. Those deposits that are now worked are in the central plateau and on the east coast.

The following information in regard to the graphite industry of Madagascar is quoted from a report[1] by James G. Carter, United States consul at Tamatave:

Exports of graphite from Madagascar, 1909–1913.

	Quantity.	Value.
	Metric tons.	
1909	200	$14,320
1910	554	55,713
1911	1,281	86,188
1912	2,638	....
1913 (first half)	2,383	....

The Madagascar graphite may be easily separated from the débris by simply washing it with the hands and, if the work is carefully done, may be concentrated up to 80 or 85 per cent. The graphite thus far produced, however, has averaged from 70 to 80 per cent, due to the fact that it has been washed almost wholly by natives with pans or sluices, the latter method giving the better results. By the use of machinery it is estimated that the concentration may be brought up to 95 or 98 per cent. As the decomposed quartzite and rotten schists retain moisture, only machinery suitable for handling such materials should be employed. Only three of the large producers of graphite have as yet installed machinery at their plants. These are the Maison Suberbie and the Syndicat Lyonnais, at Tananarivo, and Arton et Allemand, at Mamjakandriana, with European headquarters at Antwerp.

[1] Daily Cons. and Trade Repts., Jan. 29, 1913, and Dec. 24, 1913.

The greater portion of the graphite is purchased on the island by local commercial houses for exportation to their European headquarters and by the local representatives of European crucible syndicates or companies. Of the local commercial firms active in the purchase and exportation of graphite are Messrs. Ulysse Gros & Darrieux, Wm. O'Swald & Co., and the Cie. Marseillaise de Madagascar (L. Besson & Co.), with European headquarters at Paris, Hamburg, and Marseille, respectively. The first-named concern is understood to be also purchasing for a European syndicate. The Morgan Crucible Co. (Ltd.), of London, through its established agency at Tananarivo, is also one of the largest purchasers of graphite. Another concern, with purchasing agents at Tananarivo and Antsirabe, is the Syndicat d'Exploitation des Graphites de Madagascar, with headquarters at No. 50 Boulevard Haussmann, Paris. A representative of Arthur Bramwell & Co. (Ltd.), of London, has also been to Madagascar; but this office is without any information as to what purchasing connections the company has established on the island.

Purchasers of graphite for export either buy outright for cash or by contract for a certain number of tons per year at a stated price. The large purchasers also advance money to the holders of claims for working expenses. The contract usually binds the producer to sell to the contracting purchaser only. The large producers, however, except in one or two instances, are yet "unengaged" and export their own graphite.

If American concerns are interested, there seems to be no reason why they should not be able to establish direct relations with the producers of Madagascar graphite and purchase the product upon equal terms with European houses. A list of the largest producers, with whom correspondence might be carried on in regard to the purchase of graphite or the sale of machinery for working it, is herewith forwarded [and may be obtained from the Bureau of Foreign and Domestic Commerce]. The better plan, however, would be to have a representative in the place to establish the desired connections. An American prospector residing at Tananarivo [name obtainable on application at the bureau] is familiar with graphite and mining conditions in Madagascar and would doubtless be pleased to correspond with American firms with a view to purchasing or working graphite for their account.

The present price of Madagascar graphite varies from 200 to 700 francs ($38.60 to $135) per ton f. o. b., according to the percentage of carbon and size of the flakes. Graphite averaging 80 per cent carbon sells for 350 to 400 francs ($67.55 to $77.20) and that averaging 88 to 90 per cent 675 francs ($130.28).

The freight per metric ton on graphite, as quoted by the Messageries Maritimes Steamship Co., is $17 from Tamatave to New York and $20 from Vatomandry and Mananjary, the two southern ports from which graphite is shipped.

Three samples of the crude and one each of the four following grades of refined Madagascar graphite accompany this report: No. 1, 88½ per cent carbon; No. 2, 86 per cent; No. 3, 84 per cent; "averages," 80 per cent. The samples of crude graphite were taken out of a body 3 meters (9.84 feet) wide, at a depth of 10 feet. [These will be loaned by the bureau to American firms interested.]

The samples of Madagascar graphite which accompanied Mr. Carter's report were examined by the writer. The crude material was in lumps as much as 3 inches across that showed a decided foliated structure, and more than half of it appeared to be crystalline graphite, the remainder being more or less decomposed and iron-stained feldspar, quartz, etc. In some of the lumps curved flakes of graphite 0.8 inch in length occur, but in general the graphite flakes are much smaller. Three samples of the concentrate were graded as follows:

No. 1.—Said to average about 88½ per cent carbon. Thin flakes from 0.02 to 0.05 inch in width and from 0.03 to 0.15 inch in length. Luster more brilliant than No. 2 or 3.

No. 2.—Said to average about 86 per cent carbon. Slightly thicker flakes, averaging 0.03 to 0.07 inch in width and from 0.05 to 0.2 inch in length. Luster rather dull.

No. 3.—Said to average about 84 per cent carbon. Thicker flakes, averaging about 0.1 inch in width and from 0.1 to 0.4 inch in length. Luster rather dull.

A notable feature of all the samples is the apparent total absence of mica, but some altered mica (biotite) was observed in another sample of Madagascar graphite obtained from a different source. The impurities consist of fragments of quartz and altered feldspar, more or less iron stained, and possibly other minerals. In general, the refined product differs from the smaller grades of Ceylon material in being flaky and differs from most American flake in that the flakes are commonly somewhat elongate rather than nearly equidimensional.

OCCURRENCE IN MADAGASCAR.

An interesting account by P. Contanciel of the occurrence of graphite in Madagascar was published in a French journal[1] in 1912. The parts likely to be of interest to Americans are summarized below. For exact locations, maps, and diagrams the reader is referred to the original article.

The known occurrences of graphite in Madagascar are confined to the area of ancient crystalline rocks that forms the eastern half of the island. This crystalline tract is in turn divisible into a high plateau region and a lowland tract. Graphite occurs in each but in a somewhat different manner.

GRAPHITE IN THE HIGH PLATEAU TRACT.

The climate of the plateau tract is much less humid than that of the lowlands and vegetation is less prolific. The plateau is in many places separated from the lowlands lying east of it by a steep escarpment whose heavily forested slope extracts much moisture from the prevailing easterly winds.

Because of the climatic features rock exposures are much more abundant than in the lowlands, and there are no deep deposits of "laterite," that is, soil resulting from prolonged rock decay. The graphite deposits are, therefore, strictly bedrock deposits. In the commonest type the graphite is a constituent of a graphitic schist and forms flakes lying between grains of quartz or altered feldspar. Biotite or black mica is sometimes present, but in general is not abundant in the highly graphitic schists. The graphitic schists discovered up to 1912 occur in three principal bands, two of which pass near Tananarivo, the capital of the island. Most of the deposits now known have been covered by claims, but development had at the time this article was written not advanced beyond the "prospect" stage. Their exploitation would involve the crushing of the rock and the separation of the graphite by washing or other means from the feldspar, quartz, and mica with which it is intergrown.

A second mode of occurrence of graphite in the plateau tract is in so-called flat veins (filons couchés). Their exact character is not quite clear from M. Contanciel's descriptions. He states that they lie parallel to the foliation of the schists, and that some of them attain a thickness of as much as 20 meters.

Their graphite content is higher than that of the ordinary graphitic schists, and may reach 30 per cent, though seldom more. They have been the object of serious exploitation at several places, the excavations commonly being open pits, though in a few places

[1] Contanciel, P., Note sur les graphites de Madagascar: Soc. indust. min. Bull., November, 1912, pp. 505-530.

shafts and galleries have been driven. The open pits seldom exceed 25 meters in depth and are all, therefore, in more or less decomposed material which is easily excavated.

The Tsarazafy concession northwest of Tananarivo is an example of a property worked by underground methods. The method of concentration employed at the Tsarazafy concession is described as follows: The crude material, which seldom contains more than 30 per cent of graphite, is first washed in tubs by women laborers along the river bank. By this washing the graphite concentration is raised to about 50 per cent, much being lost in the process. The material is next spread on hearths heated by brush fires, to dry, and then fed to a series of screens with round openings 3, 2, and 1 millimeters in diameter. The oversize from the 3-millimeter screen is sent to crushing rolls and then again passed over the screens. The sized product from the screens goes to winnowing machines, somewhat similar to those used in vanning corn. The products of these machines are tailings that are discarded, middlings that are re-treated, and two sizes of graphite concentrate (1 to 2 millimeters and 2 to 3 millimeters). The vanning is not very efficacious in separating the fine rock dust and much of it is eliminated by further screening. The final product, averaging about 80 per cent graphite, is only 5 to 10 per cent by weight of the rock mined. After sacking it is ready for shipment. Electric power for the mill is supplied from a power plant at a falls 2 kilometers distant. The cost of mining and milling by this process is about 90 francs ($17.37) per metric ton (2,205 pounds) of concentrate produced.

The native process is still simpler, and at the Louys mine, at Isaha, is carried on as follows: A laborer breaks the lumps of crude material with a mallet or a club and throws the material into a cubical tub 0.6 meter in diameter. A current of water enters at one side of the tub and leaves at the other, and the same laborer agitates the material in the tub with a spade. The overflow from the tub goes into a slightly inclined wooden trough 4 meters long, 0.3 meter wide, and 0.3 meter deep, whose lower end is half closed by a board 0.15 meter high. The agitation in the tub tends to float off the slime, while the sand and most of the graphite remain behind. Whatever graphite floats off is caught in the trough. The washed mixture of sand and graphite is dried in the sun on floors and then passed to screens of 4, 8, 12, and 16 meshes per centimeter. After the screening the several sizes are sacked. The product averages about 70 per cent graphite and forms about 2 per cent by weight of the rock as mined. The cost of mining and milling is about 100 francs ($19.30) per metric ton (2,205 pounds) of concentrate produced.

The two plants, whose methods have just been described, were up to the time this article was written the only important producers in the plateau tract, other properties being merely prospects. As regards the future of the industry, M. Contanciel says:

> Aside from these exceptional cases, the exploitation in the high plateau tract is destined to encounter considerable difficulties. There is never a lack of water, and means of communication can easily be developed; but for crushing the rocks and for wet processes of separation it is necessary to install complicated and expensive machinery, hardly warranted by the value of the product obtained.

GRAPHITE IN THE LOWLAND TRACTS.

The lowland tract, east of the plateau tract, is characterized by great humidity and by prolific vegetation, which completely masks the bedrock. The soil resulting from rock decay ("laterite") is deep and in it the graphite occurs. The original rock before decay was probably similar to the graphitic schist of the plateau tract. The process of rock decay has served to increase somewhat the percentage of graphite by removing some of the more soluble constituents of the rock, and has yielded an incoherent and easily excavated material which requires no crushing. The greater ease and cheapness with which the graphite deposits of the lowlands can be worked, as compared with those of the plateau, is counterbalanced to some extent by transportation difficulties. Real roads are practically lacking, and if constructed are almost impossible to maintain. It is hard to conceive how difficult it is for the natives themselves to cover even small distances along the paths that are pompously called "roads," and all transportation in our day, at least, must be on the backs of men. Because obscured by vegetation, the deposits are less easily located and followed by the prospector than in the plateau tract. M. Contanciel does not describe the methods of concentration used in the lowland tract.

MEXICO.

For a number of years the United States Graphite Co. has been an important producer of amorphous graphite from mines in the State of Sonora, Mexico. The crude material is shipped by rail to Saginaw, Mich., where it is ground in continuous feed tube mills and is subsequently air floated. Some of the product is mixed with greases to make a prepared lubricant or with other pigments and oil for black, dark green, and dark brown paints. The remainder is marketed in the dry state for practically all the purposes to which any graphite is applied, except the manufacture of crucibles and related refractory products.

The following description of the graphite mines of Sonora, Mexico, has been furnished by Frank L. Hess, of this Survey, who visited these properties early in 1909:

The Santa Maria graphite mines, which are owned by the United States Graphite Co., of Saginaw, Mich., are situated about 20 miles south and a little east of La Colorada, in central Sonora. They are the largest amorphous-graphite mines in the western hemisphere and probably in the world. The country rock is composed of metamorphosed sandstone, ranging in fineness from shaly material to conglomerate containing pebbles of 1½ inches diameter. Considerable andalusite in small crystals is developed in the sandstone. The rocks are probably of Upper Triassic age. They are intruded by granite, which has been the metamorphosing agent. Intercalated with the sandstone are at least seven beds of graphite, ranging in thickness up to 24 feet and standing at high angles. The rocks are considerably folded, and the graphite beds show the effect of movement more than the inclosing sandstone; in places they are almost cut off through squeezing, while in other places they show thickening. The graphite beds are also intruded by granite dikes, and in places the walls are of granite. The graphite was undoubtedly formed through the metamorphism of coal beds, which in other parts of the State are to be found in the form of coke, anthracite, and bituminous coal. The graphite of the Santa Maria deposits is entirely amorphous, and from the main vein worked averages about 86 per cent graphitic carbon. Specimens may be picked which carry 95 per cent graphitic carbon. The graphite is shipped to Saginaw, Mich., for refining. A large part of the best pencils, both of European and American manufacture, are made from this graphite. It is also used as a lubricant, for powder coating, and for foundry facings. A few miles north of Torres, and 3 miles west of the railroad, Pettinos Brothers, of Bethlehem, Pa., own graphite deposits, for which a good price was paid a few years ago. A small amount of graphite was shipped, but the property is now lying idle. Prospecting is being carried on for graphite on the east side of Yaqui River, a few miles above Onavas. The geology is similar to that of the deposits at Santa Maria, about 75 miles west. At San Marcial, between Santa Maria and Onavas, coal is found partly graphitized; and at points on Yaqui River above Onavas unaltered coal beds are reported, which, it is said, the Southern Pacific controls and will use for fuel on its Mexican lines.

LITERATURE.

GENERAL TREATISES AND NEW PUBLICATIONS.

The best general treatise in English on the occurrence, methods of treatment, and uses of graphite is that by Fritz Cirkel, listed as No. 14 of the bibliography. During 1912 a report by B. L. Miller on the graphite deposits of Pennsylvania was published; it is listed as No. 44 of the accompanying bibliography. It describes in detail, with maps and illustrations, the graphite deposits of that State, describes briefly the occurrences of graphite in other parts of the country, and gives a large amount of general information on the character, treatment, and uses of graphite. The report may be obtained from Richard R. Hice, State geologist, Beaver, Pa.

The best general treatise on the geologic occurrence of graphite is that by Stutzer, listed as No. 75 of the bibliography. This summarizes the geology of the more important deposits of the world, but only touches briefly on uses and methods of treatment. The book is in German.

Two general treatises in German are the following: Der Graphit, by A. Haenig, 1910, and Der Graphit, by E. Donath, 1904.

The literature dealing with graphite is voluminous and contains many abstracts and quotations. The following list is selected, so far as possible, to avoid duplication and yet to convey all the important information relative to the occurrence and production of the mineral in the United States. Under each reference the general scope of the paper is described, and attention is directed to its most important features. Canadian publications are not listed unless they are of general interest or include mention of United States deposits. For references to the voluminous Canadian literature and many foreign publications the reader is referred to the monograph by Fritz Cirkel, already referred to.

INDEX TO BIBLIOGRAPHY.[1]

[1] The numerals given in this index are the numbers prefixed to the entries in the bibliography, pp. 246 to 251.

SELECT BIBLIOGRAPHY.

1. ACHESON, E. G., Seventeen years of experimental research and development. (Privately published.) Dr. Acheson chronicles his discovery and development of the processes of manufacturing carborundum, graphite, and the so-called "deflocculated" graphite. 14 pages. Illustrated.

2. ——— Discussion of artificial graphite: Mineral Industry, vol. 8, pp. 351, 352, 1899.

3. ARSEN, W. C., Transformation of other forms of carbon into graphite: Am. Electro-Chem. Soc. Trans., vol. 20, pp. 105–119, 1911. Discusses experiments by the author and others bearing upon the question whether the transformation of ordinary carbon into graphite can take place by simple heating or only in the presence of certain impurities, which act as catalytic agents. In the author's experiments all samples were fired in a small tube furnace for 15 minutes at temperatures of approximately 3,000° to 3,300° C. Comparative tests were made of various forms of carbon when pure and when mixed with 5 to 10 per cent of impurities. The presence of impurities seemed in most cases to retard rather than to accelerate the conversion to graphite. The character of the carbon used appeared to be important, some forms, such as petroleum coke, being readily converted, while others, such as lampblack, were not graphitized. The author suggests that graphite may be defined as "that allotropic form of carbon having a specific gravity of 2.25 to 2.26."

4. BAYLEY, W. S., and STEWART, C. A., Note on the occurrence of graphite schist in Tuxedo Park, N. Y.; Econ. Geology, vol. 3, pp. 535–538, 1908. Observations in the New York and New Jersey Highlands west of the Hudson River indicate that graphite occurs (1) as a component of Franklin limestone, (2) in gneisses which may be in part altered sediments but are in places certainly mashed pegmatites, (3) in coarse granite dikes and pegmatites, and (4) in fine-grained quartzitic micaceous schists, especially where these are associated with pegmatites. The last-named occurrences are the most important. Concentrating works at Bloomingdale, Highbridge, and near Brookside have all failed. Describes in detail the occurrence of graphite in schists at Tuxedo Park. The graphite plates are usually in parallel intergrowth with biotite plates. The graphitic schist is believed to be the product of metamorphism of a sediment rich in organic matter. The pegmatite is graphitic only near the schist or where it carries fragments of this rock.

5. BALL, S. H., Graphite in the Haystack Hills, Laramie County, Wyo., U. S. Geol. Survey Bull. 315, pp. 426–428, 1906. Abstract in this report. Describes character, origin, and economic value of undeveloped graphite deposits of this region. Graphite formed through contact metamorphic effects of granite and pegmatite which intruded carbonaceous sediments.

6. BASTIN, EDSON S., Origin of certain Adirondack graphite deposits: Econ. Geology, vol. 5, pp. 134–157, 1910. All these deposits have resulted directly or indirectly from the metamorphism of carbonaceous sediments. There are two principal groups: (1) Those which originated through dynamic (regional) metamorphism alone, and (2) those which have been affected by both dynamic and igneous (contact) metamorphism. Most of the disseminated deposits of crystalline graphite which are worked belong to the first class. To the second or contact metamorphic class belong the deposit at Lead Hill, near Ticonderoga, and the deposits worked by the Crown Point Graphite Co., just north of Chilson Lake. A study of quartz associated with the graphite at the Lead Hill mine indicates that the temperatures at which the graphite and associated minerals crystallized probably did not exceed 575° C.

7. ——— The graphite deposits of Ceylon; a review of present knowledge, with a description of a similar graphite deposite near Dillon, Mont.: Econ. Geology, vol. 7, pp. 419–443, 1912. One plate and 5 figures. Bibliography. Abstracts in this report.

8. BEATTIE, H. M., Acme graphite mines and mills: Eng. and Min. Jour., vol. 94, pp. 115–118, 1912. Describes the mode of occurrence of graphite and methods of milling at two mines (Pennsylvania and Continental mines) controlled by the Acme Co., near Byers, Pa. Two flow sheets.

9. BRUMELL, H. P. H., Canadian graphite: Canadian Min. Inst. Jour., vol. 10, pp. 85–104, 1907. Republished with illustrations in Canadian Min. Jour., vol. 28, pp. 163–171, 1907. Abstract in Min. World, vol. 26, p. 627, 1907. Describes the general character, distribution, and origin of graphite. Gives the history of the industry in Canada; Canadian methods of concentrating, markets, uses, and statistics of production.

10. ——— Graphite concentration: Canadian Min. Inst. Jour., vol. 12, p. 205, 1909. Reprinted in the Canadian Min. Jour., vol. 30, pp. 267–272, 1909. Describes the processes of concentration used in various Canadian mills.

11. ——— Regarding lead pencils: Canadian Min. Jour., vol. 28, p. 173, 1907. Brief history of the industry.

12. CARTER, W. E. H., On the graphite industry in Canada during 1902: Mineral Industry, vol. 11, pp. 349–351, 1902.

13. CHESTER, FREDERICK D., The flake graphite industry in the United States: Eng. and Min. Jour., vol. 88, pp. 785, 786, and 824, 1909. Discusses the causes of the many failures in the mining and milling of flake graphite. Cites certain bad practices in graphite concentration and gives formula for estimating value of finished product to be obtained from concentrates containing different percentages of graphite.

14. CIRKEL, FRITZ, Graphite; its properties, occurrence, refining, and uses; Dept. of Mines, Ottawa, Canada, 307 pages, 1907. The best general treatise on this mineral. Includes detailed descriptions of Canadian graphite deposits, descriptions of foreign occurrences, and bibliography. Illustrated. Reviews theories of T. Sterry Hunt, Weinschenk, Osann, and others. Regards the disseminated deposits of Canada as derived by metamorphism from originally carbonaceous sediments. Reviewed by Frank L. Hess, Econ. Geology, vol. 4, pp. 661–666, 1909, and by H. Mortimer Lamb, Eng. and Min. Jour., vol. 85, pp. 360–361, 1908.

15. CUSHMAN, A. S., The preservation of iron and steel: U. S. Dept. Agr. Office Pub. Roads Bull. 35, 1909. Describes tests on the rust-preventing qualities of graphite and other paint pigments when applied to iron and steel. Experiments appear to show that graphite is a rust stimulator and not a rust inhibitor, and hence that it should not be applied as a *first* coating to iron or steel. It is serviceable, however, as an outer coating.

16. DANA, E. S., System of mineralogy, 6th ed., pp. 7–8, 1904. Mineralogical characters, composition, localities, etc.

17. DAY, A. L., and SOSMAN, R. B., The expansion coefficient of graphite, Jour. Indust. and Eng. Chem. vol. 4, No. 7, July, 1912. Reports the results of measurements made in the Carnegie Geophysical Laboratory at Washington of the expansion coefficient of a bar of Acheson graphite. The writers compare their results with those obtained by others for other kinds of graphite and other forms of carbon. They are inclined to agree with Moissan and others that graphite can not be looked upon as a substance of fixed properties, basing this opinion on the variations observed not only in the coefficients of expansion of different graphites but also on other physical properties.

18. DOWNS, W. F., The occurrence, treatment and application of graphite: Iron Age, Apr. 19, 1900, p. 8; May 3, pp. 3–6; May 10, pp. 9–11, treats briefly the nature, occurrence, and uses of graphite, and discusses at length its application in the manufacture of crucibles.

19. Electrochemical and Metallurgical Industry, The works of the International Graphite Co., at Niagara Falls, vol. 7, pp. 187–188, 1909. Describes the general equipment of this plant in 1909, without giving details of the electrochemical processes. Three half-tone illustrations.

20. FITZGERALD, F. J. (chemist of the International Acheson Graphite Co.), The conversion of amorphous carbon to graphite: Jour. Franklin Inst., vol. 154, pp. 321–348, 1902. Reviews various methods of producing graphite artificially and describes in detail the Acheson process.

21. ——— The Ruthenburg and Acheson furnaces: Electrochemical and Metallurgical Industry, vol. 3, pp. 416–417, 1905. Detailed descriptions and diagrams showing construction of the Acheson graphite furnaces.

22. GALE, HOYT S., Supposed deposits of graphite near Brigham, Utah: U. S. Geol. Survey Bull. 430, pp. 639–640, 1910. Abstract in this report.

23. GOSS, W. F. M., Tests of graphite on ball bearings, with explanatory charts: Ind. World, April 20, 1908. Six series of tests were made by Prof. Goss, of Purdue University, on a specially designed ball-bearing testing machine using successively kerosene, lard oil, and vaseline, and mixtures of each of these with 4 per cent, by weight, of Dixon's Ticonderoga flake graphite. In all cases the presence of the graphite resulted in a marked decrease in frictional resistance.

24. HAENIG, A., The application of graphite to the production of crucibles for melting metals: Brass World, vol. 7, pp. 307–312, 1911. (Abstract translation from the German monograph "Der Graphit," by A. Haenig.) An excellent summary of the qualities necessary in graphites used for crucibles. Seven analyses of clays used in graphite crucibles. Describes the methods of crucible manufacture.

25. HAYES, C. W., and PHALEN, W. C., Graphite deposits near Cartersville, Ga.: U. S. Geol. Survey Bull. 340, pp. 463–465, 1907. Discusses character, origin, and uses of graphitic talcose slates of Cartersville region. Probably formed by metamorphism of a carbonaceous clay shale.

26. HESS, F. L., Graphite mining near La Colorada, Sonora, Mexico: Eng. Mag., vol. 38, pp. 36–48, 1909. Abstract in this report. The deposits were discovered in 1867, preliminary work begun in 1891, and commercial operations in 1895. The graphite bed now worked reaches 9 to 10 feet in thickness, though locally reduced

through squeezing to a thin seam, yet in other places bulging to 24 feet. The wall rock is in most places a sandstone, though locally granite. Limestone also occurs near the mine. The graphite probably represents a coal bed of Upper Triassic age, which was graphitized by the intrusion of granite. The graphite is of the amorphous variety, and it is excavated from extensive underground workings and hauled by 10 to 14 mule teams 20 miles to the railroad at La Colorada. From there it is shipped to the factory of the operating company—the United States Graphite Co., at Saginaw, Mich. Map and sketch plan of vicinity of mines. Seven half-tone illustrations.

27. Hornaday, W. D., The Santa Maria graphite mines, Mexico: Min. and Eng. World, Dec. 7, 1912. Gives the history and status of development of the mines of the United States Graphite Co. Quotes Hess (No. 26) in regard to geologic features.

28. Hyde, F. S., Discussion of assay of graphite by blast and fusion: Mineral Industry, vol. 9, pp. 380–383, 1900.

29. ——— On some characteristics of natural graphite: Mineral Industry, vol. 16, pp. 574–575, 1907.

30. ——— Some characteristics of natural graphite: Eng. and Min. Jour., vol. 85, pp. 255–256, 1908. Describes chemical and physical tests for distinguishing different kinds of natural graphite.

31. Ihne, F. W., Graphite in the South: Manufacturers' Record, vol. 54, pp. 134–138, 1909. Discusses the general character and mode of occurrence of graphite and describes in some detail the deposits in the South Atlantic States. Describes in detail the concentration process of the Southern Graphite Co., of Graphiteville, N. C.

32. ——— Graphite in the United States: Min. Sci., vol. 60, pp. 297–298, 316–318, 343–346, 1909. Describes the occurrence, distribution, and mining of graphite in the United States. Illustrated.

33. ——— General discussion of character of graphite and of graphite mining: Mineral Industry, vol. 17, pp. 489–497, 1908. Particularly full description of the Clay County, Ala., deposits.

34. Imperial Institute, Bulletin of the, Graphite and its uses, vol. 4, pp. 353–360, 1906; vol. 5, pp. 70–85, 1907. Abstract in Canadian Min. Jour., vol. 28, pp. 171–173, 1907. General discussion of the character, occurrence, uses, and concentration of graphite. Summary of its distribution in various parts of the world. Some references.

35. Iron Age, Acheson graphite lubricant, May 23, 1907. Discusses the lubricating value of "deflocculated" artificial graphite.

36. Johnson, C. M., Rapid methods for the chemical analyses of special steels, steel-making alloys, and graphite, John Wiley & Sons, 1909. Devotes a chapter to the analysis of graphite and graphite crucibles.

37. Keith, Arthur, U. S. Geol. Survey Geol. Atlas, Mount Mitchell (N. C.–Tenn.) folio (No. 124), 1905. Describes character and utilization of graphitic schists near Graphiteville, N. C.

38. Kemp, J. F., Graphite in the eastern Adirondacks, N. Y.: U. S. Geol. Survey Bull. 225, pp. 512–514, 1903. The graphite deposits are confined to Algonkian rocks and occur (1) in pegmatite veins, (2) as veinlets of graphite, (3) in quartzites, and (4) in crystalline limestones associated with gneissoid strata. Deposit at Chilson Hill near Ticonderoga is briefly described and referred to pegmatite class. Graphitic veinlets at Split Rock on Lake Champlain are described. Description of graphitic quartzites at Hague and a few other localities. These quartzites are regarded as metamorphosed bituminous shales. Milling process at Hague described. Occurrence of graphite in crystalline limestone briefly described.

39. Kemp, J. F., and Newland, D. H., Preliminary report on the geology of Washington, Warren, and parts of Essex and Hamilton counties, N. Y.: New York State Mus. Fifty-first Ann. Rept., vol. 2, pp. 537–540, 1897. Describes the rocks of Hague as gneisses of several varieties, mostly striking northwest. Crystalline limestone occurs at two points and pre-Cambrian sedimentary schists at several localities. The best exposures of such schists are at the mine at Graphite. The graphite deposit is an impregnation or dissemination of graphite in quartzite. Gives microphotographs of the garnet-sillimanite wall rock. Preliminary concentration at this time was by California stamps and buddles. The further concentration process at the finishing mill at Ticonderoga is secret. Gives a map and structure section of the locality.

40. Law, E. Stanley, Notes on a useful mineral (graphite): The Mineral Collector, vol. 12, pp. 169–173, 180–184. Discusses characters, uses, and production of graphite. Quotes Kemp on occurrence of graphite in New York. Describes in some detail the mode of occurrence and mining and milling methods in Chester County, Pa. Briefly describes the Ceylon occurrences and the methods of artificial production.

41. Lee, Willis T., Graphite near Raton, N. Mex.: U. S. Geol. Survey Bull. 530, pp. 371–374, 1913. Abstract in this report. Describes the graphite deposit near Raton, in Colfax County, N. Mex. The deposit is nearly horizontal and represents

a coal bed graphitized by the intrusion of diabase. A representative sample analyzed 77 per cent graphite. The material has been utilized somewhat in paint manufacture.

42. MEEKS, REGINALD, Discussion of market for graphite: Mineral Industry, vol. 17, pp. 497–500, 1908.

43. MERRILL, GEORGE P., The nonmetallic minerals; their occurrence and uses, pp. 6–14, 1910. General discussion of the character, occurrence, origin, and uses of graphite. Short bibliography.

44. MILLER, B. L., Graphite deposits of Pennsylvania: Pennsylvania Top. and Geol. Survey Comm. Rept. 6, 1912. Part I, pp. 1–66, treats of the history, properties, general mode of occurrence, origin, and uses of graphite, and its distribution in the United States. Part II, pp. 67–147, treats in detail of the Pennsylvania deposits, their history and geology, milling methods, production, and prices. Closes with a short bibliography.

45. MILLS, FRANK S., The economic geology of northern New York: Eng. and Min. Jour., vol. 85, p. 397, 1908. Describes particularly the property of the Macomb Graphite Co., in St. Lawrence County. The graphite is disseminated as small flakes in quartz schists. A small amount of development work has been done.

46. MINES, BUREAU OF, Dept. of Agriculture and Commerce, Japan, Mining in Japan, past and present, pp. 133–135, 1909. (Two pages in English.) Abstract in Bastin, Edson S., Graphite: U. S. Geol. Survey Mineral Resources, 1909, pt. 2, p. 833, 1911. Discusses domestic production and imports and briefly describes the principal occurrences. The bulk of the Japanese consumption is imported from Ceylon, Chosen (Korea), etc. The domestic occurrences are all in the principal Japanese island of Nippon. Most of the output is crystalline graphite, which occurs disseminated in small flakes in gneiss. Amorphous deposits, probably produced by the contact metamorphic effects of igneous rocks on coal seams, are also worked.

MINERAL INDUSTRY, 1892 to 1909, vols. 1 to 18. Pub. by Eng. and Min. Jour. Annual statements of the progress of the graphite industry. The special features of most importance as regards graphite are as follows:

47. ——— vol. 2, pp. 335–342, 1893. Describes foreign and domestic occurrences and uses, with numerous references to foreign literature.

48. ——— vol. 6, pp. 387–390, 1897. Discusses particularly the use of graphite paint for metallic surfaces.

49. ——— vol. 7, pp. 382–387, 1898. Description, by T. C. Hopkins, of graphite properties near Chester Springs, Chester County, Pa., with quotation from Weinschenk on mode of occurrence in Bavaria and Bohemia.

50. ——— vol. 8, pp. 348–352, 1899. Description, by T. C. Hopkins, of the occurrence of graphite in Berks County, Pa. Discussion, by E. G. Acheson, of artificial graphite.

51. ——— vol. 9, pp. 378–383, 1900. Discussion, by F. S. Hyde, of assay of graphite by blast and fusion.

52. ——— vol. 10, pp. 367–373, 1901. Two pages devoted to manufactured graphite.

53. ——— vol. 11, pp. 343–353, 1902. Discussion, by W. E. H. Carter, of the graphite industry in Canada during 1902. Two pages on manufactured graphite.

54. ——— vol. 12, pp. 183–187, 1903. Devotes 1½ pages to the Ceylon deposits.

55. ——— vol. 14, pp. 311–312, 1905. A short description (one-third of a page) of the graphite deposits near Charlottesville, Va.

56. ——— vol. 16, pp. 567–575, 1907. Description, by F. S. Hyde, of some characteristics of natural graphite, and descriptions by other writers of occurrence of graphite in Alabama, New Jersey, and Wyoming.

57. ———, vol. 17, pp. 488–500, 1908. General discussion, by F. W. Ihne, of graphite and graphite mining. Particularly full description of the Clay County, Ala., deposits. Discussion, by Reginald Mecks, of market for graphite.

58. ——— vol. 18, pp. 384–390, 1909. Devotes 2½ pages to foreign graphite occurrences.

59. MOFFIT, FRED H., The Nome region: U. S. Geol. Survey Bull. 314, pp. 139–140, 1907. Abstract in this report. Describes briefly (one page) the character and mode of occurrence of graphite on the south side of the Kigluaik Mountains, Seward Peninsula, Alaska.

60. MOISSAN, HENRI, The electric furnace (authorized translation by Victor Lehner), 1904, pp. 50–79. Describes the behavior of various natural terrestrial graphites upon heating or treatment with certain reagents, also graphites obtained from the terrestrial iron of Greenland and from several iron meteorites. Describes the process of formation and the characters of various artificial graphites produced both by simple elevation of temperature and by the solution of carbon in different metals. The experiments appear to indicate that graphite formed at high tempera-

tures is less readily attacked by the usual reagents than that formed at lower temperatures. The swelling exhibited by certain graphites when heated with aqua regia is believed to be due to the sudden evolution of gases. All the artificial graphites produced by simple elevation of temperature were nonswelling; all obtained from fusion with metals exhibited swelling. The temperature of swelling lies between 165° and 175° C.

61. NASON, FRANK L., Geological studies of the Archean rocks: New Jersey State Geologist Ann. Rept., pp. 27–29 and 64–65, 1889. Describes the distribution of several belts of graphitic schists in the New Jersey Highlands.

NEWLAND, D. H., The mining and quarry industry of New York State: New York State Mus. Bulls. 93, 102, 112, 120, 132, 142, 1904–1909. Annual statistics of the production of graphite and reports on the progress of the industry. The more important locality descriptions are listed below:

62. ——— Bull. 102, pp. 73–78, 1905. Describes briefly mines at "Graphite," in Warren County, Rock Pond, and Mineville, in Essex County, and Dresden, in Washington County. Devotes one-half page to milling methods.

63. ——— Bull. 120, pp. 29–31, 1907. Describes briefly mines near Conklingville, in Saratoga County, and near Rossie, in St. Lawrence County. Discusses effects of presence of mica and influence of size of graphite flake in concentration.

64. ——— Bull. 142, pp. 37–38, 1909. Describes the graphite property of W. H. Faxon, near "Graphite."

65. ——— Bull. 161, pp. 32–34, 1911. Describes the property of W. H. Faxon, near "Graphite," and that of the Empire Graphite Co., near Greenfield.

87. Watson, Thomas L., Mineral resources of Virginia, pp. 188–190, 1907. (Published by Jamestown Exposition Commission.) Mentions the localities at which graphite has been found in Virginia. No detailed descriptions.

88. White, David. Some problems of the formation of coal: Econ. Geology, vol. 3, p. 298, 1908. The discovery of hydrocarbon-bearing strata composed largely of such organisms (algæ) in rocks as old as the Ordovician strongly suggests an algal origin for the graphites interbedded in still older metamorphic sediments of the Laurentian or the Algonkian.

89. Winchell, Alexander V., Graphite near Dillon, Mont.: U. S. Geol. Survey Bull. 470, pp. 528–532, 1911. See next reference.

90. ——— A theory for the origin of graphite as exemplified in the graphite deposit near Dillon, Mont.: Econ. Geology, vol. 6, pp. 218–230, 1911. This article covers in more detail the same ground as 89. It describes the mode of occurrence of graphite on the property of the Crystal Graphite Co., near Dillon, and discusses various theories of graphite formation. To account for the veinlike deposits the writer suggests that a reversible reaction may have taken place whereby the water vapor of a granitic magma first reacted with carbon in bordering carbonaceous rocks with the resulting formation of oxides of carbon (mainly CO) and hydrogen; that these gases became incorporated in the magma; and that they were finally given off as the magma cooled and penetrated fissures in the rock where, through a reversal of the reaction, graphitic carbon and water were formed.

ABRASIVE MATERIALS.

By Frank J. Katz.

REVIEW OF THE ABRASIVE INDUSTRY IN 1913.

The total value of the abrasive materials considered in this chapter, which entered trade during 1913, increased about 8 per cent as compared with the value for 1912. There was an increase both in domestic production of natural abrasives and artificial abrasives and in importation. The value of natural abrasives produced increased about 3 per cent; of artificial abrasives, about 15 per cent; and of imports, about 2 per cent.

In the natural abrasive industry gains were shown in the production of garnet and tripoli and diatomaceous earth. There was a decrease in the quantity of millstones and of quarry products made in connection with them, such as chasers and drag stones; of grindstones and pulpstones; of oilstones, whetstones, and scythestones; of emery; and of pumice. The total estimated value of all the abrasive materials consumed in the United States during the six years 1908 to 1913, inclusive, is given in the following table:

Total value of all abrasive materials[a] consumed in the United States, 1908–1913.

Year.	Natural abrasives.	Artificial abrasives.	Imports.	Total value.
1908	$1,074,039	$626,340	$476,073	$2,176,452
1909	1,329,750	1,365,820	653,779	3,349,349
1910	1,406,805	1,604,030	977,718	3,988,553
1911	1,526,763	1,493,040	815,854	3,835,657
1912	1,601,993	1,747,120	898,892	4,248,005
1913	1,648,578	2,017,458	916,913	4,582,949

[a] Exclusive of feldspar and the various forms of silica. See chapters on feldspar and silica.

The value of abrasive materials imported for consumption into the United States during 1912 and 1913 is as follows:

Value of abrasive materials imported into the United States, 1912 and 1913.

Materials.	1912	1913
Millstones and burrstones	$27,562	$40,198
Grindstones	131,080	139,386
Hones, oilstones, and whetstones	45,398	40,222
Emery and corundum	491,725	474,299
Infusorial earth, tripoli, and rottenstone	24,253	28,696
Pumice	74,478	93,408
Diamond dust and bort	94,396	100,704
Total	888,892	916,913

NATURAL ABRASIVES.

Under the head of natural abrasives in this report are included (1) millstones and related quarry products, such as chasers and drag stones, (2) grindstones and pulpstones, (3) oilstones and scythestones, (4) corundum and emery, (5) abrasive garnet, (6) diatomaceous earth and tripoli, and (7) pumice. The difficulty of separating abrasive quartz and feldspar from the quartz and feldspar produced for other purposes has led to their omission from the chapter on abrasives, and such information as appears about them in "Mineral Resources" will be found in the chapters entitled "Feldspar" and "Silica." The statistics in this report represent only that part of the production of natural abrasives that properly comes under the abrasive industry, except as indicated below; thus only a small percentage of the sandstone that is quarried is used in the manufacture of abrasives—grindstones and pulpstones—the remainder being used chiefly in the building industry. There is difficulty in separating that portion of the production of tripoli and diatomaceous earth which is used as an abrasive from that which is not; hence the production of these substances is given in full. A large part of both of these products is not used as an abrasive, but is applied to other and diverse uses. Diatomaceous earth, for example, which is a nonconductor of heat and is of light weight, is used extensively as a packing material for furnaces, steam pipes, and boilers, and as a fireproof building material. Similarly, tripoli, in addition to being ground and used as an abrasive is used as a filtering medium. Almost the entire output of millstones, pumice, emery, and garnet (except gem garnet) is used in the abrasive industry.

Natural abrasives were produced in 1913 in 26 States, which are listed below:

Alabama: Millstones.
Arkansas: Oilstones.
California: Diatomaceous earth.
Connecticut: Diatomaceous earth.
Georgia: Tripoli.
Florida: Diatomaceous earth.
Illinois: Tripoli.
Indiana: Oilstones.
Kansas: Pumice.
Kentucky: Oilstones.
Maryland: Diatomaceous earth.
Michigan: Grindstones and scythestones.
Missouri: Tripoli.
Nebraska: Pumice.
Nevada: Diatomaceous earth.
New Hampshire: Garnet and scythestones.
New York: Millstones, emery, garnet, and diatomaceous earth.
North Carolina: Millstones and garnet.
Ohio: Grindstones, pulpstones, oilstones, scythestones.
Pennsylvania: Millstones.
Tennessee: Tripoli.
Utah: Pumice.
Vermont: Scythestones.
Virginia: Millstones and diatomaceous earth.
Washington: Diatomaceous earth.
West Virginia: Grindstones.

In the following table is given the value of the natural abrasive materials produced during the last five years:

Value of natural abrasives produced in the United States, 1909–1913, by kinds.

Abrasive.	1909	1910	1911	1912	1913
Millstones	$35,393	$28,217	$40,069	$71,414	$56,163
Grindstones and pulpstones	804,051	796,294	907,316	916,339	855,627
Oilstones and scythestones	214,019	228,694	214,991	232,218	207,352
Corundum and emery	18,185	15,077	6,778	6,652	4,785
Garnet	102,315	113,574	121,748	163,237	183,422
Abrasive quartz and feldspar	(a)	(a)	(a)	(a)	(a)
Infusorial earth and tripoli	122,348	130,006	147,462	125,446	285,821
Pumice	33,439	94,943	88,399	86,687	55,408
Total	1,329,750	1,406,805	1,526,763	1,601,993	1,648,578

a See chapters on feldspar and silica.

MILLSTONES.

PRODUCTION.

The production of millstones and related quarry products, burrstones, chasers, and drag stones in the United States in 1913 amounted to $56,163 in value, a decrease of $15,251, or 21.36 per cent, compared with the value in 1912. The production of millstones in this country in 1913 was nevertheless larger than in all but three years since 1888, when it was valued at $81,000.

For the last 25 years the returns to the Survey from this industry have shown great fluctuations, which have been difficult to account for satisfactorily. It is natural to suppose that the market for millstones, made as they are from quartz conglomerate, would have declined in recent years because of the introduction of other grinding machinery. The replacement of the millstones, it is but natural to assume, would be gradual, and the value of millstones would therefore show a steady falling off. This, however, has not been the case. From a maximum value of $200,000 in 1880 the value of millstones fell to $100,000 in 1887; from $81,000 in 1888 the value declined rapidly to $16,587 in 1891; in the following year there was a rise in value to $23,417, followed by a marked decline in the two following years, until the lowest production ever reported, namely, $13,878, was reached in 1894. Since that year the values have risen and fallen, as will be observed from the table of production, without any apparent rule.

Millstones were produced in 1913 in Alabama, New York, North Carolina, Pennsylvania, and Virginia, the same States that have produced them in recent years. The output in New York fell off about 35 per cent and it decreased slightly in the other States except Pennsylvania, which made practically the same production as in 1912. Virginia was first, New York second, and North Carolina third in value of output.

In the following table is given the value of millstones, chasers, and rider or drag stones produced in the United States from 1909 to 1913, inclusive:

Value of millstones produced in the United States, 1909–1913, by States.

State.	1909	1910	1911	1912	1913
New York	$13,138	$13,753	$13,335	$34,246	$21,987
Virginia		5,273	17,635	25,866	23,530
North Carolina	22,255	9,191	9,099	9,352	8,772
Pennsylvania				1,950	1,874
Alabama					
Total	35,393	28,217	40,069	71,414	56,163

The following table gives the value of millstones produced in the United States since 1880:

Value of millstones produced in the United States, 1880–1913.

1880	$200,000	1897	$25,932
1881	150,000	1898	25,934
1882	200,000	1899	28,115
1883	150,000	1900	32,858
1884	150,000	1901	57,179
1885	100,000	1902	59,808
1886	140,000	1903	52,552
1887	100,000	1904	37,338
1888	81,000	1905	37,974
1889	35,155	1906	48,590
1890	23,720	1907	31,741
1891	16,587	1908	31,420
1892	23,417	1909	35,393
1893	16,639	1910	28,217
1894	13,887	1911	40,069
1895	22,542	1912	71,414
1896	22,567	1913	56,163

IMPORTS.

The imports of burrstones and millstones for consumption in the United States in 1913 were valued at $40,198, as compared with $27,562 in 1912. The increase was in material imported in the rough as well as in imports of finished stones. The latter have never been large, but have increased somewhat over the imports of the four preceding years.

The value of the imports of burrstones and millstones during the last five years is given in the following table:

Value of burrstones and millstones imported and entered for consumption in the United States, 1909–1913.

Year.	Rough.	Made into millstones.	Total.	Year.	Rough.	Made into millstones.	Total.
1909	$22,125	$465	$22,590	1912	$26,236	$1,326	$27,562
1910	33,740	1,023	34,763	1913	36,276	3,922	40,198
1911	35,153	875	36,028				

THE MILLSTONE INDUSTRY.

In this report for 1909 notes were given on the millstone industry in New York and Virginia. The industry is one which undergoes little change from year to year, and statements made in the former report still hold; the descriptions are therefore given again below.

New York.—New York has led for many years in the production of millstones and chasers, the latter term being applied to stones which run on edge or on a horizontal shaft. The raw material is obtained in Ulster County, southeastern New York, and is known as Esopus stone, Esopus being an early name for Kingston, which was formerly the main point of shipment. The material suitable for millstones is quarried from the Shawangunk conglomerate, which is found near the western base of Shawangunk Mountain, in the valley of Rondout River. This material is exceedingly scanty, being confined in linear extent to a strip extending from High Falls on the north to Kerhonkson on the south, a distance of approximately 10 miles. Beyond these limits the texture and other properties of the rock have been found unsuitable for the highest grade of stones.

The methods employed in quarrying the rock are simple. The rock is pried or split out, advantage being taken of the joint planes, especially the concentric-surface joints. The tools used are the ordinary hand drill, together with plugs and feathers. Blasting is often resorted to, but the charges of powder are usually light. The rough stones thus obtained are quarry dressed and finished, these operations being performed entirely by hand, the chief tools employed being the bull point and the hammer. The operation of drilling the "eye" is performed by centering the stone and then drilling from the center of both faces inward. In many stones the eye is square. To fashion a square eye a round eye is first drilled out and then squared up. A few of the men engaged in the industry make a modification of the regular millstone for use in grinding paint. In this modification the ordinary millstone is cut in halves and an iron casting is placed between the halves, which are then joined together by an iron band.

Chasers are larger than the regular millstones. They are used for heavier work, such as grinding quartz, feldspar, barytes, etc., and, as already mentioned, they run on edge. Though they are made with a diameter as short as 24 inches, they are usually turned out with diameters ranging from 50 to 84 inches, and are as much as 22 inches in thickness. These chasers are run on pans paved with roughly cubical blocks of the conglomerate, with edges about a foot in length. In grinding quartz in such pans the chasers are used in the preliminary crushing; then rough blocks, usually three in number, are either attached to or carried along by lateral arms, which in turn are joined to a vertical revolving shaft. By the circular movement of these blocks the material placed in the pan is ground to powder.

Fourteen operators in New York reported production in 1913.

Virginia.—The millstone industry in Virginia is confined to quarries near Prices Fork, Montgomery County, about 5 miles west of Blacksburg, the site of the Virginia Polytechnic Institute. The rock is regarded as of Mississippian (lower Carboniferous) age. The material from which the stones are quarried varies from a normal conglomerate to a fine-grained quartzitic rock. It includes pebbles, some of them as large as walnuts, though most of them are smaller. The rock has a bluish cast. Its bedding planes are very distinct, and layers only an inch thick may be observed. It is extremely hard and tough and resists erosion to a marked degree. It underlies Brush Mountain for miles, and for this reason the millstones are frequently termed Brush Mountain stones. The stone can not be quarried by blasting, and it is therefore extracted by hand power, with drill and hammer, plug and feathers. Millstones and drag or rider stones are the principal products made at the Virginia quarries.

Three operating firms or individuals reported production during 1913.

North Carolina.—Three operators reported production of millstones near Salisbury, Rowan County. The stones are made of granite.

Pennsylvania.—Millstones were made at East Earl and Lincoln, Lancaster County.

Alabama.—A few millstones were quarried and made at Dutton, Jackson County.

GRINDSTONES AND PULPSTONES.

The value of the grindstones and pulpstones produced in the United States in 1913 was $855,627, a decrease of $60,712, or nearly 7 per cent as compared with $916,339, the value for 1912. The decrease is in the value of the grindstones, the pulpstone production having increased slightly over 1912.

The States and the number of quarries in each State producing grindstones in 1913 were: Michigan, 3 quarries; Ohio, 25 quarries; and West Virginia, 2 quarries. Ohio, as usual, maintained the leading position in the industry, the value of the output of the State being between six and seven times that of Michigan. The output of West Virginia was comparatively small. Ohio also produced pulpstones from 2 quarries. Montana and Utah have ceased to be producers of grindstones.

The following table shows the value of grindstones and pulpstones produced in the United States from 1909 to 1913, by States:

Value of grindstones and pulpstones produced in the United States, 1909–1913, by States.

State.	1909	1910	1911	1912	1913
Colorado	(a)	(a)	(a)	....	....
Michigan	(a)	(a)	(a)	(a)	(a)
Montana	....	....	(a)	(a)	....
Ohio	$679,930	$699,033	$742,107	$787,621	$737,572
Utah	....	....	....	(a)	....

d Includes Michigan, Montana, Utah, and West Virginia.
e Includes Michigan and West Virginia.

The value of the production of pulpstones and grindstones in the United States from 1880 to 1913, inclusive, is shown in the following table:

Value of grindstones and pulpstones produced in the United States, 1880–1913.

1880	$500,000	1892	$272,244	1904	$881,527
1881	500,000	1893	338,787	1905	777,606
1882	700,000	1894	223,214	1906	744,894
1883	600,000	1895	205,768	1907	896,022
1884	570,000	1896	326,826	1908	536,095
1885	500,000	1897	368,058	1909	804,051
1886	250,000	1898	489,769	1910	796,294
1887	224,400	1899	675,586	1911	907,316
1888	281,800	1900	710,026	1912	916,339
1889	439,587	1901	580,703	1913	855,627
1890	450,000	1902	667,431		
1891	476,113	1903	721,446		

IMPORTS.

The value of the imports of grindstones increased in 1913 to $139,386, as compared with $131,080 in 1912. This is the greatest importation recorded during the last five years and exceeds that for 1906, which amounted to $134,136.

The imports for the last five years are given in the following table:

Value of pulpstones and grindstones imported and entered for consumption in the United States, 1909–1913.

1909	$99,153	1912	$131,080
1910	106,596	1913	139,386
1911	123,727		

CANADIAN PRODUCTION.[1]

The value of the production of grindstones in Canada in 1913[2] amounted to $43,900 as compared with $44,290 in 1912. In the following table is given the value of the Canadian production of grindstones during the last six years:

Value of production of grindstones in Canada, 1908–1913.

1908	$45,128	1911	$52,942
1909	50,944	1912	44,290
1910	47,196	1913	43,900

OILSTONES AND SCYTHESTONES.

PRODUCTION.

The production of oilstones (including hones and whetstones) and scythestones in the United States during 1913 amounted to $207,352 in value, a decrease of $24,866 as compared with the value for 1912. Oilstones were produced in Arkansas, Indiana, Ohio, and Kentucky, especially in Arkansas, which has led in the production for many years. New Hampshire led in the production of scythestones, but

[1] From reports of Canada Dept. Mines.
[2] Preliminary report on the mineral production of Canada during 1913: Canada Dept. Mines, 1914.

Vermont, Ohio, and Michigan also contributed important quotas. A description of the scythestone industry in New Hampshire was given in this report for 1909, and a description of Arkansas oilstones, oilstone deposits, and industry was included in this report for 1911. In the following table is given the value of oilstones (including whetstones) and scythestones produced in the United States since 1891:

Value of oilstones and scythestones produced in the United States, 1891–1913.

1891	$150,000	1899	$208,283	1907	[1] $264,188
1892	146,730	1900	174,087	1908	[1] 217,284
1893	135,173	1901	158,300	1909	[2] 214,019
1894	136,873	1902	221,762	1910	[1] 228,694
1895	155,881	1903	366,857	1911	[2] 214,991
1896	127,098	1904	188,985	1912	[2] 232,218
1897	149,970	1905	244,546	1913	[2] 207,352
1898	180,486	1906	268,070		

IMPORTS.

The following table shows the value of all kinds of hones, oilstones, and whetstones imported into the United States in the last five years:

Value of imports of hones, oilstones, and whetstones, 1909–1913.

1909	$68,018	1912	$45,398
1910	45,819	1913	40,222
1911	54,379		

CORUNDUM AND EMERY.

PRODUCTION.

The United States produced no corundum in 1913 and has produced none since 1906.

The domestic production of emery in 1913 appears to have come entirely from the region near Peekskill, in Westchester County, N. Y. The Survey received no report of production in 1913 from the mines in Chester, Hampden County, Mass., which have for many years produced an annually diminishing quantity. The returns from New York producers have been incomplete, and the entry in the following table for 1913 is an estimate, which is, however, believed to be a close approximation to the actual quantity produced. The value given in the table is merely an estimate of the cost of mining and preparing the material as shipped from the mines, based on reports made by some of the producers. The estimated domestic production for 1913 is 957 short tons, which is 35 tons, or about 3.5 per cent, less than the estimated output for 1912. The estimated value of the output for 1913 (cost of production) is $4,785, which is $1,867, or about 38 per cent, less than that of 1912.

In the following tables are given the quantity and estimated value of the corundum and emery produced in the United States from 1881 to 1906, and the quantity and estimated value of emery produced in the United States since 1906:

[1] Includes a quantity of "rubbing stone" quarried in Indiana.
[2] Includes a quantity of honestone quarried in Kentucky and "rubbing stone" quarried in Indiana.

Annual production of corundum and emery, 1881–1906, in short tons.

ABRASIVE GARNET.

PRODUCTION.

The production of abrasive garnet in the United States in 1913 amounted to 5,308 short tons, valued at $183,422. This was an increase of 361 tons, or 6.8 per cent, in quantity, and of $20,185, or 11 per cent, in value, as compared with the production for 1912. The industry was confined, as usual, to three States, New Hampshire, New York, and North Carolina. The following table gives the quantity and value of abrasive garnet produced in the United States since 1895:

Production of abrasive garnet, 1895–1913, in short tons.

Year.	Quantity.	Value.	Year.	Quantity.	Value.	Year.	Quantity.	Value.
1895	3,325	$95,050	1902	3,926	$132,820	1908	1,996	$64,620
1896	2,686	68,877	1903	3,950	132,500	1909	2,972	102,315
1897	2,554	80,853	1904	3,854	117,581	1910	3,814	113,574

1900	3,185	123,475	1907	7,058	211,680	1913	5,308	183,422
1901	4,444	158,100						

NOTES ON THE ABRASIVE GARNET INDUSTRY.

NEW YORK.[1]

The production of garnet for abrasive purposes is a well-established industry in the Adirondack region of New York. The quarries and mills are in the upper Hudson River valley, in Warren and Essex counties. North Creek, the terminus of the Adirondack branch of the Delaware & Hudson Railroad, is the principal point of shipment.

The garnets produced are almandite, the iron-alumina variety, and have a greater hardness, about 8 in the Mohs scale, than is ordinarily ascribed to garnet.[2] The colors of the garnets from the several deposits are different shades of red.

The quarry (Hooper's mine) and mills of the North River Garnet Co., owned by Richards & Hooper, are in Warren County, about 3¼ miles southwest of North River village, with which they are connected by good roads for motor truck. The quarry in 1913 was a large cut 200 by 100 feet and 100 feet deep at the back; it is near the summit of a considerable hill and in a banded feldspar-hornblende-garnet gneiss containing a little biotite. In a second opening, a little east of the large pit, the banding of the gneiss shows in the west wall, but eastward it becomes disturbed in attitude and obscure, and in places it disappears. There are in this opening several masses or bands of finer-grained gneiss containing, besides feldspar, hornblende and garnet, also magnetite and pyrite. Such rock is not quarried. The gneiss is a part of the pre-Cambrian Grenville series, which is extensively developed in this part of the Adirondack region.

[1] Recent articles on the New York garnet deposits by W. J. Miller have been published in Econ. Geology, vol. 7, pp. 493–501, 1912; New York State Mus. Bull. 164, pp. 95–103, 1913; and New York State Mus. Bull. 170, pp. 78–82, 1914.

[2] Prof. Charles Palache has tested garnets from North River, N. Y., and from Wilmot, N. H., and Spanish garnets, which are imported for abrasive purposes, and reports that their sharpest edges scratch topaz. (Private report on the garnet deposits of Wilmot, N. H., quoted by kind permission of Prof. Palache, A. D. Little & Co., and the United Mineral Co.)

Gneiss of the type quarried occupies many acres in the hill back of and above the mill site and affords a practically inexhaustible source of garnet. The rock is of medium to moderately coarse grain and is banded by segregation of the feldspar and the hornblende. Some bands are composed more or less wholly of one or the other mineral and some of various proportions of both. The garnets are for the most part small and range in size from very small to about 1 inch in diameter, with occasional larger individuals. The largest garnet seen was about 5 inches in diameter. All the garnets are rounded, but many have discernible dodecahedral form. They are scattered abundantly in most bands of the rock; sometimes they appear sparsely and again more abundantly in the purer feldspar bands; and they average probably about 7 or 8 per cent of the rock.

The rock is broken down by blasting and reduced with sledges when necessary, and is then trammed to and dumped on a grizzly of railroad iron which has 4-inch openings. It then passes through three jaw crushers and four sets of rolls. The undersize from each set is removed by shaking screens. All is crushed to one-fourth inch or less and sent to bins, from which are fed four sets of Hartz jigs especially modified for this work. From these machines the product goes through a series of 10 double Hooper vanning jigs especially designed for this work. Only the finest garnet from the last set of vanning jigs is saved. It is treated dry on Hooper pneumatic separators, which make very good separation. The concentrates from the pneumatic separator are mixed with those from the various vanning jigs and are dried over steam coils. They are then packed for shipping in sacks containing about 150 pounds. This mill sells only unsized product, wisely saving the cost of sizing, because there are among consumers of garnets no standards as to size of grain used.

The concentrates from this mill are very clean. They constitute from 5 to 6 per cent of the crude tonnage handled. There appears to be little garnet in the tailings.

H. H. Barton & Sons Co., of Philadelphia, operate the property known as the Rogers mine. The quarry is in Warren County, 4.3 miles south of North River village, near the summit of Gore Mountain. The quarry is opened about 1,000 feet in length and 50 to 100 or more feet in width along a ravine bottom. The rock is of problematic origin.[1] It is dark gray, medium grained, massive, granular, and porphyritic, without banding or schistosity, It consists of a ground mass composed essentially of hornblende and feldspars, in which are nodules of garnet and hornblende and some feldspar and biotite. These nodules form roughly spherical or ellipsoidal masses from 2 inches to 3 feet in diameter. They consist of a core of red garnet surrounded by a shell, one-half inch to several inches thick, of crystals of black hornblende. The garnet in each nodule is a single crystal individual with imperfect dodecahedral form. This form, however, is often very obscure. The garnets are divided into thin plates by a very unique parting or system of cracks, all approximately parallel to one plane. There is also a second less well developed parting inclined at nearly 90° to the first. In some places it was observed that the principal partings of many garnets of the same vicinity in the rock are approximately parallel. There is in all cases a horn-

[1] W. J. Miller (loc. cit.) calls the rock a gneiss and describes it as a block of a member of the Grenville series, which has been included in and severely metamorphosed by syenite.

blende rim around the garnets, but although generally these rims are composed entirely of black hornblende, there are some which have feldspar, green pyroxene, and biotite. The pyroxene is associated with the hornblende. The feldspar and biotite were noticed only next the garnet and usually in a distinct layer between it and the hornblende. These garnet hornblende nodules are colloquially called pockets. They are bunched here and there and to a limited degree are grouped according to size, but in some bunches of pockets there is progressive range in size. In most places the pockets are so close as to coalesce; in a few other places they are 5 feet or perhaps more apart, but it is only exceptionally that there is so great a distance between pockets.

The rock is weathered and softened to various depths, in places as much as 25 feet; both where there is little or no drift cover and also under 20 or 30 feet of till. The garnets are mined by open-cut work in rotten or decomposed rock. Very little work is done in hard rock, which is blasted and broken by sledges. From the rotten rock and the broken hard rock the garnets are cobbed out by hand, and the remaining rock is thrown to waste piles. Much garnet, particularly in the hard rock, is wasted. The garnets obtained by the quarrymen are collected by each in a bucket and carried to a wooden platform, where they are sacked for shipment in the crude state.

The Daniel Lynch garnet mines are 7 miles north-northeast of North Creek at Minerva, Essex County. There the country rock is a coarse feldspar-hornblende gneiss in which are included nonfoliated ellipsoidal rock masses containing the garnets and other minerals. These bodies range in size from small bunches to masses 60 feet wide and 100 feet long. Several old openings for garnet indicate that these bodies are along a narrow zone several hundred yards long. In places a coarse calcite aggregate 2 feet in thickness forms an outer layer of these bodies. Within this or in places on the periphery is a coarse feldspar(oligoclase)-pyroxene-titanite aggregate which has the texture and appearance of pegmatite. The pyroxene is a very dark green to black variety (hedenbergite). The titanite is in fine crystals as much as one-fourth inch in size. In some parts in one of the openings graphite flakes up to one-half inch in diameter are present with the feldspar and pyroxene, and in the same pit is a small mass of fine-grained pegmatite composed of oligoclase, quartz, a little microcline, and very little pyroxene.

In these rocks the plagioclase feldspar is all of the same species, and the pyroxenes are all alike. It is probable that they all represent various phases of the same intrusive (pegmatitic) rock. Tongues of the feldspar-hornblende gneiss penetrate the outer portions of garnet-bearing bodies. The interior and largest part of these ellipsoidal bodies is garnet rock composed of feldspar and garnet. This is in places composed largely of feldspar, in part sericitized, in which small garnets about 1 millimeter in diameter are abundantly studded. The feldspar content changes from place to place, so that with decreasing feldspar the garnet becomes more and more abundant, and here and there are patches of clean massive garnet several inches thick. There is complete gradation between the massive garnet and the garnet feldspar aggregate. Both are merchantable material, but the garnet feldspar aggregate requires more mechanical treatment for separation of the garnet.

Garnet has been quarried from a number of pits on the Lynch property, but recently operation has been confined to one or two of them. The material is blasted from shallow cuts and is hand cobbed. Since the Warren County Garnet Mills at Riparius began operations, garnet rock from the Lynch mines has been carted to that mill for treatment.

The Sanders Bros. garnet quarry is on the north side of Mill Creek about 1¾ miles south of Riparius, Warren County. When visited by the writer there was uncovered a band, not over 30 feet in exposed width, of garnet-pyroxene rock inclosed in fine-grained gneiss. In this band are garnet, calcite, and greenish-black pyroxene (hedenbergite) aggregates of from fine to coarsely granular texture. There are some bands or schlieren almost entirely made up of greenish-black pyroxene. There is a narrow band of marble on the strike of and a short distance south of the garnet body. The material quarried is for the most part a granular aggregate of garnet and black pyroxene (hedenbergite). The rock is blasted from a small open pit, hand sorted, and carted a short distance to the Warren County Garnet Mills' plant.

The Warren County Garnet Mills in 1913 contained two sets of crushing rolls, a shaking screen, a grading machine, and a pneumatic separating table. Crude rock was dumped on the floor of the crushing room and broken by sledges if necessary. The broken rock was fed to two sets of crushing rolls in tandem, from which it was elevated to a shaking screen with one-sixteenth inch openings. Oversize was returned to the rolls. Undersize passed to the hopper of a sizer capable of grading the crushed material into 24 sizes. Each size was then treated on the Sutton, Steele & Steele pneumatic separator which was working efficiently and making a very clean garnet concentrate.

Garnet mining has been carried on at other localities in Warren and Essex counties—at Oven Mountain, 4 miles south of North Creek; at the Rexford mine, 1⅓ miles a little east of south of North Creek; at the Parker mine, just southwest of Dagget Pond and 4½ miles northwest of Warrensburg; and about 1 mile west of the village of North River.

NEW HAMPSHIRE.

The United Mineral Co., Boston, Mass., is the only producer of garnet in New Hampshire. The quarry is near North Wilmot, in Merrimac County, 4½ miles from Converse station, on the Boston & Maine Railroad. Prof. Charles Palache and Messrs. A. D. Little & Co., who examined and reported on the quarry and mill, have, with the consent of the company, kindly permitted the Survey to publish the following notes taken from their reports.

The main deposit is exposed over an area about 200 by 240 feet. The garnet rock is a uniform mixture of garnet biotite quartz and albite, with minute amounts of minor constituents. In the richest rock, garnet constitutes two-thirds of the mass. By mill record 50 per cent of the quarry rock is saved in the concentrates; the garnet content is more than one-half. The garnet is an iron-aluminum species, almandite, with considerable manganese. It forms distinct crystals with an average diameter of three-eighths inch. The range in size is from minute dots to a maximum of three-fourths inch. The crystals are dodecahedrons and trapezohedrons with spherical habit. There is no evidence of foliated structure in the rock. The garnet rock is inclosed on all sides by a coarsely foliated porphyritic pre-Cambrian granite gneiss of igneous origin. The contacts are sharp and traverse the foliation of the gneiss variously.

The following notes on the mill are condensed from an article by E. S. Bardwell:[1] The rock is quarried and afterward broken by sledges into pieces convenient for feeding to the breaker. The rock is trammed a distance of about 600 feet to the rock house. Directly beneath the floor upon which the rock is dumped is a 6 by 10 inch Sturtevant jaw breaker, crushing to 1¼ inches. This breaker has a capacity of 6 tons an hour. The broken rock falls from the breaker directly into the tramway loading bin beneath.

The broken rock is delivered by way of the 1,200-foot aerial tram into a bin at the rear of the mill. The top of the bin is on a level with the third floor of the mill. The rock is delivered by gravity to the crushing department, and first enters a pair of Sturtevant balanced rolls, 26 by 15 inches, capable of crushing 6 tons an hour to ⅜-inch size. From these rolls the product is taken by a bucket elevator, to an American Process Co. drier. It is warmed to remove any superficial moisture and to promote screening.

The revolving cylinder of the drier projects into a reinforced-concrete dust chamber which extends through the side of the mill. The dust is discarded for the reason that it contains almost no garnet.

The second elevator delivers the sand to a No. 3 Newaygo separating screen. The screen cloth is 4-mesh, 14-wire, and is set on a slope of about 45°. The oversize (over 2 millimeters) goes by chute to a pair of Sturtevant balanced rolls, 26 by 15 inches, set to crush to 2 millimeters, the product going with the undersize to the separator bin, from which material under 2 millimeters is delivered to the separating department by a belt elevator. The crushing department is usually run about four hours a day, and during this time is capable of crushing enough rock to keep the separating department supplied during the entire 10-hour run.

The crushed material first passes through a No. 3 Newaygo separating screen. This screen is situated on the upper floor of the screening tower and has two sieves; the upper screen is 6-mesh, 16-wire, and the lower is 10-mesh, 20-wire. This screen makes two oversize products—that is, through 2 millimeters on 1.4 millimeters and through 1.4 millimeters on 0.75 millimeter. These products go by way of chutes to table bins on the third floor of the mill. The undersize of 0.75 millimeter goes to another Newaygo screen on the floor below. This separator has one sieve, 24-mesh, 29-wire. Two products are made, 0.36 to 0.75 millimeter and under 0.36. The 0.36 to 0.75 millimeter size goes to a third table bin, and the under 0.36 millimeter size goes to waste.

The material from 1.4 to 2 millimeters in diameter goes to a Sutton, Steele & Steele dry concentrating table. This table makes 390 thrusts per minute, has a capacity of about 3,000 pounds an hour, and requires approximately one-half horsepower. It delivers garnet through a spout to the sacking room in the basement of the mill, middlings to the second Newaygo screen, and tailings by screw conveyor

[1] Garnet milling in New Hampshire: Eng. and Min. Jour., June 17, 1911, pp. 1209-1210.

out of the mill. Air is supplied to the table by a No. 10 Green blower making 500 revolutions a minute and belted to the line shaft. The material from 0.75 to 1.4 millimeters in diameter from the first Newaygo and that from 0.36 to 0.75 millimeter in diameter from the second Newaygo is treated alternately on a second Sutton, Steele & Steele dry-concentrating table. This table makes 425 thrusts a minute, has a capacity of about 1,500 pounds an hour, and requires approximately one-half horsepower. The delivery of products is the same as from the first table. Air is furnished to this table by a No. 6 Green blower making 965 revolutions a minute.

The tailings from these tables are practically free from garnet, but contain about 25 per cent of biotite. A Wetherill magnetic separator has been provided to save this biotite, but so far nothing has been done with the product. The sacking room is in the basement of the mill. The garnet is shipped in canvas sacks, each containing 100 pounds. The company has a freight house at South Danbury, N. H., 3 miles distant, with capacity for storing 400 tons. Here the garnet is loaded directly into the cars.

NORTH CAROLINA.

The Blue Ridge Garnet Co. produced garnet at Shooting Creek, Clay County. The quarried rock is crushed and concentrated on Bartlett tables and then graded. It is reported that all the 1913 product was shipped abroad. Garnet mines near Speedwell and Willets, in Jackson County, were idle in 1913. At Willets the Great Ruby Mining Co. reported preparations for a large production in 1914.

PENNSYLVANIA.

The garnet mines near Chelsea and Chester, in Delaware County, have not been operated in recent years.

TRIPOLI AND DIATOMACEOUS EARTH.

The material called tripoli in the trade in the United States is a light, porous, and generally purely siliceous rock which has resulted from the leaching of calcareous material from very siliceous limestones or highly calcareous cherts. Tripoli was produced in 1913 in Georgia, Missouri, Illinois, Pennsylvania, and Tennessee. Deposits in Arkansas and Oklahoma are not yet commercially productive. Some of the Missouri tripoli is and always has been produced and used as an abrasive and for other purposes, but much of it is used in the manufacture of filters. The Illinois product is used as paint, wood filler, metal polish, in soaps, in cleansers, and for making glass and for facing foundry molds.

No attempt has been made to procure from producers of tripoli a definite statement of the exact proportion used as an abrasive, nor has any attempt been made to get at the production of rough tripoli blocks worked up into filter stones. Even if this output had been ascertained it would be impossible to value the product on a uniform basis and thus to obtain a reliable ratio between quantity and value, for the reason that the price of filter stones varies and is dependent not only on the size of the stones but also on the amount of work done on each stone.

Diatomaceous earth, called also infusorial earth and kieselguhr, is a light earthy material, which from some sources is loose and powdery and from others is more or less firmly coherent. It often resembles chalk or clay in its physical properties, but can be distinguished at once from chalk by the fact that it does not effervesce when treated with acids. It is generally white or gray in color, but may be brown or even black when mixed with much organic matter. Diatomaceous earth is made up of tests of minute aquatic plants composed of a variety of opal, which, chemically, is hydrous silica. Owing to its porosity it has great absorptive powers and high insulating efficiency. The hardness, the minute size, and the shape of its grains make it an excellent metal-polishing agent.

Heretofore diatomaceous or infusorial earth has been largely used as an abrasive in the form of polishing powders and scouring soaps, but of late its uses have been considerably extended. Because of its porous nature it has been used in the manufacture of dynamite as a holder of nitroglycerine, but so far as known not in the United States. Its porosity also renders it a nonconductor of heat, and this quality in connection with its lightness has extended its use as an insulating packing material for safes, steam pipes, and boilers, and as a fireproof building material. In this country a new use of the material is reported in the manufacture of records for talking machines. For this purpose it is boiled with shellac, and the resulting product has the necessary hardness to give good results.

In Europe, especially in Germany, infusorial earth has lately found extended application. It has been used in preparing artificial fertilizers, especially in the absorption of liquid manures; in the manufacture of water glass, of various cements, of glazing for tiles, of artificial stone, of ultramarine and various pigments, of aniline and alizarine colors, of paper, sealing wax, fireworks, gutta-percha objects, Swedish matches, solidified bromine, scouring powders, papier-mâché, and many other articles. There is a large and steadily growing demand for it.

Preliminary preparation of the crude material involves drying and roasting to destroy organic matter, if that is present.

The following tables show the production of tripoli and of diatomaceous earth by States in 1913, and the value of the combined annual tripoli and diatomaceous earth output since 1880:

Production of tripoli in the United States in 1913, by States, in short tons.

State.	Quantity.	Value.
Illinois	12,994	$128,892
Missouri	7,529	83,995
Pennsylvania, Tennessee, and Georgia	274	3,694
Total	20,797	216,581

Production of diatomaceous earth in the United States in 1913, by States, in short tons.

State.	Quantity.	Value.
California and Nevada	5,785	$51,556
Connecticut, New York, and Washington	378	9,565
Maryland, Virginia, and Florida	423	8,119
Total	6,586	69,240

Production of diatomaceous earth and tripoli, 1880–1913, in short tons.

Year.	Quantity.	Value.	Year.	Quantity.	Value.	Year.	Quantity.	Value.
1880	1,833	$45,660	1892	....	$43,655	1904	6,274	$44,164
1881	1,000	10,000	1893	....	22,582	1905	10,977	64,037

IMPORTS.

The value of the imports of rottenstone and of tripoli for the last five years has been as follows:

Value of tripoli, diatomaceous earth, and rottenstone imported for consumption into the United States, 1909–1913.

1909	$24,024	1912	$24,253
1910	56,657	1913	28,696
1911	35,665		

NOTES ON THE TRIPOLI AND DIATOMACEOUS EARTH INDUSTRIES.

Illinois.—In Illinois six producers in Union County and one in Alexander County reported production in 1913. No new deposits were developed, and a number of mines formerly worked were idle during the year.

Missouri.—Five operators reported production from near Seneca and Racine, Newton County, Mo., in 1913. There were no new developments.

Oklahoma.—One company, which began development on a tripoli deposit near Peoria, Okla., suspended operations because of financial difficulty; another company reported preparations for production.

Tennessee.—A tripoli deposit was discovered near Butler, Johnson County, Tenn., which was opened and began producing in 1913. The following notes are taken from a report by L. C. Glenn: [1]

The tripoli is interbedded with the shales and thin limestones that compose the Watauga shale (Cambrian), the beds having a dip of 30 to 50 degrees. Six belts of tripoli have been found within a comparatively small area. One of these, which has been explored sufficiently to determine well its thickness and extent, shows a very large quantity of easily available tripoli.

The tripoli is a bright-yellow color, of almost uniform shade, is porous, and at the surface is mostly pulverulent. The soft material has a characteristic dry and somewhat harsh feel. The lumps that cohere are porous, light in weight, and rub to pieces readily under the pressure of the fingers, though they offer some resistance to such rubbing away. Pieces break with the brittleness of a piece of chalk. Either wet or dry, it is easily cut with a pick or shovel, and would be readily sawed or bored if pieces large enough to work in this way should be obtained. The material will grind to a powder very readily.

The texture or grain is very nearly uniform throughout the entire 38½ feet of the main bed. At no place was any grit found in it. The microscopic examination showed the

[1] Resources of Tennessee, vol. 4, No. 1, pp. 29–35, 1914.

average diameter of the particles to be slightly less in the harder or more coherent parts than in the softer or more pulverulent parts. In all parts of the deposit the material as found in nature consists of angular to subangular particles that, if mere dust specks—of which there are many—be excluded, range in diameter from 0.0015 millimeter to 0.1 millimeter. The bulk of the material ranges from 0.01 to 0.06 millimeter in size, though there is a good portion that is 0.005 millimeter or less in diameter, and occasional particles 0.1 to 0.16 millimeter are also found. The particles large enough for identification are nearly all of vein quartz, and are coated with a brownish-yellow film of limonite that is readily removed by hydrochloric acid, when the quartz is seen to be clear and glassy, with now and then a particle of amethyst. Besides the quartz there are occasional particles of garnet, limonite, and magnesite. Feldspar particles large enough for identification were rare, although the analysis raises the presumption that a part of the very finely divided material, too small for identification by microscopic methods, is probably arkosic feldspar. Besides this, much of the very finely divided material is kaolinite.

From the above description it is apparent that the tripoli of Butler, Tenn., will make excellent abrasive material. "The crude tripoli from Butler may after grinding be readily separated by screening or by air or water flotation into a number of grades ranging from the finest jeweler's material up to the coarsest grades used in the rougher scouring processes, so that a variety of grades could be marketed each suited for some special purpose."[1] Yet, without detracting from its excellence as an abrasive, it must be pointed out that from this description and as well from the analysis and geologic relations described by Professor Glenn it is evident that the Butler tripoli is different in mineral constitution from the tripoli of Missouri and Illinois. Unlike them the Tennessee material is mineralogically and chemically complex and would appear to have been derived from an originally argillaceous rock, or, at any rate, if the rock were calcareous rock, it contained a far larger amount of clastic material than the Illinois and Missouri rock. These differences will perhaps prohibit the use of Butler tripoli for some of the purposes for which the Illinois and Missouri product are consumed, but they may also adapt that material for other uses.

There may be some doubt about the propriety of calling this material tripoli, but it is here so called primarily because it is a "rottenstone," as are the other tripolis, and because it is very siliceous.

Pennsylvania.—A small production of "rottenstone" was reported from Lycoming County, Pa., and is included with the tripoli statistics.

Georgia.—As in past years, one company produced tripoli near Spring Place in Murray County, Ga.

California.—In California the diatomaceous earth industry was given new impetus in 1913 by the extensive operations of a new company, the Kieselguhr Co. of America. This company's method of quarrying the diatomaceous earth at Lompoc,[2] Santa Barbara County, and of preparing finished products, as well as the general properties and uses of diatomaceous earth were described by Percy A. Boeck in Chemical and Metallurgical Engineering, February, 1914. The following notes are taken from that paper:

The mining or quarrying of this material is carried on by means of open-face workings where the kieselguhr is taken up in huge blocks. This operation is made easier where transverse joints occur in the strata, due to local folding. Where these joints do not

[1] Glenn, L. C., op. cit., p. 34.

[2] These deposits are briefly described by Ralph Arnold and Robert Anderson, Diatomaceous deposits of northern Santa Barbara County, Cal.: U. S. Geol. Survey Bull. 315, pp. 438-447, 1907.

occur it becomes necessary to loosen the kieselguhr slightly by means of powder before the blocks can be removed from the quarry face.

Owing to the large amount of absorbed surface water in the kieselguhr it is necessary that the material be split into convenient blocks for piling and drying. The amount of absorbed water is about 25 to 45 per cent by weight, and, owing to the winds and dryness of the atmosphere of southern California, this amount is reduced to about 5 per cent by natural air drying within 40 to 50 days.

After drying, the kieselguhr is hauled by means of motor truck to the reduction works where it is reduced and transferred by means of a pneumatic system to the different warehouses. It is likewise drawn to the finishing mill from the warehouse by this means, and ground and blown into the several grades used commercially. When blocks are required the material is transported in its natural state direct from the quarry, sawed into the sizes required for building purposes, and dried before shipment. Waste material too fine to be dried is utilized in the making of brick, tile, and other refractory materials of light weight.

Besides marketing diatomaceous earth for abrasive purposes, this company puts out two grades, branded Sil-O-Cel, which is for insulation, and Filter-Cel, for filtration. The company plans also to market various kinds of insulating and refractory brick.

PUMICE.

The pumice produced in the United States in 1913 amounted to 24,563 short tons, valued at $55,408. This was a decrease of 2,583 tons in quantity and of $31,279 in value as compared with 1912.

The statistics of pumice given in the table are those of pumice used for abrasive purposes solely. The pumice used for construction—and it is known that some of the domestic article has been so used—is not included. The material has come from six States: California, from Inyo County; Kansas, from Morton and Phillips counties; Nebraska, from Furnas, Lincoln, and Harlan counties; Idaho, from Cassia and Power counties; Dakota, from Custer County; and Utah, from Millard County. In 1913 the production came from Kansas, Nebraska, and Utah.

The domestic product is almost wholly a finely comminuted material, volcanic dust or "ash." The imported material, which comes from the Lipari Islands, a group of volcanic islands north of Sicily in the Mediterranean Sea, is a massive, very finely pumiceous or vesicular rock. Very little pumice of this type has been produced in the United States.

The production of pumice in the United States during the last five years is given in the following table. The figures for domestic production and for importation are given below:

Production of pumice in the United States, 1909–1913, in short tons.

Years.	Quantity.	Value.	Price per ton.
1909	15,103	$33,439	$2.21
1910	23,271	94,943	4.08
1911	21,689	88,399	4.08
1912	27,146	86,687	3.19
1913	24,563	55,408	2.26

Value of pumice imported for consumption into the United States, 1909–1913.

1909	$100,997	1912	$74,478
1910	104,425	1913	93,408
1911	118,977		

ARTIFICIAL ABRASIVES.

The artificial abrasives include carborundum, which is a carbide of silicon, alundum, which is crystalline aluminum oxide and crushed steel. Other abrasives, or rather abrasives with other names, which have appeared on the market during the last few years, are forms of the abrasives named adapted to special uses. Such, for example, are aloxite and samite, forms of carborundum, and carborundum fire sand. Boro-Carbone is similar to alundum. The abrasive known as "corubin," so far as is known, is not made in this country, but is an European product. Alundum, whose manufacture has been detailed in this chapter in previous years, is finding extended use in the refractory as well as in the abrasive industry, and carborundum is used in certain metallurgical practice.

The production of artificial abrasives since 1906 is given in the following table:

Production of artificial abrasives in the United States, 1906–1913, in pounds.

Year.	Quantity.	Value.
1906	11,774,300	$777,081
1907	14,632,000	1,027,246
1908	8,698,000	626,340
1909	20,468,000	1,365,820
1910	23,027,000	1,604,030
1911	21,292,000	1,493,040
1912	29,002,000	1,747,120
1913	33,489,000	2,017,458

PHOSPHATE ROCK.

By W. C. PHALEN.

PRODUCTION.

The marketed production of phosphate rock in the United States in 1913 was 3,111,221 long tons, valued at $11,796,231. Compared with the production of 1912, which was 2,973,332 long tons, valued at $11,675,774, there was an increased output of 137,889 long tons, or 5 per cent, and an increased value of $120,457, or 1 per cent. In this report the term production means phosphate rock actually sold, not the quantity mined.

The marketed production of the various kinds of phosphate rock, by States, in 1912 and 1913 was as follows:

Production of phosphate rock in the United States, 1912–13, based on the quantity marketed, by States, in long tons.

State.	1912			1913		
	Quantity.	Value.	Average price per ton.	Quantity.	Value.	Average price per ton.

1907	2,265,343	10,653,558
1908	2,386,138	11,399,124
1909	2,338,264	10,796,456
1910	2,654,988	10,917,000
1911	3,053,279	11,900,693
1912	2,973,332	11,675,774
1913	3,111,221	11,796,231
Total	45,725,363	185,801,280

The more important facts brought out by the tables given above are as follows: The States producing phosphate rock in the eastern part of the United States were, as usual, Florida, Tennessee, and South Carolina. No production was reported from either Kentucky or Arkansas. Of the western group of phosphate States, Idaho and Wyoming reported a production. No phosphate came from Utah during the year.

The phosphate rock produced in Florida is of two classes, hard rock and land pebble. Taken as a whole the phosphate rock produced in this State during 1913 showed a substantial gain. This gain was due to the notably increased production of land pebble (with which is included a small quantity of river pebble sold but not mined) which more than offset the slightly decreased production of hard rock. The average prices per ton of Florida rock declined slightly.

In Tennessee the quantity of both brown and blue rock marketed increased as compared with that of 1912. The average price in Tennessee showed a slight advance.

Sales of South Carolina phosphate declined in quantity and value, but increased in average price per ton as compared with sales in 1912.

The phosphate rock marketed from the Western States declined greatly as compared with 1912, amounting to only 44 per cent of what it was that year. The production of the Western States amounted to only one-fifth of 1 per cent of that of the entire country.

The total quantity of phosphate rock mined in 1913 was 3,152,208 long tons, as compared with 3,190,587 long tons in 1912, a decrease amounting to 1.2 per cent. In Florida, however, there was an increase in the quantity of phosphate rock mined amounting to 1.6 per cent, due to the much larger quantity of land pebble mined than in 1912. The hard rock mined decreased in 1913 as compared with 1912. In Arkansas no rock was reported mined in 1913. In South Carolina the quantity mined diminished more than 24 per cent. In Tennessee the quantity mined decreased approximately 8 per cent. In the Western States, where the quantity mined is small to begin with, the rock mined decreased 49 per cent.

Stocks on hand at the close of 1913 showed a gain of 6 per cent in the Florida field and of nearly 5 per cent in the Tennessee field. In South Carolina stocks diminished by about 9 per cent.

PRODUCTION BY STATES.

FLORIDA.

In 1913 Florida, the leading State in the phosphate-rock industry, marketed 2,545,276 long tons of phosphate rock, valued at $9,563,084, or 82 per cent of the entire production of the United States. As compared with the marketed production of 1912, Florida in 1913 gained 138,377 tons, or 6 per cent, in quantity and $101,787, or 1 per cent, in value. The quantity sold for the year was the greatest recorded for the State.

In the figures given in the tables the phosphate produced is classified as hard rock, land pebble, and river pebble. There was no river pebble mined in the State in 1913, but some was sold from De Soto County. These sales are included with land pebble, to avoid divulging confidential information. There was a decrease of nearly 1 per cent in the quantity of hard rock sold. There was a substantial increase in the production of land pebble, the relatively small quantity of river pebble included with the land pebble not affecting the general statements made with reference to the latter.

As will be observed from the preceding table, the average price of hard rock decreased 57 cents per ton; that of land pebble, 2 cents per ton. The average price for the State was less by 17 cents per ton than it was in 1912.

The hard rock marketed came from Alachua, Citrus, Columbia, Hernando, and Marion counties; the land pebble from Polk and Hillsboro counties. The river pebble was sold from De Soto County.

The following table shows the quantity and value based on marketed output of each variety of phosphate rock produced in Florida from 1909 to 1913, inclusive:

Phosphate rock marketed in Florida, 1909–1913, classified by grades, in long tons.

Year.	Hard rock.		Land pebble.		River pebble.		Total.	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
1909	513,585	$4,026,333	1,266,117	$4,514,968			1,779,702	$8,541,301
1910	438,347	3,051,827	1,629,160	5,595,947			2,067,507	8,647,774
1911	443,511	2,761,449	a1,992,737	6,712,189	(b)	(b)	2,436,248	9,473,638

a Includes a small quantity of river pebble. b Included in land pebble.

TENNESSEE.

Tennessee furnished approximately 14.5 per cent of the phosphate rock marketed in the United States in 1913. Tennessee rock is classified as brown, blue, and white. The brown rock in 1913 came from Giles, Hickman, and Maury counties, the blue rock chiefly from

Lewis and Maury counties. No white rock was mined during the year.

The total production of the State was 451,559 long tons, valued at $1,774,392, a gain in quantity of 28,228 tons, or 7 per cent, and in value of $133,916, or 8.2 per cent, as compared with 1912. The average price per ton of Tennessee phosphate rock increased 5 cents in 1913, as compared with 1912.

The following table shows the tonnage and value of each grade of Tennessee phosphate rock marketed from 1909 to 1913, inclusive:

Phosphate rock marketed in Tennessee, 1909–1913, classified by grades, in long tons.

Year.	Brown rock.		Blue rock.		White rock.		Total.	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
1909	274,410	$1,035,364	66,705	$275,165			341,115	$1,310,529
1910	329,382	1,262,279	[a] 68,806	241,071			398,188	1,503,350
1911	[b] 365,068	1,450,063	[a] 72,302	263,954			437,370	1,714,017
1912	359,692	1,420,726	[a] 63,639	219,750			423,331	1,640,476
1913	[c] 451,559	1,774,392	(d)	(d)			451,559	1,774,392

[a] Includes a small quantity of hard rock from Arkansas.
[b] Includes a small quantity from Kentucky.
[c] Includes blue rock.
[d] Included under brown rock.

SOUTH CAROLINA.

The production of phosphate rock in South Carolina in 1913 was 109,333 tong tons, valued at $440,588. This was a decrease of 22,157 long tons in quantity, or 17 per cent, and of $84,172 in value, or 16 per cent, compared with 1912. Only land rock was mined and marketed, as there has been no production of river rock during the last few years. The price of the rock per ton was 4 cents greater than in 1912. The output of the State constituted approximately 3.5 per cent of that of the country in 1913.

The following table shows the quantity and value of phosphate rock marketed in South Carolina from 1909 to 1913, inclusive:

Phosphate rock marketed in South Carolina, 1909–1913, classified by grades, in long tons.

Year.	Land rock.		River rock.		Total.	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
1909	201,254	$888,611	6,700	$21,975	207,954	$910,586
1910	[a] 179,659	733,057	(b)	(b)	179,659	733,057
1911	169,156	673,156			169,156	673,156
1912	131,490	524,760			131,490	524,760
1913	109,333	440,588			109,333	440,588

[a] Includes a small quantity of river rock.
[b] Included in land rock.

WESTERN STATES.

The production of phosphate rock in Idaho and Wyoming in 1913 was only 5,053 long tons, valued at $18,167, as compared with 11,612 tons, valued at $49,241, in 1912, a decrease of 56 per cent. This production constitutes only one-fifth of 1 per cent of that of the entire country.

The average price of western phosphate rock was $3.60 per ton.

IMPORTS OF FERTILIZER MATERIALS.

The fertilizer materials imported into the United States in 1913 included a considerable diversity of substances, as will be seen from the following table, which gives figures for the last five years:

Fertilizers imported and entered for consumption in the United States, 1909–1913, in long tons.

Product.	1909		1910		1911		1912		1913

[a] Not separately classified. [b] From August 5 to December 31.

This table, strictly speaking, does not include all the material imported into the United States which goes into the fertilizer manufactured and sold in this country. To it should be added those potash salts, listed as such in the import tables of the Bureau of Foreign and Domestic Commerce, which enter largely into manufactured fertilizer. These potash salts are the chloride and the sulphate. Again, considerable imported sodium nitrate (Chile saltpeter) goes into the fertilizer industry. A large part of the sodium nitrate imported, however, is converted into nitric acid and potassium nitrate, the latter being used in the manufacture of gunpowder and other explosives, matches, pyrotechnics, in assaying and analytical operations, for curing meats, etc. The magnitude of the importation of this saline is, however, very significant. Sodium nitrate, together with potash salts, are commodities for the supply of which the United States is entirely dependent on foreign countries.

In the following table are shown the imports for consumption of materials which enter largely into the domestic fertilizer industry, limited as indicated in the statements above:

Imports for consumption of materials entering largely into the fertilizer industry in the United States for the years 1911–1913, in long tons.

	1911		1912		1913	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
Fertilizers	1,029,375	$10,762,472	999,338	$8,893,090	955,436	$10,819,253
Potassium chloride	226,148	7,651,693	215,415	7,229,121	212,170	7,075,745
Potassium sulphate	54,335	2,240,631	43,856	1,783,846	39,597	1,677,429
Sodium nitrate	544,532	16,814,268	486,779	16,544,511	612,861	21,630,811
Total	1,854,390	37,469,064	1,745,388	34,450,568	1,820,064	41,203,238

Adding the production of domestic phosphate rock to the imports of fertilizer an approximate idea at least will be gained of the quantity and value of the chief imported raw materials and of the domestic phosphate rock entering as essential constituents into our manufactured fertilizers. It must not be understood that the following table includes all the materials entering into manufactured fertilizer, as this is not the case. There are included in it chiefly the mineral ingredients which in most cases have gone through preliminary processes of purification and concentration. Even this statement has exceptions. For example, calcium cyanamid is a manufactured product and other substances listed in the table of imported fertilizers are of organic origin or are by-products in the manufacture of other substances. The omissions include also such organic material as fish scrap, dried blood, tankage, etc., and also ammonium sulphate. The table follows:

Materials entering largely into the fertilizer industry in the United States for the years 1911–1913, in long tons.

	1911		1912		1913	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
Imports: [a]						
Fertilizers	1,029,375	$10,762,472	999,338	$8,893,090	955,436	$10,819,253
Potassium chloride	226,148	7,651,693	215,415	7,229,121	212,170	7,075,745
Potassium sulphate	54,335	2,240,631	43,856	1,783,846	39,597	1,677,429
Sodium nitrate	544,532	16,814,268	486,779	16,544,511	612,861	21,630,811
Domestic phosphate rock	3,053,279	11,900,693	2,973,332	11,675,774	3,111,221	11,796,231
Total	4,907,669	49,369,757	4,718,720	46,126,342	4,931,285	52,999,469

[a] Imports are for consumption.

EXPORTS.

During 1913 there were exported 1,366,508 long tons of phosphate rock, valued at $9,996,580. As compared with 1912 this was an increase of 159,988 tons in quantity and of $1,000,124 in value.

The great bulk of the phosphate exported from the United States is from the Florida field. By reference to a preceding page of this report it will be observed that the production of Florida in 1913 was

2,545,276 long tons, valued at $9,563,084, whereas the exports which amounted to only 1,366,508 long tons were valued at $9,996,580, or $433,496 more. There are certain reasons for this apparent lack of correspondence in values.

From the figures tabulated for the Florida production it is evident that land pebble or the lower-grade Florida rock largely predominates and that the total value of the production is consequently proportionately lowered. The proportion of hard rock in the exported material is much greater than in the ordinary production, and this proportion, according to information published by the State geologist of Florida, amounted in 1912 to 39.12 per cent (and there is no apparent reason at the present time to believe that the proportion materially changed in 1913). According to Survey figures the hard-rock production constituted 20.50 per cent of the total Florida production in 1912 and 19.24 per cent in 1913.

The Survey does not collect figures of exported phosphate rock, but accepts those compiled by the Bureau of Foreign and Domestic Commerce. In the figures published by that bureau the grades of rock exported are not shown separately, nor are the sources of such rock given. The figures of exportation for 1913 include rock shipped from Tennessee and possibly from other localities of production. As the value of the exports represents "value at the time of exportation in the ports of the United States whence exported," it is assumed that the declared value at the port of shipment includes freight costs from mine to seaboard.

In the light of these facts—that is, the addition of freight charges and the large proportion of high-grade and consequently more valuable rock present in the exports as compared with the ordinary production—the apparent lack of correspondence in valuation is explained.

PRODUCTION IN PRINCIPAL COUNTRIES.

The production of phosphate rock in the principal producing countries of the world for the years 1910 to 1912, inclusive, was as follows:

Production of phosphate rock in principal producing countries, 1910–1912, in metric tons.

Country.	1910		1911		1912

NOTES ON THE DOMESTIC PHOSPHATE INDUSTRY.

THE SOUTHERN FIELDS.

The States of Florida, Tennessee, and South Carolina have for many years been the main source of phosphate rock in the United States. The output of Florida, the leading State in phosphate-rock production, has about reached its maximum, particularly so far as the hard-rock industry is concerned. The land-pebble industry continues to show a vigorous growth.

In Tennessee the brown-rock deposits, which several years ago were given but a brief future existence, promise to yield as much or more phosphate than has already been extracted from them, as they are now worked on a large scale with modern machinery and under modern mining methods. Pioneer methods are, however, still employed in some parts of the brown-rock phosphate regions and are attended by a great waste of good material. With the passing of the brown and blue phosphate fields into the control of the larger fertilizer corporations, which practice modern mining methods and have installed expensive plants to treat the mined rock, a gradual change has taken place and the life of the fields is being thereby prolonged.

The South Carolina field was the first to be exploited on a commercial basis. Though mining has fallen off in this field, it is quite likely that much rock remains for future use. As the most readily accessible material has been removed, the remaining rock will be correspondingly expensive to mine. The product, moreover, being of medium grade, can not compete with higher-grade rock in the manufacture of superphosphate. Hardly any rock is being exported from this field at the present time.

THE WESTERN FIELDS.

The new western phosphate field was discovered in 1906, and although for economic reasons it has not yet produced on a large scale, it is quite probable that the main production of the future will come from the West, where the principal deposits are located on the public domain. Some of the economic reasons that retard the development of the western phosphate fields are comparative newness, lack of transportation facilities, high freight rates, and remoteness from centers of consumption.

Since the discovery of the western fields systematic investigation has been prosecuted by the Survey, and the results have been published in part. This work has resulted in the discovery of new and important deposits, and its systematic conduct has greatly added to the known extent of the deposits.

PHOSPHATE RESERVES.

Lands remaining in Government ownership that are known to contain valuable phosphate deposits and those that are believed to contain such deposits have been withdrawn from entry temporarily. These reserves are located in Florida, Idaho, Utah, Wyoming, and Montana. The work of surveying the western phosphate lands is still going on, and from the following table will be seen the extent of the territory covered in these preliminary surveys.

Approximate area of phosphate lands, in square miles.

Year.	Reconnaissance surveys.	Detail surveys.	Total.	Withdrawn.	Restored.
1908				7,000	75
1909	1,000	800	1,800	600	3,600
1910	1,400	500	1,900	65	90
1911	1,200	800	2,000	55	237
1912	400	400	800	1,890	495
1913	800	1,500	2,300	360	1,020
Total	4,800	4,000	8,800	9,970	5,517

During the progress of the classification of phosphate lands to date, as a result of presidential orders 2,870,671 acres of land were included in the phosphate reserves January 1, 1914. The phosphate land withdrawn, restored, and outstanding at the end of 1913 is shown in the following table:[1]

Phosphate land withdrawn, restored, and outstanding on Jan. 1, 1914.

State.	Total withdrawals.	Restorations.	Outstanding withdrawals.
Florida	122,656	2,279	120,377
Idaho	2,300,341	1,299,065	1,001,276
Montana	293,378	134,541	158,837
Utah	581,039	544,846	36,193
Wyoming	3,111,362	1,557,374	1,553,988
Total	6,408,776	3,538,105	2,870,671

THE PHOSPHATE INDUSTRY IN THE SOUTHERN STATES.

FLORIDA DEPOSITS.

Location.—The Florida phosphate deposits are the most extensively developed in the United States. They comprise three classes—hard rock, land pebble, and river pebble. The land-pebble industry is the most important at present. The hard-rock industry ranks next. It suffers from competition with the land-pebble industry for reasons stated below, and declined in 1913 as compared with 1912. No river pebble was mined in 1913, but a small quantity was sold from stock on hand.

The area of hard-rock phosphate deposits extends as a narrow strip along the western part of the Florida peninsula from Suwanee and Columbia counties on the north to Citrus and Hernando counties on the south—a distance of approximately 100 miles. The land-pebble area is located farther south in Polk and Hillsboro counties.

Hard rock.—The hard-rock phosphate occurs in a soft matrix of phosphate sands, clays, and other material. The bowlder deposits occur in the form of irregularly sized pockets—the bowlders themselves varying in size from a few inches up to several feet.

[1] For a complete discussion of the classification of the public lands underlain not only by phosphate rock but by coal, oil, gas, salines, and other mineral deposits the reader is urged to secure a copy of Bulletin 537 of the Survey. Copies of this bulletin can be obtained, free of charge, by addressing the Director of the U. S. Geological Survey, Washington, D. C.

The phosphate content of this class of deposits ranges from less than 10 to more than 30 per cent of the mass, the marketable product being not more than 15 per cent of the total mined material. The rock itself runs as high as 85 per cent in tricalcium phosphate $Ca_3(PO_4)_2$. Practically all the rock mined is shipped abroad and sold on a guaranty of 77 per cent tricalcium phosphate.

Land pebble.—The land-pebble deposits are much more regular than the hard rock and occur in beds of varying thickness. For this reason active mining can be carried on cheaply. Moreover, improvements in mining and handling have made it possible to procure relatively low-grade rock cheaply. These reasons have contributed to the present great activity in the land-pebble industry. The phosphate content of the marketed land pebble usually ranges from 60 to 75 per cent tricalcium phosphate.

METHODS OF MINING.

The methods of mining the two main classes of phosphate rock in Florida differ considerably. In working the hard-rock deposits, the material is either dug out or dredged; in the pebble-phosphate field, hydraulic mining is employed. The details connected with these and the subsequent operations are outlined in the report for 1912 and consequently will not be repeated here.

TENNESSEE PHOSPHATE DEPOSITS.

The phosphate deposits of Tennessee are located in the central part of the State, the centers of production in 1913 being in Hickman, Maury, Giles, and Lewis counties. The output comprises brown and blue rock entirely—the white deposits of Perry and Decatur counties not having been worked during the year.

BROWN-ROCK PHOSPHATE.

Brown-rock phosphate, so called in contrast with the bluish-black rock, is variable in character, depending on the formation from which it has been derived. It occurs in plates of varying thickness and also in the form of a porous material which disintegrates to a phosphate sand. The two forms are often associated.

The beds occur in two distinct forms, known as collar and blanket deposits—the first named occurring where the horizontal phosphatic limestone bed outcrops on the slope of a steep hill. The blanket deposits, as the name implies, occur in broad areas lying near the surface. In the Mount Pleasant region in Maury County, about 10 miles southwest of Columbia, the county seat; at the Century mines of the Federal Chemical Co., 8 miles west of Columbia, near Wales, Giles County; and on lower Swan Creek the conditions have been favorable for the formation of such deposits. From their secondary mode of origin, they are of irregular thickness, and scattered through them are chimneys, bowlders, or horses of the original phosphatic limestone. The brown rock is sold under guaranty of 70 to 80 per cent tricalcium phosphate.

BLUE-ROCK PHOSPHATE.

Important deposits of blue-rock phosphate occur along Leatherwood Creek in the western part of Maury County; to the south and east of Centerville, and on both sides of Swan Creek, Hickman County; and in the eastern part of Lewis County. Deposits are also known in Perry and Wayne counties.

From its mode of origin as a sedimentary rock, the blue rock was mixed with clay, sand, pebbles, and gravel from various sources. Thus all stages occur between sandstone and shale at one end of the series and the pure blue phosphate rock at the other. In thickness the phosphate stratum varies from a few inches up to 4 feet rarely, and more often to only 2 or 3 feet. The content in calcium phosphate ranges from 30 to 85 per cent, but rock of the latter content does not occur in quantity.

METHODS OF HANDLING.

Brown rock.—In the process of mining brown rock the overburden is first removed by scrapers or steam shovels, but if heavy it may be removed by a drag line excavator. Mining is done in open pits with steam shovel loading into side-dump cars. In these cars the ore is removed to the washers, where, after first being crushed, it is dumped into sets of log washers. From the second set of log washers it goes to a rinsing screen with spray pipe extending through its center. The oversize is then carefully picked to remove limestone, flint, and mud balls. The plate rock is then ready for drying. The sand phosphate undergoes different treatment, the details of which were outlined in this report for 1912. Drying is accomplished by piling on wood in the open and setting the wood on fire. The more modern way is to dry in rotary kilns.

Blue rock.—Blue rock is a tough granular rock resembling limestone. It is not amenable to washing for the removal of impurities; hence the operations connected with its preparation for market are confined to mining, crushing, drying, screening, and stocking.

Blue-rock mining is conducted by first stripping around the face of the hill. This is accomplished by blasting and stripping with steam shovels. The subsequent operations are those generally involved in mining any flat-lying bed where the overburden is too thick to remove. The room and pillar method of mining is employed. Tunnels are run from the surface, and from these tunnels rooms 25 feet wide are turned at right angles and at regular intervals, leaving pillars about the same width. These rooms may be run any distance, and when work is complete the pillars are drawn, allowing the roof to cave. The roof as a rule forms an excellent support and requires no considerable timbering to prevent falls.

The rock is cut by drills and then loosened by blasting. It is then broken up by picks. The crushed material is next loaded on tram cars and hauled to the mouth of the adit and then to the drying and crushing plant, at which it is prepared for shipment. Washing is not necessary, as it is for brown rock, and the ore is fed from the tram cars to the crusher, where it is broken into fragments an inch and a half in diameter. From the crusher it goes to a rotary kiln drier. The rock contains a low percentage of moisture and some producers do not consider drying necessary. The drying tends to increase the quantity of bone phosphate, however, owing to the presence of organic matter and carbonate of lime, which are removed during the process.

SOUTH CAROLINA PHOSPHATE ROCK.[1]

The phosphate-rock deposits of South Carolina are confined to a belt along the coast, extending inland as much as 20 miles and running from a point about 20 miles beyond Charleston on the north to Beaufort on the south. The most important deposits are situated between the mouth of Broad River and a point near the source of Wando River. The rock occurs in two forms, as land rock and as river rock. The average composition of the South Carolina rock, as compiled by C. U. Shepard[2] on the basis of many hundred analyses, shows that the phosphoric acid present is equivalent to 55 to 61 per cent calcium phosphate.

Phosphate-rock mining in South Carolina began in 1867. Until about 1885 its production constituted more than 95 per cent of the phosphate marketed in the United States. With the advent of Florida and Tennessee into the phosphate industry, the South Carolina production diminished, and in 1913 its marketed production was only 3.5 per cent of the total for the United States. The table of production for the State on a preceding page shows a steady decrease during the last four years, the output now being virtually what it was between 1875 and 1880. No river rock has been mined since 1910. Land mining is confined chiefly to the Ashley district, but at the end of 1913 only 1 dredge was operating on the north side of the river and 2 on the south side. The Virginia-Carolina Chemical Co. is the chief producer, and only one other company is operating. The large washing plant at Lambs is at present the only one in operation, although in the fall of 1913 three other plants were working, 2 on Stono River and 1 on Chisholm's Island, near Beaufort. Conditions in the field are such that profitable mining is practicable only with the use of machinery capable of handling large quantities of material.

Though all the indications are that the South Carolina phosphate field has passed the period of its maximum production, the fact must not be lost sight of that there is a large quantity of 60 per cent phosphate rock still in the ground, which improved machinery may at some later time render workable. Moreover, the South Carolina rock has two advantages: In the first place, the former importance of the field led to the building of a group of large fertilizer factories at Charleston, and the expense of shipping is therefore almost negligible; and, secondly, the rock grinds easily and makes an excellent superphosphate, which, on account of its good mechanical condition, is preferred by many planters to the higher-grade rock of the neighboring fields.

On the other hand, the highest-grade rock that the field can be expected to produce does not average more than 61 per cent lime phosphate, and generally exceeds 3 per cent iron oxide and alumina.

---

[1] Compiled and quoted in part from a longer report on the phosphate-rock deposits of South Carolina by G. S. Rogers (U. S. Geol. Survey Bull. 580-J, 1914).

[2] Shepard, C. U., South Carolina phosphate, Charleston, S. C., 1880.

The cost of production is considerably higher than in the Florida and Tennessee fields, so that the 70 per cent phosphate rock from those States can be delivered at Charleston at a price only slightly above that of the local product. This offsets the first of the two points in favor of the South Carolina rock, and the influence of the last can hardly be sufficient to compensate permanently for a difference of 10 per cent in phosphate content. The preference for the South Carolina rock is chiefly local, and, although the demand within the State may continue for some time, it probably can not affect the general phosphate industry.

ARKANSAS.

No phosphate rock was mined in Arkansas in 1913. A prospective producer at St. Joe, Searcy County, reports that he expects to begin mining operations in March, 1914. The White River Phosphate Co. reports some prospecting work done on its deposits in Izard County.

KENTUCKY.

For many years the beds of phosphate rock in the Ordovician limestone near Midway, Woodford County, central Kentucky, have attracted attention. During the last few years more interest has been taken in the Kentucky deposits and a small output has been produced, but no production was reported to the Survey for 1913.

VIRGINIA.

APATITE DEPOSITS.

Rock of igneous origin, rich in titanium and phosphorus, occurs in the eastern foothills of the Blue Ridge in Virginia, near Roseland, about 7 miles northwest of Arrington on the Southern Railroad, and 24 miles northeast of Lynchburg. The titanium occurs in the form of ilmenite, the phosphorus in the form of apatite, these being the dominant minerals. The rock occurs in dikelike forms of varying size and irregular shape, and to it the name nelsonite has been applied.[1]

Many varieties of rock have been included under this name, for example, ilmenite nelsonite, magnetite nelsonite, biotite nelsonite, hornblende nelsonite, and rutile nelsonite, from the dominant mineral which may be present, and gabbro nelsonite, from the rock-type gabbro, which some of the facies of nelsonite resemble. Ilmenite nelsonite, to which the name was first applied, is the normal and most abundantly occurring variety. The apatite present is the fluorapatite, chlorine being present only in traces. The content of the nelsonite in apatite ranges from 0.3 to 30 per cent.

Experiments having as their object the commercial utilization of nelsonite have been carried on at the Bureau of Soils. Both the minerals ilmenite and apatite contain elements which seriously affect each other so far as commercial applicability is concerned.

---

[1] Watson, Thos. L., Mineral resources of Virginia, p. 300, 1907; Geology of the titanium and apatite deposits of Virginia: Virginia Geol. Survey Bull. 3 A, pp. 100 et seq., 1913. Watson, Thos. L., and Taber, Stephen, The Virginia rutile deposits: U. S. Geol. Survey Bull. 430, p. 206, 1909.

The problem, then, first, is to separate them. Two mechanical methods have been tried, depending (1) on differences in specific gravity, (2) on the magnetic properties of the ilmenite. Neither of these methods was found entirely satisfactory. The chemical method was then resorted to. In the experiments performed by W. H. Fry, of the Bureau of Soils, it has been found that ilmenite may be almost completely freed from apatite by means of sulphuric acid with a minimum of waste and without involving great expense. Moreover, all the products obtained can be utilized commercially.

Preliminary experiments showed that ilmenite is entirely unattacked by dilute sulphuric acid, while apatite is acted on quite energetically by this reagent. Subsequently it was shown that the apatite remaining in ilmenite after mechanical separation can nearly all be extracted by means of dilute sulphuric acid without appreciably affecting the ilmenite. The details connected with the experiments are outlined in the article by Waggaman cited below.[1]

Thus the possibility is shown of obtaining phosphate fertilizer material from this occurrence.

ALGERIAN PHOSPHATE-ROCK INDUSTRY.[2]

DEPOSITS.

The deposits of phosphate rock in Algeria are continuations of the deposits in Tunis. The two important mining districts in Algeria are located near the towns of Setif and Tebessa, in the eastern part of the State. They have been developed during the last 15 years, the production having increased from 1,057 short tons in 1899 to 550,000 in 1912. The percentage of phosphate in the rock exported from the Setif district ranges from 58 to 63 per cent and that in the rock from the Tebessa district, from 58 to 68 per cent.

TEBESSA DISTRICT.

The deposits of Kouif, the most important exploited in Algeria, belong to the Constantine Phosphate Co., of Constantine. They are located near Tebessa, close to the Tunisian frontier. Of the 5 beds, 3 are workable, the thickness ranging from 3 to 9 feet, 3 to 4½ feet, and 1⅗ to 3 feet, in the different beds. The average percentage of phosphate in the rock varies, being, respectively, 58.64 per cent, 68.50 per cent, and 48 per cent in the 3 beds. Where the overburden does not exceed 24 feet in depth, open-cut mining is practiced; where the overburden is deeper, the rock is mined by tunneling. Because of the basin, or saucer shape of the deposits, the tunnels are inclined.

A 16-mile branch line connects the mine with the railroad from Tebessa to the port of Bône. More than half of this railroad—the section from Tebessa to Souk-Ahras—is a narrow-gage, single-track line, capable of transporting only 330,000 tons of rock annually. Owing to insufficient railroad facilities the phosphate company reduced the quantity of rock mined from 712,817 tons in 1911 to 113,225 tons in 1912. For the same reason, it is intended either to double track the line from Tebessa to Souk-Ahras or to construct a broad-

[1] Waggaman, W. H., A possible commercial utilization of nelsonite: Jour. Ind. and Eng. Chemistry, vol. 5, No. 9, pp. 730–732, 1913.
[2] Daily Cons. and Trade Repts., pp. 1240–1242, Aug. 30, 1913.

gage railroad. Thus far no definite action has been taken, and it may be as much as three or four years before increased railway facilities render possible an increased production in the district.

Important deposits of phosphate rock have been found at Dy Nord and Djebel-Onck, about 62 miles south of Tebessa, which are believed to contain 300,000,000 to 400,000,000 tons of rock. These deposits have not been thoroughly explored, and estimates are therefore not entirely dependable. They have not been exploited, owing to lack of railroad facilities. After the reconstruction or improvement of the line from Tebessa to Souk-Ahras, it is likely that its prolongation to the deposits of Djebel-Onck will receive serious consideration.

SETIF DISTRICT.

In 1906 La Compagnie des Phosphates de Paris leased for 20 years the deposits in the commune of Bordj-Rhir. Its shipments are made by the way of a 12-mile cable to El Anasser, on the railway from Setif to Algeria; thence they go to the port of Bougie, from which the exports amounted to 64,986 short tons in 1910, 64,824 tons in 1911, and 62,702 tons in 1912.

La Compagnie Algérienne des Phosphates is exploiting two deposits in the commune of Tocqueville. The beds are from 1 to 6 feet thick. The phosphate is transported by a 9-mile narrow-gage branch line to the railway station of Texter-Tocqueville. In 1900, 17,807 short tons and in 1912, 230,864 short tons of rock were mined. At present 350 workmen are employed.

Another French company, with a capital of $1,000,000, is exploiting the Mzaita mine in the communes of Maadia. A broad-gage railroad has been built from the mine to the station of Ain-Tassers, and an electric plant of 150 horsepower has been installed for the stamp mill. Only 7,560 tons of rock were extracted in 1912, but it was intended to mine 100,000 tons in 1913, and it is expected that eventually 300,000 tons of rock will be mined annually. The estimated supply of rock is 16,500,000 tons.

EXPORTS OF ALGERIAN PHOSPHATE ROCK, 1902–1911.

The following table gives the quantities in short tons of phosphate rock exported from Algeria to France and to other foreign countries during the decade 1902–1911.

Exports of Algerian phosphate rock, 1902–1911, in short tons.

Year.	France.	Foreign countries.	Year.	France.	Foreign countries.
1902	51,497	89,739	1907	86,761	291,337
1903	77,249	262,004	1908	93,238	308,858
1904	75,479	292,810	1909	44,088	322,696
1905	79,254	303,630	1910	41,276	307,791
1906	72,841	282,788	1911	37,050	331,515

The total exports of phosphate rock in 1912 were 411,269 tons, or 42,704 tons more than in 1911.

LOCAL MANUFACTURE OF FERTILIZERS.

The director of the only company in Algeria manufacturing phosphate fertilizers estimates that the consumption in Algeria in 1912 of phosphate rock mined in the country was about 60,000 tons.

The Société des Engrais et Produits Chimiques constructed a plant at Bône about six years ago for producing superphosphate by treating the crushed rock with sulphuric acid. Plants have been subsequently established near Algiers and Oran. The company, which manufactures the sulphuric acid used at its works, is doing a satisfactory business and produces the greater part of the phosphate fertilizer used in the country.

MARKET.

Algerian mining companies sell their phosphate rock c. i. f. at the important European markets at prices which on July 4, 1913, were as follows: For 63 to 68 per cent phosphate, at British ports and Hamburg, $11\frac{1}{3}$ cents per unit; at Italian ports, $11\frac{1}{5}$ cents; at Antwerp, $11\frac{6}{10}$ cents. For 58 to 63 per cent phosphate, the prices at these ports were, respectively, 11 cents, $10\frac{8}{10}$ cents, and $10\frac{8}{10}$ cents. Sales are based on the metric ton (2,204.6 pounds) and the price is obtained by multiplying the percentage of phosphate in the rock by the current rate paid. Thus the price in Great Britain for rock containing 65 per cent of phosphate would be $7.37 per ton.

COST OF MINING.

No information could be obtained from the Algerian authorities as to the actual cost of exploitation at the mines. This varies materially according to local conditions. As was stated by the government inspector of mines, it was found that the mining companies are not inclined to furnish such information.

COST OF TRANSPORTATION.

The cost of transportation from mine to shipping port varies materially according to cost of shipment from mine to railroad, but according to information received from the government inspector of mines it varies from $1.50 to $2 a ton.

SURVEY PUBLICATIONS RELATING TO PHOSPHATES.

The following papers relating to phosphates have been published by the United States Geological Survey or by members of its staff.

The Government publications, except those to which a price is affixed, may be obtained free by applying to the Director, United States Geological Survey, Washington, D. C. The priced publications may be purchased from the Superintendent of Documents, Government Printing Office, Washington, D. C. Those indicated as being "Out of print" or "Exhausted" are not available for distribution but may be seen at the larger libraries of the country.

SALT, BROMINE, AND CALCIUM CHLORIDE.

By W. C. Phalen.

SALT.

PRODUCTION.

The marketed production of salt in the United States, including Hawaii and Porto Rico, in 1913, was 34,399,298 barrels of 280 pounds each, or 4,815,902 short tons, valued at $10,123,139. In 1912 the production was 33,324,808 barrels, or 4,665,473 short tons, valued at $9,402,772. There was a gain in 1913 of more than 3 per cent in quantity of salt produced and of nearly 8 per cent in value, as compared with 1912.

The average price of salt per barrel in 1913 was 29.428 cents, or $2.10 per short ton, as compared with 28.215 cents per barrel, or $2.02 per short ton, during 1912. The price of salt has been slowly rising in recent years.

In the following table are given the quantity and value of salt produced in the United States from 1893 to 1913, inclusive:

Marketed production and value of salt in the United States, 1893–1913.

Year.	Quantity.	Value.	Year.	Quantity.	Value.
	Barrels.			*Barrels.*	
1893	11,897,208	$4,154,668	1904	22,030,002	$6,021,222
1894	12,968,417	4,739,285	1905	25,966,122	6,095,922
1895	13,669,649	4,423,084	1906	28,172,380	6,658,350
1896	13,850,726	4,040,839	1907	29,704,128	7,608,323
1897	15,973,202	4,920,020	1908	28,822,062	7,553,632
1898	17,612,634	6,212,554	1909	[1]30,107,646	8,343,831
1899	19,708,614	6,867,467	1910	[1]30,305,656	7,900,344
1900	20,869,342	6,944,603	1911	[1]31,183,968	8,345,692
1901	20,566,661	6,617,449	1912	[1]33,324,808	9,402,772
1902	23,849,231	5,668,636	1913	[1]34,399,298	10,123,139
1903	18,968,089	5,286,988			

[1] Includes production of Hawaii and Porto Rico.

PRODUCTION BY GRADES AND STATES.

Salt is produced in various ways. At the outset, the methods of production are divided into two distinct classes. This is owing in part to the fact that salt itself occurs naturally in two very distinct ways—(1) as rock salt in beds or associated with bedded or sedimentary deposits, and (2) in the form of natural brines or bitterns. However, the larger part of our salt production is derived by converting the naturally occurring rock salt into artificial brines, which are pumped to the surface and there evaporated.

The two methods of production referred to above are (1) the mining of rock salt and its purification and separation into marketable sizes, and (2) the production of salt by evaporation of the artificial or natural brines, bitterns, or other solutions containing it.

The processes employed at the present time in the manufacture of salt by evaporation may be outlined as follows: (1) Solar evaporation; (2) direct heat evaporation (*a*) in open kettles, (*b*) in open pans; (3) steam evaporation (*a*) in jacketed kettles, (*b*) in grainers; (4) vacuum pan evaporation. Of the classes enumerated, direct heat evaporation in open kettles and steam evaporation in jacketed kettles have become practically obsolete.

Production by grades.—By the processes outlined above are produced the different main grades of salt made from brine, together with many modifications of them put on the market under different trade and proprietary names. The production of brine salt for the last five years is shown in the following table:

Marketed production of brine salt in the United States, 1909–1913, by grades, in barrels.

Year.	Table and dairy.		Packers' salt.					
			Common fine.		Common coarse.		Packers'.	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
1909......	3,042,824	$2,240,128	7,745,204	$2,736,917	2,843,393	$929,111	385,802	$169,744
1910......	3,514,748	2,249,827	6,153,296	2,158,386	2,602,737	799,405	327,304	147,434

[a] A small output reported directly as packers' is included under common coarse.

Production of rock salt.—In order to differentiate the rock-salt and the brine-salt industries in the United States, which are quite different, the following table is added, giving the quantity and value of the rock salt mined in the United States during the last five years:

Marketed production of rock salt in the United States, 1909–1913, in short tons.

Year.	Rock salt.	
	Quantity.	Value.
1909..............	[a] 831,421	$1,287,967
1910..............	[a] 975,231	1,613,113
1911..............	[a] 872,509	1,578,016
1912..............	[b] 992,846	1,697,829
1913..............	[b] 1,062,291	1,968,567

[a] Includes California, Idaho, Kansas, Louisiana, Michigan, New York, and Utah.
[b] Includes California, Kansas, Louisiana, Michigan, New York, and Utah.

Rock salt is produced by deep shaft mining in the eastern, central, and southern parts of the United States. The active mines are located, respectively, at Retsof and Halite, Livingston County, N. Y.; one near Detroit, Mich.; two at Kanopolis, Ellsworth County, and one at Lyons, Rice County, Kans.; and one each at Weeks and Avery islands, Iberia Parish, southern Louisiana.

Rock salt occurs near the surface in consequence of the dry climate, and is mined in open cuts or pits, in Sevier Valley, Utah, near Salina, Redmond, and Gunnison, in both Sevier and Sanpete counties. A small production of rock salt near the surface is also reported from near Saltus and Ward, San Bernardino County, Cal.

Production by States.—The following table gives the production and value of the salt produced in the United States from 1910 to 1913, inclusive, by States:

Marketed production and value of salt, 1910–1913, by States, in barrels.

State.	1910		1911		1912		1913

The following table presents in concise form general information of interest to the salt trade. It gives for the two years 1912 and 1913 the number of operating plants in the individual States, together with their relative rank as to both quantity and value of the salt produced; also the percentage of increase or decrease in both quantity and value of salt produced.

Number of operating plants, rank of States, average price per ton in 1912 and 1913, and percentage of increase or decrease in 1913.

State.	1912				1913				Percentage of increase (+) or decrease (−).

[a] Includes both rock and brine salt.
[b] Rock salt.
[c] Brine salt.
[d] The low value of salt in Virginia is due to the fact that the salt is in the form of brine, which is not utilized for its salt content, but is worked up into other sodium salts.

DOMESTIC CONSUMPTION.

The following table gives the consumption of salt in the United States during 1913. In addition to the domestic production, 34,399,298 barrels, 1,105,466 barrels were imported. These imports were in part offset by exports amounting to 502,065 barrels, leaving an excess of imports over exports of 603,401 barrels, which, added to the domestic production, makes the total salt consumed in the United States 35,002,699 barrels. As compared with 1912 this is an increase of 1,125,012 barrels. The imported salt constituted 3.2 per cent of the domestic consumption for the year, which is a slightly greater ratio than for 1912, when it was 2.9 per cent. The significance of these figures is that the United States furnished very nearly all the salt consumed by its people during 1913. The country is amply able to supply the entire home demand, as the capacity of its salt mines and plants is considerably in excess of the present output. Many plants that are either now running at fractional capacity or entirely inactive could easily resume operations should trade conditions warrant. Most of the small quantity imported comes to Atlantic ports, the very low charge for ocean carriage enabling it to compete with the domestic product.

Supply of salt for domestic consumption, 1890–1913, in barrels.

Source.	1890	1900	1910	1912	1913

IMPORTS.

In 1913 there were imported into the United States 309,530,500 pounds, or 1,105,466 barrels, of salt, valued at $421,745; the corresponding imports in 1912 were 279,625,900 pounds, or 998,664 barrels, valued at $370,648.

Prior to the tariff act of 1913 salt imported into the United States for curing fish was admitted free of duty, which was not the case with salt imported for other purposes. Since the duty has been removed from all salt the necessity for differentiating by classes the imported product no longer obtains; hence the statistics of imports of salt imported for curing fish are no longer kept separate, but are included with salt imported in containers or in bulk. For this reason a comparison of the salt imported by grades during 1913 and 1912 can not be made.

According to figures obtained from the Bureau of Foreign and Domestic Commerce of the Department of Commerce, the quantity and value of the salt imported and entered for consumption in the United States in the last five years are as follows:

Salt imported and entered for consumption in the United States, 1909–1913, in pounds.

Year.	In bags, barrels, and other packages.		In bulk.		For the purpose of curing fish.		Total quantity.	Total value.
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.		
1909	65,581,839	$220,503	135,735,445	$132,884	97,722,473	$84,440	299,039,757	$437,827
1910	53,143,200	178,000	118,796,400	104,822	102,265,982	88,100	274,205,582	370,922
1911	61,648,200	181,405	108,055,700	95,801	114,475,300	97,824	284,179,200	375,030
1912	57,453,400	179,199	133,080,800	112,749	89,091,700	78,700	279,625,900	370,648
1913	70,433,300	209,752	185,743,900	160,400	[a] 53,353,300	[a] 51,593	309,530,500	421,745

[a] This class was not carried separately after Oct. 3, 1913.

EXPORTS.

The exports of salt in 1913 were 140,578,092 pounds, or 502,065 barrels, valued at $515,194. As compared with the exports in 1912, which were 124,819,713 pounds, or 445,785 barrels, valued at $418,525, this was an increase of 56,280 barrels in quantity and of $96,669 in value. Both the quantity and the value of the domestic salt exported in 1913 were the greatest ever recorded in the history of the industry in the United States. The export of salt of domestic production from the United States from 1909 to 1913 is shown below:

Salt of domestic production exported from the United States, 1909–1913.

Year.	Quantity.	Value.
	Pounds.	
1909	80,306,820	$269,273
1910	98,026,369	320,926
1911	97,745,833	335,285
1912	124,819,713	418,525
1913	140,578,092	515,194

SALT INDUSTRY BY STATES.

CALIFORNIA.

In quantity of salt produced in 1913 California ranked sixth among the salt producing States; in the value of the product the State ranked fifth. The output of the State was 1,082,993 barrels of 280 pounds each, or 151,619 short tons, valued at $759,485, a decrease of 7,007 barrels, or 981 tons, in quantity, but an increase of $139,289 in value as compared with 1912. The value for 1913 represents an average of more than 70 cents per barrel, or $5.01 per ton, as compared with 57 cents per barrel, and $4.06 per ton, in 1912. The prices of California salt in 1913 generally averaged much higher than the prices for the United States at large, which, as stated in the introductory paragraph, averaged 29.426 cents per barrel and $2.10 per short ton. Thus the average price of California salt in 1913 was very nearly two and one-half times that of the rest of the country.

The great bulk of the salt produced in California comes from sea water and is produced by solar evaporation along the shores of San Francisco Bay, in Alameda and San Mateo counties; near Long Beach, in Los Angeles County; and on San Diego Bay, in San Diego County. The salt crop, so called, is harvested chiefly during the fall, and the size of the crop depends very much on the condition of the weather. The severe winter of 1913–14 and the late rains reduced the crop very materially and caused in part the increase in price. Another difficulty encountered by some of the manufacturers was the scarcity of labor.

The basic salt in California is solar salt, and its sale either in the harvested form or after it has been crushed (half ground) or washed and ground for table and dairy use, and known as granulated, constitutes about 75 per cent of the trade. Three firms on the coast recrystallize their product. The cost value of crude solar salt in the stack is fairly well established at $2.50 per ton. The price received f. o. b. shipping point will vary with the varying demands of the industries supplied. The highest grades of salt, such as table and dairy, have practically a uniform market at all times and are not subject to the fluctuation of the crude solar article. The other grades marketed for curing hides, hay, fish, and for making ice cream, have varying prices, according to the work necessary to get them into shape for the market.

About 75 per cent of the salt made on San Francisco Bay is made on the east shore, and the salt companies there forward their product to San Francisco on their own barges or lighters and make all their prices and costs f. o. b. San Francisco. The freight charges from the plants on the west shore of the bay to San Francisco are fixed.

The headquarters of the salt industry are at Alvarado, Newark, Mount Eden, Russell, and Arffs, in Alameda County, on the east shore of San Francisco Bay, and at Redwood City and San Mateo, in San Mateo County, on the west shore of the bay. In the southern part of the State solar salt is made at Ostend station near Long Beach, in Los Angeles County, and on San Diego Bay, San Diego County.

In addition to the output by solar evaporation, salt is also produced in small quantity at inland points, as follows: Keeler, Inyo County; Ward, San Bernardino County; Saltus, San Bernardino County; and near Cedarville, Modoc County. At Cenada, Kern County, the property of the Diamond Salt Co. is now held by the Consolidated Salt Co. Though a large tonnage of salt was obtained by the company in 1913, none of it was sold. The company is awaiting the installation of a railroad track and other facilities for handling its product. It expected to begin operations in the spring of 1914, when all the various grades will be produced. A description of the occurrence of salt at this place was given in the report for 1912.

IDAHO.

Salt was made by two operators in Idaho in 1913. The output came from Stump Creek, Bannock County, but the headquarters of the operators are at Auburn, in Wyoming. The industry is purely local, and is carried on in a very small way. A complete account of the salt resources of the region along the Idaho-Wyoming border has been prepared by C. L. Breger, and the reference to it is listed in the bibliography at the end of this chapter.

KANSAS.

Kansas ranked fourth among the States in both the quantity and the value of salt produced in 1913. The State produced both rock salt and evaporated salt, made by the open pan, grainer, and vacuum-pan processes. Rock salt in Kansas came from the mines at Kanopolis, Ellsworth County, and at Lyons, Rice County. Salt made by evaporative processes came from Ellsworth, Ellsworth County; Anthony, Harper County; Hutchinson, Reno County; and Lyons and Sterling, Rice County.

The production for the year amounted to 2,698,079 barrels of 280 pounds each, or 377,731 short tons, valued at $860,404, a substantial increase as compared with 1912, amounting to 124,453 barrels in quantity and to $16,112 in value.

The rock-salt beds of Kansas furnish all the salt now marketed in the State, including that produced by the evaporative processes. The beds occur in rocks of Permian age. The "salt beds," the name applied to the rock salt layers themselves and the shale layers associated with them, lie within the Marion formation. They grow thinner to the east to beyond Wellington and Little River and die out possibly without coming near the surface. It is thought that the salt springs at Geuda Springs, Sumner County, have their origin in these salt beds. How far the salt beds extend westward is unknown. In the north-south direction the beds are fairly well known from drill records from Kanopolis, Ellsworth County, on the north, to Anthony, Harper County, on the south—that is, very nearly to the Kansas-Oklahoma State line. The beds thin northward. At Anthony they are 404 feet thick (depth 946 to 1,350 feet); at Kingman, 415 feet thick (depth 665 to 1,080 feet); at Hutchinson, 380 feet thick (depth 430 to 810 feet); at Lyons, 275 feet thick (depth 793 to 1,068 feet); and at Kanopolis about 250 feet thick (depth 630 to 880 feet). If the rate of decrease in thickness from Hutchinson northward were maintained, the salt beds would disappear before the north boundary of the State was reached. It must be remembered that where more than one record is obtainable at a given place—for example, at Hutchinson—the exact thickness of the beds, as well as the distanct of the topmost of them below the surface, will vary somewhat and sometimes considerably from the figures given above. The records of the wells at Kanopolis, Lyons, Hutchinson, Kingman, and Anthony contain no reference to appreciable quantities of gypsum below the salt.

Another most interesting question in connection with the geology of the salt beds is their relation to the extensive gypsum deposits in different parts of Kansas and of the Great Plains area. The rock gypsum in the northern part of the State, in Marshall County, lies but a few feet above the Cottonwood limestone, which would place it considerably below the Marion formation. Farther south, in the central gypsum field, the rock gypsum occurs in the Wellington shale. If, therefore, the correlations made by Grimsley[1] are correct, the salt beds were deposited at a period of time intermediate between the formation of the Marshall County rock gypsum and that in the vicinity of Solomon.

It is difficult to understand how such extensive deposits of salt could be formed without a larger amount of gypsum being formed underneath them. The records of the wells at Kanapolis, Lyons, Hutchinson, Kingman, and Anthony contain no reference to gypsum immediately underlying the salt beds. The question is as to what became of the calcium sulphate held in solution by the ocean water from which the rock salt was obtained. It is barely possible that during the period of the formation of the Marshall County gypsum, the inland sea did not reach southward to the salt beds area, and that after the gypsum was principally precipitated out of the inclosed ocean water and before concentration was carried far enough to precipitate the salt, surface movements resulted in draining this partially purified water southward over new areas from which fresh ocean water was excluded, thus permitting the continued evaporation to deposit the salt now found in the salt beds from the same water from which the Marshall County gypsum was produced. It is known that the Permian rocks, in general, become quite thin northward, entirely excluding the upper members of the Permian. So far as this has a bearing on the subject it would tend to favor the view just expressed.[2]

LOUISIANA.

Salt occurs in two districts in Louisiana (1) in the north central and northern part of the State, in the valley of Red River and its tributaries and (2) in the southern part, the most important deposits

---

[2] Haworth, Erasmus, Geology of Kansas salt; Kansas Mineral Resources Ann. Bull. 1898, pp. 88–89, 1899.

and those worked at present occurring in close proximity to the Gulf coast.

The most important salt deposits of the State are located on the Five Islands, so called, situated near the southern coast. From two of these islands, namely, Grand Côte (Weeks Island) and Petite Anse (Averys Island) rock salt is being mined at the present time. Owing to the fact that there are only two producers in the State the figures of production can not be given.

The details connected with the mining of the salt and the geology of these deposits which, with those in Texas, are unique among the salt occurrences of the United States have been described in this chapter in previous years and for that reason will not be given here.

MICHIGAN.

Michigan ranked first among the States in 1913 in both quantity and value of salt produced. The production of the State was 11,528,800 barrels, or 1,614,032 short tons, valued at $3,293,032, a gain of 582,061 barrels in quantity and of $318,603 in value as compared with 1912, in which year the production was 10,946,739 barrels, or 1,532,543 short tons, valued at $2,974,429.

The salt produced in Michigan is obtained from two distinct sources: (1) From rock salt and (2) from natural brines.

The rock salt deposits now worked are in the southeastern and western parts of the Lower Peninsula and are exploited in two ways: (1) Rock salt itself is actually mined from the deposits, and (2) water is allowed to come into contact with the salt and the brine thus formed, which may be considered artificial, is forced to the surface and there evaporated.

The salt industry of Michigan, associated with the natural brines, is confined to the Saginaw Valley. The brine is entirely distinct, not only in its geographic but also in its geologic relations from that in the southeastern and western parts of the lower peninsula. With the salt production in the Saginaw Valley are connected the bromine and the calcium chloride industries. The manufacture of salt in Saginaw Valley is not so important as it is in the other parts of the Lower Peninsula.

Rock salt is mined at Oakwood, near Detroit, Wayne County. In the southeastern part of the State evaporated salt is made at Marine City, Port Huron, and St. Clair in St. Clair County, and at Detroit, Oakwood, Ecorse, and Wyandotte in Wayne County. In the western part of the State evaporated salt is made at East Lake, Manistee, and Filer City in Manistee County, and at Ludington in Mason County. In the Saginaw Valley salt is made at Bay City, Bay County, and Mount Pleasant in Isabella County, and at Carrollton, Saginaw, Saginawtown, and St. Charles in Saginaw County. Calcium chloride is also made at Mount Pleasant and Saginawtown, and bromine at Midland and Mount Pleasant.

The rock salt of the Lower Peninsula of Michigan is found in the lower part of the Monroe formation (Silurian). In the extreme southeast corner of the State the rock salt disappears, and wells drilled at Trenton show the edge of the salt-producing area there, as salt occurs in only one of them. The thickness of the salt-bearing beds increases to the north and this increase holds good into Canada.

In the southwestern part of the State no rock salt occurs, but to the north, at Manistee and Ludington, salt is obtained in the form of brine from beds approximately 2,000 feet below the surface. At Frankfort, still farther north in Benzie County, wells deep enough to penetrate the salt-bearing rocks have been sunk, but they did not strike salt and not even very strong brine. It is possible that Frankfort was just without the area of salt deposition. Wells at St. Ignace and Cheboygan likewise show no salt.

Another place in which rock salt has been found in small quantity, but in which it has not yet been developed, is Alpena, located in the northeastern part of the Lower Peninsula on the shores of Thunder Bay, an arm of Lake Huron. Here five beds of salt with streaks of gypsum and anhydrite are known; these beds aggregate about 300 feet in total thickness.

The brines of the Saginaw Valley occur in the sandstones of the Marshall formation (Mississippian). Thus they are distinct both geographically and geologically from the rock salt horizons described above. It is the sandstones of the Marshall formation which yield the brine so extensively used in the manufacture of salt, bromine, and calcium chloride. The towns and cities already mentioned in the Saginaw Valley are those most prominently identified with these chemical industries.

NEVADA.

The salt produced in Nevada in 1913 amounted to 8,971 barrels, or 1,256 tons, valued at $7,947, a decrease as compared with 1912, when the production was 12,536 barrels, or 1,755 tons, valued at $15,752.

The salt produced in Nevada came from Sand Springs and Leete, in Churchill County, and from Sheepshead, in Washoe County. No work was done at Parran, Churchill County, except to clean out ditches and to prepare for future production. No production was reported from the Silver Peak playa in Esmeralda County.

NEW YORK.

New York ranked second among the States in 1913 in both quantity and value of salt produced. The output of the State was 10,780,514 barrels, or 1,509,272 short tons, valued at $2,865,187, an increase of 253,293 barrels, or 35,461 short tons, in quantity and of $249,853 in value, compared with 1912. The output of the State falls into several classes: Rock salt was made at Halite (Cuylerville post office), and at Retsof, Livingston County. Solar salt was produced in the vicinity of Syracuse, Onondaga County, and brine utilized in the manufacture of soda products came from Tully, Onondaga County. Evaporated salt, or salt made by artificial evaporation in open pans, grainers, or vacuum pans, from brines derived by allowing water to come into contact with the rock salt in place, is the most important class made in the State. Salt thus produced is made at Le Roy, in Genesee County; Piffard, in Livingston County; Watkins, in Schuyler County; Ithaca and Myers, in Tompkins County; and at Rock Glen, Silver Springs, and Saltvale in Wyoming County.

The salt beds of New York belong in the Salina formation (Silurian). This group of rocks contains the gypsum deposits of western New York as well. The Salina as a whole has the form of an irregular lense, the maximum thickness of which is found between Oneida Creek and Cayuga Lake. From this region the formation diminishes in thickness both eastward and westward, a fact which has been determined by plotting the sections of deep drillings which, to the number of more than 200, are distributed over the area in which the salt beds are near enough to the surface to be reached practicably.

The district under which rock salt is known to exist in New York comprises the greater part of Genesee County south of Le Roy, the eastern half of Wyoming County, nearly the whole of Livingston County, and the part of Ontario County west of Canandaigua Lake and chiefly south of the New York Central Railroad. There can hardly be any doubt that rock salt exists west of Warsaw, but the borings put down in Erie County seem to have been beyond the western limit of the deposits.

East of Canandaigua Lake the borings put down at Dundee, Watkins, Ithaca, Ludlowville, and Tully all reached the rock-salt beds. The area underlain by rock salt west of Canandaigua Lake has been computed to be over 1,000 square miles in areal extent; east of this lake the area must be as large or even larger. The northern limit can not be assigned, owing to the solution of the rock salt as it approaches the surface. It is approximately defined by a line drawn from a point south of Oneida Lake westward to Buffalo. South of this line the deposits are encountered at progressively increasing depths in accordance with the dip of the strata, which ranges from 40 to 50 feet per mile. The most easterly point where salt has been found is Morrisville, Madison County. Between this point and Lake Erie salt has been found in almost all the central tier of counties in the State.

OHIO.

Ohio ranked third among the States in 1913 in both quantity and value of salt produced. The output of the State was 5,310,135 barrels, or 743,419 tons, valued at $1,318,156, compared with 5,269,179 barrels, or 737,685 short tons, valued at $1,364,136, in 1912. It will be seen that though the output was larger in 1913 than in 1912 the price received from the product was less.

Ohio salt comes from two districts, the one located in the northeastern part of the State and the other in the southeastern. In northeastern Ohio the salt produced comes from Cleveland in Cuyahoga County, Wadsworth in Medina County, Akron in Summit County, and Rittman in Wayne County. Brine is pumped at Fairport Harbor in Lake County and at Barberton in Summit County, and is used directly in the manufacture of soda. The brine utilized in making salt and soda is obtained by allowing water to come into contact with beds of salt. In the southeastern part of the State, Pomeroy, in Meigs County, is the center of the industry, and in addition to the salt, bromine and calcium chloride are also produced from the natural brines there occurring. The industry in the southeastern part of the State, along Ohio River, suffered considerably from floods during the spring of 1913.

The geology of the occurrence of salt in northeastern Ohio and that of the brine in southeastern Ohio is quite distinct. The salt horizon in the northeastern part of the State is in the Monroe formation of the Silurian. The salt occurs at the same geologic horizon as that in southeastern Michigan near Detroit, Wyandotte, and along St. Clair River. Though the production has been restricted to five counties, as indicated above, the salt deposits are not limited to that territory.

The surface rocks near Pomeroy, in Meigs County, southeastern Ohio, and at Mason, W. Va., lie near the top of the Conemaugh formation, formerly known as the Lower Barren Coal Measures. The depths of wells in this region have undergone great variation. At first wells were very shallow, but later they were extended to greater depths as the supply of brine near the surface became exhausted. When the supply from these deeper wells became inadequate they were sunk to still greater depths. At present salt works both in Ohio and in West Virginia are pumping brine from depths of 1,100 to 1,350 feet. The brine-bearing strata dip toward Pomeroy from the northwest, and as the brine has been removed from the wells the supply has been renewed from the rocks lying at higher levels in that direction. The wells along Ohio River procure their brine chiefly from a horizon approximately near the base of the salt sand of the Carboniferous.

OKLAHOMA.

The small production of salt in Oklahoma in 1913 came from Harmon County. The salt plains of Harmon County are located in small canyons in the gypsum hills south of Elm Fork of Red River, about 5 miles east of the Texas border and 1½ miles south of the north county line. The plains are known locally as the Chaney or Salton salt plain and the Kiser salt plain. They are both small, neither covering an area of more than an acre, and they are not more than a mile apart. The salt is contained in spring water that issues from shallow beds occurring below gypsum. Springs also boil up from the level floor of the plains. A local industry has been carried on for many years in this region at the old Kiser Salt Works and also farther west. The latter springs were worked in 1911, 1912, and 1913, and are now known as the Salton salt beds. The old Kiser salt beds were worked in 1913 by W. H. Stockman. Stock salt is produced at both plains.

PENNSYLVANIA.

Salt, bromine, and calcium chloride are obtained on the North Side, Pittsburgh, Pa. They are obtained from a natural brine, which probably comes from a sand in the Pocono formation (of Mississippian age) which may possibly correspond with the Berea sandstone.

TEXAS.

The production of salt in Texas in 1913 was 355,529 barrels, or 49,774 short tons, valued at $278,008, as compared with 373,064 barrels, or 52,229 tons, valued at $290,328, in 1912. The main salt production was reported from Palestine, in Anderson County, and Grand Saline, in Van Zandt County, in the eastern part of the State. The plant at Colorado, in Mitchell County, in the western part of the State, was not operated during the year.

UTAH.

The production of salt in Utah in 1913 was 330,443 barrels, or 46,262 short tons, valued at $191,686, as compared with a production of 283,293 barrels, or 39,661 short tons, valued at $154,734 in 1912. The salt produced in Utah came from the shores of Great Salt Lake at Garfield and Saltair. Rock salt was produced in the Sevier Valley near Salina and Redmond, in Sevier and San Pete counties, and also near Gunnison, in San Pete County. Though the salt is obtained in the form of rock salt and is sold in large quantity as such, some of it is dissolved, recrystallized, and retailed in the refined form as table and dairy packers' salt, etc. A small production of salt was reported from Saldura, in Tooele County.

VIRGINIA.

Deposits of salt and gypsum occur in Washington and Smyth counties, Va., in a belt of country 20 miles long, running northeast from the village of Plasterco. The Saltville branch of the Norfolk & Western Railway, which joins the main line at Glade Spring, renders the region accessible. The rocks in which the deposits occur are of Mississippian age.

Two gypsum and one salt or alkali works are in operation in the region. Since 1895, when the Mathieson Alkali Works came into control of the property, the brine has been converted into soda products. Over 50 wells have been drilled near Saltville and Plasterco, about 25 of which are now in operation. They range in depth from a few hundred to 2,280 feet, the average depth being about 1,000 feet. The shallower wells are dry and have to be flushed with water through the outer casing. The deeper wells are wet and brine flows into them as fast as it is pumped out.

WEST VIRGINIA.

The production of salt in West Virginia in 1913 was 113,921 barrels of 280 pounds each, or 15,949 short tons, valued at $63,803. The corresponding figures for 1912 were 139,121 barrels, or 19,477 short tons, valued at $66,023. The marked decrease in quantity in 1913 was due in part of the floods in Ohio River in the spring of 1913, which caused much destruction and a consequent closing down of plants for repairs.

The salt in West Virginia, both along Ohio and Kanawha rivers, is obtained from natural brines carrying appreciable quantities of bromine, which, together with calcium chloride, is extracted from them. The geology of the brine-bearing beds at Mason is similar to that at Pomeroy, Ohio, on the opposite side of Ohio River, in Meigs County. The geology of these brine-bearing beds has been worked out by J. A. Bownocker and published in Bulletin 8 of the Ohio Geological Survey; it has been repeated in this report in previous years, and has been outlined under Ohio in the present report. Natural brines also occur near Malden, W. Va., which is located on Kanawha River, a few miles above Charleston, the State capital. The record of a gas well on Cool Spring Branch of Burning Springs Hollow, about 3 miles from Malden, throws some light on the geology of the beds from which the brine is obtained. The record of the well, which is known as the Edwards well No. 1, has been published in a report by I. C. White.[1] According to White the sandstone known to the oil men as the salt sand furnishes the brine in the Kanawha Valley. This sandstone belongs to the Pottsville group and lies very near the base of the coal measures.

HAWAII.[2]

The production of salt in Hawaii in 1913 was 6,071 barrels, or 850 short tons, valued at $5,950, a decrease of 2,215 barrels, or 310 tons, in quantity and of $3,230 in value as compared with 1912.

PORTO RICO.

Both the quantity and the value of the salt produced in Porto Rico in 1913 were less than in 1912. The salt is made by solar evaporation, and unfavorable weather was responsible for a large part of the reduction. Exports to this country have been greatly curtailed since salt has been admitted free of duty into the United States. Another factor causing a falling off in the manufacture of salt in Porto Rico is competition from Curacao, where both wages and living expenses are less than in Porto Rico.

BIBLIOGRAPHY.

BROMINE.

PRODUCTION.

The following table gives the production of the bromine produced in the United States since 1880:

Marketed production and value of bromine, 1880–1913.

Year.	Quantity.	Value.	Year.	Quantity.	Value.
	Pounds.			*Pounds.*	
1880	404,690	....	1898	486,979	$126,614
1883	301,000	....	1899	433,004	108,251
1884	281,100	$67,464	1900	521,444	140,790
1885	310,000	89,900	1901	552,043	154,572
1886	428,334	141,350	1902	513,893	128,472
1887	199,087	61,717	1903	598,500	167,580
1888	307,386	95,290	1904	897,100	269,130
1889	418,891	125,667	1905	1,192,758	178,914
1890	387,847	104,719	1906	1,283,250	165,204
1891	343,000	54,880	1907	1,379,496	195,281
1892	379,480	64,502	1908	760,023	73,783
1893	348,399	104,520	1909	569,725	57,600
1894	379,444	102,450	1910	245,437	31,684
1895	517,421	134,343	1911	651,541	110,902
1896	546,580	144,501	1912	647,200	145,805
1897	487,149	129,094	1913	572,400	115,436

The bromine industry is centered in Michigan, Ohio, Pennsylvania, and West Virginia. Accounts of the bromine industry in these States have appeared in this report during previous years, and the reader is referred to these earlier chapters for detailed information.

CALCIUM CHLORIDE.

PRODUCTION.

In connection with the salt and bromine industry in Michigan, Ohio, Pennsylvania, and West Virginia, a considerable quantity of the calcium chloride contained in the brines is recovered.

Statistics for this substance have been collected since 1909 and the following table shows the quantity and value of the output from 1909 to 1913, inclusive:

Quantity and value of calcium chloride marketed in the United States, 1909–1913, in short tons.

Year.	Quantity.	Value.	Year.	Quantity.	Value.
1909	12,853	$63,198	1912	18,550	$117,272
1910	10,971	74,713	1913	19,611	130,030
1911	14,606	91,215			

LIME.

By Ralph W. Stone.

PRODUCTION.

The lime manufactured in the United States in 1913 amounted to 3,595,390 short tons, valued at $14,648,362. This was an increase of 65,928 tons, or 1.87 per cent, in quantity and of $678,248, or 4.85 per cent, in value, when compared with the output for 1912, which was 3,529,462 short tons, valued at $13,970,114. The production in 1913 was the largest in the history of the industry, both in the quantity manufactured and in the value of the output. The average price per ton in 1913 was $4.07, as compared with $3.96 in 1912, and with $4.03 in 1911. The increase in average price was general for the entire country, increased cost of labor and supplies and scarcity of labor being given as the reason by the majority of producers. The value given represents the value of bulk lime f. o. b. at point of shipment and does not include any weight or cost of barrel or package.

The total number of plants reporting operations in 1913 was 1,023 as compared with 1,017 in 1912 and with 1,139 in 1911. Although a small increase is thus shown many of the States exhibit a decrease in plants due in part to the tendency of the industry toward combination, which tendency appears to be established by the record for the last few years, notwithstanding the fact that the total number of kilns reporting operations increased from 2,203 in 1912 to 2,338 in 1913. Many of the operators, however, did not report either in 1912 or in 1913 the number of kilns composing their plants. Isolated lime manufacturers, operating on a small scale, reported their plants as idle on account of cost of production and cost and scarcity of labor, which prevented competition with lime shipped in from the outside. In 1913 44 States, including Hawaii and Porto Rico, reported a production of lime, Nevada also contributing a small output. In 1912 there were 43 States. The five leading States in 1913 were, in order of production, Pennsylvania, Ohio, Wisconsin, Virginia, and West Virginia. In 1912 the order was Pennsylvania, Ohio, Wisconsin, West Virginia, and Maine. The increase in Virginia was for a large quantity of lime burned and used by alkali manufacturers. This output was not included in the 1912 figures. Pennsylvania produced 2.37 per cent of the lime output and Ohio 1.38, but Ohio's production was from 38 plants, while Pennsylvania's output was from 494 operations, mostly the stack kilns of farmers burning lime in small quantities for use as a soil enricher for their own or their neighbors' farms. Although the number of operators in Pennsylvania was practically the same in 1913 as in 1912, this practice of burning in small quantities has been gradually falling off, on account of the difficulty in obtaining labor and wood for burning, as well as of the increased cost of coal. Also many of the farmers prefer patent fertilizers as cheaper and easier to obtain. The lime burned for use by the farmers is valued at 6 to 12 cents per bushel of 70 to 80 pounds, according to whether the fuel is purchased or obtained on the farm. Wood-burned lime has usually a higher value than the coal-burned lime, but the low average price per ton for this lime decreases considerably the average for the entire State. Also in Maryland, Virginia, and West Virginia a considerable quantity of lime is burned in small quantities for agricultural use. A quantity of marl burned or dried and used for agricultural purposes is included in the lime figures for New York, North Carolina, South Carolina, and Wisconsin. A quantity of limestone is sold each year to various burners of small lime kilns and the value of this lime is not included in the lime figures, but is included under the value of stone in the limestone report. This also applies to a considerable quantity of stone quarried and sold to sugar refiners, smelters, and alkali works and burned by them into lime after the stone leaves the hands of the quarrymen. A quantity of lime manufactured in Duluth, Minn., from stone quarried in Ohio is not included in the 1913 figures, as the company quarrying the stone no longer owns the lime plant. Stone from Ohio is also shipped to Wisconsin and there used for the manufacture of lime not included in these figures.

The following table gives the value of the total lime production in the United States for the years 1896 to 1903 and the quantity and value of the production from 1904 to 1913, inclusive:

Production of lime in the United States, 1896–1913.

Year.	Quantity.	Value.	Year.	Quantity.	Value.
	Short tons.			*Short tons.*	
1896		$6,327,900	1905	2,984,100	$10,941,680
1897		6,390,487	1906	3,198,087	12,480,653
1898		6,886,549	1907	3,092,524	12,656,705
1899		6,983,067	1908	2,766,873	11,091,186
1900		6,797,496	1909	3,484,974	13,846,072
1901		8,204,054	1910	3,505,954	14,088,039
1902		9,335,618	1911	3,392,915	13,689,054
1903		9,255,882	1912	3,529,462	13,970,114
1904	2,707,809	9,951,456	1913	3,595,390	14,648,362

Detailed statistics of the production of lime in 1912 and 1913 are given in the following table:

Quantity and value of lime burned in the United States in 1912 and 1913, by States, in short tons, showing rank of State, average price per ton, and number of plants in operation.

1912.

State or Territory.	Rank of State by quantity.	Quantity.	Value.	Rank of State by value.	Average price per ton.	Number of plants in operation.
Alabama	14	79,957	$297,178	17	$3.72	13
Arizona	24	18,528	101,680	24	5.49	4
Arkansas	22	22,404	102,833	23	4.59	5
California	17	72,978	555,822	8	7.62	20
Colorado	29	7,281	36,478	30	5.01	7
Connecticut	15	75,981	371,356	12	4.89	10
Florida	27	12,327	69,938	25	5.67	4

[b] Includes Hawaii, Kansas, Montana, Nevada, Rhode Island, and South Carolina.

USES.

Lime is used for a great variety of purposes, which have been given in detail in previous reports on this subject. The principal uses, as far as it is possible to give them, are shown in the following table. Under the head of "dealers—uses unspecified" is included a considerable quantity of lime which would necessarily raise the figures for all the other products, but the manufacturers were not able to classify the figures given under this heading. Lime used for building represents over one-third of the total output—probably over one-half if this product were segregated from the quantity sold to dealers. In 1913 production of building lime showed a decrease both in quantity and in value of output, but a considerable increase in average price. The output of lime sold to chemical works, sugar factories, tanneries, and dealers and for other uses increased both in quantity and value, while that sold as a fertilizer or soil sweetener decreased both in quantity and value. A considerable quantity of very finely powdered unburned limestone has also been used for the purpose of correcting soil acidity in recent years, and it is possible that this product may have had an influence on the decrease of lime used for this purpose.

Production of lime in the United States in 1912 and 1913, by uses, in short tons.

1912.

	Quantity.	Value.	Average price per ton.
Building lime	1,556,446	$6,571,479	$4.22
Chemical works	282,984	989,309	3.50
Paper mills	290,347	1,107,532	3.81
Sugar factories	30,988	186,164	6.01
Tanneries	40,595	178,686	4.40
Fertilizer	604,607	1,852,530	3.06
Dealers—uses not specified	560,286	2,467,694	4.40
Other uses [a]	163,209	616,720	3.78
Total	3,529,462	13,970,114	3.96
Hydrated lime, included in total	416,890	1,829,064	4.39

1913.

	Quantity.	Value.	Average price per ton.
Building lime	1,358,099	$6,011,856	$4.43
Chemical works	388,369	1,339,228	3.45
Paper mills	284,090	1,187,154	4.18
Sugar factories	32,236	216,768	6.72
Tanneries	49,591	217,390	4.38
Fertilizer	590,229	1,798,566	3.05
Dealers—uses not specified	692,265	3,153,457	4.56
Other uses [a]	200,511	723,943	3.61
Total	3,595,390	14,648,362	4.07
Percentage of increase (+) or decrease (−) in 1913	+1.87	+ 4.85	....
Hydrated lime, included in total	493,269	2,205,657	4.47
Percentage of increase (+) or decrease (−) in 1913	+18.32	+20.59	....

[a] Includes lime for sand-lime brick, slag cement, alkali works, steelworks, glassworks, smelters, sheep-dipping, disinfectant, manufacture of soap, cyanide plants, glue factories, purification of water, etc.

HYDRATED LIME.

The hydrated lime business has exhibited a marked advance each year since the first records of production were compiled in 1906, and although the increase of 18.32 per cent in quantity and 20.59 per cent in value for 1913 showed a very healthy growth it was much less than in 1912, when the increase was 36.87 per cent in quantity and 33.31 per cent in value.

The output for 1913 was 493,269 tons, valued at $2,205,657; for 1912 it was 416,890 tons, valued at $1,829,064, an increase in 1913 of 76,379 tons in quantity and of $376,593 in value. The average price per ton increased from $4.39 in 1912 to $4.47 in 1913. The number of hydrating plants was increased by 16, or from 64 in 1912 to 80 in 1913. Many of the new plants in 1913 showed but a small output for this year, but the outlook is very good for 1914. Twenty-four States reported hydrating plants in operation in 1913, as compared with 20 States in 1912.

The following table shows the quantity and value of the hydrated lime produced in the United States from 1906 to 1913, inclusive, together with the average price per ton and the total number of manufacturers reporting to the Survey:

Production of hydrated lime in the United States, 1906–1913, in short tons.

Year.	Quantity.	Value.	Average price per ton.	Number of plants reporting operations.
1906	120,357	$479,079	$3.98	30
1907	140,135	657,636	4.69	33
1908	136,441	548,262	4.02	46
1909	204,611	904,900	4.43	50
1910	320,819	1,288,789	4.02	51
1911	304,593	1,372,057	4.50	60
1912	416,890	1,829,064	4.39	64
1913	493,269	2,205,657	4.47	80

The following table shows the number of lime-hydrating plants reported to the Survey as operating in the United States during the last eight years, and draws attention to the steady development of this phase of the lime industry:

Number of lime-hydrating plants in operation in 1906–1913, by States.

IMPORTS.

The imports of lime for consumption in the United States in 1913 were reported by the Bureau of Foreign and Domestic Commerce as 4,139 short tons, valued at $48,538, as compared with 4,268 short tons, valued at $48,153, in 1912, a decrease in quantity of 129 tons, but an increase in value of $385.

The tariff act of October, 1913, changed the status of imported lime somewhat. The duty on lime was formerly 5 cents per 100 pounds, including the weight of barrel or package. The present duty is 5 per cent ad valorem.

EXPORTS.

In 1913 there were exported from the United States 294,746 barrels of lime, valued at $212,345, as compared with 260,669 barrels, valued at $199,515, in 1912.

FUELS.

The statistical inquiry of the Survey into the efficiency of various fuels in burning lime has yielded some results, though far from what could be wished. Information sufficient to make reliable averages is lacking, for many producers did not reply to the inquiry, and although some gave figures evidently based on measurements, others sent what appear to be mere guesses. The reports, however, are of interest, and something can be gleaned from them.

Reports on the quantity of lime burned by 1 pound of coal ranged according to the kind of coal used from 1.5 to 6 pounds, but the average was about 3.6 pounds of lime burned by 1 pound of coal. Coke used as fuel for burning lime averaged (in the few reports received) 4.2 pounds of lime to 1 pound of coke. Producer gas is used in a few places, and what little information was received on its use shows that producer gas burns from 3 to 4.1 pounds of lime and averages about 3.42 pounds of lime burned to 1 pound of coal converted into producer gas.

Wood reported as a fuel showed a range from 1,000 to 6,400 pounds of lime burned by a cord of wood. In spite of this wide range the data are believed to be sufficient for an approximate average. The figures submitted by producers show that 1 cord of wood burns approximately 4,000 pounds of lime and varies with the kind of wood used.

It is hoped that in the future more satisfactory data can be obtained on this question of the efficiency of different fuels.

The following tables show the kinds of fuels and number of kilns using the various fuels as reported for 1912 and 1913:

Numbe. of kilns using various kinds of fuel, by States, in 1912 and 1913.

ECONOMIC NOTES ON LIME.

At the annual meeting of the National Lime Manufacturers' Association held in New York City, February 4–5, 1914, Henry S. Spackman, chairman of the committee on standard specifications for lime, presented the authorized report from the proceedings of the American Society for Testing Materials, taken from the report of the meeting of that body held in June, 1913. Mr. Spackman was chairman of the committee of the American Society for Testing Materials to formulate standard specifications for lime. The proposed standard specifications as amended and published in Rock Products, Vol. XIII, No. 8, pp. 48–49, February 22, 1914, are as follows:

SPECIFICATIONS FOR LIME AS AMENDED.

1. Lime is a product resulting from the calcination at a temperature below the sintering point of a material containing carbonates of calcium or calcium and magnesium, which may be or has been converted to a paste or a dry flocculent powder by slacking.

2. Limes may be divided into two commercial forms:

(*a*) *Quicklime.*—A product coming from the kiln, without subsequent treatment other than sorting, crushing, or pulverization, which slakes on the addition of water. Quicklime may be shipped either as lump lime or pulverized lime. Lump lime shall be kiln size. Pulverized lime is lump lime reduced in size by mechanical means.

Quicklimes are divided into two grades: (1) Selected: A well-burned lime, picked free from ashes, coke, clinker, or other foreign material; (2) run-of-kiln: A well-burned lime without selection.

(*b*) *Hydrate.*—A dry flocculent powder resulting from the hydration of quicklime. Hydrates are divided into two classes: (1) Building and chemical: A lime hydrated to definite chemical proportions, and reduced to a fineness suitable for building purposes; (2) agricultural: A lime reduced to a powder by hydration. As calcium and magnesium oxides play an important but distinct part as fertilizers, agricultural hydrates are divided into two classes, namely, high-calcium and magnesium hydrates.

3. Where quicklime or hydrated lime is to be used for chemical or agricultural purposes the desired content of calcium or magnesium oxide shall be specified in advance by the purchaser.

* * * * * * *

I. Chemical Properties and Tests.

* * * * * * *

(B) Chemical tests.

8. (*a*) Selected quicklime shall contain not under 90 per cent of calcium and magnesium oxides, and not over 3 per cent of carbon dioxide.

(*b*) Run-of-kiln quicklime shall contain not under 85 per cent of calcium and magnesium oxides, and not over 5 per cent of carbon dioxide.

9. Building and chemical hydrates shall contain not over 5 per cent of carbon dioxide, and not under 1 per cent of water in excess of that required to fully hydrate the calcium oxide present.

10. (*a*) High-calcium agricultural hydrate shall contain not over 5 per cent of magnesium oxide, and not over 10 per cent of carbon dioxide; and shall contain not under 80 per cent of calcium and magnesium oxides after water of hydration has been subtracted.

(*b*) Magnesium agricultural hydrate shall contain not under 5 per cent of magnesium oxide, and not over 10 per cent of carbon dioxide; and shall contain not under 80 per cent of calcium and magnesium oxide figured on any anhydrous basis.

II. Physical Properties and Tests.

(A) Quicklime.

11. An average 5-pound sample of selected or run-of-kiln quicklime shall be put in a box and slaked with sufficient water to produce a lime putty, which shall be allowed to stand for 24 hours, then washed through a standard 10-mesh sieve. Not over 3 per cent of the weight of selected quicklime, nor over 5 per cent of the weight of run-of-kiln quicklime, shall be retained on the sieve. The sample taken for this test shall not be crushed finer than will pass a 1-inch ring, either before being sent to the laboratory or at the laboratory. (Section 11 was referred back to committee for further consideration.)

(B) Hydrated lime.

12. (*a*) Building and chemical hydrates shall leave by weight a residue of not over 5 per cent on a standard 100-mesh sieve.

(*b*) Agricultural hydrate shall leave no residue on a standard 4-mesh sieve, and shall leave by weight a residue of not over 10 per cent on a standard 20-mesh sieve.

* * * * * * *

HYDRATED LIME.

On account of the marked increase in the manufacture and use of hydrated lime certain important features of the subject which have been well presented by E. W. Lazell, in a paper entitled "The twentieth century form of lime,"[1] are given below.

Probably the earliest method of burning lime was a heap of stone on the ground, with logs of wood for fuel. The pile of stones later was replaced by a crude shaft excavated in the side of a hill, the interior of the shaft being lined with larger stones of the same material as those to be burned. At the bottom of the shaft there was a horizontal passage to the outside. At the place where the horizontal passage joined the vertical shaft, an arch of limestone was made, and on top of this more limestone was placed, until the shaft was completely filled. A fire was then built under the arch, and the burning was continued until the stone was calcined. At a somewhat later date kilns were built in the open, having vertical walls of masonry of a circular or square cross section, but in other ways resembling the shaft in the side of the hill. These types of kilns are still to be found scattered throughout the country. From these early and crude types of lime kilns, the modern shaft kiln, with separate ovens for the fuel, has been developed.

Three factors have operated jointly to keep the lime industry in a comparatively simple, primitive, and undeveloped state.

First, the prevalence and wide distribution of lime rock. Limestone occurs in every State and Territory of the United States, although some States are so poorly supplied (such as Delaware, North Dakota, and Louisiana) that they never can become important producers. This general distribution of the raw material has resulted in many small plants, often poorly and uneconomically constructed, scattered throughout the whole country.

Second, the ease of burning the stone to lime. The comparatively easy and simple process of burning, with the resulting small outlay of capital required to erect a plant, has caused many persons to enter the business without familiarity or previous knowledge of it. Such plants are generally operated in an uneconomical manner and produce a poor quality of lime, the operators often being satisfied with day wages as a return on their investment.

Third, the perishable character of the burned lime. The perishable character of lime has also contributed to keep the burning in the hands of small producers located near some convenient market.

* * * * * * *

These conditions have materially changed in the past few years. Improved methods of quarrying, handling the stone, and burning, while requiring more capital, have resulted in a decreasing cost per unit of output, and larger, more economically operated plants have thus caused the closing down or abandoning of many smaller crude plants. A larger factor in bringing about the centralization of the industry into a comparatively few advantageous locations has been the railroads. A plant well located as to transportation costs can reach broader markets more economically than many small plants. Thus the availability of transportation is to-day concentrating the industry in spite of the three factors mentioned, which by themselves would have kept the industry in the hands of many small producers.

In spite of improvements in the methods of producing lime, greater ease of transportation, and of larger, more economical plants, the output of the kilns—that is, the burned lime—is brought into the market in much the same manner as it was centuries ago. Further, the method of using the lime has scarcely changed.

One of the earliest examples of the employment of mortar in masonry is presented by the pyramids of Egypt. An examination of the mortar between the stones in the Pyramid of Cheops has shown it to be identical with that employed in Europe to-day, although its preparation must have taken place more than 2,000 years before the Christian era. Mortar made from lime was employed by most of the ancient races, notably the Phoenicians, Greeks, and Romans. * * *

The only improvement in the form of the merchantable lime known to the writer is that of hydrated lime. The fact that lime could be slaked to the form of a dry powder has long been known, and three methods have been used in the past to produce this powder.

---

[1] Rock Products, vol. 13, No. 10, Mar. 22, 1914.

1. Lime, in comparatively small pieces about the size of an egg, is placed in a basket and immersed in water for one or two minutes, until hydration has commenced, when it is withdrawn. The wet lime is generally put in heaps or silos in order to conserve the heat and prevent the escape of the vapor. The material swells, cracks, and become reduced to a dry powder.

2. Lumps of lime are placed in a heap and wetted at intervals so that the mass is equally moistened throughout. The slaking proceeds as in the first instance.

3. Small pieces of lime are exposed to the air for a munber of months. The material absorbs both water and carbon dioxide from the atmosphere, falling to dry powder. The powdered form consists of a hydrated subcarbonate of lime containing about 10 to 11 per cent of water.

These methods of dry-slaking lime are crude, and unless the greatest care is exercised the resulting product will contain particles of unslaked lime. Further, the hydrates produced by these methods are generally short and possess poor sand-carrying capacity; in fact, hydrated lime produced by any of the above methods is only suitable for use on the soil, and such hydrates should not be confounded with hydrated lime manufactured by modern methods.

The modern method of manufacturing hydrated lime depends upon the addition of an exact amount of water to a predetermined exact amount of lime. By no other method is it possible to produce a hydrate which will contain sufficient combined water to satisfy the demands of the calcium oxide present. It is important that all the calcium oxide is satisfied, otherwise the hydrate will be unsound and unsuitable for many uses.

This point will be insisted upon in any specifications that may be drawn for hydrated lime to be used in the building trade. It is vital that each manufacturer recognize the fact that the formation of hydrated lime is a chemical change, involving the presence of exact amounts of lime and water. Since the process is chemical, it requires the same careful supervision as any other chemical process, such as the manufacture of Portland cement. The production of hydrated lime has been retarded more by the manufacture of only partly hydrated lime than from any other cause. It has only been a few years since it was nearly impossible to buy completely hydrated lime, and even at the present time the records of our laboratories show that more unsound hydrate is offered for sale than sound material, for which conditions the manufacturer is directly responsible. From a selfish standpoint, it is to the advantage of the manufacturer to produce a completely hydrated lime since such a lime contains the maximum amount of water. * * *

It is to the interest of progressive manufacturers to build their business to such dimensions as to warrant the employment of skilled experts and engineers, in order that the cost of manufacturing may be reduced to the lowest possible unit, and, further, to present their products to the market in such form that they will keep and at the same time be convenient to use. The day of the barrel is passing. It is not feasible to market a bulky commodity in a package worth practically as much as the contents. * * * Does not the manufacture of hydrate offer a solution to most of the troubles encountered in the marketing of lime? * * *

One of the greatest difficulties in connection with the burning of lime is due to the perishable quality of the product. In general this means that the common form of lime, lump lime, can not be stored for any great length of time without deterioration, and this makes the operation of the plant dependent upon the seasons and the whims of the weather. Kilns are fired up, damped down or put out, according to the season of the year and the condition of the weather. This unevenness of operation results in higher unit cost. Since hydrated lime can be stored in bins, in a manner similar to cement, it is therefore possible to make the operation of the plant more continuous, thereby introducing economies in the unit costs. Further, the manufacture of hydrated lime also means an increased market, since hydrated lime can be used for a number of purposes for which lump lime is not suitable. * * *

The greatest advantage to the dealer is the ease of handling, less deterioration of the product, and the freedom from fire risk. These three facts alone should convince the dealer that it is more economical to handle hydrated lime than lump lime. * * * In general it may be stated that hydrated lime is suitable for any use in the building trade to which lump lime can be put, and it would appear that as soon as the material comes into general use, its advantages will be found to far outweigh its disadvantages. The use of hydrated lime does away with the necessity of slaking lime to a paste, thus saving the large amount of space required, as well as the labor. Since hydrated lime comes into the market in convenient packages, it is possible to proportion the mortar so as to have exact quantities present. This point is always appreciated by the architect and engineer, since it is a well known fact that when lump lime is used as much sand as possible is added to it, with the result that the mortar is lean and possesses little strength. The sand-carrying capacity of lump lime has been much overrated, especially by the manufacturer, with the result that it is the common practice to oversand the mortar. * * *

As to the uses of hydrated lime in general, it may be stated that they are identical with those of lump lime, except in such chemical industries where the heat of slaking becomes an important factor. To the writer's knowledge, hydrated lime has supplanted lump lime in a number of chemical industries for the following reasons: The greater convenience in handling, the ability to more definitely proportion the amount used, and because of the more uniform lime content of this product. This has been the case even where the cost per ton of hydrated lime is higher than that of lump lime. If hydrated lime is correctly manufactured, and the particle of core and unhydrated lime removed, the resulting product possesses a higher grade of purity than the original lime from which it was made. Further, the product is more uniform, and these two facts appeal strongly to the chemical users of lime. * * *

In June, 1910, the writer presented the results obtained from an extended series of tests on both hydrated and lump-lime mortar, to the American Society for Testing Materials. One of the most important conclusions drawn from these investigations was that the mortar produced from hydrated lime was stronger than that produced from the corresponding lump lime slaked to a paste. This conclusion was to be expected, since it is possible to manufacture hydrated lime by mechanical means under good chemical control, which is more thoroughly slaked than it is possible to slack lump lime on the job. The user in dealing with hydrated lime is handling a tested product which can be definitely proportioned and will produce known results. With lump lime the user is dependent always upon the thoroughness of slaking and it is well known to all users of lime that unless the paste is run off and stored for some considerable time there is no assurance of complete and thorough slaking.

Practically all those who investigate the strength of lime mortars have recommended the use of hydrated lime rather than lump lime. In Bulletin No. 30, of the Bureau of Standards, the following statement is made: "The proportion of impurities in hydrated lime is generally less than that in the lime from which it is made. In building operations hydrated lime may be used for any purpose in place of lump lime, with precisely similar results. The consumer must pay the freight on a large amount of water, but the time and labor required for the slaking is eliminated and there is no danger of spoiling it either by burning or incomplete slaking. * * * For all building purposes hydrated lime is to be preferred to lump lime. By its use the time and labor involved in slaking may be saved and the experience of the laborer is eliminated as a factor in the problem." * * *

In conclusion, it may be stated that hydrated lime possesses advantages for the manufacturer, dealer, and user.

To the manufacturer it means more uniform operation of the plant, less waste in the form of fine lime and forkings, no loss through air slaking, the doing away with the barrel plant, and the manufacture of a product possessing good keeping qualities.

To the dealer it means no fire risk, no loss by air slaking, no barrels to add to the cost of lime, and a more convenient package.

To the user it presents a material possessing all the advantages of lime with none of its disadvantages, the certainty of producing a mortar having definite proportions of lime and sand, and, further, this mortar possesses greater strength than ordinary lime mortar.

Warren E. Emley[1] discusses the process of manufacture of hydrated lime elsewhere in this volume of Mineral Resources, and also in a publication by the Bureau of Standards.

BIBLIOGRAPHY.

UNITED STATES GEOLOGICAL SURVEY PUBLICATIONS RELATING TO LIMESTONE AND LIME.

Publications mentioned in the following list may be obtained on application to the Director United States Geological Survey, Washington, D. C., except those with prices affixed, which may be bought from the Superintendent of Documents, Government Printing Office:

Adams, G. I., and others, Economic geology of the Iola quadrangle, Kansas: Bull. 238, 83 pp., 1903. 25 cents.

Ball, S. H., Portland cement materials in eastern Wyoming: Bull. 315, pp. 232–244, 1907. 50 cents.

Bassler, R. S., Cement materials of the Valley of Virginia: Bull. 260, pp. 531–544, 1905. 40 cents.

Bastin, E. S., The lime industry of Knox County, Me.: Bull. 285, pp. 393–400, 1906. 60 cents.

Burchard, E. F., Portland cement materials near Dubuque, Iowa: Bull. 315, pp. 225–231, 1907. 50 cents.

——— Structural materials available in the vicinity of Minneapolis, Minn.: Bull. 430, pp. 280–291, 1910.

——— Structural materials available in the vicinity of Austin, Tex.: Bull. 430, pp. 292–316, 1910.

——— Lime: Mineral Resources U. S. for 1909, pt. 2, pp. 543–555 (75 cents); idem for 1910, pt. 2, pp. 609–626 ($1.25); idem for 1911, pt. 2, pp. 645–718 ($1.10).

——— Concrete materials produced in the Chicago district: Bull. 340, pp. 383–410, 1908.

Burchard, E. F., Butts, Charles, and Eckel, E. C., Iron ores, fuels, and fluxes of the Birmingham district, Alabama: Bull. 400, 204 pp., 1910.

Burchard, E. F., and Emley, W. E., The source, manufacture, and use of lime: Mineral Resources U. S. for 1913, pt. 2, pp. ——, 1914.

Butts, Charles, Limestone and dolomite in the Birmingham district, Alabama: Bull. 315, pp. 247–255, 1907. 50 cents.

——— Variegated marble southeast of Calera, Shelby County, Ala.: Bull. 470, pp. 237–239, 1911.

Clapp, F. G., Limestones of southwestern Pennsylvania: Bull. 249, 52 pp., 1905.

Catlett, C., Cement resources of the Valley of Virginia: Bull. 225, pp. 457–461, 1904. 35 cents.

Crider, A. F., Cement resources of northeast Mississippi: Bull. 260, pp. 510–521, 1905. 40 cents.

——— Geology and mineral resources of Mississippi: Bull. 283, 99 pp., 1906.

Darton, N. H., Marble of White Pine County, Nev., near Gandy, Utah: Bull. 340, pp. 377–380, 1908. 30 cents.

——— Geology and water resources of the northern portion of the Black Hills and adjoining regions in South Dakota and Wyoming: Prof. Paper 65, 104 pp., 1909.

——— Structural materials in parts of Oregon and Washington: Bull. 387, 36 pp., 1909.

——— Cement materials in Republican Valley, Nebraska: Bull. 430, pp. 381–387, 1910.

Darton, N. H., and Siebenthal, C. E., Geology and mineral resources of the Laramie Basin, Wyoming: Bull. 364, 81 pp., 1909.

Diller, J. S., Limestone of the Redding district, California: Bull. 213, 1903. 25 cents.

Duryee, E., Cement investigations in Arizona: Bull. 213, pp. 372–380, 1903. 25 cents.

SAND AND GRAVEL.

By Ralph W. Stone.

PRODUCTION.

The total production of sand and gravel in the United States in 1913 reported directly to the United States Geological Survey was 79,555,849 short tons, valued at $24,217,508, a net increase in quantity of 11,201,286 short tons and in value of $1,104,300 over the production of 1912. Sand for building purposes constituted nearly one-third of the total production. In 1913 a production of 25,397,383 tons of building sand was recorded with a value of $8,007,949. This is an increase in quantity of 1,621,370 tons and in value of $39,822 over the production of 1912. The average value per ton, which increased from 31 cents in 1911 to 33½ cents in 1912, fell to 31½ cents in 1913.

Quantity and value of sand and gravel produced in the United States, 1904–1913, in short tons.

Years.	Quantity.	Value.
1904	10,679,728	[a] $5,748,099
1905	23,204,967	11,223,645
1906	32,932,002	12,698,208
1907	41,851,918	14,492,069
1908	37,216,044	13,270,032
1909	59,565,551	18,336,990
1910	69,410,436	21,037,630
1911	66,846,959	21,158,583
1912	68,354,561	23,113,208
1913	79,555,849	24,217,508

[a] Includes a very small quantity of gravel.

The following table gives the total production of glass sand in the United States in each of the last 10 years:

Quantity and value of glass sand produced in the United States, 1904–1913, in short tons.

Years.	Quantity.	Value.	Average value per ton.
1904	858,719	$796,492	$0.92
1905	1,060,334	1,107,730	1.04
1906	1,089,430	1,208,788	1.11
1907	1,187,296	1,250,067	1.05
1908	1,093,553	1,134,599	1.04
1909	1,104,000	1,163,375	1.05
1910	1,461,089	1,516,711	1.04
1911	1,538,666	1,543,733	1.01
1912	1,465,386	1,430,471	.97
1913	1,791,800	1,895,991	1.06

The following table gives the production of molding sand in the United States in each of the last 10 years, or since 1904, when the first statistics of molding sand were collected:

Quantity and value of molding sand produced in the United States, 1904–1913, in short tons.

Years.	Quantity.	Value.	Average value per ton.
1904	3,439,214	$2,125,370	$0.62
1905	3,084,098	2,102,423	.68
1906	3,371,103	2,063,151	.61
1907	3,682,494	2,460,754	.67
1908	1,980,677	1,342,802	.67
1909	3,122,806	2,146,220	.68
1910	3,636,167	2,431,254	.67
1911	3,376,717	2,132,469	.63
1912	4,485,380	2,718,726	.61
1913	3,563,583	2,230,217	.63

The tables following give the production of the various kinds of sand and the production of gravel by States in 1912 and 1913.

Production of sand and gravel in the United States in 1912 and 1913, by States and uses, in short tons.

1912.

[a] Included in "Concealed totals."

The production of gravel exceeded that of building sand by more than 13,000,000 tons. The total production of gravel in 1913 was 38,526,498 tons, valued at $8,842,811, or an increase in quantity of 8,754,913 tons and in value of $1,101,794 over the production of 1912. These figures show an average cost per ton of slightly less than 23 cents, or 3 cents less than the average value per ton of gravel in 1912. This large quantity of gravel was used for many purposes, including concrete, paving, filter beds, roofing, road making, and railroad ballast.

Molding sand, which in 1912 for the first time exceeded a production of 4,000,000 tons, seems to have had a severe setback in 1913, if the returns are as complete as in 1912. The production of molding sand reported for 1913 is 3,563,583 tons, valued at $2,230,217, a decrease in quantity of 921,797 tons, and in value of $488,509 from the production of 1912. Although New Jersey made a good increase in production, there was a very large decrease in Illinois, Indiana, Michigan, New York, Ohio, and West Virginia. Thus the depression in the iron and steel trades shows itself, or an overproduction in 1912 is counterbalanced.

Glass sand, on the contrary, was marketed in greater quantity than ever, the total quantity produced in 1913 being 1,791,800 tons, valued at $1,895,991. This is an increase in quantity of 326,414 tons and in value of $465,520 over the production of 1912. The average value per ton rose from 97 cents in 1912 to $1.05 in 1913. The revision of the tariff on glass seems to have had no effect on the production of glass sand, if we may judge by the quantity reported sold.

Grinding and polishing sand fell off 344,490 tons from the production of 1912, in which year the production exceeded that of 1911 by 347,235 tons. The value of the product in 1913 was $540,399, or $91,737 less than in 1912.

The production of fire and furnace sand remained practically the same, totaling about 519,000 tons, and the output of engine sand reported was about 255,000 tons less than in 1912.

Paving sand production nearly doubled in quantity in 1913. The production reported was 3,335,508 tons, valued at $1,020,389, as compared with 1,788,530 short tons, valued at $670,680 in 1912, an increase in quantity of 1,546,978 tons and in value of $349,709.

Railroad ballast sand is this year separately recorded for the first time. The reported production of 2,335,196 short tons, valued at $266,852, is not the total quantity of sand ballast used by the railroads in the United States in 1913, for the reason that some railroads keep no record of the quantity of sand produced and used by them in making cuts and ballasting their road beds, it being with them only a matter of moving material from one point on the right of way to another point. The quantity and value given above were actually reported.

The entire report of the production of sand and gravel is necessarily incomplete because it is impracticable to attempt to get or to estimate the quantity of sand produced by the thousands of individuals who each year dig a small quantity for their own use. This production, of which there is no count or accounting, may average less than a ton for the individual producer, but the aggregate may be hundreds of thousands of tons. The figures each succeeding year should be nearer the actual production, as the list of producers is added to annually.

The gravel figures for 1913 do not include a considerable quantity of chats or tailings from the Missouri zinc mines. The production of chats in Missouri and Kansas in 1913 was 2,028,889 tons, valued at $304,333. The gravel figures do include 125,897 tons of chert, valued at $52,883, used for road building in Alabama.

The unit of measurement given in the tables of production is the short ton. Much of the sand is reported as sold by the cubic yard, a cubic yard varying in weight from 2,300 to 3,000 pounds, according to the condition of the sand, according to the material of which the gravel is composed, and according to the custom of the locality. All of the glass sand is sold by the short ton, and also a considerable quantity of the molding, building, and other sand; hence the quantities reported were all reduced to this unit.

IMPORTS.

Sand valued at $172,257 was imported into the United States in 1913, as compared with imports valued at $141,690 in 1912 and at $147,268 in 1911. This is largely building sand brought to the United States as ballast, or from Canada as a near source of supply, but it includes a small quantity of French molding sand which comes to this country barreled in lump and is here ground and pulverized before marketing.

SAND FOR STEEL MOLDING.

The principal requirement of a sand for steel molding is a high degree of refractoriness, and therefore clean quartz sand containing more than 95 per cent silica is used. The size of the grain demanded varies with the weight of the casting and the place occupied in the mold. Steel molding sands are commonly white but may be yellow or light brown.

The specifications for sand bought by the Panama Canal Commission for use on the Isthmus in making steel castings were as follows:

Sand, silica, to be sharp, free from loam and other organic matter, and suitable for steel castings; shall show the following upon analysis:

SiO_2	95–100 per cent.
Fe_2O_3	under 1 per cent.
CaO	under 1 per cent.
MgO	under 1 per cent.

It will be noted that size of grain and color are not mentioned. A New Jersey sand which answered the requirements of these specifications and was shipped to the Panama Canal in hundreds of barrels is here compared with other steel-molding sands. The tests made by the writer were on samples in the Survey collection, which are contained in 3-ounce jars.

Sieve test of steel-molding sands.

Locality.	Retained on—			
	40-mesh.	80-mesh.	100-mesh.	Pan.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*
Burlington, N. J	15	83	1.5	0.5
Lake Majella, Cal	11.5	87	1.5	....
Niles, Ohio	32	61	4	3
Millville, N. J	64	32	2	2
Ottawa, Ill., glass or silica	47	50	1.5	1.5
Ottawa, Ill., white steel	37.5	43.5	12.8	6.2
Ottawa, Ill., yellow steel	54	40	3	3
Pacific Grove, Mo	1	95.5	2	1.5

The sand from Burlington, N. J., was used on the Panama Canal. It is not known to the writer for what specific purposes it was used in steel molding. It is presumed to be adapted to general work. The test shows that it can be separated by screening into three different sizes. The coarse size, or 15 per cent, thus obtained appears to be a little larger in grain than glass or silica sand from Ottawa, Ill., and slightly smaller than steel sand from Millville, N. J. The bulk of this sand, or 83 per cent, which ranges from 40 to 80 mesh is comparable in size with many glass sands, while the remaining 2 per cent is almost a silica flour. Each of these three sizes would have its particular use in casting steel; the coarse sand is fitted for the body of a mold or parts where a smooth surface is not demanded; the medium sand for smooth surfaces, sharp corners where wear will come, and the throat of the mold through which a considerable quantity of molten metal will pass. The finest size could be used for facing parts of the mold. The raw sand is judged to be a high-grade sand for general use.

The sand from Burlington as shown by the test is practically identical in size with a steel molding sand dug at Lake Majella, near Pacific Grove, Cal. The most noticeable difference is that the former is a grayish white and the latter yellowish white. As the Lake Majella sand is a high-grade silica sand there would seem to be no reason for Pacific coast steel foundaries paying freight on steel sand from the Mississippi Valley. The deposit at Lake Majella is in dunes of considerable size and extent.

A grayish-white sand from Niles, Ohio, which is used by a steel company in Cleveland for green sand molding, is found by the sieve test to be one-third 20–40 mesh and two-thirds 40–80 mesh. This is just the opposite of two sands from Silver Run, Millville, N. J., which are two-thirds 20–40 mesh and one-third 40–80 mesh. The sands at Millville occur in the bank in distinct yellow and white bands, which may or may not be mixed in digging. These distinct differences in percentages of different sizes of component grains adapt them to different uses in refined molding.

Steel sands from Ottawa, Ill., vary in size of grain only slightly among themselves, and, so far as known to the writer, the white steel sand from this locality is identical with the best glass sand from Ottawa. The yellow sand, although not so valuable for glass making, probably is as good for steel molding as the clear white sand. These sands are derived from disintegrated St. Peter sandstone, as is also the sand from Pacific Grove, Mo. The latter has grains of the most uniform size of the sands tested. The 1 per cent coarse sand of the Missouri sample is identical with the 54 per cent of the yellow sand from Ottawa; and the 95 per cent of the sand from Missouri is only a shade less yellow than the 40 per cent of the yellow sand from Ottawa.

Sand made by crushing quartzite which analyzes over 95 per cent silica is also used in considerable quantities in casting steel. A sand of this kind which is produced in southeastern Pennsylvania and is said to be used in large quantities as a steel and fire sand varies in size from ⅛-inch grain to flour.

It is apparent that the size of grain varies considerably with the character of the work to be done. A sand suitable for making a mold in which steel pigs are to be cast is very different from a sand adapted to use in molding light weight, sharply detailed steel castings.

Steel molding sands vary in color, being commonly white, gray-white, yellowish, or light brown. Silica sand may be yellow and yet have less than 0.05 per cent of iron.

High-grade silica sand has no bond and a binder must be added to make a sand which can be molded. Some steel plants use a mixture of 5 parts old or burned sand, 5 parts fresh sand, and 1 part fire clay. Another mixture is approximately equal parts of old and fresh sand gaged with silica flour, molasses water, and fire clay. Some molders use 7 parts silica sand, 2 parts ground ganister or silica rock, and 1 part silica clay, bonded with molasses water. All these mixtures are changed to suit varying conditions.

Cores for steel molds are made of a variety of material, depending largely on the size of the space to be occupied. Small cores may be made of an open sand with a binder, and large cores are made of grit mixed with iron molding sand, and tempered with 1 shovelful of flour to 10 shovelfuls of grit and a thin vegetable oil.

SAND AND GRAVEL FOR FILTRATION PLANTS.

Clear, white, quartz sand of the proper size is the common material used in filter beds. The floor of filters may be made of broken trap, granite, or other rock screened to the proper size, or of clean, sized gravel.

The specifications for the filtration plant at Washington, D. C., which called for proposals for furnishing 140,200 cubic yards of filter sand and 42,300 cubic yards filter gravel, were as follows:

Filter gravel.—On the floor of the filters and surrounding the underdrains shall be placed gravel or broken stone having a maximum depth of 1 foot. Instructions will be given by the Engineer officer in charge as to the exact arrangement and positions of the various layers when the stone commences to be received upon the ground, but the arrangement will be approximately as follows: The lower 7 inches shall consist of broken stone or gravel which will remain upon a screen with a mesh of 1 inch, and which has but very few stones over 2 inches in diameter. Above this shall be placed 2½ inches of broken stone or gravel which has passed a screen with a mesh of 1 inch, and which remains upon a screen with a clear mesh of ⅜ inch, and above this shall be placed 2½ inches of broken stone or gravel, which has passed a screen with a mesh of ⅜ inch, and which is coarser than the ordinary sand, and entirely free from fine material.

The material for all of the layers may be broken trap rock or granite screened to the proper sizes, or gravel screened from sand and gravel banks of a sandy nature. Gravel screened from hardpan or clayey material can not be sufficiently cleaned. The gravel shall not contain more than a very small amount of shale or limestone. The gravel shall be washed entirely free from fine material, so that water passing through it or agitated in contact with it will remain substantially clean.

Filter sand.—The filter sand shall be clean river, beach, or bank sand, with either sharp or rounded grains. It shall be entirely free from clay, dust, or organic impurities and shall, if necessary, be washed to remove such materials from it. The grains shall, all of them, be of hard material which will not disintegrate and shall be of the following diameters: Not more than one-half of 1 per cent by weight shall be less than 0.13 millimeter; not more than 8 per cent less than 0.26 millimeter. At least 7 per cent by weight shall be less than 0.34 millimeter, at least 70 per cent less than 0.83 and at least 90 per cent less than 2.1 millimeters. No particle shall be more than 5 millimeters in diameter, and the sand shall be passed through screens or sieves of such mesh as to stop all such particles, and no screen or sieve shall be used containing at any point holes or passages allowing grains larger than the above to pass. The diameters of the sand grains will be computed as the diameters of spheres of equal volumes. The sand shall not contain more than 2 per cent by weight of lime and magnesia taken together and calculated as carbonates. In all other respects the sand shall be of a quality satisfactory to the Engineer officer in charge.

The filter sand shall be placed in the filters in three layers, each layer to be about 1 foot thick, and the sand shall not be dropped from a height into final position or otherwise unduly compacted. The first two layers may be filled in to only approximate depths and the surfaces need not be smoothed. The final layer shall be brought to a true and even grade, and the surface left smooth and uniform.

The specifications for the plants at Springfield, Mass., and Toronto, are practically identical, as follows:

The filter sand shall be clean sand, with either sharp or rounded grains. It shall be entirely free from clay, dust, or organic impurities, and shall, if necessary, be washed to remove such materials from it. The grains shall, all of them, be of hard material which will not disintegrate. The effective size shall not be less than 0.25 millimeter nor more than 0.35 millimeter. The uniformity coefficient shall not be more than 3.0. The sand shall be free from dust and shall not contain more than 1 per cent finer than 0.13 millimeter, and shall be entirely free from particles over 5 millimeters in diameter. The sand shall not contain more than 2 per cent by weight of lime and magnesia taken together as carbonates. In all other respects the sand shall be of a quality satisfactory to the engineer.

ASBESTOS.

By J. S. Diller.

PRODUCTION.

The production of asbestos in the United States is small, but in manufactured asbestos products the United States surpasses any other country. The total output of asbestos in this country for 1913 was about 1,100 short tons, and all of it came from 2 producers in Georgia and 1 in Arizona. For this reason exact figures can not be given without divulging confidential information.

Georgia produced asbestos of the amphibolite variety, anthophyllite. In 1913 the production of Georgia increased decidedly over the output of that State in 1912, and the Sall Mountain Asbestos Co. continues to be the largest producer.

The latest reports from Arizona indicate that the market is active for Arizona crude fiber at prices comparing favorably with No. 1 Canadian. A small initial production is accredited to 1913.

Annual marketed production of asbestos in the United States, 1890–1913, in short tons.

Year.	Production.			Year.	Production.		
	Quantity.	Value.	Average price per ton.		Quantity.	Value.	Average price per ton.
1890	71	$4,560	$64.23	1902	1,005	$16,200	$16.12
1891	66	3,960	60.00	1903	887	16,760	18.90
1892	104	6,416	61.69	1904	1,480	25,740	17.39
1893	50	2,500	50.00	1905	3,109	42,975	13.82
1894	325	4,463	13.73	1906	1,695	28 565	16.85
1895	795	13,525	17.01	1907	653	11,899	8.22
1896	504	6,100	12.10	1908	936	19,624	20.97
1897	580	6,450	11.12	1909	3,085	62,603	20.29
1898	605	10,300	17.02	1910	3,693	68,357	18.51
1899	681	11,740	17.24	1911	7,604	119,935	15.77
1900	1,054	16,310	15.47	1912	4,403	87,959	19.98
1901	747	13,498	18.07	1913	1,100	11,000	10.00

The largest annual production of asbestos in the United States was in 1911, when the output amounted to 7,604 short tons, valued at $119,935. In 1912 the output declined to 4,403 short tons, and the falling off continued throughout 1913. The cause of the sharp decline is the fact that the mill of the Chrysotile Asbestos Corporation of Vermont was closed during the entire year.

WORLD'S PRODUCTION.

The world's supply of asbestos is drawn largely from the Province of Quebec in Canada, although the rapid development of the Russian output is making that country an important factor in the world's supply, as is shown in the following table:

World's production of asbestos, 1907–1912, in short tons.[a]

Country.	1907	1908	1909	1910	1911	1912
United States	653	936	3,085	3,693	7,604	4,403
Africa:						
Cape Colony	604	1,267	1,674	1,403	1,253	(b)
Natal	....	....	....	3	13	(b)

f Min. Jour., London.

PRICES.

Prices of asbestos in the United States are controlled by the Canadian market. Most of the mines have sold their output ahead for a considerable time. Prices in 1913 were higher than in 1912, as is shown in the accompanying table:

Range of New York prices per short ton for Canadian chrysotile fiber during 1912 and 1913.

	1912	1913
No. 1 crude	$300–$325	$320–$350
No. 2 crude	175– 200	200– 225
No. 1 fiber	....	100– 125
No. 2 fiber	....	75– 100
Shorter fibers	....	10– 30

The trade appears to expect prices to be advanced 10 or 15 per cent during 1914, owing to the increase in wages demanded. Recent offers for Arizona fiber indicate that it will rank with the Canadian in market value. The price of the amphibole variety of asbestos fiber averaged $10 a ton in 1913.

IMPORTS.

The imports given in the first of the accompanying tables are total imports for calendar years and are almost identical with the imports for consumption for the same period.

Canada is by far the most important source of the asbestos used in the United States. Unmanufactured asbestos, including ground, is admitted free, but manufactured asbestos is dutiable at from 25 to 40 per cent ad valorem.

The Canadian exports of asbestos during the 12 months ending December 31, 1913, are reported by the customs department of the Dominion[1] as 103,812 short tons, valued at $2,848,047. Of this quantity 86,564 short tons were shipped to the United States, that is, more than 83 per cent of all that was exported by Canada and more than 63 per cent of all that Canada produced in 1913.

As is shown in the accompanying table, the total imports of unmanufactured asbestos other than that from Canada amounted in 1913 to only 173 short tons, or about 0.2 per cent of the imports from Canada. The greater portion of this asbestos came from Russia, in part by way of Germany, and a few tons came from Italy.

The comparatively small imports of manufactured asbestos come mainly from Europe, in particular from England, Germany, and Austria-Hungary.

General imports of asbestos into the United States, calendar years 1912 and 1913, in short tons.

The value of the manufactured and unmanufactured asbestos imported for consumption into the United States during the calendar years 1909 to 1913 is shown in the following table:

Value of asbestos imported for consumption into the United States, 1909–1913.

Year.	Unmanufactured.	Manufactured.	Total.
1909	$993,254	$240,381	$1,233,635
1910	1,235,170	308,078	1,543,248
1911	1,413,541	290,098	1,703,639
1912	1,456,012	363,759	1,819,771
1913	1,928,705	378,961	2,307,666

[1] Preliminary report on the mineral productions of Canada during the calendar year 1913: Canada Dept. Mines, p. 16, 1914.

ASBESTOS IN THE UNITED STATES.

ARIZONA.

Arizona has long been known for the peculiar occurrence as well as the high grade of its asbestos, although it has not been a producer. The asbestos occurs with serpentine in limestone. The serpentine, like the limestone in which it occurs, is derived from material of sedimentary origin and as to its original source is therefore in strong contrast with the serpentine derived from peridotite.

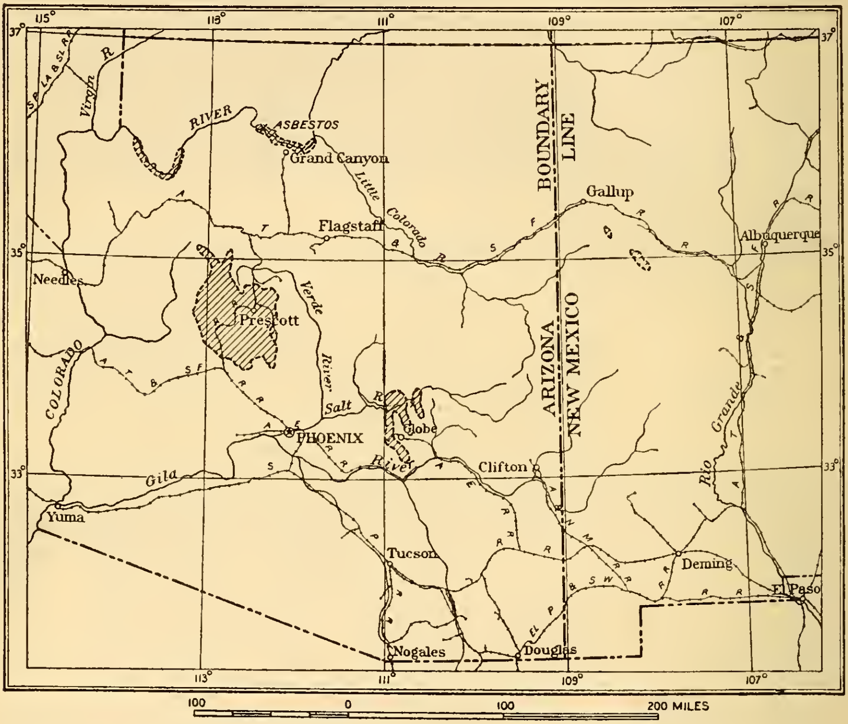

FIGURE 12.—Map showing asbestos prospects (X) in Arizona. Shading shows areas of pre-Cambrian rocks.

Chrysotile was discovered some years ago in the depths of the Grand Canyon under Grand View, as well as at Bass's, 30 miles farther west. Lately, however, chrysotile of the same sort and mode of occurrence has been found in the vicinity of Globe, on Ash Creek. Both localities are indicated in figure 12.

CHRYSOTILE ASBESTOS OF THE GRAND CANYON.

The asbestos of the Grand Canyon lies west of the mouth of the Little Colorado. The belt is a long, narrow strip lying at a definite geologic horizon among the Algonkian strata in the depths of the Grand Canyon of the Colorado about 4,000 feet below the rim and in places about 1,000 feet above the river. It has been studied at two localities in the canyon, one beneath Grand View[1] where the

[1] Pratt, J. H., U. S. Geol. Survey Mineral Resources, 1904, pp. 1137-1140, 1905.

serpentine-asbestos belt is exposed for nearly 2 miles with a width of only a few feet, and the other 30 miles farther west in the canyon beneath Bass's camp[1] where the same belt has a length of about three-fourths of a mile.

According to Noble the same asbestos belt outcrops for several miles in the canyon west of Powells Plateau. Owing to its inaccessibility the locality has not yet been examined.

The strata in which the chrysotile occurs are part of a thick series of Algonkian rocks which dip generally to the north or northeast at angles of 10° to 20° and are broken here and there by normal faults, generally of small displacement. These rocks form part of the north wall of the great gorge of the Colorado, where they are separated from both the overlying Cambrian and the underlying Archean by conspicuous unconformities. The strata, although deep seated and of great age, are as a body not crushed, fractured, or metamorphosed as are those of Canada and Vermont, where the chrysotile is contained in serpentine derived from the alteration of peridotite.

A section of the rocks with which the asbestos is associated in the Grand Canyon is given below, as measured by Noble[2] on Asbestos (Hakataia) Creek.

Section of asbestos-bearing rocks in Asbestos Creek Canyon.

	Feet.
Diabase.	
Layer of green serpentine	2
Pure white crystalline limestone	1½
White crystalline limestone with bands and nodules of serpentine	2
Serpentinous nodular and banded layer carrying veins of asbestos	1
Banded crystalline limestone with bands and nodules of serpentine	10
Nodular cherty limestone	4
Soft blue slate	5

The limestone above the diabase contains some serpentine and small veins of asbestos rather widely distributed, but on the whole this material appears to be much less abundant and persistent than that below the diabase.

The asbestos below the diabase is not absolutely constant in horizon, but may lie, according to Noble, anywhere from 3 to 15 feet below the contact.

The serpentine and asbestos occur in the limestones only where these strata are invaded by the diabase sill; where the diabase lies between shales there is no development of these minerals within the invaded strata. In no place in the area are they developed within the diabase itself. It is, therefore, clear that they are a contact-metamorphic phenomenon conditioned by the invasion of the limestones by the diabase. It seems probable, as suggested by Diller, that the serpentine which incloses the veins of asbestos is derived from some mineral in the limestones and not from the diabase. The limestones themselves are magnesian and locally siliceous in the form of chert bands and nodules. In another part of the area the conversion of the shales to jaspers where they are in contact with the diabase is evidence that the fumarolic action accompanying the injection of diabasic magma was manifested by aqueous and probably siliceous emanations and was fairly intense. It seems possible that the operation of the fumarolic action upon the elements already present in the magnesian limestones might have been sufficient to convert the more siliceous portions into serpentine. The occurrence of the asbestos in veins that cut both the nodules of serpentine and the limestones is evidence that the formation of the cross-fiber asbestos was itself a somewhat later phenomenon.[3]

[3] Noble, L. F., op. cit., pp. 521–522.

THE ASBESTOS.

The serpentinous layer that carries the asbestos is usually from 12 to 14 inches in thickness, and the general trend of the asbestos veins within it is parallel to the bedding of the limestone. Locally the asbestos fiber is 4 inches in length from side to side of the vein, but generally the veins do not exceed 2½ inches and in many places they appear as a series of small parallel veins. The larger veins are remarkable for their continuity. According to Pratt,[1] below Grand View, where the outcrop of the serpentine-asbestos layer is in places as much as 18 or even 24 inches in thickness, there may be in it two or three large parallel veins of asbestos that continue for 150 feet. Within this thin layer containing the asbestos, cross-fiber veins more than an inch in width are common. The width of the veins at this horizon varies greatly from place to place, so that a 3-inch vein in one locality may be represented by a zone of numerous small veins in another; but, according to Noble, the actual continuity of the zone that carries the asbestos is rarely broken.

The asbestos veins have but few partings, and these are generally of chalcedonic quartz with rough borders instead of the smooth, sharp lines like those which generally mark the sides of the veins. The asbestos is generally of a beautiful golden-yellow color, though in places shading to pale green. It is finely fibrous, smooth, silky, and of great tensile strength, so that it compares favorably with the crude asbestos from any other country.

Locally as much as 40 per cent of the 12-inch layer may be Nos. 1 and 2 crude, with 10 per cent of lower grades, but in general the thin layer would probably not average more than 15 per cent of all grades.

The eastern area under Grand View has been most extensively prospected. A few years ago the Hance Asbestos Co. opened a number of cuts along the outcrops and ran tunnels down the dip, some of them for 75 feet.

The large proportion of crude to other grades in this Grand Canyon deposit is remarkable. Ordinarily such a deposit could be profitably mined, but the narrow limits of the asbestos belt, taken in connection with its attitude and the difficulties of getting the asbestos across the river and out of the canyon to the railroad, appear to render successful mining very problematical, except in a small way with donkeys for transportation. In any case, the development of this deposit would have to be on a small scale only and for high-grade material.

Whatever part the asbestos of the Grand Canyon may play in the industry of the country, it will ever be recognized as one of the most exceptional and interesting deposits yet discovered. The entire absence of rock crushing and the remarkable continuity of the asbestos veins approximately in the plane of stratification clearly indicate that the veins were not deposited in open fissures, but by the replacement of serpentine in the planes of weakness somewhat later than the development of the serpentine itself. Here, too, we have convincing evidence of the development of asbestos by igneous intrusion. We may, therefore, the more readily accord to the granite dikes in Canada and elsewhere a decided influence in the formation of the asbestos near their contacts.

CHRYSOTILE OF ASH CREEK NEAR GLOBE.

The most important event during 1913 concerning the occurrence of asbestos in the United States was the discovery by T. D. West of an important deposit of chrysotile in the region of Globe, Ariz. Four-

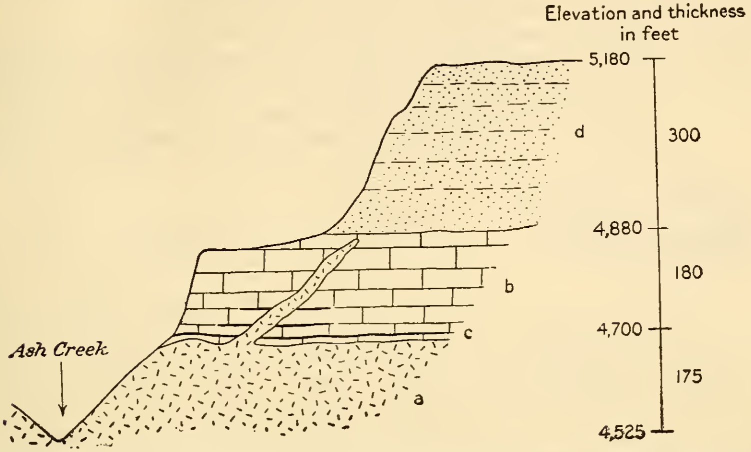

FIGURE 13.—Section of east slope of Ash Creek, 25 miles northeast of Globe, Ariz.; 220 miles S. 30° E. of Bass's Ferry in Grand Canyon. a, Diabase; b, gray limestone, in part cherty, locally banded and containing sheets and nodules of serpentine and some asbestos; c, three asbestos belts 12 to 24 inches in thickness lie parallel with the bedding in layers of gray to white limestone; d, mainly quartzite with some conglomerate. Nodules of serpentine occur here and there in the locally banded limestone near the asbestos belts.

teen claims were taken up by T. D. West and Fred Patee on Ash Creek, about 25 miles in a direct line N. 25° E. of Globe. Ash Creek is a short stream and carried about 4 miner's inches of cool clear water September 28, 1914. It heads against Sycamore Creek and flows north through a rugged canyon into Salt River. At the point where the asbestos occurs the canyon is about 600 feet deep and its eastern slope presents the general section shown in figure 13.

The asbestos belts contain cross-fiber veins of chrysotile, which constitutes in some places from 25 to nearly 50 per cent of the mineral matter of the belt. Most of the chrysotile fiber is from one-half inch to 1 or 2 inches in length. A generalized section showing the detailed structure of the asbestos belt is shown in figure 14.

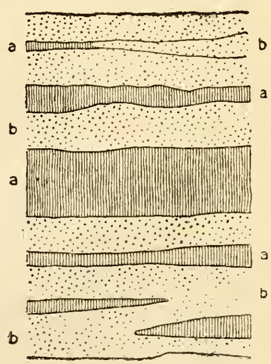

FIGURE 14.—Generalized detail section of asbestos belt. Cross-fiber veins of chrysotile (a), separated by pale-green to gray serpentine (b).

The asbestos belt, especially the one near the contact with the diabase, is more or less continuous for a mile, but varies greatly from place to place.

The bands of serpentine in the asbestos belt are generally of light-green color and compact, splintery, conchoidal fracture. In places the serpentine is gray like chalcedony but is easily distinguished by its softness.

The principal asbestos belt is the one nearest the contact with the diabase, although usually separated from the diabase by a few feet of limestone. Other belts, generally smaller, occur farther up in the limestone to a distance of about 30 feet. The higher-grade asbestos belts appear to be associated with a dike of diabase penetrating limestone from the main body of diabase below.

These nodules of serpentine with partial borders of asbestos, as shown in figure 15, occur in the white to gray limestones near the asbestos belts. The nodules are of various colors from brown to deep leek green. The quantity of serpentine and chrysotile is small as compared with that of the asbestos belts.

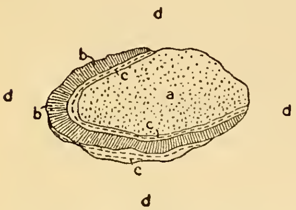

FIGURE 15.—Nodule of serpentine (a) with chrysotile (b), bordered mostly on both sides by serpentine (c), but partly by white limestone (d).

COMPOSITION AND QUALITY OF ARIZONA CHRYSOTILE.

The quality of the chrysotile is excellent. For electric insulation it has been tested by several large firms and pronounced better than the Canadian. This view is demonstrated by a comparison of the following chemical analyses, which show the Grand Canyon asbestos to contain only 0.51 per cent of iron oxide, while the best analyses of Canadian chrysotile yet reported from Thetford, Black Lake, and Danville, the three great centers of Canadian production, contain from 2.26 to 2.60 per cent of iron oxide.

8. Theoretical composition: Dana, E. S., A textbook of mineralogy, p. 477.

The chemical analyses of this table (Nos. 2 to 7, inclusive) are quoted from the monograph of Fritz Cirkel.[1] In moisture content as well as in magnesia the Grand Canyon chrysotile is close to the Canadian, but in silica it is somewhat higher, although a little less than the theoretical composition (8) of pure chrysotile.

[1] Chrysotile-asbestos: Its occurrence, exploitation, milling, and uses, 2d ed., p. 31. Dept. Mines, Ottawa, Canada, 1910.

The Grand Canyon type of chrysotile occurring at Ash Creek is remarkable (where not affected by weathering) for its silky luster, flexibility, and tensile strength.

To test the latter a number of samples were prepared of groups of fibers $1\frac{1}{2}$ to 2 inches in length and so numerous that when twisted three times they formed a yarn about $\frac{3}{100}$ of an inch in thickness. The average of a number of tests of chrysotile yarn made of Ash Creek, (Ariz.) fiber showed that it will support $15\frac{4}{5}$ pounds, while the Canadian chrysotile under the same conditions supported $15\frac{1}{2}$ pounds. The strength of the fiber is much impaired by weathering, and it is still difficult to get material at Ash Creek as fresh as that of the large quarries at Thetford.

Among the most valuable properties of asbestos are its heat resistance. Its melting point is high and its conduction is low. For this reason it is good for fireproofing and heat insulation. When heated, chrysotile gives off most of its water at red heat. In a blast-lamp flame having a temperature between 1,200° and 1,300° C. the Grand Canyon and the Ash Creek chrysotile, like the best grades of silky Canadian fiber, lose water and their threads apparently melt and change form to a somewhat glassy enamel-like substance which is not isotropic like glass but granular doubly refracting, owing to the fact that the chrysotile under high heat breaks up into olivine (Mg_2SiO_4) and enstatite ($MgSiO_3$), which do not fuse in the ordinary blast lamp. According to Brun [1] olivine fuses at 1,750° C., and some members of the pyroxene group as high as 1,350° to 1,410° C.

CALIFORNIA.

California contains much serpentine that has been crushed and penetrated by various dikes, so that it might well be regarded as good ground for the asbestos prospector. Numerous prospects have been reported but have not resulted in definite production. Hitherto the prospects reported have been in the Sierra Nevada, especially in Placer County near Towle and Iowa Hill, but in 1913 two other localities attracted attention, one on Mears Creek in Shasta County and the other in the southern part of Napa County. The samples submitted from Placer County are mainly of the slip-fiber type. Those from Shasta and Napa counties are for the most part of the cross-fiber type, but in quantity, size, and quality of fiber they do not warrant great expectations.

About the head of Mears Creek in Shasta County, west of Sims station (Hazel Creek post office), there is a large area of serpentine that was prospected in 1913. Much of the rock has completely changed to serpentine, but in places there is much olivine and pyroxene remaining to show the original character of the igneous rock from which the serpentine has been derived. It is cut by a variety of dikes in the vicinity of the asbestos deposits. Cross-fiber veins are common up to half an inch in thickness, but no large veins of high-grade chrysotile were observed. On the other hand, the property contains a remarkable deposit of slip fiber in which the fiber lies nearly horizontal parallel to the vein as if the motion producing it were horizontal comparable to that of the faulting connected with the San Francisco

[1] Econ. Geology, vol. 7, p. 4.

earthquake. This clear, white fiber softened by weathering on the outcrop but hard beneath has a variable thickness up to 3 or 4 feet. Lengthwise it has been traced more or less continuously for nearly a mile. The locality is on a steep, rocky slope from 3 to 7 miles west of the railroad, and Mears Creek running directly through the locality affords good water power.

GEORGIA.

The outlook in Georgia continues to grow slowly but steadily more encouraging. The output increased 53 per cent in 1913, as compared with that of 1912. There were two points of production, one near Asbestos station on the Gainesville & Northwestern Railroad, 3 miles southwest of Sall Mountain, in White County, and the other near Hollywood on the Tallulah Falls Railroad, in Habersham County.

The Sall Mountain Co. has been in continuous operation for many years. In 1913 it removed its mill from Sall Mountain to Gainesville on the main line of the Southern Railway, at its junction with the Gainesville & Northwestern Railroad, over which its raw material is transported from quarry to mill.

The mill and quarry at Hollywood began operations about December 1, 1913. The material and product is similar to that of the Sall Mountain Co.

Much of the Georgian asbestos is exported, but experiments now under way may result in its being used to advantage in the manufacture of asbestos wood and similar products.

Dr. Oliver B. Hopkins, of the Georgia Geological Survey, has recently prepared a paper concerning the asbestos deposits of Georgia and has kindly permitted the following abstract to be made from his manuscript:[1]

After a few general statements concerning (1) the history and importance of the asbestos industry, (2) the principal sources of raw material, and (3) the types and modes of occurrence of asbestos, Dr. Hopkins takes up the asbestos deposits of Georgia in particular.

The asbestos deposits of Georgia are associated with the crystalline schists of pre-Cambrian age and are limited in their distribution to the areas of basic igneous rocks which form a belt across the northwestern portion of the State from Rabun County to Harris County; this belt is relatively more important in Rabun and Habersham counties. Small quantities of slip fiber occur in the diorites and gabbros, but the more important deposits are those of mass fiber associated with peridotites and pyroxenites. The whole rock mass is fibrous, and Hopkins calls attention to the fact that usually as much as 95 per cent of the rock quarried in Georgia is realized as fiber, while in the case of the chrysotile deposits of Canada the average extraction of fiber for 1912 was only 6.45 per cent of the rock quarried. Although the extraction of the Canadian cross-fiber chrysotile is less than one-fourteenth that of Georgia mass-fiber asbestos, the price is nearly three times as great. This gives, according to Hopkins, a decided advantage to the Georgian product, especially since the mining can be done more economically and the milling is much more simple.

[1] This paper was read before Section E of the American Association for the Advancement of Science at Atlanta, and is to be published in a volume of papers read at that meeting concerning the mineral resources of the Southern States.

Owing to the slight demand, little Georgia asbestos is being put on the market at the present time. With a good demand for the material at from $8 to $12 a ton a number of deposits in the State could probably be worked with profit and a large amount of material could be put on the market.

The field relations and the microscopic study of the material indicate that the mass-fiber anthophyllite is derived from enstatite-olivine rock.

VERMONT.

The large area of peridotite and serpentine of the Province of Quebec in Canada, which furnishes so large a part of the world's supply of asbestos, extends southwest across the international boundary into Vermont and has long been regarded as one of the most promising asbestos fields in the United States.

The Lowell Lumber & Asbestos Co. began operations in Vermont in 1907, erected a mill on the southwestern slope of Mount Belvidere, and began the production of asbestos in 1908. The mill was enlarged and the output increased to its greatest yield in 1911. Owing to labor troubles and especially also, it is said, to the decline of trade in the countries affected by the Balkan War, the mill shut down during part of 1912, and in 1913 there was no production at all. In response to inquiries the president, W. G. Gallager, states:

> That the principal work done was getting ready for the installation of electric power and the enlargement of the plant, which we expect to have completed by the coming summer. We also expect to have the transportation problem solved by building a railroad either from Johnson, Vt., or Morrisville, Vt. This we also hope to have in operation before the snow flies next winter.

WYOMING.

Prospecting continues in the Casper and Wind River mountains of Wyoming, but there has been no definite production for the market. Some interesting experiments have been made in the use of Wyoming asbestos for boiler covering by the Chicago & North Western Railway Co. Vice President R. H. Aishton [1] reports that:

> A conductivity test was made, and the results show that the Wyoming asbestos contains better heat-resisting qualities than the two samples of Canadian asbestos compared with it.

The practical boiler covering test will not be completed for 12 or 18 months when the engine comes up for repair. Definite results are not yet available, but they appear to promise a line of utilization for Wyoming fiber.

QUARRYING ANG MINING ASBESTOS.

The mass-fiber asbestos of Georgia is obtained in quarries. The whole rock mass is fibrous, and after the removal of the soil almost the entire body of rock quarried may be milled into marketable product.

In Vermont, and especially also in Canada, where the chrysotile is associated with serpentine resulting from the alteration of peridotite, the chrysotile is quarried. The only exception to this statement is

---

[1] Letter, Feb. 2, 1914.

that at Thetford, Canada, the material is removed from the Bell quarry by cars on rails through a 1,100-foot tunnel, which affords an opportunity for actual underground working, that is mining asbestos.

The chrysotile in Arizona is a product of contact metamorphism in limestone and outcrops, so far as is known, only in canyons. It occurs at Ash Creek in a narrow irregular belt, and the amount of chrysotile that can be removed from open cuts on the steep canyon slopes is limited. To obtain that which lies within the canyon walls, the limestone must be tunneled and the asbestos removed by regular mining methods. The bulk of it could be "hand cobbed" ready for the market. There is also much short but excellent fiber that should be carefully saved for more convenient transportation or manufacture at the mine. That this asbestos can be mined is considered feasible, but whether or not it can be mined at a profit has not yet been demonstrated by actual experience.

PROSPECTING FOR ASBESTOS.

Asbestos of the cross-fiber type of chrysotile is most commonly found in large areas of serpentine derived from the alteration of basic intrusive rocks, such as peridotite and pyroxenite. Large areas of serpentine, especially of much crushed rock masses, are therefore the most promising in which to search for asbestos. The purer the serpentine the better the prospect in Canada and elsewhere, especially if the serpentine is cut by dikes of fine-grained granitic rocks, such as occur in the great asbestos region of Thetford and Black Lake in the Province of Quebec.

In Arizona, which is just now attracting considerable attention, the case is very different. Although it is true that the chrysotile is associated with serpentine, the quantity of serpentine is small, and it occurs in beds of limestone near their contact with an intrusive mass of diabase, as illustrated in figure 13. The chrysotile and serpentine are due to the contact metamorphism of the limestone by the diabase. In some places, particularly in the Grand Canyon, the diabase cuts the limestone approximately parallel to the bedding, and chrysotile occurs along both the upper and the lower contacts, but the lower contact as far as yet seen has the largest amount of chrysotile. Both contacts should be prospected.

It is not yet certainly known whether or not the limestone containing chrysotile asbestos on Ash Creek is the same horizon as that containing the same material in the asbestos region of the Grand Canyon.

The limestone carrying chrysotile in the Grand Canyon region is known to be Cambrian. That of Ash Creek is believed to be either Cambrian or older, and below the "Globe limestone," Carboniferous and Devonian, described by Ransome in the Globe folio.[1] The horizon of the chrysotile on Ash Creek may be in the cherty dolomitic limestone, separated from the Devonian by 400 feet of quartzite.[2]

As the chrysotile is found only in limestone near the contact of diabase, such contacts should be thoroughly prospected throughout the country between Ash Creek and the Grand Canyon of the Colorado, for there may be other localities of importance.

---

[1] Ransome, F. L., U. S. Geol. Survey Geol. Atlas, Globe folio (No. 111), p. 5, 1904.
[2] Ransome, F. L., Copper deposits near Superior, Ariz.: U. S. Geol. Survey Bull. 540, pp. 139–143, 1914.

Pre-Cambrian rocks are exposed at a number of points in northeastern Arizona and northwestern New Mexico. The general outlines of the areas as well as the localities at which asbestos is known to occur are shown in figure 12 and may serve as a suggestive guide to prospectors. Of the two asbestos localities in the Grand Canyon the one farthest west is Bass's and the other is Hance's. The locality northeast of Globe is on Ash Creek. Between the Grand Canyon and Ask Creek, a distance of about 175 miles, the pre-Cambrian rocks are so deeply covered by Paleozoic strata as to render them inaccessible, unless these rocks have been brought to the surface by great faults at places not now known. In the Globe area west of Ash Creek, as well as in the Prescott area and also in the westernmost area in the Grand Canyon, no asbestos has been found, but it should be looked for.

The conditions of mining and transporting asbestos in Arizona will necessarily limit its production, but as the material is of high grade it may, if economically handled, be made profitable. In getting the best fiber, much short fiber will accumulate that can be milled and manufactured later by hydroelectric power.

To the east, in New Mexico, the pre-Cambrian rocks come to the surface again. A small area of them about 20 miles southwest of Grant might contain asbestos deposits more advantageously located than in the other localities mentioned.

The apparently increasing demand for the mass-fiber type of asbestos, such as has been mined for years at Sall Mountain, Ga., is of interest. This type of asbestos occurs in thoroughly crystalline basic igneous rocks, such as pyroxenites bordering upon peridotites, and has been found in many places in the Appalachian Mountains in North Carolina and Georgia; but it has been successfully mined in Georgia alone. The grade of this asbestos being low, the possibility of its successful financial development is more limited than in the case of higher grades. If hard, fresh white asbestos rock of this type could be milled and separated by an air process the product might find extended application and larger demand in the manufacture of paper.

ASBESTOS IN FOREIGN COUNTRIES.

CANADA.

The asbestos mines of Canada are located in the eastern townships of the Province of Quebec. The most productive localities are at Thetford, Black Lake, and Danville.

The asbestos is chrysotile and occurs in thin irregular veins traversing masses of serpentine rock that have resulted from the alteration of peridotite. The veins vary from a mere film to 2 or 3 inches in thickness. The chrysotile fiber runs directly across the vein from side to side unless interrupted by partings, which may contain a bit of serpentine or oxide of iron.

The chrysotile veins traverse the serpentine in all directions, but do not continue for great distances. The whole mass of rock is quarried in open cuts and the veins of crude fiber are separated from milling rock by hand picking. The crude-fiber grades 1 and 2 containing fiber about an inch or more in length afford the best spinning material, and when broken from the rock and bagged this material is ready for the market.

The other rock material from which the crude grades have been separated and which is yet sufficiently rich in fiber is prepared for market by being dried, crushed, fiberized, and separated by a process of milling into various grades ranging from mill fiber to asbetic.

Canada is the world's chief source of asbestos. In 1909 Canada furnished 81 per cent of the world's output; in 1910, 85 per cent; and in 1911, about 82 per cent. The production of Canada is rapidly and rather uniformly increasing. The output of all other countries, except Russia, is relatively unimportant.

However small its domestic production of asbestos, the United States is the chief manufacturer of asbestos goods and draws its supply of raw material from Canada.

Canadian activity in the production of asbestos in 1913 [1] was confined to the districts of Black Lake, Thetford, and Danville, in Quebec. None of the quarries formerly operated at East Broughton were worked, although small shipments were made by one firm from stock.

The total output in 1913 was 132,564 [short] tons as against 102,759 tons in 1912, an increase of 29,805 tons, over 29 per cent. The sales and shipments of asbestos fiber in 1913 were 136,951 tons, valued at $3,830,909, or an average of $27.97 per ton, as against sales in 1912 of 111,561 tons, valued at $3,117,572, or an average of $27.95. Stock on hand at December 31, 1913, was reported as 20,786 tons as compared with stocks of 23,288 tons at the beginning of the year.

A new mill is in course of construction at Danville.

The output and sales of crude and mill stock separately is shown for 1912 and 1913 in tabulated statements following. The classification is based on valuation. Crude No. 1 comprises material valued at $200 per ton and upward, and crude No. 2, under $200; mill stock No. 1 includes mill fiber valued at from $30 upward; No. 2, from $15 to $30; and No. 3, under $15.

The total sales of crude in 1913 were 5,660.3 tons, valued at $989,162, or an average of $174.75, as against sales in 1912 of 5,662.9 tons, valued at $890,351, or an average of $157.22, practically the same quantity but at a higher average price.

The total sales of mill stock in 1913 were 131,291 tons, valued at $2,841,747, or an average of $21.64 per ton, as against 105,898 tons in 1912, valued at $2,227,221, or an average of $21.03 per ton, a large increase in quantity but at substantially the same average price.

There was a falling off in the amount of both crude and mill fiber in stock at the end of the year, indicating a revival of business and increasing demand.

Output, sales, and stocks of Canadian asbestos in 1913, in short tons.

RUSSIA.

Next to Canada, Russia sends the largest importation of raw asbestos for manufacture in the United States. A brief account of the asbestos deposits of Russia was published [2] in this report

[1] McLeish, John, Preliminary report on the mineral production of Canada during the calendar year 1913; Canada Dept. Mines, pp. 14-16, 1914.
[2] U. S. Geol. Survey Mineral Resources, 1908, pt. 2, pp. 702-703, 1909.

for 1908. The asbestos field is a large one, lying on the eastern slope of the Ural Mountains, and the mining is chiefly in the district of Ekaterinburg. The country is flat, and the serpentine, derived apparently from pyroxenite, is deeply weathered, so that it can be easily worked in open cuts for the asbestos it contains. Owing to the strong industrial demand for asbestos, the production has been on the increase of late. It nearly doubled in the space of the five years from 1907 to 1912.

The asbestos produced annually in the Ural Mountains since 1902 is as follows: [1]

Production of asbestos in the Ural Mountains, 1903–1912.

	Short tons.		Short tons.
1903	5,785	1908	11,935
1904	8,244	1909	14,654
1905	7,985	1910	12,203
1906	8,815	1911	17,071
1907	9,741	1912	18,138

The total production of asbestos in the Ural Mountains during the 10 years ending with 1912 was 114,570 short tons. There were 20 quarries in operation in 1912.

The spot price of the Russian asbestos is between 2 rubles ($1.03) and 2 rubles and 20 kopeks ($1.18) per pood; that is, $57.21 and $65.56 per short ton.

An increasing quantity of asbestos is exported abroad, viz, 6,372 short tons in the first six months of 1913.[2]

RECENT INVESTIGATIONS CONCERNING ASBESTOS.

In studying the conduction of heat with reference to heating devices, C. P. Randolph, of the General Electric Co.'s research laboratory at Great Barrington, Mass., determined the efficiency of insulations containing asbestos and published his results in the following table: [3]

Thermal resistivity of insulations containing asbestos.

Material.	Density (pounds per cubic foot).	Temperature (° C.).	Resistivity (° C. per watt per cubic inch).
Diatomaceous earth and asbestos	20.7	400–0	550
85 per cent magnesia	13.5	400–0	600
35 per cent magnesia	29.8	0–400	480
Air-cell asbestos	15.6	0–200	400
Asbestos fire felt	7.18	200	740
	7.18	300	620
	7.18	400	430
Navy brand asbestos fire felt	19.8	500	465
	....	300	523
	....	100	793
Asbestos roll-fire fire felt	35.8	0–600	490
"C" fiber	22.9	100	518
	22.9	200	448
	22.9	300	395
	22.9	400	374
	22.9	500	358
Asbestos fiber	12.5–18.7	500	450–550
Asbestos sponge felt	34.4	100	1,020
	....	200	830

[1] Min. Jour. (London), Aug. 16, 1913, p. 778, given in poods.
[2] Chamber of Commerce Jour., London, December, 1913, p. 386.
[3] Gen. Elec. Rev., vol. 16, pp. 122-123, February, 1913.

The temperature given represents approximately the temperature of the side on which the heat flux enters, the temperature of the other side being always about 10° C.

Nature and composition of insulations containing asbestos listed in the table.—The "diatomaceous earth and asbestos" is the "nonpareil high-pressure covering" made by the Armstrong Cork Co., Pittsburgh, and is a mixture of kieselguhr (pure SiO_2) and asbestos, held together with a binder. The measurement given is the average of values found at five temperatures from 100° to 500° C., none of which vary from the mean by more than 8 per cent and which show neither a definite increase nor decrease with the temperature. The material withstands heating to 500° C., with only a slight tendency to crumble and may safely be used at the above temperature. It is self-supporting.

The material listed as "85 per cent magnesia" is made from magnesium carbonate and asbestos fiber by the Johns-Manville Co., Boston. It can not be used safely where it will be exposed continuously to temperatures above 300° C., as it disintegrates and carbon dioxide is evolved. If it is then subject to moisture, it will hydrate. It possesses no distinct temperature coefficient, and the value given for the resistivity is the average of five measurements at temperatures from 100° to 500° C. The deviation from the mean is not more than 8 per cent. The material is self-supporting.

The material listed as "35 per cent magnesia" was made by the Keasbey-Mattison Co., Ambler, Pa., and contains 35 per cent magnesium carbonate with 60 per cent fiber. It can safely be used continuously at temperatures not in excess of 300° C. It is self-supporting and is called "magnasbestos."

The "air-cell asbestos" (Johns-Mansville) is also known as "asbestocel corrugated fireproof paper." It is a self-supporting corrugated paper about $\frac{1}{32}$ inch thick, held in shape by a paper backing. The value given for the resistivity is accurate no closer than 10 per cent, as it varies greatly with different samples. This material can not be used at temperatures exceeding 200° C., as it apparently contains an organic binder.

The "asbestos fire felt" (Johns-Manville) is the lightest self-supporting material we have ever been able to secure. The manufacturer states that it is made of pure asbestos fiber loosely felted together. It has a tough outer shell and is essentially a molded material. It can be used continuously at temperatures not in excess of 300° C.

The "navy brand asbestos fire felt" is the same material as the above, except that the density is much greater, and, according to the manufacturer, it is constructed of specially selected long-fiber asbestos. It withstands temperatures of 500° C. perfectly, while heating at 500° C. for eight days does not affect appreciably the resistivity—increasing it slightly, in fact.

The "asbestos roll fire felt" (Johns-Manville) is an asbestos cloth, flexible and very tough. It is made of pure long-staple asbestos, can be used at temperatures up to 600° C., and has no distinct temperature coefficient.

The "C fiber" listed (Johns-Manville) consists of asbestos fiber with a small amount of some powdered material. It can be used at 500° C., but is not self-supporting.

The "asbestos fiber" figures relate to five samples from the Eimer-Amend Co., New York. They apparently do not change on heating to 500° C.

The "asbestos sponge felt" (Johns-Manville) consists of layers of asbestos paper each about 0.04 inch thick. The manufacturer states that it is made of asbestos fiber and finely ground sponge. It can not be used at temperatures exceeding 200° C., as it loses all strength above this [temperature]. It is a self-supporting material.

GYPSUM.

By Ralph W. Stone.

PRODUCTION.

The gypsum industry is growing at a healthy rate. In 1903 a little over 1,000,000 tons of crude gypsum were mined, in 1913 the production was well over 2,500,000 tons. In 10 years the production has fallen short of that of the preceding year only three times, the greatest setback being in 1904, when the production as reported was more than 100,000 tons less than that of 1903.

The number of short tons of raw gypsum mined in 1913 was 2,599,508, an increase of 98,751 tons over the 2,500,757 tons mined in 1912. The gypsum sold without calcining and used principally as an ingredient in Portland cement and in paint, and as land plaster, amounting to 463,136 short tons, valued at $697,066, showed an increase in quantity of 21,528 tons and in value of $73,544, as compared with 441,608 short tons, valued at $623,522, in 1912; and the material calcined for plaster increased in quantity 42,175 short tons and in value $137,370. The total value of gypsum and gypsum products produced in 1913 was $6,774,822, as compared with $6,563,908 in 1912, an increase of $210,914.

Gypsum was produced in 18 States and in Alaska. Eighty-two quarries or mines were worked. The total number of mills reporting in 1913 was 67. This includes mills using domestic material that calcined plaster as well as those that ground raw gypsum for land plaster and for other purposes. New York was the largest producer of raw gypsum; Iowa ranked second; and Michigan was third. Sales of gypsum products are credited to Illinois, Minnesota, Washington, and Wisconsin, although these States are not producers. This is rendered necessary by the trend of the gypsum industry toward assembling calcined gypsum, retarder, fiber, sand, etc., and preparing plasters for the market at local mixing mills from which they may be more readily and economically distributed to the trade territory. Sales made from mixing plants as reported to the Survey are credited to the State in which the warehouse is located.

The quantity of raw gypsum ground and sold for land plaster amounted to 54,815 short tons, valued at $95,953, in 1913, compared with 53,065 tons, valued at $107,058, in 1912, an increase in quantity of 1,750 short tons and a decrease in value of $11,105. The average price per ton at the mills received for land plaster was reported to be $1.75 in 1913, compared with $2.02 in 1912, $1.85 in 1911, and $2.05 in 1910. The quantity of raw gypsum sold for the manufacture of paint, for Portland cement, for bedding plate glass, and for various other purposes, amounted to 408,321 short tons, valued at $601,113, in 1913, compared with 388,543 short tons, valued at $516,464, in 1912, an increase in quantity of 19,778 tons and in value of $84,649. The average price of this class of products in 1913 was $1.47 per ton, compared with $1.33 in 1912, and with $1.47 in 1911. The average price of calcined gypsum products, including wall plasters, plaster of Paris, Keene's cement, and dental plaster was $3.43 per ton, the same as in 1912.

The following tables give the statistical data regarding the gypsum industry in 1912 and 1913, by States:

Production of gypsum in the United States in 1912 and 1913, by States and uses, in short tons.

1912.

1886	95,250	1898	291,638	1910	2,379,057
1887	95,000	1899	486,235	1911	2,323,970
1888	110,000	1900	594,462	1912	2,500,757
1889	267,769	1901	633,791	1913	2,599,508
1890	182,995	1902	816,478		
1891	208,126	1903	1,041,704		

The following table showing the marketed production of gypsum by uses in the United States from 1909 to 1913 should be of particular interest as it shows the trend of the trade. An increasing quantity of crude gypsum is being sold for Portland cement manufacture, and the average price per ton, which fell off 15 cents in 1912, increased 14 cents, making it $1.47 in 1913 or 1 cent lower than in 1911.

The quantity sold crude for land plaster has remained nearly the same for four years, but the average value per ton dropped 27 cents in 1913, or from $2.02 to $1.75. As 88 per cent of gypsum sold crude in 1913 was used for Portland cement, the average price per ton of all crude gypsum—$1.51—is close to that of the gypsum sold for Portland cement. The considerable decrease in the average price of land plaster is more than counterbalanced by the slight increase in value of the larger item.

Although the sale of calcined gypsum for dental plaster and to glass factories was 15,546 tons less in 1913 than in 1912, and that used as plaster of Paris, wall plaster, etc., increased only 1,740 tons, that sold for Portland cement and other purposes was 55,981 tons more than in 1912. The total increase in calcined gypsum sold in 1913 over that sold in 1912 was 42,175 tons. The average price per ton remained the same, $3.43. It is interesting to note that nearly 95 per cent of the calcined gypsum sold in the United States, or 1,680,157 tons, is used for wall plaster, Keene's cement, plaster of Paris, etc. About one and one-quarter million tons of this quantity represents mixed wall plaster.

Marketed production of gypsum in the United States, 1909–1913, by uses, in short tons.

IMPORTS.

Gypsum imported into the United States comes almost wholly from Nova Scotia and New Brunswick and enters the ports of the New England and North Atlantic States, over one-half of it entering the port of New York.

A marked advance in the quantity and value of imports was made in 1913. There was an increase of 34,686 tons of unground gypsum as compared with an increase of 22,283 tons in 1912, the total importation of unground gypsum in 1913 being 447,383 short tons, valued at $473,594. The figures give an average value per ton of unground gypsum of $1.058, or about 2 cents a ton higher than in 1912.

The quantity of ground or calcined gypsum imported is very small.

The following table gives such statistics concerning the imports of gypsum and gypsum products as are issued by the Bureau of Foreign and Domestic Commerce:

Gypsum imported and entered for consumption in the United States, 1909–1913, in short tons.

Year.	Unground.		Ground or calcined.		Value of manufactured plaster of Paris.	Total value.
	Quantity.	Value.	Quantity.	Value.		
1909	350,160	$376,790	3,437	$21,799	$26,548	$425,137
1910	415,321	444,263	2,414	15,072	42,776	502,111
1911	389,874	413,119	388	3,353	34,334	450,806
1912	412,697	430,183	3,702	19,709	38,589	488,481
1913	447,383	473,594	4,542	31,277	52,051	556,922

PRODUCTION IN OTHER COUNTRIES.

The following table gives the production of gypsum in the principal producing countries from 1910 to 1912, inclusive, so far as the figures are available:

Production of gypsum in principal producing countries, 1910–1912, in short tons.

Country.	1910		1911		1912	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
Algeria	55,751	$115,109	57,220	$119,264	(a)	(a)
Australia	19,092	47,278	15,110	37,584	(a)	(a)
Canada	b 525,246	934,446	b 518,383	993,394	b 578,458	$1,324,620

a Data not yet available. b Quantity marketed. c Exports. d Total value not stated.

TRADE AND MANUFACTURING CONDITIONS.

A number of producers reported business conditions as practically the same in 1913 as in 1912; a small number found trade poorer because of drought and poor crops; nine producers considered it better. The average price of raw gypsum throughout the country advanced 10 cents in 1913 over that of 1912, while the average price of calcined material remained the same. Four new mills were in operation in 1913, 1 each in California, New York, Oklahoma, and Oregon, and 3 new mills were reported under construction in 1913, 1 each in California, Colorado, and South Dakota.

There were 82 active gypsum mines, including quarries and pits, in the United States in 1913, 1 being in Alaska. These mines supplied 67 plants in the United States. Of these plants 45 used gypsum, 9 used gypsite, 12 used both gypsum and gypsite, and 1 reported the use of selenite crystals. Four plants produced ground gypsum only, and 63 plants calcined some of their product. Of these calcining plants 57 were equipped with kettles, 3 with rotary kilns, and 3 with stationary kilns. There were 181 calcining kettles in operation mainly 8 and 10 feet in diameter. The total daily capacity for all these kettles as reported was 14,344 short tons, giving an average of 79 tons per kettle.

On comparing these statistics with those of 1912, when there were 76 gypsum plants in operation, 69 of which were calcining plants and 63 of which were equipped with a total of 192 kettles, it is found from the producers' reports that there was a net loss of 9 plants, a loss of 6 calcining plants, and a net loss of 11 kettles. There was an apparent loss of 1,325 tons in the total daily capacity and a loss of 3 tons a day in the average daily capacity per kettle. The loss in number of calcining plants was due in part, particularly in New York, to the replacement of several small mills by one of larger capacity. These summaries do not include the equipment of several plants termed "mixing mills," which are auxiliary mills established at commercial centers, such as Chicago, Ill., Milwaukee and Superior, Wis., Minneapolis and St. Paul, Minn., and Cleveland, Ohio. These mills do no calcining, but receive the calcined plaster and prepare it for the market in various forms by the addition of fiber, retarder, and sand.

Keenes cement was made at 5 of the gypsum plants in 1913, a loss of 1 from the number of plants reporting the manufacture of this cement in 1912.

The fuel used at 43 calcining plants was coal; oil was used at 17 plants, wood at 1 plant, and coal and oil at 2 plants. The oil-burning plants are in Arizona, California, Kansas, Nevada, New Mexico, Oklahoma, Oregon, Texas, and Washington.

GYPSUM PRODUCTS.

The bulk of the gypsum produced in the United States, as well as in foreign countries, is manufactured by grinding and by partial or complete calcination into the various plasters, such as plaster of Paris, molding and casting plaster, stucco, so-called cement plaster or hard wall plaster, flooring plaster, hard-finish plaster, etc. Refined grades of gypsum plaster are used in dental work, also as cement for plate glass during grinding, for making pottery molds, stereotype molds, molds for rubber stamps, and as an ingredient in various patent cements. A steadily increasing quantity of gypsum is used in the raw state as a retarder in Portland cement. Considerable quantities are ground without burning and used as land plaster or fertilizer; smaller quantities are used in the manufacture of paint, wall tints, crayons, paper, imitation meerschaum and ivory, and as an adulterant. The pure white or tinted, fine-grained, massive form, known as alabaster, is much used by sculptors for interior ornamentation—less, however, in this country than abroad.

For plaster of Paris and for dental molding and casting plasters, a high grade of rock gypsum, ground very fine, is required, and the product is not mixed with any foreign substance or retarder, but is used in the pure or "neat" condition. Such plasters are quick setting and are usually white in color. Much of the so-called cement plaster is made directly from gypsite, an impure unconsolidated earthy or sandy form of gypsum, which in many places is found to contain a suitable percentage of foreign material, so that the addition of a retarder is not necessary to effect a slow set. Where gypsite deposits are not available, cement or hard wall plasters are made from rock gypsum by the addition of various mineral or organic retarders. A large part of the structural plaster now produced is used in specially prepared conditions that appeal to the builder on account of their convenience. A plaster board is pressed from plaster interlaminated with sheets of thin cardboard, felt, or wood. This plaster board is furnished in thin sheets of different sizes—as $\frac{1}{4}$, $\frac{3}{8}$, and $\frac{1}{2}$ inch thick by 32 by 36 inches, comprising 8 square feet of surface; $\frac{3}{8}$ inch thick by 27 by 48 inches, equivalent to 1 square yard; also 32 by 24 inches, 32 by 18 inches, and 24 by 18 inches. This board is designed to be nailed directly to the studding in place of lath and to receive a coat of wall plaster directly on its outer surface. Fibered plaster is molded into both solid and hollow blocks and tiles, which are used in partitions and interior construction, and these, as well as the plaster board, have been proved to be of value as fire retarders. Gypsum tile or partition blocks are commonly 12 inches wide, but vary in thickness from 2 to 8 inches. They are made 24 and 30 inches long, except 8-inch blocks, which are 15 inches long. Gypsum tiles are lighter than clay tiles; they are straight and true; they can be cut by a handsaw; and on account of light weight and large size they can be laid rapidly.

The employment of gypsum wall plasters has assumed noteworthy proportions in the last few years. Plaster manufacture represents the most important single application of gypsum in this country. Hard wall plasters consist of plaster of Paris and some fiber, like hair or wood fiber, with the addition of a retarder. They may contain either hydrated lime or clay to increase their plasticity and spreading properties. This is not necessary with plasters made from gypsite, because the raw material contains considerable quantities of clay. Hard wall plasters are of two general grades, one having a brown or gray coat, and the other a white or tinted finish coat. They are somewhat more expensive than lump lime and inferior to it in deadening sound, but the material is delivered to the work in a more convenient form to handle than lump lime, and by reason of its more rapid set it gives opportunity to complete a job in less time.

A number of hard-finish anhydrous plasters are also made from gypsum, the most prominent representative of the group being Keenes cement, which was originally manufactured under English patents that have expired. The name "Keenes" is now applied by several manufacturers in the United States to their product, made by calcining very pure rock gypsum in lump form at a red heat and adding to the resulting dehydrated lime sulphate a substance like alum or borax. Keenes cement makes a very white and very hard plaster. It is used as a backing and surface for artificial marble and for ornamental moldings and castings and is capable of taking a high polish. Its use as a wall plaster is increasing, but when so used it may be mixed with lime. Flooring plaster is another example of this type of plaster. Gypsum is used in the manufacture of calcimines, in water paint and tints, and, to a considerable extent, as an ingredient in dry colors, notably in Venetian reds. When used in excess in mixed paints, it is regarded as an adulterant. The unburned or the dead-burned forms of gypsum may be used to a certain extent with oil paints, because they are chemically inactive. The partly dehydrated form is not suitable for such use, but can be used with water.

The Government has not undertaken a thorough investigation of gypsum products nor made any extensive tests of gypsum plasters. It is hoped that when this is done by the Bureau of Standards definite data may be obtained regarding some of the properties which are now in doubt. It is maintained by some that the strength of gypsum plaster decreases with time. The change, if any, is probably so slight that it might be necessary to extend an inquiry on this point over several years to obtain definite results. So long as gypsum plasters properly applied have proved perfectly satisfactory after many years, this point would seem not to be of commercial interest. Whether gypsum plaster has an injurious effect on metal lath has not been demonstrated conclusively, so far as the writer is aware.

In a letter to the Survey, discussing certain properties of gypsum plaster and lime plaster, the Pittsburgh branch of the Bureau of Standards, Department of Commerce, says:

It is quite possible that some hard wall plasters containing a fiber retarder and a considerable percentage of clay or hydrated lime possess a greater spreading power than lime plaster; but the spreading power of a plaster, by which we assume is meant the number of square yards which can be covered per unit of weight, is not of particular importance, because, first, the spreading power should be based on unit of cost of material rather than on unit of weight; and second, the cost of application of a wall plaster being ordinarily four to five times the cost of the raw material, it follows that any slight variation in the cost of the material would not make any particular difference in the cost of the wall.

While it is true that hard wall plasters shrink less on drying than lime plasters, this can hardly be called a point in their favor, because lime plasters have proven entirely satisfactory.

The ability to unite with coloring agents, so as to produce any desired tint, while true of gypsum plaster, is equally true of lime, the facts of the matter being that the manufacturers of hard wall plaster have put on the market plasters already tinted, while the lime manufacturers have not. It will also be noted in this connection that with the lime plaster it is possible to obtain a glossy finish, which is not possible with the hard wall plaster. Moreover, on account of the quick setting of the ordinary hard wall plasters, it is difficult to obtain an even surface, which would add greatly to the beauty of the tint. For this reason a number of architects specify that tinted surfaces must be finished with a 7-foot straight edge, and it has been found impossible to use this on a hard wall plaster.

Although gypsum plaster is not suited to many kinds of masonry work, it is recommended by the producers for use as mortar in setting gypsum block and tile in interior partitions. Gypsum plaster has been used extensively for the exterior finish of temporary structures, such as exposition buildings; it should be used successfully for permanent exterior construction in arid climates; it is so used in southern California, and might be also in parts of Utah, Nevada, Arizona, and New Mexico. Gypsum blocks are used for exterior construction in places in Utah and Arizona.

OCCURRENCE OF GYPSUM AND GYPSITE IN THE UNITED STATES.

The following pages concerning the occurrence of gypsum in the various States have been extracted verbatim from Federal and State reports and other sources, or rewritten by the present writer to suit the needs of this report.

Alaska.—The following notes on gypsum mining in Alaska have been prepared by E. F. Burchard, of the United States Geological Survey, who visited the gypsum mines in October, 1912:

The only extensive gypsum deposit known in southeastern Alaska is operated by the Pacific Coast Gypsum Co. and is situated in the eastern part of Chichagof Island, about a mile from Iyoukeen Cove. The limits of the deposit have not yet been ascertained. At the surface the deposit is covered by gravel except near the shaft house, and no footwall nor hanging wall has been encountered in the mine workings. Several solution channels filled with gravel more or less cemented have been encountered in mining. The gravel is of the same character as that in the bed of Gypsum Creek. The gravel-filled channels extend below the 160-foot level. One channel has been tunneled for 35 feet without being cut through. Thin dikes of basaltic rock cut the gypsum beds, and a vein of anhydrite ranging in thickness from 6 inches to more than 10 feet has been encountered in the lower workings. This anhydrite is much harder to drill than the inclosing gypsum, and it is left in the mine. The gypsum is generally of a light bluish-gray color, although some is white, and occurs in massive beds, which dip 30°–60° NE. The main body of gypsum is of a high degree of purity.

The mine shaft is 160 feet deep, with a 26-foot sump. The first level is at 75 feet and the second at 160 feet. The general trend of the gypsum deposit is in a direction slightly north of west, and the levels extend for 750 feet east and west and 270 feet north and south, with the shaft near the middle of the exploited area. Altogether the underground workings are reported to measure probably 1 mile.[1] Overhand stoping is the method employed in mining, and considerable broken gypsum rock is stored in the stopes.

The gypsum is hoisted to rock bins of 1,200 tons capacity, from which it is dumped into tramcars and drawn by a steam locomotive to the wharf. Owing to a recent collapse of the old wharf, about 2,500 tons of gypsum rock which had been stored in the bunkers were lost. A new wharf was under construction in 1912. It will carry bunkers near the middle instead of at the outer end, as on the old one, but the tramway will extend the whole length of the wharf. The production of gypsum from this mine, which began in 1906, was slightly curtailed during 1912, owing to the difficulty in loading rock while the new wharf was under construction; but a much larger output is assured for 1913. Shipments of crude gypsum are made by barges to Tacoma, Wash., where the material is calcined and manufactured into wall plaster of various grades in the company's plaster mill.

Adjoining on the east the claims now being worked for gypsum by the Pacific Coast Gypsum Co. and extending to the shore of Chatham Strait are other claims which have been located on reported deposits of gypsum.

Arizona.—Gypsum occurs at several localities in southern Arizona, the following being noteworthy: Navajo County, Fort Apache Reservation, Snowflake, Winslow, and Woodruff; Cochise and Pinal counties, in the low hills along the course of San Pedro River, and at Douglas; Pima County, in the foothills of the Santa Catalina Mountains north of Tucson, and in Santa Rita Mountains southeast of Tucson. The gypsum deposits in the Santa Rita Mountains are of considerable thickness and extent. The occurrence on Fort Apache Reservation consists of large selenite crystals. Gypsum has been quarried at Douglas since 1908 and at Winslow since 1909.

Arkansas.—Large deposits of gypsum are said to exist at Tokie, in Pike County, but its fitness for plaster can not be definitely stated. Extensive beds 15 inches to 15 feet thick occur in Logan County in the bank of Little Missouri River in T. 8 N., R. 25 W.

Colorado.—Gypsum-bearing localities in Colorado occur at intervals from the northern to the southern border of the State along the eastern foothills of the Rocky Mountains and also near Arkansas River in Custer County, on Gunnison River in Delta and Montrose counties, along Grand and Eagle rivers in Eagle County, and along Frying Pan Creek in Eagle and Pitkin counties. The gypsum varies in thickness up to 30 feet; much of it is good quality; and the supply may well be regarded as very great. Beds have also been prospected on Bear Creek, near Morrison, and 8 miles southeast of Morrison on Deer Creek. Quarries have been worked in the past at Ruedi, near Perry Park, and at the Garden of the Gods, near Colorado City. In 1913 gypsum was quarried at Loveland, near Coaldale, and at Stone City. Two mills were operated, one at Loveland and one at Portland.

California.—Gypsum is widely distributed in the Tertiary rocks of California. It is found throughout nearly all the coast ranges, particularly south of San Francisco Bay, in the foothills of the Great Valley, in the valleys of southern California, and in the Palen and Maria mountains. In the Palen Mountains the deposits are probably of Paleozoic or earlier age. Deposits are known to occur in

[1] These approximate measurements were furnished to the Survey by Mr. T. H. George, superintendent of the mine.

the counties of Fresno, Ventura, Kings, Monterey, Kern, San Luis Obispo, Santa Barbara, Los Angeles, San Bernardino, Riverside, and Orange. They are generally shallow and of the variety known as gypsite.

The principal deposits are located on Santa Barbara Creek, French Point, Point Sal, Castaic, Palmdale, in the Pelen Mountains, in the Maria Mountains, at Mecca, and at other places in the Colorado Desert.

Gypsum has been quarried in Fresno County, at Coalinga and Mendota; Kern County near Fellows, Mohave, McKittrick, and Bakersfield; Los Angeles County at Palmdale and Castaic; Monterey County, King City; Riverside County, Corona; San Bernardino County, Amboy; and Ventura County, Fillmore.

In 1913 gypsum was ground for wall plaster or land plaster at five mills in California, as follows: One each at Amboy, Los Angeles, McKittrick, Bakersfield, and Fillmore.

Florida.—A deposit of soft gypsum, probably gypsite, occurs 6 miles west of Panasoffkee, Sumter County, in a low-lying area known as Bear Island. The gypsum is 6 to 7 feet thick and contains bowlders of impure limestone. It is not used.

Idaho.—Gypsum occurs in Washington County, Idaho, in the bluffs overlooking Snake River about 10 miles northeast of Huntington, Oreg., which is the nearest town. Short tunnels and prospect pits have shown that the material consists of lenticular masses of rock gypsum banded with grayish and greenish material, possibly chloritic. Development discloses thicknesses ranging from 6 to 30 feet or more. The hill slopes are too steep and there is too much stripping necessary to render extensive open quarrying practicable, but the material can be obtained by mining. A railroad that connects with the Oregon Short Line at Huntington passes down the Oregon side of Snake River within 2,000 feet of the gypsum outcrop and near enough for the rock to be carried across the river on an aerial cableway. The deposits here are apparently of the same series that occur on the Oregon side of Snake River, a few miles farther south. The Washington County gypsum deposits are held by the Northwest Gypsum Plaster Co., of Huntington, Oreg.

Iowa.—Gypsum in Iowa is confined mainly to a single area of 60 to 70 square miles near Fort Dodge, Webster County. It occurs in one bed, which varies from 10 to 25 feet in thickness, and is probably of Permian age. The bed is practically horizontal and at least 40 square miles of it may be regarded as available for use. The average thickness of the gypsum suitable for plaster is 10 feet, and the yield per acre of a bed of this thickness is 30,000 tons. Except immediately along Des Moines River and its tributaries, the bed is covered by a mantle of glacial drift 60 to 80 feet in thickness.

The first gypsum mill in Webster County was erected in 1872. Operators along the river strip off the drift and quarry the gypsum. Back on the prairie the bed is reached by shafts. The Iowa gypsum is extensively worked, 5 plaster mills being in operation in Webster County in 1913 and 1 paint mill that uses gypsum.

Gypsum of Mississippian age and associated with anhydrite occurs more than 500 feet below the surface at Centerville, Appanoose County. Whether or not it is of economic importance is undetermined.

Kansas.—The area in which gypsum is found in Kansas is an irregular belt extending northeast and southwest across the State. It is naturally divided into three districts, which, from the important centers of manufacture, may be named the northern or Blue Rapids area, in Marshall County; the central or Gypsum City area, in Dickinson and Saline counties; and the southern or Medicine Lodge area, in Barber and Comanche counties. A number of small intermediate areas have been developed, which connect the three main areas more or less closely.

The deposits in the northern area are in the lowest part of the Permian rocks, those of the central area are higher in the system, and those near Medicine Lodge are near the top of the Permian as exposed in Kansas. The beds in the southern area are the continuation of the gypsum hills of Oklahoma.

Both rock gypsum and gypsite or gypsum earth occur in extensive deposits. The rock-gypsum beds are so vast in extent as to be almost inexhaustible, and only those favorably situated with respect to transportation are developed. Near Blue Rapids the bed is 8 to 9 feet thick; near Gypsum City, 5 to 14 feet; at Dillon 18 feet; and in the Medicine Lodge area beds vary from 3 to 20 feet thick. Some of the rock gypsum is suited to the manufacture of fine grades of plaster of Paris.

Gypsite is found in low, swampy ground in central Kansas in deposits several acres in extent and up to 18 feet deep. It is particularly adapted to wall and cement plasters, but many of the gypsite deposits have been exhausted. The first gypsum mill in Kansas was erected at Blue Rapids in 1872. Four mills were operated in Kansas in 1913, 3 at Blue Rapids, and 1 at Medicine Lodge. The last-named plant produces Keene's cement.

Louisiana.—Thick beds of gypsum have been encountered in deep drill holes at St. Charles, Calcasieu Parish, associated with sulphur, and at Pine Prairie, St. Landry Parish. Gypsum also occurs at Rayburn's salt work, Bienville Parish.

Michigan.—The history of Michigan's gypsum industry begins at an early date. Rock gypsum was known to the Indians and fur traders and had been used for making plaster before the first gypsum mill was erected in 1841. This mill was on Plaster Creek between Grandville and Grand Rapids and in one of the areas that produces to this day.

The principal gypsum areas are: (1) In the vicinity of Grand Rapids near the western side of the Lower Peninsular, and (2) at Alabaster, north of Saginaw Bay on Lake Huron. The deposits occur in the Michigan formation, the lower formation of the Grand Rapids group, of Mississippian age, which outcrops as a ring around the interior coal basin. At Grand Rapids there is an upper ledge 6 feet thick separated by 1 foot of shale from a lower ledge 12 feet thick; and at Grandville, 5 miles southwest, two ledges 11 and 14 feet thick are separated by 4 feet of limestone. The gypsum is very pure and is taken from quarries and underground workings.

At Alabaster an extensive exposure of gypsum 23 feet thick has been worked back from its original outcrop on the shore of Lake Michigan for more than a quarter of a mile, the quarry now being very large. A 10-foot bowlder-clay cover is stripped and the rock is blasted from a horseshoe shaped face. The bottom of the quarry is about 15 feet above the lake level. Several thin beds underlie the quarry within a depth of 90 feet. Gypsum has been found in a number of wells in northern Arenac County and southeast Ogemaw County in the Monroe formation of the Silurian; in Mackinac County, near Point Aux Chenes, 7 miles west of St. Ignace, and in the vicinity of St. Martins Bay. Eight plants were operated in 1913 in Michigan, 7 being near Grand Rapids and 1 at Alabaster.

Montana.—Rock gypsum deposits occur in the eastern foothills of the main Rocky Mountain Range in Cascade, Carbon, and other counties of Montana. There are several beds of gypsum ranging from a few feet to as much as 50 feet in thickness. They occur intercalated with red and green shales and limestones of Mississippian age. Mills are located at Armington, Bridger, and Great Falls, but only at Great Falls was there any production in 1913. A gypsum claim has been developed at Limespur, Jefferson County. The rock is favorably situated with respect to transportation. In many places the undeveloped gypsum beds are within 5 miles of railroads. The supply far exceeds any demand that can be expected in many years.

Nevada.—The best-known gypsum deposits are in northwestern Nevada, near Moundhouse and Lovelocks. Large deposits also occur in southern Nevada, in the Spring Mountians and other ranges to the south. In Esmeralda County there are large bodies near Hawthorne, and an extensive bed is exposed at the Ludwig mine in the Yerington district, Lyon County.

The gypsum near Moundhouse lies on the east flank af the Virginia Mountains in the form of a thick bed standing nearly vertical. Its greatest width is 390 feet. The main deposit is cut off abruptly at one end by diorite and pinches out in the other direction in a few hundred yards. The gypsum and its inclosing limestone are entirely surrounded by diorite.

The deposit at Lovelocks is pure white or grayish white rock gypsum, which at its broadest outcrop covers a hill slope for some 1,200 feet. At the point of broadest exposure the gypsum is folded into an anticline and its measurement is difficult, but probably it nowhere exceeds 200 feet. At another place in the vicinity the gypsum is 130 feet thick.

Gypsum, in white and red lenticular masses ranging up to 75 feet in thickness, occurs in Carboniferous strata in the Spring Mountains, and as white granular layers it is found in lake beds of Tertiary or later age widely distributed in the State.

Three mills manufactured plaster in Nevada in 1913, 1 at Moundhouse, 1 at Reno, and 1 at Arden; and gypsum was quarried at Bouse, Clark County, for shipment to California.

New Mexico.—The "Red Beds," which contain rock gpysum in many places, occur in large areas in New Mexico. The largest area is in eastern New Mexico, principally in the valley of the Pecos, but it connects with the area entering the State along Canadian River from northern Texas, Oklahoma, and Kansas. The central division of the "Red Beds" area is drained by the Rio Grande and its tributaries, and there is also an area in western New Mexico in the region of the Zuni Mountains. Along the western base of Sierra Nacimiento in Sandoval County there are immense beds of massive gypsum. At Gallina the gypsum bed is over 40 feet thick, at Senorita it measures 54 feet, and at San Miguel copper mine the total thickness of massive white gypsum in a single bed is 60 feet. A bed of practically pure gypsum of this thickness extending for miles would be considered a practically inexhaustible resource, but at the head of a tributary to Rio Salado, about 3 miles southeast of Ojo del Espiritu Santo, the gypsum bed reaches a maximum thickness of about 100 feet. In addition to the areas of bedded gypsum there are accumulations of white gypsum sands in Otero County. These sands form dunes which cover an area of about 270 miles. They are deposited on a plain and so form a slightly elevated area. The highest dunes are about 50 feet. The sand is almost snow-white and the eastern edge of the deposit is sharp and abrupt like a snow drift. A small deposit of gypsum sands occurs about 10 miles north of Torrance near Pinoswells, Torrance County. Development of the vast resources of gypsum has been retarded by the limited markets and the long distances that the raw or manufactured materials must be transported. Railroad facilities are lacking to many of the gypsum deposits in this State. In 1913 plaster mills were operated at Acme, Chaves County, at Ancho, Lincoln County, and at Oriental, Eddy County; but the mill at White Sands was idle. Gypsum was quarried for use in Portland cement at El Rito.

New York.—The gypsum in New York State occurs as rock gypsum interbedded with shales and shaly limestones of the Salina formation. Several gypsum beds, separated by shale, usually occur in any given section. They are lenticular in shape, but of such horizontal extent that in any given quarry they are usually of practically uniform thickness. Those that are worked vary from 4 to 10 feet in thickness, but at Fayetteville a 30-foot bed is exposed. Underground mines furnish most of the gypsum in the western part of the State, but where the heavier beds outcrop near Syracuse they are quarried. The area in which the gypsum-bearing formations are found extends more than 150 miles through the central part of the State, the workable portion of the belt including parts of Madison, Onondaga, Cayuga, Ontario, Genesee, Monroe, Livingston, and Erie counties. The center of the industry is now in the western part of the State, and whereas the output was formerly marketed largely as raw gypsum, principally for agricultural purposes, it is now converted mainly into wall plasters, plaster board, and gypsum tile or partition blocks in plants operated in connection with the mines.

Large quantities of crude gysum are shipped to Portland cement mills in New York and Pennsylvania. Although the annual production is more than 500,000 tons, the exhaustion of the New York gypsum deposit can not be foreseen, as an area 150 miles long and 10 to 20 miles wide is underlain by at least 4 feet of rock gypsum.

Gypsum was quarried in 1913 at Union Springs, Cayuga County; Akron, Erie County; Oakfield, Genesee County; Caledonia, Livingston County; Garbutt, Monroe County; Jamesville and Fayetteville, Onondaga County. Seven mills reported production of gypsum in either the raw or the calcined condition in New York State in 1913. These mills are located as follows: One at Fayetteville, 2 at Garbutt, 1 at Jamesville, 2 at Oakfield, and 1 at Wheatland.

Ohio.—The gypsum deposits of Ohio which have been prospected or developed consist of beds of rock gypsum occurring in the northwestern part of the State in the Silurian system. Some of the deposits are exposed close to the level of the waters of Sandusky Bay, and have been known since the first settlements were made on its northern shore. An area of 1,500 to 2,000 acres of land has been thoroughly prospected with a drill, and it has been shown that there are from 150 to 200 acres of workable gypsum in beds 3 to 7 feet in thickness in Portage Township, Ottawa County. Considerable water is encountered in the workings, so that it is necessary to use pumps. Four plants were operated in Ohio in 1913, three of them being in the area north of Sandusky Bay, near Port Clinton. On the south shore of the bay, about 2½ miles northwest of the town of Castalia, another area of workable gypsum has been developed. Gypsum has been encountered also in many deep borings in northern and central Ohio.

Oklahoma.—The gypsum in Oklahoma may be considered as occurring in four regions: (1) The Kay County region; (2) the main line of gypsum hills, extending from Canadian County northwest through Kingfisher, Blaine, Major, Woodward, Woods, and Harper counties to the Kansas line; (3) the second gypsum hills, parallel with the main gypsum hills, and from 50 to 70 miles farther southwest, which extend from the Keechi Hills, in southeastern Caddo County, northwestward through Washita, Custer, Dewey, and Ellis counties; and (4) the southwestern region, occupying part of Greer, Jackson, Harmon, and Beckham counties. The deposits in Kay County consist of soft, earthy gypsum, or gypsite. In the other three regions rock gypsum predominates, although there are numerous localities where gypsite occurs in workable bodies. In the main line of gypsum hills there are three distinguishable beds of gypsum which extend for many miles. These vary from 4 to 30 feet in thickness, and one bed more than 50 feet thick of massive white gypsum, with only one parting 5 to 7 feet thick, has been found. In the second line of hills the gypsum beds are more irregular and are very thin in the northwestern and the southeastern portions of the area, but localities are known where 60 feet of massive gypsum are exposed.

The southwestern region contains beds of rock gypsum that maintain a fairly constant thickness of 18 to 20 feet for many miles. The reserves of rock gypsum in Oklahoma are enormous, but the gypsite deposits adjacent to the railways are limited. In this State materials for plaster are obtained from open quarries rather than from mines. The supply for wall plaster has been drawn largely from gypsite deposits which are comparatively soon worked out. New deposits are, however, being discovered from time to time. Some ledges of rock gypsum are being quarried, but gypsite, so long as it lasts, will probably be used for wall plasters because it costs less to quarry since it can be taken up rapidly by means of scrapers instead of requiring blasting and breaking, and because the material is often found to contain nearly, if not exactly, the right proportions of silica and other impurities to make a good wall plaster when calcined, and therefore does not require the addition of retarders. Gypsite that is unusually impure or that contains considerable surface soil may be brought up to the requisite standard by the addition of rock gypsum.

Eight plants produced gypsum, including that ground for land plaster, for wall plaster, and for plaster of Paris in Oklahoma in 1913 as follows: One each at Acme, Bickford, Eldorado, Homestead, Okarche, Okeene, Southard, and Watonga.

Oregon.—Gypsum occurs in Oregon in two localities. One is on the eastern border of the State near the middle point of the boundary line on a ridge dividing Burnt River and Snake River at Gypsum, about 6 miles north of Huntington. The gypsum occurs here as elongated lenses, in places 10 to 40 feet thick, interstratified in a sedimentary series of limestone and shale with a few intercalated strata of volcanic tuffs. The gypsum is in part white and crystalline, but contains in places thin strata and films of greenish chloritic mineral. It is worked at present by open quarrying. The rock is carried down to the calcining plant on Snake River by means of an aerial cableway 6,100 feet long. The weight of loaded buckets on the cableway develops 50 horsepower for operating an air compressor and pneumatic tools at the quarry. The kettles are fired with oil.

Another deposit of gypsum occurs in Crook County, near the town of Bend, but it has not yet been developed. It is reported that this material is in part gypsite and that it has been used as fertilizer.

South Dakota.—In the Black Hills uplift there is brought to the surface an elliptical outcrop of the "Red Beds" surrounding the high ridges and plateaus of the central portion of the Black Hills. The hook-shaped outcrop zone in South Dakota is over 140 miles long and has an average width of 3 miles, except in a few districts where the rocks dip deeply and where it is much narrower. The formation consists mainly of red, sandy shale, with included beds of gypsum at various horizons, some of which are continuous for long distances and others are of local occurrence. The thickness of the deposits varies greatly, but in some districts over 30 feet of pure white gypsum occur, and nearly throughout the outcrop of the formation the deposits are of sufficient thickness and extent to have commercial value. A bed at Hot Springs is 33½ feet thick, and north of Edgemont a 25-foot bed is continuous for many miles. The average thickness about Rapid is 10 feet. The gypsum beds are convenient of access from Hot Springs, Rapid, Spearfish, Newcastle, and Edgemont. A plaster mill was formerly operated at Hot Springs, but the only operators reporting in 1913 were one plant near Rapid and one at Black Hawk.

Texas.—The largest area in Texas containing deposits of gypsum lies east of the foot of the Llano Estacado, in northern Texas. The beds have an approximately northeast strike and extend from Red River to the Colorado in an irregular line, the sinuosities of which are produced by the valleys of the eastward-flowing streams. This belt is a continuation of the deposits in Oklahoma.

In the eastern part of El Paso County, to the east of the Guadalupe Mountains, there is an area of gypsum which extends beyond the border of the State northward into New Mexico. It lies north of the Texas & Pacific Railway and west of Pecos River. In a few localities this great plain of gypsum is overlain by beds of later limestone and conglomerate. The gypsum is conspicuously exposed along the course of Delaware Creek, a stream rising in the foothills of the Guadalupe Mountains and flowing eastward into the Pecos.

In the Malone Mountains, in El Paso County, there is a third area which contains notable deposits of rock gypsum. This locality has the advantage of being situated near the Southern Pacific Railroad. Extensive deposits of good alabaster in beds up to 4 feet thick are reported at Kiowa Peak in the northwestern corner of Stonewall County. The only area exploited for gypsum at present is in northern Texas. Four plants, 3 at Acme and 1 at Hamlin, were engaged in the manufacture of plaster in 1913. Keenes cement is made at one of these plants.

Utah.—The more important known deposits in Utah occur in the central and southern portions of the State. They are all of the rock-gypsum type, except the one near Fillmore, which is composed of selenite crystals and gypsum sand blown from dry lakes into dunes. Important localities are as follows: (1) Iron County, where enormous deposits are reported. (2) Emery and Wayne counties, along the west side of the San Rafael Swell, where gypsum beds 4 to 50 feet thick are continuous for many miles. The area contains within 2 miles of the outcrop about 10 billion tons of good rock gypsum. (3) Juab County, large deposits near Nephi and Levan. The Nephi gypsum deposit forms the entire mass of a prominent spur at the entrance to Salt Creek valley. Two beds, one 55 and the other 65 feet thick, are high-grade gypsum, and a 75-foot bed that separates them is only less pure. (4) Millard County, vast deposit at White Mountain near Fillmore. Mounds and dunes of gypsum and sand crystals which constitute this deposit are estimated to contain 450,000 tons. (5) Wayne County, in South Wash. The extensive deposit of rock gypsum and gypsum sand in Wayne County is said to extend unbrokenly for about 2 miles. Deposits are also known in Kane County, near Kanab; in Grand County, between Grand River and the La Sal Mountains; in Sanpete County, near Gunnison; in the eastern part of Washington County, between Duck Lake and Rockville; and at other places. In 1913, 3 mills produced plaster in Utah, 1 at Nephi and 2 at Sigurd. Keenes cement is made at one of the mills at Sigurd.

Virginia.—All the workable gypsum deposits of Virginia occur in Washington and Smyth counties in the valley of the North Fork of Holston River. The area within which the known deposits are located is a narrow belt 16 miles in length, extending from a short distance southwest of Saltville to a point about 3 miles west of Chatham Hill post office.

The material occurs as rock gypsum intimately associated with salt deposits and interbedded with shale and shaly limestone of Carboniferous age. The gypsum-bearing shales outcrop around a syncline, and the dip of the gypsum beds is so high as to require mining except at the surface. The bodies of gypsum are large masses and lenses interbedded with red and gray clays. The beds of gypsum average 30 feet in thickness at the localities at which they are now worked. The rocks of the district dip at a high angle, usually between 25° and 45°, so that certain wells which have been drilled are in the gypsum for long distances; and accordingly great thicknesses of gypsum have been erroneously reported, because the inclination of the deposits was not taken into account.

The development of the gypsum industry in this area has been governed almost entirely by transportation facilities. The deposits at Saltville and Plasterco, which are on a branch of the Norfolk & Western Railway, furnished the principal output up to 1907. Recently a railroad 4 miles long has been built to North Holston, and the gypsum deposits at this point have been developed by shaft mining.

In 1913 two plaster mills reported production from Virginia, one at North Holston and one at Plasterco.

Wyoming.—The gypsum deposits of economic importance in Wyoming occur in the "Red Beds," which consist largely of red sandstone and shale. This formation outcrops about the base of many mountain ranges or is exposed by erosion as the core of small or secondary folds. The areas where gypsum deposits are known to occur are the Rawlins uplift, Freezeout Hills, Grand Canyon of the Platte, Black Hills, and Laramie, Medicine Bow, Shirley, Seminoe, Ferris, Rattlesnake, Bighorn, Absaroka, Prior, Wind River, Gros Ventre, and Salt Creek mountains. In all there are about 1,500 miles of the gypsum-bearing formation exposed, and throughout this extent there are generally present beds of gypsum ranging from 5 to 20 feet thick, and in places reaching thicknesses of 30 to 50 feet. The material is generally found to be of excellent quality. Besides the rock gypsum, there are secondary surficial deposits of gypsite, which occur in depressions below the gypsum outcrops.

Three mills produced plaster in Wyoming in 1913. Two of them at Laramie utilized gypsite as raw material and one at Red Butte, 10 miles south of Laramie, worked rock gypsum and gypsite.

FLUORSPAR AND CRYOLITE.

By Ernest F. Burchard.

FLUORSPAR.

PRODUCTION.

One of the noteworthy features of the fluorspar industry in 1913 was the slight decrease both in the quantity of domestic spar sold and in the quantity of spar imported. The sales of gravel spar to open-hearth steel furnaces slightly exceeded those in 1912, but it is probable that, owing to the depression in the manufacture of iron and steel during the latter part of 1913, less spar was actually consumed than in 1912 and that considerable stocks were accumulated. This condition foreshadows a greater decrease in production in 1914. The first shipments were reported from a recently opened fluorspar vein at Wagon Wheel Gap, Colo., and shipments were reported for the first time since 1908 from Arizona. A considerable revival of activity in Kentucky fluorspar mines took place during 1913.

The total quantity of domestic fluorspar reported to the Survey as marketed in 1913 was 115,580 short tons, valued at $736,286, as compared with 116,545 short tons, valued at $769,163, marketed in 1912, a decrease in quantity of 965 short tons and in value of $32,877. This decrease represents only 0.83 per cent of the quantity but about 4.27 per cent of the value of the product marketed in 1912. The production and sales of fluorspar in 1912 were by far the greatest ever recorded, and those of 1913 make a close second. The average price per ton for the whole country, considering all grades of fluorspar—gravel, lump, and ground—was approximately $6.37 in 1913, as compared with $6.60 in 1912, a decrease of 23 cents a ton, or nearly 3.5 per cent. This value represents the selling price on board cars or barges at railroad or water shipping points; and, with reference to the product from Colorado, New Mexico, and New Hampshire, the price reported for much of the spar includes the cost of a long wagon haul—$1.50 to $3 a ton. In Illinois the principal producing mines are near river transportation and many of the mines reporting from Kentucky are near a railroad, so that the cost of long wagon hauls has not entered to an important extent into the reported value of the fluorspar from those States.

The total quantity of domestic gravel spar marketed in 1913 was 101,767 short tons, valued at $597,024, as compared with 99,285 short tons, valued at $578,294, in 1912, an increase in quantity of

2,482 tons and in value of $18,730. The average price per ton of domestic gravel spar was nearly $5.87 in 1913, as compared with $5.82 in 1912, an increase of about 5 cents a ton. The sales of domestic lump spar in 1913 were 5,676 short tons, valued at $39,059, as compared with 5,315 short tons, valued at $36,553, in 1912, an increase in quantity of 361 tons and in value of $2,506. The average price per ton of lump spar was approximately $6.88 in both 1912 and 1913. The sales of domestic ground spar in 1913 were 8,137 short tons, valued at $100,203, as compared with 11,945 short tons, valued at $154,316, a decrease in quantity of 3,808 tons and in value of $54,113. The average price per ton of ground spar was $12.31 in 1913 as compared with $12.92 in 1912, a decrease of 61 cents a ton. According to these statistics the entire decrease in both quantity and value of fluorspar marketed in 1913 was confined to the sales of ground spar, both the gravel and the lump spar marketed having shown actual increases in quantity and in value as compared with 1912.

Fluorspar was produced in 1913 in six States—Illinois, Kentucky, New Mexico, Colorado, New Hampshire, and Arizona—in the order named. Increases in sales were reported in Arizona, Colorado, Kentucky, and New Mexico, and decreases in Illinois and New Hampshire. Gravel spar was produced by all the States except Arizona; sales of lump spar were reported from Illinois, Kentucky, and Arizona, and of ground spar from Illinois and Kentucky. The product of the mines in New Hampshire and New Mexico is classed as gravel spar, since it is sold entirely for flux in steel making, but much of the spar shipped from these two States would yield an excellent grade of lump spar if it were hand picked.

It is impossible to give in detail the production of fluorspar from Illinois and Kentucky separately, because in publishing the statis ics of production of the various minerals it is the custom of the Survey to conceal the output of individuals; therefore the production of a single State is not given unless three or more producers report from that State, except when the producers interested have given express permission for the publication of their figures. Thus, while it is possible to give the total production of fluorspar in Illinois and Kentucky for 1913, it is not possible to give it by grades.

The total stocks of fluorspar reported at the mines or at shipping points December 31, 1913, were 15,252 short tons, as compared with 8,663 short tons on hand at the close of 1912, according to revised reports. Owing to inaccurate methods of estimating stocks, these figures can be regarded as only approximate; it is found, however, that the stocks on hand at the close of one year, together with the tonnage mined during the following year, less the tonnage marketed during that year, generally check reasonably well with the stocks reported on hand at the close of the second year.

The following table gives the quantity and value of the different grades of fluorspar marketed in the United States in 1912 and 1913:

Fluorspar marketed in 1912 and 1913, in short tons.

State.	Gravel.		Lump.		Ground.		Total quantity.	Total value.
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.		
1912.								
Illinois, Kentucky	97,150	$565,784	5,315	$36,553	11,945	$154,316	114,410	$756,653
Other States[a]	2,135	12,510					2,135	12,510
Total	99,285	578,294	5,315	36,553	11,945	154,316	116,545	769,163
1913.								
Illinois	91,663	525,456	5,676	39,059	8,137	100,203	85,854	550,815
Kentucky							19,622	113,903
Other States[a]	[b] 10,104	71,568	([b])	([b])			10,104	71,568
Total	101,767	597,024	5,676	39,059	8,137	100,203	115,580	736,286

[a] Includes, 1912: Colorado, New Hampshire, and New Mexico; 1913: Arizona, Colorado, New Hampshire, and New Mexico.
[b] Small quantity of lump spar from Arizona included with gravel.

The annual production of fluorspar from 1883 to 1913 is given in the following table. Beginning with the year 1906, the quantities reported represent marketed production.

Production of fluorspar in the United States, 1883–1913, in short tons.

Year.	Quantity.	Value.	Year.	Quantity.	Value.
1883	4,000	$20,000	1900	18,450	$94,500
1884	4,000	20,000	1901	19,586	113,803
1885	5,000	22,500	1902	48,018	271,832
1886	5,000	22,000	1903	42,523	213,617
1887	5,000	20,000	1904	36,452	234,755
1888	6,000	30,000	1905	57,385	362,488
1889	9,500	45,835	1906	40,796	244,025
1890	8,250	55,328	1907	49,486	287,342
1891	10,044	78,330	1908	38,785	225,998
1892	12,250	89,000	1909	50,742	291,747
1893	12,400	84,000	1910	69,427	430,196
1894	7,500	47,500	1911	87,048	611,447
1895	4,000	24,000	1912	116,545	769,163
1896	6,500	52,000	1913	115,580	736,286
1897	5,062	37,159			
1898	7,675	63,050	Total	918,904	5,692,551
1899	15,900	96,650			

Figure 16 shows graphically the course of fluorspar production in the United States from 1883 to 1913. Two periods of fluctuation in output—between 1889 and 1898 and between 1902 and 1908—are in strong contrast with the large and steady increase in production in the periods 1898 to 1902 and 1908 to 1912. For convenience of comparison the imports, beginning with the first full year for which records are available, 1910, are shown on the same diagram.

The total quantity of fluorspar reported to the Survey as mined in the United States in 1913 was 124,130 short tons, as compared with 117,282 short tons mined in 1912.

COMPOSITION OF GRAVEL SPAR MARKETED.

Fluorspar or fluorite, chemically, calcium fluoride (CaF_2), consists of calcium and fluorine in the proportion of 51.1 to 48.9. The mineral

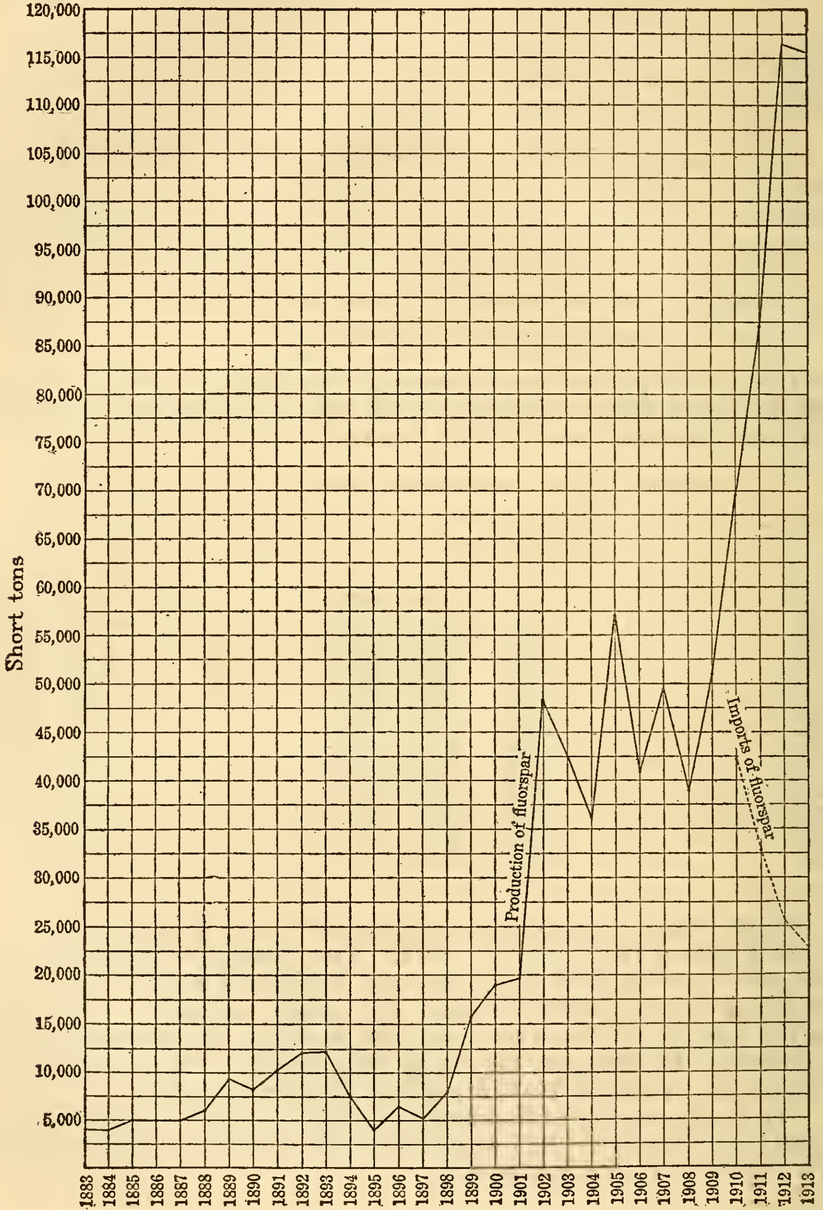

FIGURE 16. Production of fluorspar in the United States 1883–1913, and imports 1910–1913.

is crystalline, only slightly harder than calcite. It crystallizes in the isometric system and is found commonly in cubical crystals. In color the spar ranges according to purity from a clear, slightly bluish or green glasslike substance through various other brilliant colors to dark purple, although much of it is white and opaque. It is seldom, however, that absolutely pure spar is marketed, although lump spar used in the manufacture of chemicals is often found to contain less than 1 per cent of impurtity. A large number of chemical analyses made on receipts of gravel spar at the Minnequa works of the Colorado Fuel & Iron Co. during 1912 and 1913 indicate the percentages of the principal constituents as shown in the accompanying table. These percentages may be considered as only approximately the averages of monthly receipts, as the tonnages on which they are based are not in all cases equivalent.

Analyses of gravel fluorspar from Colorado, Illinois, and New Mexico.

	Calcium fluoride (CaF_2).	Silica (SiO_2).	Lime carbonate ($CaCO_3$).	Oxides, mostly iron (Fe_2O_3) and alumina (Al_2O_3).	Barium sulphate ($BaSO_4$).
1912.					
Colorado (unwashed spar):					
Jamestown	82.16	10.64	2.26	4.27	....
	79.38	11.12	2.80	4.49	....
	79.22	12.16	1.85	4.75	....
Morrison	71.65	23.26	1.52	2.04	....
Jefferson	68.34	28.33	1.34	1.69	....
Duffields	80.55	14.55	3.07	1.50	....
New Mexico (unwashed spar): Deming	92.31	5.28	1.19	1.07	....
Illinois (washed spar): Rosiclare	87.64	4.15	6.41	1.58	....
1913.					
Colorado (unwashed spar):					
Jamestown	80.32	10.32	2.58	6.46	....
	83.78	9.24	2.18	5.56	....
Morrison	72.21	21.93	2.78	3.08	....
	83.73	11.13	2.21	2.66	....
Jefferson	59.23	35.98	1.76	3.05	
Wagon Wheel Gap	90.08	2.21	1.17	2.14	Between 3.22 and 6.00
New Mexico (unwashed spar): Deming	88.94	8.35	1.34	1.29	....
Illinois (washed spar): Rosiclare	90.41	3.35	4.33	1.03	....

Comparisons of these analyses is of interest. Shipments from Jamestown, Colo., averaged nearly the same in the two years. From Morrison, they averaged a little better in 1913, but from Jefferson considerably lower in grade than in 1912. A new producer is reported from Wagon Wheel Gap, and the spar shipped appears to be of an excellent grade, the fact being considered that it probably has not been subjected to mechanical cleaning or concentration. The presence of barite, or barium sulphate, in this deposit is also of interest. Notes on this deposit are given on a later page.

USES OF FLUORSPAR.

It is estimated that about 80 per cent of the domestic fluorspar output, mainly in the form of gravel spar, and practically all of the imported fluorspar, is consumed as a flux in basic open-hearth steel furnaces. It is used also as a flux in blast furnaces, iron foundries, and silver, copper, and lead smelters; in the manufacture of fluorides of iron and manganese [1] for steel fluxing; in the manufacture of glass, enameled, and sanitary ware, and of hydrofluoric acid; in the pro-

[1] For notes on the uses of these fluorides see Goldmerstein, L., Prolonging the life of the Bessemer process: Iron Age, Jan. 22, 1914, pp. 250-251; and The fluorine process in the open hearth: Iron Age, Mar. 19, 1914, pp. 724-725.

duction of aluminum; in the electrolytic refining of antimony and lead; and for many other purposes.

Fluorspar for making iron and steel should carry at least 80 per cent of calcium fluoride, (CaF_2) and preferably it should be purer. For most other chemical purposes it should contain 95 per cent or more of calcium fluoride.

TRADE CONDITIONS.

The strong demand for American fluorspar that existed in 1911 and 1912 was slightly less active in 1913, especially during the latter part of the year. The demand in the eastern United States was supplied chiefly by 4 mines in Hardin County, Ill., 2 of which have important production and are equipped with large mills, and by 7 mines in Crittenden County and 1 in Caldwell County, Ky. Prices of gravel and lump spar remained about the same, but prices of ground spar dropped about 4.7 per cent. In Kentucky, conditions showed a decided improvement, the quantity of spar sold from this State in 1913 having increased more than 87 per cent over the marketed output of 1912. Two more mines produced spar and 1 more shipped spar in 1913, making 9 mines and 8 shippers in Kentucky. Shipments were limited, however, in both Illinois and Kentucky by the idleness of open-hearth steel plants during a portion of the year. The quantity mined in southern Illinois might have been greater had not the large mines at Fairview and Rosiclare been twice flooded by the Ohio River in the spring of 1913.

A small tonnage of high-grade spar was shipped from New Hampshire for flux in steel manufacture in Massachusetts. In Colorado 6 producers reported an output of fluorspar, and a considerable quantity was produced from 1 mine near Deming, N. Mex. The product from both of these States was shipped to the open-hearth steel plant of the Colorado Fuel & Iron Co., at Minnequa, Colo. The output of these States was adequate to the requirements of the steel plant in 1913. In Colorado the production was from the vicinity of Jamestown, Jefferson, Morrison, and Wagon Wheel Gap. Wagon Wheel Gap is a new producing locality. A small production of lump spar was reported from the Castle Dome district, Arizona, for the first time in several years.

Low-grade fluorspar imported from England is reported to control the market along the Atlantic Seaboard and to compete with domestic spar even as far inland as Pittsburgh. The imports, as noted on another page, showed a decrease of more than 13 per cent.

The following table shows the production during the last five years of open-hearth steel which has a most important bearing on the market for gravel spar:

Production of open-hearth steel in 1909–1913, in long tons.[a]

	Basic.	Acid.	Total.
1909	13,417,472	1,076,464	14,493,936
1910	15,292,329	1,212,180	16,504,509
1911	14,685,932	912,718	15,598,650
1912	19,641,502	1,139,221	20,780,723
1913	20,344,626	1,255,305	21,599,931

[a] Statistics from 1909 to 1911 according to Ann. Repts. Am. Iron and Steel Association, and since 1911 (1913 subject to revision) from report of Am. Iron and Steel Inst., both of Philadelphia, Pa.

IMPORTS.

Prior to August, 1909, fluorspar was imported into the United States duty free, and the full statistics of importation were not obtainable before that date. A duty of $3 a ton on imported fluorspar continued in force from August, 1909, until October, 1913, when it was reduced to $1.50 a ton. Large quantities of gravel spar produced at a low cost from the tailings of lead mines and from the gob in abandoned mines in England have been shipped to this country as ballast at a very low freight rate. The material thus produced is high in silica and is almost entirely consumed by makers of open-hearth steel. According to American producers spar from England at present competes with American fluorspar as far west as Pittsburgh and practically fixes the market price at that point, while in the Lehigh and Susquehanna valleys of Pennsylvania and other localities near the Atlantic seaboard English fluorspar can be purchased advantageously.

The imports of fluorspar entered for consumption into the United States in 1913 were 22,682 short tons, valued at $71,463, as compared with 26,176 short tons, valued at $71,616, in 1912. This represents a decrease in quantity of 3,494 short tons, or about 13 per cent, and in value of $153, or about 0.2 per cent. The value assigned to the material in 1913 averaged $3.15 a ton, as compared with $2.74 a ton in 1912, an increase of 41 cents a ton, or about 15 per cent. The imports of fluorspar in 1913 amounted to about 22.3 per cent of the domestic production of gravel spar, as compared with about 27 per cent in 1912. The reported average price of imported spar at dock, exclusive of the duty, amounted to about 53 per cent of the price of domestic gravel spar at mines or nearest shipping points in 1913. According to the prices reported, the average cost to the consumer, including the duty of $3 a ton, but excluding freight charges, was $5.74 a ton in 1912, as compared with $5.82 for domestic gravel spar, and in the latter part of 1913 the cost of the imported material, including the duty of $1.50 a ton, was $4.65, as compared with $5.87 for domestic gravel spar. The freight charges on domestic spar to points where it is consumed are generally higher than on foreign spar from the docks to eastern steel plants, so that the differences in cost to the consumer are relatively greater than are indicated. Foreign spar is, however, not of as high grade as the mechanically treated spar from Illinois and Kentucky, and, since fluorspar is of value chiefly according to its purity, purchasers find that the purer American spar is more efficient and consequently cheaper in the end.

The following table (see also fig. 16) shows the imports of fluorspar into the United States since August 1, 1909:

Fluorspar imported, 1909–1913, in short tons.

	Quantity	Value.	Average price per ton.
1909	6,971	$26,377	$3.78
1910	42,488	135,152	3.18
1911	32,764	80,592	2.46
1912	26,176	71,616	2.74
1913	22,682	71,463	3.15

APPARENT CONSUMPTION OF FLUORSPAR.

No accurate estimate of the annual consumption of fluorspar in the United States can be made without a knowledge of the stocks maintained by the consumers. These stocks are probably variable, but as the value of fluorspar as a flux in open-hearth steel making and in other metallurgical operations has become so generally appreciated, consumers are taking care to keep larger stocks in reserve. However, the sales of domestic spar plus the imports (there are no considerable exports at present) should give from year to year an index to the quantity entering into consumption and should indicate the relative increase or decrease in consumption. The apparent consumption of spar in 1913 was 138,262 short tons, as compared with 142,721 short tons in 1912, a decrease of more than 3 per cent.

The following table indicates the apparent consumption of fluorspar in the United States in the years 1910, 1911, 1912, and 1913:

Apparent consumption of fluorspar, 1910-1913, in short tons.

	Sales of domestic spar.	Imports.	Apparent consumption.
1910	69,427	42,488	111,915
1911	87,048	32,764	119,812
1912	116,545	26,176	142,721
1913	115,580	22,682	138,262

FLUORSPAR AT WAGON WHEEL GAP, COLO.

The fluorspar at Wagon Wheel Gap occurs in a fissure vein in rhyolitic tuffs and breccias. The relations of this vein to the local geology and to the hot springs have been described by Emmons and Larsen.[1] The vein is thin—2 to 5 or 6 feet thick, generally not more than 3 feet—and contains in addition to fluorite small quantities of other minerals, such as barite, calcite, quartz, and altered pyrite. The pyrite occurs mostly in the altered wall rock. The fluorite is comparatively pure. It occurs in tabular masses, in fibrous forms, in crusts, and in crystals. Some of the fluorite shows well-defined banding of varying shades of pink and white. The fluorite carries low values of precious metals, assays having shown, respectively, 0.007 ounce and 0.03 ounce gold, and 0.283 ounce and 4.55 ounces silver to the ton.[2]

There are three hot springs at Wagon Wheel Gap, the temperatures of which are 135° F., 150° F., and 140° F. Emmons and Larsen show that the hot springs and the fissure vein are undoubtedly connected, since the strike of the vein passes through one spring and close to the second. A deposit of travertine surrounds spring 1, and this deposit appears to be bisected by the vein (projected). A partial analysis of the travertine was made by George Steiger, of the United States Geological Survey, with the following results:

[1] Emmons, W. H., and Larsen, E. S., The hot springs and the mineral deposits of Wagon Wheel Gap, Colo.: Econ. Geology, vol. 8, No. 3, pp. 235-246. April-May, 1913.
[2] Assayed with unusual precautions by Edmund Newton, Minnesota Univ. School Mines.

Partial analysis of travertine from Wagon Wheel Gap, Colo., hot spring.

	Per cent.
Lead (Pb)	None.
Zinc oxide (ZnO)	0.007
Barium oxide (BaO)	0.045
Fluorine (F)	0.22
Copper (Cu)	None.

If these percentages be recalculated to a mineral basis they correspond to a content of 0.008 per cent of sphalerite (ZnS), 0.078 per cent of barite ($BaSO_4$), and 0.45 per cent of fluorite (CaF_2). It is thus evident that the fluorite has been deposited by the hot water, which probably has its source at considerable depth.

CANADA.

According to the revised mineral statistics Canada produced 40 short tons of fluorspar, valued at $240, or $6 a ton, in 1912, as compared with 34 tons, valued at $238, or $7 a ton, in 1911. No production was reported for 1913 in the preliminary report for that year recently issued.

GREAT BRITAIN.

The production of fluorspar in England has an important bearing on the industry in the United States, for practically all the competing material is imported from that country. Since 1903 the output of Great Britain has exceeded 10,000 tons annually, and except in 1908, 1911, and 1912, there has been a steadily increasing annual production of spar up to 1912, the latest year for which statistics are available. According to the official report of output of mines and quarries issued by the British home office at London, there were produced in 1912, a total of 47,246 long tons of fluorspar, valued at $84,010, or $1.78 a ton, as compared with 55,231 long tons, valued at $92,176, or $1.67 a ton, produced in 1911. In 1912, 23,862 tons were produced in Derbyshire, mostly from quarries and open workings (probably mine dumps) and 23,384 tons from mines and mine dumps in Durham. Of the 1911 output, 5,045 tons were produced from mines in Derbyshire, including large quantities produced from mine dumps and 23,644 tons from quarries in the same county, while 26,542 tons were produced from mines and mine dumps in Durham. When the output of fluorspar in England in 1912 is compared with the imports of fluorspar into the United States in that year, and in view of the fact that the imports are derived almost wholly from England, it appears that more than 55 per cent of the production of England was shipped to the United States in 1912, as compared with about 52 per cent in 1911.

CRYOLITE.

IMPORTS AND PRICES.

No cryolite is produced in the United States, the entire supply used in this country being imported from Ivigtut, an Eskimo hamlet on the southern coast of Greenland.

The quantity of cryolite reported to have been imported for consumption into the United States in 1913 was 2,559 long tons, valued at $52,557 as compared with 2,126 long tons, valued at $48,293, in 1912. The average price per ton declared in 1913 was apparently $20.54, as compared with $22.72 in 1912. Cryolite was imported free of duty in 1913.

PEAT.

By Charles A. Davis.

INTRODUCTION.

The peat deposits of the United States form one of the most important of the undeveloped resources of the country. Peaty swamps cover, in the aggregate, large areas in the region east of the Ninety-seventh meridian and north of Ohio River; they occur also along the Atlantic coast as far south as and including Florida. On the Pacific coast peat beds have been reported from southern California northward to the Canadian boundary. These potentially valuable swamp lands have for some years attracted the attention of those who have followed the progress which has been made in Europe in extending the use of peat for fuel and for various other purposes, but only in a limited degree and in a more or less speculative or often purely academic way.

The extent of the peat deposits of the United States is not yet well known. Very little systematic search for peat has been undertaken, but from what has been done it seems probable that a large percentage of the swamps and bogs which occur throughout the glaciated region of the country and on the poorly drained parts of the Atlantic Coastal Plain conta'n more or less peat of commercial value. A larger percentage of the swamps of the extreme northern part of the country along the Canadian border than of the Coastal Plain region will undoubtedly be found to contain peat of commercial value. In all cases, however, where peat is sought swamp land should be examined in attempting to locate deposits of this important raw material.

The most extensive use of peat in Europe has been for fuel. Most of the attempts which have been made to utilize peat deposits in the United States also have aimed at their development as sources of fuel. A chief reason for this has prabably been the fact that the best peat deposits in the United States lie almost entirely outside of the region of occurrence of known workable coal fields and in regions where the climate is so severe that there is need for large supplies of fuel for domestic use. In the same region there is also a constantly growing demand for cheap fuel for manufacturing.

The States in which the largest areas of swamp land are known are Minnesota, Wisconsin, Michigan, the northern parts of the States immediately south of them, New York, the New England States, Pennsylvania, New Jersey, and also parts of the States south, especially a narrow strip along the Atlantic border where the land is flat, poorly drained, and has a large annual rainfall. The fact that all these States, with the exception of northern Illinois, Indiana, Ohio, and Pennsylvania, receive their supplies of fuel from rather distant coal fields, largely by rail, has made fuel costly, especially in the last few years, and many attempts have been made to convert peat into fuel, both for domestic use and, to some extent, for manufacturing purposes. Up to the present time, however, practically none of these attempts at the production of a serviceable fuel from peat have been commercially successful.

It does not seem necessary in this place to go into the details of the causes of failure, but the whole matter may be summed up by stating that the lack of success has apparently not been caused by the peculiarities of the peat fuel itself, since in practically every case where the material has been offered for sale it has found a ready market and has been sold at prices which, while less than those paid for other fuels, were ample to have made the manufacturer of the material remunerative. Although failure has been the history of the production of peat for fuel in the United States, European countries in which peat is abundant have been increasing its production and use both for domestic fuel and for power until at the present time there are probably between 15,000,000 and 20,000,000 tons of peat produced and used annually for fuel in the countries of northern Europe. Because this steady increase in the use of peat for fuel and for other purposes goes on in European countries; because improvements are constantly being made there in methods of recovery and use which are adapted to utilization on a large scale; and because our peat deposits in the United States are not only neglected but also are often wastefully burned up to remove the peat from the surface of the ground, a brief review of the methods in use in northern Europe for the economical production and use of peat for fuel is given here.

EUROPEAN METHODS OF PRODUCING PEAT FOR FUEL.

The oldest and simplest method of preparing peat for fuel is that still extensively employed by the peasantry of Ireland and other countries of northern Europe. The peat deposit is drained as thoroughly as possible by open ditches, after which a special type of spade is used to cut the peat out from the beds in the form of bricks. The brick-shaped blocks thus formed are laid out on the surface of the bog and dried by exposure to sun and wind. Peat fuel made in this way is, however, very easily broken and very bulky, and the method is only adapted to very local production and consumption, and not to transportation. Peat fuel recovered in this way is called cut peat.

A second method by which a much more satisfactory product is obtained is coming into general use wherever peat fuel is made. The method is simple and, to a certain extent, resembles that just described, but differs from it in that the peat is reduced to a pulp by suitable machinery before being formed into bricks. The processes and the machinery for pulping and handling the raw peat have been greatly improved during the last 10 years until at the present time the necessary processes of digging, conveying, reducing to pulp, and spreading the pulp on the drying grounds are all mechanical and are carried on by machines which work together and are all operated by a single portable and generally self-propelling engine.

The most serious difficulty which has operated against the production and use of peat as fuel is the fact that, as it lies in the bog, it contains about 90 per cent of water. Long experience has shown this water content can not be reduced below 80 per cent, even by most careful and thorough draining; consequently, in the production of air-dried peat, in which form it is actually used as fuel, and which contains from 10 to 25 per cent of moisture, from 8 to 10 tons, depending on the actual water content, of raw material must be handled to produce a single ton of salable fuel. Thus the charges for excavating, transporting, reducing to pulp, spreading, and drying the raw material must be all charged against the very small proportion of the dry product. Even if this charge is very small per ton, the fact that it must be multiplied by at least eight times makes it a formidable matter in estimating the cost of the final product, which, to be commercially profitable, must be sold at a low price.

The processes of production of peat for fuel, after the peat deposit is ready to work, when reduced to the lowest possible terms are: (1) Digging, (2) elevating and transporting to the macerating machinery, (3) pulping or maceration, (4) forming the pulp and spreading it in some way so that it may be quickly and thoroughly dried, (5) tending the material during the process of drying, and (6) gathering and storing. In five of these operations first named, from 8 to 10 times the weight of the salable material must be handled in the form of water, which is eliminated in the course of drying. Hence, the less this waste material is handled and the shorter the distances and the more directly it is transported the greater the chance of final profit when the fuel which is the result of all the operations is ready for the market.

These facts have led to a large amount of experimental work on the part of mechanical engineers and other practical and trained men both abroad and, to a somewhat less extent, in the United States and Canada.

Within the last three years there have been several very compact and powerful machines or, better, combinations of machines developed which are self-moving and operate directly on the surface of the bog. In this way the inventors claim to eliminate all needless transportation of the wet material with its high percentage and great weight of waste water. These machines combine digging, macerating, and spreading devices in such a way that until the wet, thoroughly pulped peat is spread in brick form on the surface of the bog or on other drying grounds to dry there is no break in the forward movement. The several types of automobile machines or plants in use have been developed independently, and although they present fundamental likenesses in their construction each of them attains in a practical and simple way the same end, namely, they dig, move, pulp, and take to the drying grounds large quantities of raw material with an outlay of power and manual labor small in comparison with what was formerly used to attain the same actual tonnage of final product. Peat fuel prepared as described is called machine peat.

PRESSING WATER FROM PEAT.

It has long been realized by those who have given the matter attention that it is very desirable to avoid the uncertainties inherent in the method of drying peat by spreading in the open air, because weather and climatic conditions limit production. The most certain solution of the problem seemed to be the invention of some form of mechanical device for ridding the peat of water. With this in view, there have been attempts made for more than 50 years to invent presses having capacity and power enough to remove the water from peat on a commercial scale by mechanical pressure. During this time about every form of press that could be devised has been given experimental or even commercial trial, but without any commercial success up to the present time.

The difficulties which have been encountered have been due in part to the peculiar capacity which the peat itself has for holding the water, which is a part of it as it lies in the bog. This water is held in at least three ways: First, mechanically mixed with the particles of vegetable matter which make up the solid matter of the peat. (This water is termed by some writers "free water.") Second, the water is held in the minute cavities in and between the cells and fibers of the vegetable structures which the processes of decay have not thoroughly broken down. This water is held in the peat by capillarity and is more difficult to remove by pressure than the free water. Third, a certain percentage of the water present in the peat is held in the vegetable matter itself, in the walls of the cells, fibers, and tissues. This water is probably chemically combined with the fundamental organic substances of which the vegetable matter is composed. Water in such combination can not be removed by pressure, at least not until the chemical substances, of which it is a part, are decomposed, but can only be dried from the substances with which it is combined. There is also a fourth way in which water may be combined, and doubtless is combined, in most kinds of peat: This is what may be termed colloidal water, and is apparently in chemical combination with the substances with which it is associated. This water in whatever percentage it may be present is seemingly never removed by pressure, but must be removed by destroying the chemical bonds by which it is combined with the organic matter. This destruction can be brought about by heat or by evaporation, but the assumed union is not destroyed by pressure alone.

During the year 1913 reports were received from Europe of the development of a press which, although it has not yet been thoroughly tested on a commercial scale, apparently has made a very considerable reduction of the water content of a number of kinds of peat on an experimental scale. The results reported were such as to warrant the further development of the press to determine its value when tried with many kinds of peat, and late in 1913 a small machine of commercial size was finished and tested under conditions similar to those found in commercial operations. It is claimed for this press that, although it has a large capacity, it will be very cheaply operated and will require but little power. It reduces the water content of the material which is pressed to below

60 per cent. At the same time that this press was under construction two other machines were being constructed for the same purpose, but entirely independently, in the United States. No reports have been received from tests of these American machines.

BRIQUETTED PEAT.

Peat which has been thoroughly dried and reduced to a powder can be successfully briquetted without a binder, much as the brown coals are briquetted in various European countries. The heavy, thoroughly decomposed black peats are better for briquetting than the light-colored and bulky brown peats, but with a suitable press and with well-dried materials briquetting is practicable for almost any kind of peat, although the lighter kinds do not make as good briquets as those of greater specific gravity.

Briquetting as a means to make from peat a fuel that could be successfully transported was attempted early in the history of the process in various parts of Europe, especially in Germany and Holland, where brown coal briquets were received with enthusiasm by the consumers of fuel. For various reasons, however, only a single peat-briquet factory is known to be in operation in Europe at the present time. A chief cause of the lack of success in several of the peat-briquetting enterprises of Germany was the difficulty in securing enough dry peat to keep the briquetting plant in operation at full capacity for a sufficient number of days in the year to make the output of the plant normal. To prepare the peat for briquetting it has to be handled very much as is done in the production of machine peat until it is air dry; after it has reached as nearly as possible the air-dried state the peat bricks are gathered, crushed or ground into powder, and artificially dried in mechanical driers to a moisture content which has been found by experiment to be the optimum for the given peat and locality. After the powdered peat is dried and cooled, the briquetting is done by special presses, which are designed for the material which is to be briquetted. The briquetting plant is much more costly than the plant for producing air-dried machine peat. Some of the earlier peat-fuel factories which were established in the United States were briquetting plants, and these, without exception, were unsuccessful, never having reached the productive stage.

PEAT POWDER.

In 1911 it was announced from Sweden that peat powder was being produced on a large scale in a single plant at Back, the processes of preparing the material for use being almost identical in principle to those used in making briquets, the only difference being that when the peat powder was thoroughly dried it was burned and was not briquetted. Peat in powdered form and consumed in proper burners makes a very efficient fuel, and the factory at which it is produced in Sweden is reported to be turning out from 10,000 to 12,000 tons of dry peat powder per annum. It is also reported, as the result of carefully conducted tests, that peat fuel in this form is nearly as efficient, ton for ton, as the best English coal and that the cost to the consumer is considerably less. Late reports indicate that peat powder has been successfully used in railroad locomotives as well as in boiler furnaces of the ordinary stationary plant. Peat powder has also been used to some extent in the reduction of iron from its ores, and in other ways.

PEAT COKE OR CHARCOAL.

Peat, when thoroughly macerated and formed into thoroughly dried bricks, can be reduced to coke or charcoal by heating to high temperatures in properly constructed retorts. The residue obtained, although called peat coke, is not a true coke, but a charcoal, in that there is no fusion of particles or masses of the original peat. If the quality of the peat is good, the charcoal partakes of some of the characteristics of coke; it is hard and tough, withstanding considerable more pressure than ordinary wood charcoal and possessing all of the valuable properties for metallurgical work which wood charcoal has. The modern method of coking peat involves the use of large vertical iron and masonry retorts designed and fitted for the recovery of by-products which result from the condensation of the gases formed by the action of the heat on the peat. These by-products are: Fuel gas, which may be used for continuing the coking process after it is once started, or for running gas engines, or for any other purposes for which gas may be used. Next, the more easily condensible gases yield ammonia, which is generally recovered as the sulphate; acetic acid, which is obtained from the tar water, as it is called; acitone; and a certain quantity of methyl alcohol. The heavier tars obtained from the gases given off by the retorts may be made to yield illuminating and lubricating oils, creosote, and other similar products, paraffin, and a dense, heavy substance closely resembling asphalt, and having the same commercial uses as that substance. In other words, all of those products may be obtained which are recoverable from the dry distillation of wood. The successful operation of a peat-coking plant on a commercial scale depends chiefly upon the quantity and quality of the air-dried machine peat bricks which can be made at the locality where the plant is located. In order to get the best quality of coke the peat used must be low in mineral matter or ash, and in sulphur, and, after maceration, must dry into dense, hard bricks. The cost of installing and operating a plant for the production of peat coke is high.

PRODUCER GAS FROM PEAT.

During the last 10 years there has been great progress made in England, Germany, and Russia in the extent to which low-grade fuels are used in gas producers of different kinds. Among fuels of the bituminous class which have been thoroughly tried and proved successful in commercial operations is peat. This fuel has been successfully used not only in small installations in the European countries mentioned, but air-dried peat bricks also form the sole fuel employed in large central electric power plants. The most noteworthy of these installations are one at Schweger-Moor, near Osnabruck, in northwestern Germany, and two in Italy, where plants developing as much as 4,000 horsepower have been in commercial operation for some years. These plants develop producer gas by the Mond system, by which, in addition to the gas generated, ammonia in the form of sulphate is recovered to a very profitable extent in cleansing the gas. Profitable ammonia recovery from producer gas depends on the fact that peat, as compared with coal, contains a relatively high percentage of combined nitrogen, from which ammonia is formed during distillation. It is now possible by the improved methods of recovery which have been developed in the last few years to recover as ammonia as much as 70 or even 80 per cent of the entire quantity of the combined nitrogen in the fuel. This, with a percentage of nitrogen equal to 1½ per cent of the total dry weight of the peat, yields enough sulphate of ammonia to pay for running the entire plant, leaving the gas free for whatever use it may be put to. It will thus be seen that this is a most important way of utilizing peat as a source of power, the chief if not the only drawback being the difficulty of securing dry fuel enough to run the producer-gas plant to its capacity. This difficulty, if modern methods of handling the raw material are used, should not exist, since it is perfectly possible to keep the gas-producer plant fully supplied with satisfactory material throughout the year by taking the precaution to plan the production of peat for fuel on the right scale to allow for unfavorable seasons.

PEAT AS FUEL FOR STEAM PLANTS.

There now seems no question that it is entirely practicable to use peat as a fuel for steam boilers if the boilers used have furnaces properly designed for this particular type of fuel and if the raw supply is located where there is a market for power. In northern Germany, at the Wiesmoor, near Aurich, there is a very large central electric-power station entirely fired by peat fuel which distributes electricity over a radius of some 25 miles and which is reported to be entirely successful from every point of view. Moreover, in the regions of Germany where brown coal is mined it is common practice to burn the raw unconsolidated fuel as it comes from the mines, containing as high as 60 per cent moisture, under boilers having furnaces and grates of special construction. This fuel is only slightly different from half-dry, untreated peat in appearance and physical structure; and if the brown coal is successfully used, there is no reason apparent why partly dried crude peat could not be used to nearly as good advantage for generating steam if the boiler furnaces and grates were correctly designed.

The utilization of this type of fuel in some of the manufacturing regions of this country would materially improve the fuel situation in such districts. There would be apparently no difficulty in procuring a sufficient supply of the right sort of fuel as soon as the demand for it was made. However, in the present state of our fuel markets it is not to be expected, of course, that a large plant would be erected in the vicinity of a peat bog in the hope that some one would establish a peat-fuel industry to supply its needs. It would be necessary, in developing a plant of this type, to begin by making provision to dig and dry the requisite fuel and to have it ready for use when the plant was completed. With the machinery and methods already developed and in use, there seems to be no doubt that such a plant could be easily established for using commercially either steam or gas engines.

PEAT FUEL IN SPECIAL INDUSTRIES.

From Russia, in districts where coal and petroleum are now or have lately become very high in price as compared with the recent past, it has been reported during the last year that machine peat has been successfully used in glass factories. The reports also indicate that such factories have been able to sustain themselves against competition in other districts because of the low price at which their fuel could be obtained and because of the satisfactory results obtained by the use of this fuel. Peat fuel and the gas obtained from it have also been reported as used in glass manufacture in parts of Germany. It has long been the custom in parts of Germany and Russia where peat is abundant to use it in foundry work, as the fuel obtained from peat is very free from sulphur and gives a good melting heat when thoroughly dry and fired in properly constructed furnaces. Producer gas from peat is used in some German localities in foundry work. From Sweden reports have been received of the successful use of peat powder in the reduction of iron and other metals from the ores, and also in subsequent processes of refining. Peat coke or charcoal has an extensive use in making steel where a particularly high quality of material is desired. This special use consumes practically all of the peat charcoal which is manufactured in Europe.

OTHER COMMERCIAL USES OF PEAT IN EUROPE.

During the last year reports have been received again that the demand for the coarser and less decomposed types of peat for bedding for horses and cattle has largely increased. Some of the factories at which this material is prepared and baled have more than doubled their capacity in order to meet the constantly increasing demand for their output. The finer material, which is obtained in the course of shredding and sorting the raw cut-peat blocks from which litter is made, is sold under the name "peat mull" as packing material for glassware, perishable fruits, and so on. To a somewhat less extent the mull finds a market as a medium for mixing with and absorbing liquid foodstuffs, such as beet-sugar molasses, the mixture making a good and easily fed stock food, popular as a fattening ration for all kinds of live stock. Other and more digestible materials, however, are being substituted in some parts of Europe for the peat mull, but as packing material its use is reported to be increasing.

DOMESTIC USE OF PEAT IN 1913.

FUEL.

As already stated, peat has much less use in the United States than its merits, as judged by what has been accomplished in Europe, would seem to demand. The production of peat for fuel during the calendar year 1913 was entirely insignificant, so far as can be learned. The men who in previous years reported small outputs of machine peat reported that, for one reason or another, their production had been discontinued in the summer of 1913.

There were no new fuel plants at work, so far as known. There were in the course of construction, however, experimental peat-fuel plants in various parts of the country, which their builders expected to have in operation during the season of 1913, but which were delayed by unavoidable causes. These peat-fuel enterprises will doubtless be developed in another year.

FERTILIZER FILLER AND FERTILIZERS.

As in past years, domestic peat was produced in larger quantities for fertilizer filler and fertilizers than for all other purposes combined. So far as can be learned, this use of peat is peculiar to the United States, and apparently its continuance here has been possible because of the richness in combined nitrogen of the peats used for the purpose and because of their thorough decomposition. The whole number of plants for the manufacture of these materials was less than in 1912, as some of those operated in that year had suspended operations in 1913. The chief causes of the closing of these plants seem to have been a very unfavorable drying season combined with the low price at which their output had been contracted for prior to the beginning of the operating season.

All told, 7 plants reported the production and sale of peat for fertilizer and similar uses in 1913, instead of 11 as in 1912. Of the 7 which actually operated in 1913, only 2 were carried on by the same firms included in the list of 1912. It may be stated in explanation, however, that one large producer of the previous year was rebuilding the plant, which had been destroyed by fire; another company had sold its factory; so that the production appears as from new owners. There were 4 new plants established in 1913, all of which began production so late in the season that their output was much below their possible capacity, although all of these new plants reported satisfactory market conditions. The older plants reported some increased production for the year. The 7 factories making peat fertilizer products in 1913 were located by States as follows: Illinois, 2; Indiana, 1 (1 additional building); Massachusetts, New Jersey, Pennsylvania, and Florida, 1 each.

The total production of peat for fertilizer uses reported for 1913 was 28,460 tons, valued at $169,600. The average selling price reported was $5.95 a ton, ranging from $5 to $6 a ton, for carload lots shipped in bulk, to $8 a ton when sold in small lots shipped in burlap bags. The sales for fertilizer filler are reported to be made on the basis of the nitrogen and moisture content of the kiln-dried peat. When sold directly for fertilizer, the peat is sold in the "sun-dry" state, either with or without the addition of mineral salts.

STOCK FOOD.

A considerable quantity of kiln-dried peat was sold as the absorbent for mixing with liquid foodstuffs, especially refuse molasses, for feeding stock that is being fattened for market. It is reported by many users of this type of food that they get excellent results from its use, which seems to be increasing in parts of the country where sugar is made or refined. The production and sale of peat for this use was reported in 1913 at 4,800 tons, valued at $27,600.

PAPER STOCK.

The one factory in the country where peat is known to be used in making paper was being enlarged and extensively remodeled and was not in operation during the greater part of 1913; hence no report of the use of peat during the year has been received.

STABLE LITTER.

There was no production of peat for stable litter in the United States during 1913, but about the usual quantity was imported from Holland, which has been for many years the source of supply for this material for the United States. This material is imported and sold under the name of "peat moss." The quantity brought into the county in 1913 was 9,966 metric tons, or 10,983 short tons, valued at $55,719.

PRODUCTION OF PEAT IN 1913.

The following summary gives the quantity of peat products made and used in the United States in 1913 so far as these have been reported:

Production and consumption of peat in the United States in 1913, in short tons.

Use.	Production.		Imports.		Consumption.	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
Fertilizer	28,460	$169,600			28,460	$169,600
Stock food	4,800	27,600			4,800	27,600
Stable litter			10,983	$55,719	10,983	55,719
Total	33,260	197,200	10,983	55,719	44,243	252,919

MINERAL WATERS.

By R. B. Dole.

CHARACTER OF STATISTICS.

The following statistics on the production of domestic mineral waters have been compiled from individual reports furnished by the owners or operators of springs, and they are intended to include only statistics on natural waters that are bottled and sold in their natural state or only slightly altered from their natural state. Natural still waters that have been artificially carbonated and natural carbonated waters that have lost part of their carbon dioxide are included, and doubtless some waters from which iron has been removed are also included; but artificial waters and natural waters that have been flavored, concentrated, fortified, diluted, or otherwise essentially modified in chemical character are excluded in so far as available information permits such segregation. Waters that are sold by flat or meter rates or are delivered to consumers through pipes or that are otherwise obviously municipal supplies or adjuncts to them are excluded. This is the nearest that it is practicable to approach the commonly accepted definition of a natural mineral water. No distinction is made between mineral water flowing or pumped from a natural spring and that flowing or pumped from a dug, bored, driven, or drilled well. Many of the best known mineral waters in the United States come, not from springs as is popularly supposed, but from wells.

Distinction for practical purposes between table and medicinal waters is entirely arbitrary. In general, table waters are clear and sparkling and without distinct mineral taste or odor; many medicinal waters are highly mineralized or have a distinct taste and odor. Yet some table waters are more strongly mineralized than some medicinal waters and many medicinal waters contain less mineral matter than certain city supplies. A logical distinction between medicinal and other waters might be based on minimum contents of certain substances that cause physiologic reaction; practically, however, no such distinction is made in this country. The basis used in this report for separating medicinal from table waters is the report of the spring owner, and his separation is based in turn on his personal knowledge that some of his customers buy the water to use regularly on their tables as a beverage and that others buy it for an aid during illness.

A few strongly-mineralized waters are not sold as table waters and a few widely sold table waters are not used medicinally, but most waters are sold for both uses.

The statistics do not include the water given away or consumed at spring resorts, which constitutes a large part of the annual production.

MINERAL-WATER TRADE IN 1913.

OUTPUT AND VALUE.

The two following tables give the production and value by States of mineral waters produced in 1912 and 1913. The number of active springs, the average price per gallon, and the value both of medicinal and of table waters are given, together with the total quantity and value. The quantity of mineral water used in the manufacture of soft drinks is separately reported in a later table.

Production and value of mineral waters in the United States, 1912 and 1913, by States.

1912.

State.	Commercial springs.	Quantity sold.	Average price per gallon.	Value of medicinal waters.	Value of table waters.	Total value.

Total	838	57,867,399	10	1,428,005	4,203,386	5,631,391

[a] Includes Delaware, District of Columbia, South Dakota, and Utah.

Though reports were received from a greater number of springs, the production and value of both medicinal and table water were less in 1913 than in 1912. The total quantity sold in 1913 was 57,867,399 gallons, valued at $5,631,391, whereas in 1912 the sales were 62,281,201 gallons, valued at $6,615,671. The decrease in total production was therefore 4,413,802 gallons, or 7 per cent, and the decrease in value was $984,280, or 15 per cent. An appreciable part of this apparent decline of output is caused by reclassification of the statistics, on account of which returns regarding certain waters hitherto included have been omitted from the compilation of production in 1913. If the excluded values were retained, however, there would still be shown a decrease in output. The slight falling off in average price per gallon from 11 to 10 cents is caused partly by the reclassification, but mostly by decrease in the sales of high-priced medicinal waters and increase in the sales of low-priced table waters rather than by essential reduction in price of individual waters.

The State of New York leads in the number of commercial springs, quantity of water sold, and value of table water, and nearly ties Wisconsin for first place in total value, though the value of medicinal water marketed from New York is relatively low. Indiana leads in the value of medicinal water sold, but takes seventh rank in total value of waters. The leaders in the number of commercial springs are New York and Massachusetts; California and Virginia are tied for third place and are closely followed by Connecticut and Pennsylvania, each of which had 43 active springs in 1913. In total output New York is followed by Wisconsin, and that State in turn by Minnesota. In value of medicinal water California comes close to Indiana and is followed by Texas and Virginia. The sales of table water in New York and Wisconsin are more than twice as great as those in any other State, though California and Maine also had notable sales. Wisconsin leads in total value of mineral waters, is closely followed by New York, and thereafter in order by California, Maine, Virginia, Massachusetts, and Indiana, the total values for all other States falling below the $200,000 mark.

The number of springs reporting in 1913 was 838, as compared with 746 in 1912, an increase of 92. The appreciable extension of the collection of these statistics is indicated by the fact that only from three States and the District of Columbia were reports for less than three active springs received, as compared with seven States and the District of Columbia in 1912. No reports of mineral water sales were received from Arizona and Idaho. Only two States, New York and Wisconsin, reported sales of more than 5,000,000 gallons of water, but 15 others reported large sales, ranging from Colorado, 1,053,429 gallons, to Minnesota, 4,802,053 gallons. In three States, Wisconsin, New York, and California, the total value of the mineral-water output exceeded $500,000.

The following table gives the annual production and total value of mineral waters in 1883, 1885, and each fifth year thereafter to 1905, with the production and value for each year since 1909, inclusive:

Production of mineral waters, 1883–1913.

Year.	Commercial springs.	Quantity sold (gallons).	Value.	Year.	Commercial springs.	Quantity sold (gallons).	Value.
1883	189	7,529,423	$1,119,603	1909	760	64,674,486	$6,894,134

1900	561	45,276,995	5,791,805	1913	838	57,867,399	5,631,391
1905	564	46,544,361	6,491,251				

CONDITION OF MINERAL-WATER TRADE.

The reported production and value of mineral waters reached the maximum in 1909. There was a decline in 1910, followed by an increase in 1911, but in 1912 and 1913 there has been a decrease in the volume of business in spite of the fact that the field of the statistics has been extended and reports have been received from an increasing number of operators. Not only has this change taken place, but there is also a tendency toward a lower price, which may be attributed to decreased sales of high-priced waters and increased sales of low-priced waters. The general tendency toward a decline in price is doubtless due to demand for good pure potable bottled waters at moderate cost in place of the former demand for waters reputed to possess exceptional curative properties. Detailed examination of the statistics for the last few years shows that the installation of municipal purification plants in several large cities has been followed by marked decrease in the sales of spring waters in the immediate vicinity, and doubtless general improvements in the quality of public water supplies in smaller municipalities throughout the country has similarly affected the mineral-water business and has contributed to the present lowered production.

Comparative production of mineral waters, 1912–1913.

State.	1912			1913			Increase (+) or decrease (—) in number of springs.	Increase (+) or decrease (—) in quantity sold.	Percentage of increase (+) or decrease (—) in quantity sold.	Increase (+) or decrease (—) in value of product.	Percentage of increase (+) or decrease (—) in value of product.

[a] Included under Miscellaneous States.

[b] Includes in 1912, Delaware, District of Columbia, Nebraska, Nevada, New Mexico, South Dakota, Utah, and Wyoming; in 1913, Delaware, District of Columbia, South Dakota, and Utah.

Nearly half the trade was in the hands of a few very large producers. Five springs sold more than 1,000,000 gallons each and 20 springs more than 500,000 gallons each, or an aggregate of 23,408,057 gallons, valued at $2,090,126. Fifty-four springs did more than $20,000 worth of business each, selling a total of 28,769,596 gallons for $3,642,964. Yet though half the sales were made by a few producers, the business as a whole is one of numerous small producers supplying local demand; for besides the big dealers just mentioned there are 784 others whose annual sales range in value from $5 to $20,000 and whose individual fields of activity occupy every State in the Union except Arizona and Idaho.

Increase of production is reported from 20 States; the greatest proportionate growth was in North Dakota, which advanced from a reported nonproduction in 1912 to a production of 582,356 gallons, valued at $14,403, in 1913; the sales in Florida during 1913 were nearly treble those in 1912. Among the 17 States of the million-gallon class 8 report increase and 9 decrease of sales, though in 4 of the 17 States the change was practically nothing; the greatest relative increases were in Tennessee (37 per cent) and California (34 per cent) and the greatest relative decrease was in Minnesota (46 per cent).

RANGE OF PRICE.

The price for which mineral waters are sold is governed almost entirely by supply and demand, and the value of the containers in which they are sold constitutes an appreciable part of the value of the packages. These conditions give to mineral waters as a class a wider range of price than pertains to almost any other mineral product.

Some widely distributed waters are sold in bottles that are not returnable, and the cost of the containers is usually included in the net value of the waters ready for the market. Other waters, especially table waters in local demand, are sold in returnable carboys whose value is not usually included in the net value of the waters. Consequently State average prices may be greatly affected by one or two high-priced medicinal waters or by a large number of low-priced table waters. In these statistics effort has been made to eliminate freight and marketing charges and the value of returnable containers and thus to give the net value of the waters at their source.

Range of price per gallon of mineral water in 1913.

Price per gallon (in cents.)	Number of springs.	Quantity sold.	Value.	Percentage of number of springs.	Percentage of total quantity.	Percentage of total value.

[a] Exclusive of 18 springs whose waters are used exclusively for the manufacture of soft drinks.

The preceding table shows the number of springs and the quantity and value of mineral water sold within certain ranges of price during 1913. Practically four-fifths of the mineral water was sold at prices ranging from half a cent to 10 cents a gallon, and only 5 per cent at prices greater than 30 cents a gallon. The water from 529 springs was sold for 10 cents or less a gallon and the water from 5 springs was sold at prices ranging from about $1 to about $5 a gallon. This table shows strikingly the great effect of demand on the price of mineral water. As a general rule, most of the higher-priced waters are sold for medicinal use, though several high-priced spring waters that are widely sold are on the market chiefly as table waters. The summary indicates moreover that the great bulk of the mineral-water business is in supplying table water at relatively low price.

That the general trend is toward decrease in price is indicated by the following table, which shows the average price per gallon of mineral water for the last five years and for each five years from 1885 to 1905.

Price per gallon of mineral water, 1885–1913, in cents.

Year.	Price per gallon.	Year.	Price per gallon.
1885	14.4	1909	10.7
1890	18.7	1910	10.2
1895	19.8	1911	10.7
1900	12.8	1912	10.6
1905	13.9	1913	9.7

SOFT DRINKS.

Though the manufacture and sale of soft drinks is an important branch of the mineral-water industry, the statistics regarding it are yet somewhat incomplete because of difficulty in obtaining reports from all manufacturers. The returns show that 5,259,494 gallons of mineral water went into the manufacture of soft drinks during 1913, as compared with 5,139,527 gallons in 1912, an increase of 2 per cent. The figures in the following table indicate the trend of this consumption. It should be remembered that these data do not in any way represent the total production of soft drinks, by far the greater part of which are compounded with municipal or private supplies not classified as mineral waters.

Gallons of mineral water used in manufacture of soft drinks, 1913, by States.

Rank.	State.	Quantity.	Rank.	State.	Quantity.
		Gallons.			*Gallons.*
1	Wisconsin	749,763	8	Maryland	171,000
2	Massachusetts	729,777	9	New York	168,570
3	Connecticut	639,217	10	Colorado	163,787
4	Minnesota	420,672		Other States	1,489,292
5	Pennsylvania	342,639			
6	Ohio	194,684		Total	5,259,494
7	Michigan	190,093			

IMPORTS.

The total imports of natural and artificial mineral waters in 1913, as reported by the Bureau of Foreign and Domestic Commerce, Department of Commerce, amounted to 3,364,676 gallons, valued at the points of shipment at $955,788. The imports have decreased in quantity more than 100,000 gallons a year since 1911, though their value was about $26,000 greater in 1913 than in 1912. More than 1,000,000 gallons each was imported in 1913 from France and Germany and nearly 400,000 gallons from Austria-Hungary; in other words, two-thirds of the imported mineral water consumed in the United States came from Germany, France, and Austria-Hungary. The next largest, but much smaller, importations were from Spain, Italy, Belgium, and England.

Mineral water imported and entered for consumption in the United States, 1900, 1905, and 1909–1913, in gallons.

Year.	Quantity.	Value.	Year.	Quantity.	Value.
1900	2,382,410	$663,803	1911	3,604,703	$1,037,485
1905	3,150,030	926,357	1912	3,499,497	930,091
1909	3,464,524	1,085,177	1913	3,364,676	955,788
1910	3,306,303	983,136			

EXPORTS.

Large quantities of a few domestic waters are exported, but no statistics regarding such shipments are available. The quantity and the value of these waters are included in the statistics of production for the United States.

MINERAL-WATER TRADE BY STATES.

ALABAMA.

Returns from Alabama indicate that the mineral-water trade in 1913 was practically the same as in 1912. The sales amounted to 169,687 gallons, or 4,009 gallons more than in 1912, and the value of the output was $19,343, or $1,092 less than in 1912. The average price reported was 11 cents a gallon, against an average of 12 cents in 1912. Fourteen springs reported sales; one spring active in 1912 was idle in 1913, and one spring's output, which was not reported, was estimated on the basis of the sales in 1912. There was some decrease in the sale of medicinal waters, but an appreciable increase in the sale of table waters, so that trade in the latter formed the greater part of the business. Five bathing establishments and resorts accommodating nearly 1,500 guests at 9 springs were maintained. In addition to the quantity reported as sold, 70,000 gallons of mineral water was used in the manufacture of soft drinks.

The following 14 springs reported sales:

Alabama Mineral Springs, McWilliams, Wilcox County.
Bailey Springs, Florence, Lauderdale County.
Bladon Spring, Bladon Springs, Choctaw County.
Blount Springs, Blount Springs, Blount County.
Bromberg Gulf Coast Lithia Spring, Bayou La Batre, Mobile County.
Dixie Spring, Dixie Spring, Walker County.
Healing Springs, Healing Springs, Washington County.
Ingram Lithia Wells, near Ohatchee, Calhoun County.

Livingston Spring, Livingston, Sumter County.
Luverne Mineral Spring, Luverne, Crenshaw County.
MacGregor Spring, Spring Hill, Mobile County.
Matchless Mineral Wells, east of Greenville, Butler County.
Purity Spring, Spring Hill, Mobile County.
White Sulphur Wells, near Jackson, Clarke County

ARKANSAS.

The mineral water business in Arkansas increased somewhat during 1913, principally because of the operation of new springs, the total sales having increased from 1,396,032 gallons, valued at $132,257, in 1912 to 1,428,869 gallons, valued at $151,412, in 1913, an increase of 2 per cent in quantity and of 15 per cent in value. The average price per gallon rose from 10 to 11 cents.

The following table shows the record for the last five years:

Production and value of mineral waters in Arkansas, 1909–1913.

Year.	Commercial springs.	Quantity sold.	Value.	Average price per gallon.
		Gallons.		*Cents.*
1909	10	1,213,742	$153,163	13
1910	10	1,065,676	89,772	8
1911	8	1,560,157	118,994	8
1912	11	1,396,032	132,257	10
1913	16	1,428,869	151,412	11

Sales were reported this year from five more springs than in 1912 and the number of bathing establishments increased from two to three, accommodations for guests increasing from 4,000 to 5,500, exclusive of the capacity of Hot Springs. More than one-half the mineral water is sold for medicinal use.

The United States Government maintains under the direction of the Secretary of the Interior the Hot Springs Reservation of about 900 acres, including Hot Springs Mountain, North Mountain, West Mountain, Sugarloaf Mountain, and Whittington Lake Park. The springs are all grouped about the base of Hot Springs Mountain, their aggregate flow being somewhat more than 800,000 gallons a day. Twenty-three pay bath houses and the Army and Navy General Hospital are supplied with hot water from these springs. The majority of the active springs of Arkansas are at or near Hot Springs.

The 16 springs reporting sales are as follows:

Arkansas Lithia Springs, near Hope, Hempstead County.
Arsenic Springs, Hot Springs, Garland County.
Chewaukla Spring, Hot Springs, Garland County.
De Soto Springs, Hot Springs, Garland County.
Glenaqua Mineral Springs, Hot Springs, Garland County.
Happy Hollow Spring, Hot Springs, Garland County.
Imperial Spring, Hot Springs, Garland County.
Iron and Magnesia Springs, Hot Springs, Garland County.
Lithia and Sulphur Springs, Sulphur Springs, Benton County.
Mountain Blood Spring, near Hot Springs, Garland County.
Mountain Valley Springs, Mountain Valley, Garland County.
Oaklawn Mineral Well, Hot Springs, Garland County.
Ozarka Spring, Eureka Springs, Carroll County.
Park Springs, Bentonville, Benton County.
Potash Sulphur Springs, Hot Springs, Garland County.
Ravenden Springs, Ravenden Springs, Randolph County.

CALIFORNIA.

There was a large increase during 1913 in the mineral-water sales of California, 2,801,393 gallons having been reported, as compared with 2,089,951 gallons in 1912, an increase of 711,442 gallons, or 34 per cent. The total value of the product, however, remained practically the same, being $531,925 in 1913, as compared with $532,971 in 1912; this was chiefly because the greater part of the increased output was in a few table waters that were sold at lower prices than formerly. The average price per gallon fell from 26 to 19 cents. Though two-thirds of the total output was sold for table use, California ranked second in 1913, as in 1912, in the production of medicinal waters. The State also ranked third in number of active springs and in value of output. The record for the last five years is as follows:

Production and value of mineral waters in California in 1909–1913.

Year.	Commercial springs.	Quantity sold.	Value.	Average price per gallon.
		Gallons.		*Cents.*
1909	44	2,179,187	$444,230	20
1910	41	2,008,697	394,841	20
1911	40	2,310,237	578,439	25
1912	41	2,089,951	532,971	26
1913	49	2,801,393	531,925	19

Five new springs were added to the list of producers in 1913; five idle in 1912 reported sales in 1913; two other springs formerly active were idle; and the output of three that failed to report was estimated—the total number of active springs thus having been increased to 49, or 8 more than in 1912. Mineral-water baths and resorts accommodating a total of 4,800 guests were maintained at 23 springs. A total of 50,000 gallons was reported as having been used in the manufacture of soft drinks.

The 46 springs reporting are as follows:

Ætna Springs, Lidell, Napa County.
Alder Glen Spring, Cloverdale, Sonoma County.
Alhambra Spring, Martinez, Contra Costa County.
Alma Spring, Alma, Santa Clara County.
Barcal Springs, Preston, Sonoma County.
Bartlett Springs, Bartlett Springs, Lake County.
Boyes Hot Springs, Boyes Springs, Sonoma County.
Bythinia Springs, Santa Barbara, Santa Barbara County.
Caliente Mineral Spring, Agua Caliente, Sonoma County.
California Geysers, The Geysers, Sonoma County.
Castalian Water, Inyo County.
Castle Rock Spring, Eubanks, Shasta County.
Console Spring, Colton, Riverside County.
Cooks Springs, near Williams, Colusa County.
Crystal Spring, Los Angeles, Los Angeles County.
El Granito Spring, El Cajon, San Diego County.
Elliotta White Sulphur Spring, Riverside, Riverside County.
Elysian Spring, Los Angeles, Los Angeles County.
Fouts Springs, Fouts Springs, Colusa County.
Grizzly Spring, near Sulphur Creek, Colusa County.
Lepori Vichy Springs, near Napa City, Napa County.
Lytton Spring, Lytton, Sonoma County.
Mercey Spring, Fresno County, near South Dos Palos.
Mokelumne Hill Spring, Mokelumne, Calaveras County.
Napa Soda Springs, Napa Soda Springs, Napa County.
Paraiso Hot Springs, Paraiso Springs, Monterey County.

Paso Robles Hot Springs, Paso Robles, San Luis Obispo County.
Pinkham Spring, Santa Barbara, Santa Barbara County.
Purity Springs, Sausalito, Marin County.
Radium Sulphur Springs, Colegrove, Los Angeles County.
Redwing Springs, Middletown, Lake County.
Rose Spring, Los Angeles, Los Angeles County.
Samuel Soda Springs, Monticello, Napa County.
San Benito Spring, near Hollister, San Benito County.
Shasta Springs, Shasta Springs, Siskiyou County.
Soboba Lithia Hot Springs, San Jacinto, Riverside County.
Table Rock Spring, Little Shasta, Siskiyou County.
Tamalpais Spring, San Rafael, Marin County.
Tia Juana Springs, San Ysidro, San Diego County.
Tolenas Spring, near Suisun City, Solano County.
Upper Soda Spring, Dunsmuir, Siskiyou County.
Valley Springs, Valley Springs, Calaveras County.
Veronica Medicinal Springs, near Santa Barbara, Santa Barbara County.
Vito Nuevo Spring, Mono County.
Walters Springs, Pope Valley, Napa County.
Witter Medical Springs, Witter, Lake County.

COLORADO.

Returns from Colorado indicate a decrease in quantity of water sold in 1913, due chiefly to a falling off in the sales of one large producer. The sales reported are 1,053,429 gallons, valued at $89,820, as compared with 1,178,308 gallons, valued at $75,314, in 1912. Though the decrease in quantity amounts to 11 per cent, the total value of the product increased $14,506, or 19 per cent, this being accompanied by an increase in the average price from 6 to 9 cents.

The following is the record for the last five years:

Production and value of mineral waters in Colorado, 1909–1913.

Year.	Commercial springs.	Quantity sold.	Value.	Average price per gallon.
		Gallons.		*Cents.*
1909	15	1,077,820	$111,158	10
1910	14	1,638,984	115,289	7
1911	14	1,436,066	104,763	7
1912	11	1,178,308	75,314	6
1913	11	1,053,429	89,820	9

Reports were received from no new springs during 1913. Colorado mineral waters are sold chiefly for table use. The number of bath resorts has increased from three in 1912 to five in 1913. Besides the quantity reported sold 163,787 gallons was used in the manufacture of soft drinks.

The 11 springs reporting are as follows:

Boulder Springs, Crisman, Boulder County.
Canon City Soda Spring, Canon City, Fremont County.
Clark Magnetic Mineral Spring, Pueblo, Pueblo County.
Columbia Well, Denver, Denver County.
Crystal Springs, Fowler, Otero County.
Marshall's Magnetic Mineral Spring, Pueblo, Pueblo County.
Navajo, Shoshone, Manitou, and Cheyenne springs, Manitou, El Paso County.
Pueblo Mineral Spring, Pueblo, Pueblo County.
Ute Chief Spring, Manitou, El Paso County.
Ute Iron, Ouray, Little Chief, and Iron Springs Geyser springs, Manitou, El Paso County.
Yampah Spring, Glenwood Springs, Garfield County.

CONNECTICUT.

The mineral-water sales in Connecticut during 1913 amounted to 2,458,327 gallons, an increase of 348,096 gallons, or 16 per cent, over sales in 1912; but the value of the output dropped from $153,383 in 1912 to $136,878 in 1913, a decrease of 11 per cent. This decrease in value in spite of a marked increase in output is the result chiefly of general decrease in price but great increase in production of table waters and of decrease in sales of a few relatively high-priced medicinal waters. The average price per gallon dropped from 7 cents in 1912 to 6 cents in 1913. The record for sales for the last five years follows:

Production and value of mineral waters in Connecticut, 1909–1913.

Year.	Commercial springs.	Quantity sold.	Value.	Average price per gallon.
		Gallons.		*Cents.*
1909	22	691,296	$42,375	6
1910	24	1,608,775	109,853	7
1911	28	2,164,701	182,744	8
1912	28	2,110,231	153,383	7
1913	43	2,458,327	136,878	6

Fourteen new springs, all but two of which sell table water exclusively, reported, and the production of one delinquent spring was estimated on the basis of the previous year's business, the number of active springs having been thus increased to 43. Nearly all the water is sold for table use. No resorts or mineral-water baths were reported as having been in operation at any of the springs, but nearly 640,000 gallons was used in the manufacture of soft drinks.

The 42 springs reporting are as follows:

Althea Spring, Waterbury, New Haven County.
Ansantawae Spring, Milford, New Haven County.
Aspinock Spring, Putnam Heights, Windham County.
Bailey Spring, Mill Plain Road, Fairfield County.
Barcla Spring, Danbury, Fairfield County.
Berkshire Spring, Cornwall Bridge, Litchfield County.
Buttress Spring, Woodbridge, New Haven County.
Chalybeate Spring, Oxford, New Haven County.
Cherry Hill Spring, Highwood, New Haven County.
Colonial Spring, Danbury, Fairfield County.
Crystal Spring, near Little River, Middlesex County.
Crystal Spring, near Derby, New Haven County.
Diamond Spring, Cheshire, New Haven County.
East Hill Spring, Derby, New Haven County.
Elco Spring, Elco Springs, Hartford County.
Ellis Mountain Spring, Danbury, Fairfield County.
Foxhunter Spring, Salisbury, Littlefield County.
Granite Rock Spring, Higganum, Middlesex County.
Gra-Rock Spring, Canton, Hartford County.
Hallett Spring, Stratfield, Fairfield County.
Hermitage Spring, Monotowese, New Haven County.
Highland Spring, near Mount Higbee, Middlesex County.
Hillside Spring, West Meriden, New Haven County.
Hosmer Spring, Willimantic, Windham County.
Indian Spring, Shelton, Fairfield County.

Live Elm Spring, Meriden, New Haven County.
Live Oak Spring, Meriden, New Haven County.
Mammanasco Spring, Ridgefield County.
Mohawk Spring, Torrington, Litchfield County.
Mountain View Spring, Middletown, Middlesex County.
Mountainville Spring, Danbury, Fairfield County.
Oak Spring, Middletown, Middlesex County.
Park Spring, Willimantic, Windham County.
Pequabuck Mountain Spring, Bristol, Hartford County.
Pequot Spring, Old Mystic, New London County.
Red Rock Spring, Meriden, New Haven County.
Richardson Spring, Torrington, Litchfield County.
St. George Spring, Ridgefield, Fairfield County.
Shantok Spring, Uncasville, New London County.
Tonica Spring, Highland Park, Hartford County.
Varuna Spring, North Stamford, Fairfield County.
Venture Rock Spring, Stonington, New London County.

DELAWARE.

Reports have been received from only one spring in Delaware during the last three years, the water being used principally on the table by residents of Wilmington. The spring is:

Kiamensi Spring, near Wilmington, Newcastle County.

DISTRICT OF COLUMBIA.

As only two springs, whose water is sold for table use, mainly in Washington, reported sales from the District of Columbia in 1913, statistics on them have been included with those of other States having less than three reporting springs.

The same springs reported in 1911 and 1912 and are:

Gitchie Crystal Spring, Benning.
Red Oak Spring, near Langdon.

FLORIDA.

The addition of two new springs to the list of producers in Florida nearly trebled the output during 1913, when the total sales amounted to 343,123 gallons, valued at $37,474, as compared with 123,485 gallons, valued at $17,521, in 1912. The average price per gallon continued to fall, dropping from 14 cents in 1912 to 11 cents in 1913. About half the water was sold for medicinal use. Bathing establishments and resorts for about 900 guests were maintained at six springs. One water on the market in 1912 was not sold in 1913, but Purity Spring and Stomawa Well were added to the list, and thus the total number of commercial springs in the State has been increased by one.

The 10 springs reporting sales are:

Chumuckla Spring, McDavid, Santa Rosa County.
Espiritu Santo Spring, Safety Harbor, Pinellas County.
Lackawanna Spring, near Jacksonville, Duval County.
Newport Spring, Newport, Wakulla County.
Orange City Mineral Spring, Orange City, Volusia County.
Panacea Mineral Spring, Panacea, Wakulla County.
Purity Spring, Tampa, Hillsboro County.
Quisisana Spring, Green Cove Springs, Clay County.
Stomawa Well, near Tampa, Hillsboro County.
Wekiwa Springs, Wekiwa Springs, Orange County.

GEORGIA.

The returns from Georgia indicate a falling off in quantity during 1913, but a notable increase in value. This apparent anomaly was due mostly to increase in the sales of some rather high-priced table waters, because of which the average price per gallon increased from 6 to 9 cents. The total sales in 1913 amounted to 750,893 gallons, valued at $69,442, as compared with 861,365 gallons, valued at $55,031, in 1912, these figures corresponding to a decrease of 13 per cent in quantity and an increase of 26 per cent in value. A little more than 10 per cent of the water is sold for medicinal use. Two springs, Dalton Mineral and Holly, reported production for the first time. Resorts accommodating about 700 people were in operation at 7 springs and mineral-water baths were maintained at 4.

The 18 springs reporting sales are:

Benscot Lithia Springs, Austell, Cobb County.
Bowden Lithia Spring, Lithia Springs, Douglas County.
Catoosa Springs, Catoosa Springs, Catoosa County.
Chalybeate Spring, Chalybeate, Meriwether County.
Dalton Mineral Spring, near Dalton, Whitfield County.
Daniel Mineral Spring, Union Point, Green County.
Duke Spring, near Cedartown, Polk County.
Electric Lithia Spring, Hillman, Taliaferro County.
High Rock Magnesia Spring, near Atlanta, Fulton County.
Holly Springs, Holly Springs, Cherokee County.
Jay Bird Spring, near Helena, Dodge County.
Miller's Mineral Spring, Milledgeville, Baldwin County.
Murrow Spring, Tifton, Tift County.
Pine Mountain Spring, West Point, Harris County.
Swift Lithia Spring, Elberton, Elbert County.
Utoy-Flora Spring, Utoy, Fulton County.
White Elk Spring, Macon, Bibb County.
White Oak Spring, Macon, Bibb County.

ILLINOIS.

According to the returns received from Illinois 1,216,442 gallons of mineral water, valued at $68,549 was sold during 1913; the sales in 1912 amounted to 1,143,625 gallons, valued at $74,445. Thus in 1913 there was an increase of 6 per cent in quantity but a decrease of 8 per cent in value, with a drop in the average price from 7 to 6 cents per gallon. The value of the medicinal waters, which constituted about one-tenth of the trade, decreased a little, most of the falling-off being in the value of the table waters. The record of the State for the last five years is as follows:

Production and value of mineral waters in Illinois, 1909–1913.

Year.	Commercial springs.	Quantity sold.	Value.	Average price per gallon.
		Gallons.		*Cents.*
1909	14	639,460	$49,108	8
1910	16	1,117,620	83,148	7
1911	14	1,304,950	82,330	6
1912	17	1,143,625	74,445	7
1913	21	1,216,442	68,549	6

Reports were received from 21 active springs, of which one, Sulphur Lick Spring, is new, and three idle in 1912 reported production. About 130,000 gallons was used in the manufacture of soft drinks. Bathing establishments were operated at six and resorts for guests at four springs.

Sales were reported from the following 21 springs:

Abana Spring, Libertyville, Lake County.
Aqua Vitæ Mineral Spring, Maquon, Knox County.
Brady Spring, Joliet, Will County.
Central Park Sulphur Spring, Peoria, Peoria County.
Cumberland Mineral Spring, Greenup, Cumberland County.
Glen Flora Mineral Spring, Waukegan, Lake County.
Gravel Spring, near Jacksonville, Morgan County.
Indian Spring, Streator, Lasalle County.
Macinac Mineral Springs, near Carlock, Woodford County.
Mokena Mineral Spring, Mokena, Will County.
Montgomery Magnesia Spring, Montgomery, Kane County.
Namonomia and Old Ironsides springs, Dixon Springs, Pope County.
Pekin Mineral Spring, Pekin, Tazewell County.
Perry Spring, Perry, Pike County.
Ripley Mineral Spring, Cooperstown, Brown County.
Sanicula Spring, South Ottawa, Lasalle County.
Scott's Springs, Galatia, Saline County.
Sulphur Lick Spring, Wedron, Lasalle County.
White Diamond Spring, South Elgin, Kane County.
White Eagle Spring, Edgemont, St. Clair County.

INDIANA.

Statistics from Indiana show 383,557 gallons of mineral water sold in 1913 for $205,621, at an average price of 54 cents, as compared with 993,163 gallons sold for $677,718, in 1912, at an average price of 68 cents. This apparently enormous decline is caused, however, by the omission of reports from certain springs that were included in 1912, and not to any essential change in the business, and the change in price is accounted for in the same manner. One new spring reported in 1913, increasing the number of active springs to 16, and 1 delinquent has been considered idle. The greater part of the mineral water is sold for medicinal use. At eight springs there are resorts accommodating more than 2,000 people and at these springs the water is also used for bathing. Very little mineral water is used for the manufacture of soft drinks.

The following 16 springs have reported sales:

Blue Cast Magnetic Spring, Woodburn, Allen County.
Blue Lick Spring, Blue Lick, Clark County.
Bronson Spring, Terre Haute, Vigo County.
Carlson Mineral Springs, Laporte, Laporte County.
Cartersburg Mineral Spring, Cartersburg, Hendricks County.
Coats Spring, Littles, Pike County.
Colomagna Springs, Columbus, Bartholomew County.
Craig Spring, Greenwood, Johnson County.
Knott's Mineral Spring, Porter, Porter County.
McCullough Spring, Oakland City, Gibson County.
Mudlavia Lithia Spring, Kramer, Warren County.
Paoli Lithia Spring, Paoli, Orange County.
Pluto, Proserpine, and Bowles springs, French Lick, Orange County.
Reid Mineral Spa Lithia Spring, near Richmond, Wayne County.
West Baden Mineral Springs, West Baden, Orange County.
White Crane Spring, Dillsboro, Dearborn County.

IOWA.

The output of mineral water in Iowa during 1913 suffered appreciable decrease, chiefly because of a falling off in the sales of one large producer. The total sales amounted to 48,665 gallons, valued at $7,369, at an average price of 15 cents The sales reported in 1912 were 84,300 gallons, valued at $11,375, at an average price of 14 cents. The decrease in quantity was 42 per cent, and in spite of an increase of 1 cent in the average price, the decline in value was $4,006, or 35 per cent. One spring, active in 1912, was reported idle in 1913, and no new springs were reported. About four-fifths of the water was sold for table use. In addition to the quantity given above, about 100,000 gallons of mineral water was used in the manufacture of soft drinks. The five springs reporting sales are as follows:

Crystal Spring, Estherville, Emmet County.
Egralharve Spring, Montgomery, Dickinson County.
Fry's Spring, Colfax, Jasper County.
Heston's Spring, Fairfield, Jefferson County.
White Sulphur Spring, Linwood, Scott County.

KANSAS.

The output of mineral water in Kansas during 1913 showed a marked decrease, the total sales amounting to 337,193 gallons, valued at $60,026, as compared with 428,677 gallons, valued at $75,919, in 1912. This corresponds to a decrease of 21 per cent in both quantity and value. The average price per gallon remained 18 cents. As no new springs reported and two springs hitherto active were idle, the number of commercial springs was reduced to 14, the output of one of which was estimated from the output in 1912. Resorts for guests, with bathing establishments, were maintained at four springs, and accommodated about 170 guests.

The following 13 springs reported sales:

Abilena Spring, Abilene, Dickinson County.
Aganippe Spring, near Independence, Montgomery County.
Blasing's Mineral Spring, near Manhattan, Riley County.
California Spring, Ottawa, Franklin County.
Crystal Spring, Coffeyville, Montgomery County.
Geyser Mineral Springs, Rosedale, Wyandotte County.
Hiatts Crystal and Mineral Springs, Winfield, Cowley County.
Ke-Lo Artesian Well, Kingman, Kingman County.
Magnesium and Choteau springs, Independence, Montgomery County.
Phillip's Mineral Spring, Topeka, Shawnee County.
Riverview Spring, Winfield, Cowley County.
Sycamore Mineral Spring, Sabetha, Brown County.
Waconda Spring, Waconda Springs, Mitchell County.

KENTUCKY.

The mineral-water business in Kentucky during 1913 was about the same as in 1912. The reported sales were 475,675 gallons as compared with 477,341 gallons in 1912, a decrease of less than 1 per cent, and the value of the sales in 1913 was $53,334 as compared with $56,555 in 1912, a decrease of 6 per cent. The average price decreased less than a cent a gallon, being 11 cents in 1913. Reports were received from three new springs, Crystal Spring, Kentucky

Carlsbad Spring, and St. Patrick's Well. The output from two springs from which reports could not be obtained has been estimated on the basis of the production reported for 1912. The total output was about equally divided between table and medicinal waters. There were resorts at six of the springs with accommodations for about 2,300 people, and bath establishments were maintained at two of these resorts. In addition to the sales already reported, about 79,000 gallons of mineral water was used in making soft drinks.

The 12 springs from which reports were received are as follows:

Anita Springs, La Grange, Oldham County.
Blue Rock Spring, Fisherville, Jefferson County.
Crystal Spring, Pollard, Boyd County.
Glen Lily Spring, near Bowling Green, Warren County.
Hamby's Spring, Dawson Springs, Hopkins County,
Kentucky Carlsbad Spring, Dry Ridge, Grant County.
Kentucky Mineral Well, Lorain, Taylor County.
Lexington Lithia Springs, Lexington, Fayette County.
Robson Spring, Fort Thomas, Campbell County.
Royal Magnesian Spring, near La Grange, Oldham County.
St. Patrick's Well, Louisville, Jefferson County.
Sanders Lithia Springs, Sanders, Carroll County.

LOUISIANA.

Though the number of commercial springs in Louisiana is small the individual productions are large. Five springs reported in 1913 a total output of 700,795 gallons, valued at $39,657, or at an average price of 6 cents a gallon. The corresponding figures for 1912 are 561,660 gallons, valued at $33,345. The increased business in 1913 represents 25 per cent increased production and 19 per cent increased value. Nearly five-sixths of the water was sold for table use. The record of sales for the last five years is as follows:

Production and value of mineral waters in Louisiana, 1909–1913.

Year.	Commercial springs.	Quantity sold.	Value.	Average price per gallon.
		Gallons.		*Cents.*
1909	5	1,375,000	$103,850	8
1910	4	2,313,000	163,975	7
1911	5	1,520,550	110,998	7
1912	4	561,660	33,345	6
1913	5	700,795	39,657	6

The notable drop in production after installation of the new waterworks in New Orleans has apparently been followed by partial recovery of the trade. No new spring was reported, but one temporarily idle in 1912 reported sales in 1913. Resorts were operated at two springs.

The five springs that made returns are as follows:

Abita Springs, Abita Springs, St. Tammany Parish.
Geyser Spring, Hammond, Tangipahoa Parish.
Greenwell Spring, Magnolia, East Baton Rouge Parish.
Krotz Spring, Krotz Springs, St. Landry Parish.
Ozone Spring, Pearl River, St. Tammany Parish.

MAINE.

The production of mineral water in Maine during 1913 was practically the same as in 1912. The quantity sold amounted to 1,174,262 gallons, valued at $368,436, as compared with 1,179,192 gallons, valued at $432,765, in 1912. The decrease in value, $64,329, or 15 per cent, is equivalent to a decrease in average price from 37 to 31 cents a gallon.

The following table shows the record of sales for the last five years:

Production and value of mineral waters in Maine, 1909–1913.

Year.	Commercial springs.	Quantity sold.	Value.	Average price per gallon.
		Gallons.		*Cents.*
1909	33	1,515,541	$402,593	27
1910	29	1,238,171	404,539	33
1911	28	1,254,783	431,740	34
1912	31	1,179,192	432,765	37
1913	32	1,174,262	368,436	31

Two new producers reported—Arctic Spring, at Bangor, and Bartlett Artesian Well, at Lewiston. The output of one spring that failed to report was estimated on the basis of the production for 1912. In addition to the quantity above reported nearly 95,000 gallons was used in the manufacture of soft drinks. Two resorts for guests, but no mineral-water baths, were operated.

The names of the 31 springs reporting are:

Arctic Spring, Bangor, Penobscot County.
Bakers Puritan Spring, Pine Point, Cumberland County.
Bartlett Artesian Well, Lewiston, Androscoggin County.
Blue Hill Mineral Spring, Blue Hill, Hancock County.
Forest Springs, Litchfield, Kennebec County.
Glenrock Cold Spring, Greene, Androscoggin County.
Glenwood Spring, Augusta, Kennebec County.
Glenwood Mineral Spring, St. Albans, Somerset County.
Hanover Spring, Hanover, Oxford County.
Highland Mineral Spring, Lewiston, Androscoggin County.
Indian Hermit Spring, Wells Village, York County.
Kennebunk Mineral Spring, Kennebunkport, York County.
Keystone Mineral Spring, East Poland, Androscoggin County.
Littlefield Spring, Gardiner, Kennebec County.
Mount Desert Spring, Northeast Harbor, Hancock County.
Mount Zircon Spring, Milton Plantation, Oxford County.
Mystic Spring, Saco, York County.
Oak Grove Spring, Brewer, Penobscot County.
Paradise Spring, Brunswick, Cumberland County.
Pine Spring, Topsham, Sagadahoc County.
Pine Croft Spring, Freeport, Cumberland County.
Poland Spring, South Poland, Androscoggin County.
Purity Spring, West Scarboro, Cumberland County.
Redman Farm Spring, Belfast, Waldo County.
Rocky Hill Spring, Fairfield, Somerset County.
Seal Rock Spring, Saco, York County.
Skowhegan Crystal Spring, Skowhegan, Somerset County.
Thorndike Mineral Spring, near Thorndike, Waldo County.
Underwood Spring, Falmouth Foreside, Cumberland County.
Wawa Lithia Spring, Ogunquit, York County.
Windsor Spring, Lewiston, Androscoggin County.

MARYLAND.

The mineral-water business of Maryland decreased 10 per cent in quantity and 20 per cent in value during 1913, while the average price dropped from 10 to 9 cents a gallon. The sales totaled 1,390,437 gallons, valued at $126,883, mostly table water, whereas in 1912 the sales amounted to 1,606,373 gallons, valued at $157,541.

The following record for the last five years indicates a maximum production in 1911 followed by a decline:

Production and value of mineral waters in Maryland, 1909–1913.

Year.	Commercial springs.	Quantity sold.	Value.	Average price per gallon.
		Gallons.		*Cents.*
1909	7	938,496	$91,569	10
1910	8	1,163,828	102,371	9
1911	12	1,657,756	150,966	9
1912	13	1,606,373	157,541	10
1913	12	1,390,437	126,883	9

No new spring was reported, the output of one that failed to report was estimated, and one spring active in 1912 was reported out of business in 1913, these changes making the total number of commercial springs 12. Only one resort for guests was operated, but two mineral baths hitherto unreported were in operation, and in addition about 170,000 gallons of spring water was used in the manufacture of soft drinks.

The 11 springs reporting sales are as follows:

Altamont Spring, near Deer Park, Garrett County.
Buena Vista Spring, Edgemont, Washington County.
Carroll Springs, Forest Glen, Montgomery County.
Caton Spring, Catonsville, Baltimore County.
Chattolanee Spring, Chattolanee, Baltimore County.
Crystal Rock Spring, Berwyn, Prince Georges County.
Gneiss Rock Artesian Well, Ruxton Heights, Baltimore County.
Indian Spring, Hillsdale, Baltimore County.
Mardela Mineral Spring, Mardela, Wicomico County.
Rock Crystal Spring, Rognel Heights, Baltimore County.
Royal Spring, Franklintown, Baltimore County.

MASSACHUSETTS.

Returns from Massachusetts for 1913 indicate a decline of 13 per cent in production and 14 per cent in value of mineral water. The reported sales are 3,907,395 gallons, as compared with 4,502,806 gallons in 1912, the total value being $213,802 in 1913 and $247,397 in 1912. The average price, 6 cents a gallon, remained the same. The additional quantity used in the manufacture of soft drinks decreased from 900,000 gallons in 1912 to 730,000 gallons in 1913. In spite of these decreases the State ranks second in number of commercial springs and fourth in total production.

The following record shows a gradual decline in trade since 1909:

Production and value of mineral waters in Massachusetts, 1909–1913.

Year.	Commercial springs.	Quantity sold.	Value.	Average price per gallon.
		Gallons.		*Cents.*
1909	60	5,424,082	$228,067	4
1910	55	4,691,159	241,949	5
1911	56	4,610,474	218,870	5
1912	54	4,502,806	247,397	6
1913	60	3,907,395	213,802	6

Output was reported by six new springs and the production of two was estimated from the sales reported in 1912, so that there were in all 60 active springs. Two bathing establishments and two small resorts were reported. Practically eight-ninths of the trade was in table water. The 58 reporting springs are as follows:

Abbott Spring, Methuen, Essex County.
Avonia Spring, Weymouth, Norfolk County.
Ballardvale Spring, Ballardvale, Essex County.
Belmont Crystal Spring, Belmont, Middlesex County.
Belmont Hill Spring, Everett, Middlesex County.
Burnham Spring, Methuen, Essex County.
Cadwells Crystal and Los Altos springs, Woburn, Middlesex County.
Chapmans Crystal Spring, Stoneham, Middlesex County.
Cold Spring, South Braintree, Norfolk County.
Crescent Spring, Brockton, Plymouth County.
Crystal Spring, West Peabody, Essex County.
Deep Glen Spring, West Lynn, Essex County.
El-Azhar Spring, Tyngsboro, Middlesex County.
Goulding Spring, Whitman, Plymouth County.
Granite Rock Spring, Brockton, Plymouth County.
Highland Spring, West Abington, Plymouth County.
Holyoke Spring, West Lynn, Essex County.
Indian Spring, Brockton, Plymouth County.
King Philip Spring, Mattapoisett, Plymouth County.
Klines Spring, Lawrence, Essex County.
Leicester Polar Spring, Spencer, Worcester County.
Massasoit Spring, West Springfield, Hampden County.
Milton Spring, Milton, Norfolk County.
Moose Hill Spring, Swampscott, Essex County.
Mountain Park Spring, Swampscott, Essex County.
Mount Blue Spring, Hingham, Plymouth County.
Mount Holyoke Lithia Spring, South Hadley, Hampshire County.
Mount Pleasant Spring, Lowell, Middlesex County.
Mount Vernon Spring, Mount Vernon, Essex County.
Nemasket Spring, Middleboro, Plymouth County.
New Abbott Spring, Methuen, Essex County.
Nobscot Mountain Spring, Framingham, Middlesex County.
Norwood Spring, Norwood, Norfolk County.
Oak Hill Spring, Brockton, Plymouth County.
October Mountain Spring, Lenox, Berkshire County.
Paradise Spring, Rowley, Essex County.
Pearl Hill Mineral Spring, Fitchburg, Worcester County.
Pepperell Spring, Pepperell, Middlesex County.
Pequot Mineral Spring, North Natick, Middlesex County.
Pine Crest Spring, Pittsfield, Berkshire County.
Pocahontas Spring, Lynnfield Center, Essex County.
Puritan Spring, Andover, Essex County.
Purity Spring, Spencer, Worcester County.
Robbins Springs, Arlington Heights, Middlesex County.
Roberge Mineral Spring, Worcester, Worcester County.

Sand Spring, Williamstown, Berkshire County.
Shawmut Spring, West Quincy, Norfolk County.
Simpson Spring, South Easton, Bristol County.
Sippican Spring, Marion, Plymouth County.
Sterling Spring, West Lynn, Essex County.
Stevens Spring, Lawrence, Essex County.
Twin Elm Spring, Lexington, Middlesex County.
Valpey Spring, Lawrence, Essex County.
Wampanoag Spring, Williamstown, Berkshire County.
Whitman Spring, Whitman, Plymouth County.
Wilbraham Mountain Spring, Wilbraham, Hampden County.
Ye Cape Cod Pilgrim Spring, South Wellfleet, Barnstable County.

MICHIGAN.

Reported sales of mineral water in Michigan showed a marked decrease in 1913. The total production was 884,893 gallons, valued at $52,642, or at an average price of 6 cents a gallon, as compared with a production in 1912 of 1,420,465 gallons, valued at $75,611, or at an average price of 5 cents a gallon. These figures represent a decrease of 38 per cent in output and of 30 per cent in value.

The following is the record of sales for the last five years:

Production and value of mineral waters in Michigan, 1909–1913.

Year.	Commercial springs.	Quantity sold.	Value.	Average price per gallon.
		Gallons.		*Cents.*
1909	19	2,760,604	$104,454	4
1910	17	1,454,020	69,538	5
1911	19	1,713,401	72,253	4
1912	18	1,420,465	75,611	5
1913	20	884,893	52,642	6

Beaver, Giant Mineral, and Moorman springs reported sales for the first time, and the output of two that failed to report was estimated on the basis of sales in 1912. Two springs active in 1912 were idle in 1913 and one idle in 1912 was active in 1913; thus the number of commercial springs increased to 20. About 7 per cent of the water is sold for medicinal use. In addition to the sales reported 190,000 gallons was used in the manufacture of soft drinks.

The 18 springs reporting sales are:

Andrews Magnetic Mineral Spring, St. Louis, Gratiot County.
Arctic Spring, Grand Rapids, Kent County.
Beaver Springs, Bangor, Van Buren County.
Bromo-Hygeia Well, Coldwater, Branch County.
Charlevoix Mineral Spring, Charlevoix, Charlevoix County.
Cooper Farm Spring, Birmingham, Oakland County.
Crystal Springs, Grand Rapids, Kent County.
Eastman Springs, Benton Harbor, Berrien County.
Giant Mineral Spring, Springwells Township, Wayne County.
Lake Superior Mineral Spring, Marquette, Marquette County.
Moorman Spring, Ypsilanti, Washtenaw County.
Mount Clemens Crystal Springs, Mount Clemens, Macomb County.
Ogemaw Spring, Maltby, Ogemaw County.
Ponce de Leon Spring, Paris Township, Kent County
Sanitas Spring, Topinabee, Cheboygan County.
Sterling Spring, Crystal Falls, Iron County.
Victory Spring, Mount Clemens, Macomb County.
White Oak Spring, Battle Creek, Calhoun County.

MINNESOTA.

The marked decrease in 1913 in the sales of water from Minnesota springs is traceable to a decline in demand for spring water for table use in Minneapolis after the installation of a municipal filtration plant. The total sales were 4,802,053 gallons, valued at $183,759, as compared with 8,881,018 gallons, valued at $252,277, in 1912. This decrease is equivalent to 46 per cent in quantity and 27 per cent in value, the disproportion between these decreases being due to increase in the average price from 3 tc 4 cents a gallon.

The following table shows the record for the last five years:

Production and value of mineral waters in Minnesota, 1909–1913.

Year.	Commercial springs.	Quantity sold.	Value.	Average price per gallon.
		Gallons.		*Cents.*
1909	20	13,746,142	$614,291	5
1910	19	9,962,370	281,009	3
1911	17	8,703,319	270,039	3
1912	18	8,881,018	252,277	3
1913	16	4,802,053	183,759	4

No new springs were reported in 1912, and two springs formerly active were reported idle. With the exception of water valued at about $6,000 for medicinal use the water sold was for the table and no resorts or bathing establishments were maintained at the springs. More than 400,000 gallons of mineral water was reported as being used in the manufacture of soft drinks.

The 16 reporting springs are as follows:

Clear Spring, Excelsior, Hennepin County.
Deep Mineral Spring, Crookston, Polk County.
Donaldson Artesian Well, Minneapolis, Hennepin County.
Fifield Artesian Well, Winona, Winona County.
Glenwood-Inglewood Spring, Minneapolis, Hennepin County.
Highland Spring, St. Paul, Ramsey County.
Indian Medical Spring, Elk River, Sherburne County.
Mankato Mineral Springs, near Eagle Lake, Blue Earth County.
Owatonna Vichy Spring, Owatonna, Steele County.
Owens Spring, Glenwood, Pope County.
Pokegama Spring, near Detroit, Becker County.
Red Star Spring, Cold Spring, Stearns County.
Rock Spring, Shakopee, Scott County.
Silver Spring, Marshall, Lyon County.
Silver Spring, Ortonville, Bigstone County.
Swasteka Spring, Cold Spring, Stearns County.

MISSISSIPPI.

There was a marked decrease in the sales of mineral water in Mississippi during 1913 in spite of the inclusion of returns from five new springs. The reported production was 346,652 gallons, valued at $81,800, as compared with 639,905 gallons, valued at $126,241, in 1912. The average price per gallon increased, however, from 20 to 24 cents. These changes are equivalent to a decrease of 46 per cent in quantity and of 35 per cent in value. The output of one spring for which no report was made was estimated on the basis of the report for 1912, and three springs active in 1912 were reported idle or out of business in 1913. Seven resorts accommodating 1,650 guests and five mineral-water baths were operated.

The names of the 11 reporting springs are:

- Alkanasia Spring, Jackson, Hinds County.
- Allison's Wells, Way, Madison County.
- Browns Wells, near Hazlehurst, Copiah County.
- Butler Spring, near Oxford, Lafayette County.
- Castalian Spring, near Durant, Holmes County.
- Cooper's Well, Raymond, Hinds County.
- Madison Spring, Pocahontàs, Madison County.
- Red Springs, Stewart, Choctaw County.
- Robinson Springs, near Pocahontas, Madison County.
- Stafford Mineral Springs, Vosburg, Jasper County.
- Vosburg Lithia Spring, Vosburg, Jasper County.

MISSOURI.

According to statements received from spring owners in Missouri the output in 1913 was 697,467 gallons, valued at $84,316, or at an average price of 12 cents a gallon. The output in 1912 was 608,385 gallons, valued at $81,114, or at an average price of 13 cents a gallon. These figures indicate an increase of 15 per cent in quantity and of 4 per cent in value. The decided increase in quantity without corresponding increase in value is due chiefly to increase in sales of low-priced waters. About three-fourths of the total output is said to be used medicinally. Six new springs reported activity, and the total number of commercial springs was 34. Six resorts, exclusive of those at Excelsior Springs, and six mineral-water baths were operated during the year. In addition to the spring water reported sold, 91,000 gallons was used in the manufacture of soft drinks.

The following 34 springs made returns of sales:

- American Spring, St. Louis, St. Louis County.
- B. B. Springs, Bowling Green, Pike County.
- Belcher Artesian Well, St. Louis, St. Louis City.
- Blue Lick Springs, Blue Lick, Saline County.
- Bokert Springs, near De Soto, Jefferson County.
- Carrollton Spring, Carrollton, Carroll County.
- Chalybeate Springs, Paris Springs, Lawrence County.
- Chouteau Springs, near Boonville, Cooper County.
- Crystal Lithium Spring, Excelsior Springs, Clay County.
- Cusenbary Spring, Mount Washington, Jackson County.
- Excelsior Saline Spring, Excelsior Springs, Clay County.
- Grand River Mineral Spring, near Mercer, Mercer County.
- Haymaker Spring, Mercer County, near Lineville, Iowa.
- Jackson Lithia Spring, Mount Washington, Jackson County.
- Lithia No. 1 Spring, Excelsior Springs, Clay County.
- Livertone Spring, Pike County.
- Mee Soda Well, Excelsior Springs, Clay County.
- Musick Spring, Eldorado Springs, Clay County.
- Natrona Soda Spring, Excelsior Springs, Clay County.
- Old Orchard Spring, Old Orchard, St. Louis County.
- Peerless Spring, Excelsior Springs, Clay County.
- Regent, Siloam, Soterian, and Sulpho-Saline springs, Excelsior Springs, Clay County.
- Salax Spring, Excelsior Springs, Clay County.
- Salt Sulphur Well, Excelsior Springs, Clay County.
- Soda Saline spring, Excelsior Springs, Clay County.
- Sweet Springs, Sweet Springs, Saline County.
- Vaile Springs, Independence, Jackson County.
- White Springs, Independence, Jackson County.
- Windsor Spring, Windsor, Henry County.
- Wyaconda and La Grange springs, La Grange, Lewis County.

MONTANA.

Returns from Montana indicate an increase in the quantity of mineral water sold but a decrease in the value of the output. The total sales in 1913 were 180,200 gallons, valued at $3,246, or at an average price of 2 cents, whereas 160,150 gallons was sold in 1912 for $13,198, or at an average price of 8 cents. These figures represent an increase of 13 per cent in quantity sold, but a decrease of 75 per cent in value. The remarkable change in average price is, however, traceable to the omission of statistics for 1913 on one high-priced water, which is understood not to be sold now, and to the inclusion of statistics regarding another low-priced table water; consequently, the change in total value is robbed of much of its apparent significance. Bathing establishments are maintained at two of these springs and a small resort at one. Most of the water was sold for table use. No new spring was reported, but one hitherto idle had a large output.

The three springs reporting are as follows:

Lissner Mineral Spring, Helena, Lewis and Clark County.
Rock Creek Spring, Red Lodge, Carbon County.
White Sulphur Spring, White Sulphur Springs, Meagher County.

NEBRASKA.

The sales reported in Nebraska for 1913 were 105,985 gallons, valued at $10,599, or at an average price of 10 cents a gallon. About one-third of this was used medicinally and, in addition to the quantity just reported, about 120,000 gallons was used in the manufacture of soft drinks. Heretofore the details of production in Nebraska have been included in those of other States having less than three active springs. There was not a sudden increase in business in 1913, but reports were received from a spring concerning which data have hitherto been unavailable. At one of the springs a small resort and a bathing establishment are maintained.

The names of the three springs reporting are:

Brown Park Spring, South Omaha, Douglas County.
Curo Mineral Spring, South Omaha, Douglas County.
Shogo Lithia Spring, Milford, Seward County.

NEVADA.

One spring in Nevada idle in 1912, reported production in 1913, and one new spring also reported, making the number of active springs three. The total sales in 1913 amounted to 4,897 gallons of table water, valued at $1,584, or at an average price of 32 cents a gallon, in addition to which about 2,000 gallons of spring water was used in the manufacture of soft drinks. A resort for about 100 people and a bathing establishment are maintained at one of the springs.

Reports were received from the following three springs:

Diamond Spring, Reno, Washoe County.
Ruby Spring, Halleck, Elko County.
Shoshone Spring, Franktown, Washoe County.

NEW HAMPSHIRE.

There was a notable increase in the mineral-water business in New Hampshire during 1913, the sales reported being 402,355 gallons, practically all table water, valued at $12,707, as compared with 240,568 gallons, valued at $10,000, in 1912. These figures correspond to an increased production of 161,787 gallons, or 67 per cent, and an increased value of $2,707, or 27 per cent, in spite of a decrease of the average price from 4 to 3 cents. Laconia Spring reported for the first time, and the production for another spring from which statistics could not be obtained was estimated on the basis of the report for 1912, making in all nine active springs. No resorts or bathing establishments are maintained at any of the springs reporting, but about 85,000 gallons of spring water, in addition to that already noted, was used in the manufacture of soft drinks.

The eight springs reporting are:

Crystal Spring, East Concord, Merrimack County.
Granite State Springs, Plaistow, Rockingham County.
Laconia Spring, Weirs, Belknap County.
Lafayette Mineral Springs, Derry, Rockingham County.
Mount Madison Spring, Gorham, Coos County.
White Mountain Mineral Spring, Conway, Carroll County.
Willow Spring, South Nashua, Hillsboro County.
Wilton Spring, near Wilton, Hillsboro County.

NEW JERSEY.

According to the estimates from mineral-spring operators in New Jersey, the sales in 1913 decreased 13 per cent in quantity and 10 per cent in value. The total sales reported were 2,067,277 gallons, valued at $188,546. The corresponding figures for 1912 were 2,386,-217 gallons, valued at $209,726. The average price, 9 cents a gallon, remained the same.

The following table shows the output for the last five years:

Production and value of mineral waters in New Jersey, 1909–1913.

Year.	Commercial springs.	Quantity sold.	Value.	Average price per gallon.
		Gallons.		*Cents.*
1909	11	1,419,500	$127,025	9
1910	11	1,583,050	133,139	8
1911	12	2,233,627	210,123	10
1912	12	2,386,217	209,726	9
1913	14	2,067,277	188,546	9

Two new springs reported, the Great Notch and the Rock, and the output of one spring that failed to report was estimated on the production during 1912. Practically the entire output was sold for table use. No resorts or mineral-water baths were maintained at springs, but about 17,000 gallons of water was used in the manufacture of soft drinks.

The following 13 springs made returns of sales:

Alpha Mineral Spring, Springfield, Union County.
Culm Rock Spring, Pluckemin, Somerset County.
Great Notch Spring, Great Notch, Passaic County.
Grey Rock Spring, Trenton, Mercer County.
Indian Spring, near Rockaway, Morris County.
Indian Lady Hill Spring, Asbury Park, Monmouth County.
Kalium Spring, Collingswood, Camden County.
Kanouse-Oakland Spring, Oakland, Bergen County.
Pilgrim Spring, Ridgefield Park, Bergen County.
Rock Spring, West Orange, Essex County.
Trinity Springs, Ridgefield, Bergen County.
Washington Rock Spring, Plainfield, Union County.
Watchung Spring, North Plainfield, Somerset County

NEW MEXICO.

Four springs, or two more than in 1912, reported sales of mineral water during 1913, the total output being 154,800 gallons, valued at $16,730, or at an average price of 11 cents a gallon. Nearly all the water was sold for table use and no resorts or bathing establishments were reported.

The four reporting springs are:

Aztec Spring, Taylor Springs, Colfax County.
Coyote Springs, Albuquerque, Bernalillo County.
Macbeth Spring, near Las Vegas, San Miguel County.
Ojo Caliente Spring, Ojo Caliente, Taos County.

NEW YORK.

New York again led the States in total quantity of mineral water sold and nearly tied Wisconsin in value of the product. The total output during 1913 was 9,801,255 gallons, valued at $871,601, or at an average price of 9 cents a gallon. The sales for 1912 were 10,008,801 gallons, valued at $1,034,477, or at an average price of 10 cents a gallon. Comparison of these figures shows a decrease of 2 per cent in quantity and of 16 per cent in value.

The following record for the last five years indicates only a slight decline in production since 1911:

Production and value of mineral waters in New York, 1909–1913.

Year.	Commercial springs.	Quantity sold.	Value.	Average price per gallon.
		Gallons.		*Cents.*
1909	52	8,813,563	$948,325	11
1910	46	8,780,903	858,635	10
1911	51	10,245,261	939,003	9
1912	57	10,008,801	1,034,477	10
1913	64	9,801,255	871,601	9

Ten new springs were added to the list and three springs active in 1912 are understood to be idle, these changes increasing the number of commercial springs to 64. Less than one-tenth of the water was sold for medicinal use. It was reported that five resorts, exclusive of those at Saratoga Springs, accommodated 3,600 guests, and that four mineral-water baths were operated during 1913. In addition to this business nearly 170,000 gallons of mineral water was used in the manufacture of soft drinks. The list of 64 commercial springs in 1913 is as follows:

Arlington Spring, Arlington, Dutchess County.
Arondack Spring, Saratoga Springs, Saratoga County.
Arrowhead Spring, Weedsport, Cayuga County.
Artesian Lithia Spring, Ballston Spa, Saratoga County.
Baldwin Mineral Spring, Cayuga, Cayuga County.
Black Rock Spring, Rensselaer, Rensselaer County.
Breesport Spring, Breesport, Chemung County.
Briarcliff Spring, Briarcliff Manor, Westchester County.
Cascadian Spring, Nyack, Rockland County.
Chemung Spring, Chemung, Chemung County.
Clinton Spring, Franklin Springs, Oneida County.
Coesa Spring, Saratoga Springs, Saratoga County.
Cold Springs, Whitesboro, Oneida County.
Comstock Spring, Ballston Spa, Saratoga County.
Crystal Springs, near Oswego, Oswego County.
Deep Rock and Os-We-Go springs, Oswego, Oswego County.
Diamond Rock Spring, Lancaster, Erie County.
Eagle Spring, Edgewoode, Greene County.
Elixir Spring, Clintondale, Ulster County.
Elk Spring, Lancaster, Erie County.
Flint Spring, West Sand Lake, Rensselaer County.
Franklin Lithia Spring, Franklin Springs, Oneida County.
Garden City Spring, Garden City, Nassau County.
Garden White Sulphur Spring, Sharon Springs, Schoharie County.
Geneva and Red Cross Mineral springs, Geneva, Ontario County.
Glen Alex Spring, Washington Mills, Oneida County.
Gramatan Spring, Bronxville, Westchester County.
Granite Spring, Granite Springs, Westchester County.
Great Bear Spring, near Fulton, Oswego County.
Great White Sulphur Spring, Richfield Springs, Otsego County.
Greendale Crystal Spring, Hudson, Columbia County.
Hathorn No. 1 Spring, Saratoga Springs, Saratoga County.
Hathorn No. 2 Spring, Saratoga Springs, Saratoga County.
Keeseville Spring, Keeseville, Essex County.
Lithaca Spring, Ithaca, Tompkins County.
Lithia Polaris Spring, near Boonville, Oneida County.
Madrid Indian Mineral Spring, Madrid Springs, St. Lawrence County.
Mammoth and Ideal springs, North Greenbush, Rensselaer County.
Mohawk Springs, Amsterdam, Montgomery County.
Mohican Spring, Ballston Spa, Saratoga County.
Monarch Spring, Matteawan, Dutchess County.
Mount Beacon Spring, Beacon, Dutchess County.
Mount View Spring, Poughkeepsie, Dutchess County.
Oasis Cold Spring, Bergen, Genesee County.
Paris Spring, Sauquoit, Oneida County.
Real Rock Spring, Breesport, Chemung County.
Red Jacket Spring, Seneca Falls, Seneca County.
Red Rock Spring, Fine View, Jefferson County.
Richland Spring, Richland, Oswego County.
Sagamore Spring, Oyster Bay, Nassau County.
Saratoga Gurn Spring, Saratoga Springs, Saratoga County.
Saratoga Vichy and Victoria No. 2 springs, Saratoga Springs, Saratoga County.
Setauket Spring, Setauket, Suffolk County.
Shell Rock Spring, near Rensselaer, Rensselaer County.
Sparkling Spring, Buffalo, Erie County.
Split Rock Spring, Franklin Springs, Oneida County.
Standard Spring, Troy, Rensselaer County.
Sun-Ray Spring, Ellenville, Ulster County.
Trèspur Spring, McGraw, Cortland County.
Valley Spring, Omar, Jefferson County.
Vita Spring, Fort Edward, Washington County.

NORTH CAROLINA.

The returns from North Carolina show marked increase in the mineral-water business during 1913. The sales amounted to 176,068 gallons, valued at $23,877, as compared with 144,708 gallons, valued at $22,385, in 1912, an increase of 22 per cent in quantity and of 7 per cent in value. The average price per gallon decreased from 16 to 14 cents. Parks Spring reported production for the first time. One spring active in 1912 was idle during 1913, and the output from one spring from which no report was received was estimated on the basis of the production for 1912, these changes increasing the number of commercial springs to 17. Eleven resorts accommodating 1,600 guests were maintained at springs, together with five establishments for bathing in mineral water. A small quantity of water also was used in the manufacture of soft drinks.

The 16 springs reporting are:

All Healing Spring, Taylorsville, Alexander County.
Barium Rock Spring, Barium Springs, Iredell County.
Buckhorn Lithia Spring, Bullock, Granville County.
Connelly Springs, Connelly Springs, Burke County.
Derita Mineral Spring, Derita, Mecklenburg County.
Haywood White Sulphur Spring, Waynesville, Haywood County.
Huckleberry Spring, Durham, Durham County.
Jackson Springs, Jackson Springs, Moore County.
Midas Spring, near Huntersville, Mecklenburg County.
Moores Springs, Moores Springs, Stokes County.
Mount Vernon Springs, Mount Vernon Springs, Chatham County.
Panacea Spring, Warren County, near Littleton.
Parks Springs, Caswell County, near Danville, Va.
Seven Springs, Seven Springs, Wayne County.
Shelby Lithia Spring, Shelby, Cleveland County.
Smith Lithia Spring, Oxford, Granville County.

NORTH DAKOTA.

Five new springs in North Dakota reported total sales of mineral water during 1913 amounting to 582,356 gallons, valued at $14,403, in addition to which 42,000 gallons was used in the manufacture of soft drinks.

The names and locations of these five springs are as follows:

Granite Spring, Minot, Ward County.
Kenmare Spring, Kenmare, Ward County.
Saskawea Mineral Spring, Northwood, Grand Forks County.
Stony Creek Spring, Bowbells, Burke County.
Williston Spring, Williston, Williams County.

OHIO.

The mineral-water trade of Ohio again made a decided gain during 1913, the sales rising from 2,709,745 gallons in 1912 to 3,317,639 gallons in 1913, and the total value increasing from $117,287 in 1912 to $125,084 in 1913. The increase in quantity was 22 per cent and in value 7 per cent. There was a slight decrease in the sales of medicinal water, but a notable increase in the sales of table water.

The following table of sales during the last five years shows, contrary to conditions in most other States, a general increase in the mineral-water business since 1911:

Production and value of mineral waters in Ohio, 1909–1913.

Year.	Commercial springs.	Quantity sold.	Value.	Average price per gallon.
		Gallons.		*Cents.*
1909	31	2,709,060	$112,775	4
1910	30	2,226,188	95,989	4
1911	28	1,958,547	86,478	4
1912	30	2,709,745	117,287	4
1913	33	3,317,639	125,084	

Two new springs reported in 1913 for the first time, Puritas Spring and the Purity Spring. Nearly nine-tenths of the water was sold for table use. Five resorts accommodating 500 guests and three bathing establishments were operated during the year and in addition to the water reported as sold, 195,000 gallons was used in the manufacture of soft drinks.

The 33 springs reporting sales are as follows:

Alba Spring, Rockport, Cuyahoga County.
Beech Rock Spring, near Zanesville, Muskingum County.
Bellmore Springs, near Signal, Columbiana County.
Belmont Spring, Bridgeport, Belmont County.
Chalybeate Spring, Newark, Licking County.
Collingwood Springs, Toledo, Lucas County.
Crum Mineral Spring, Austintown, Mahoning County.
Crystal Fountain Springs, Plainville, Hamilton County.
Crystal Spring, Newark, Licking County.
Deerfield Spring, Deerfield, Portage County.
Fargo Mineral Springs, Ashtabula, Ashtabula County.
Fisher's Magnesia Spring, Clintonville, Franklin County.
Glenwood Spring, near Chillicothe, Ross County.
Highland Springs, Akron, Summit County.
Maple Grove Mineral Spring, near Chillicothe, Ross County.
Minnehaha Spring, Rockport, Cuyahoga County.
Norwalk Sulphur Spring, Norwalk, Huron County.
Oak Place Spring, Akron, Summit County.
Oak Ridge Springs, Greenspring, Sandusky County.
Painesville Mineral Spring, Painesville, Lake County.
Peerless and Puritas springs, West Park, Cuyahoga County.
Puritas Spring, West Park, Cuyahoga County.
Purity Spring, South Euclid, Cuyahoga County.
Quakerdale Spring, Colerain, Belmont County.
Reynold's Artesian Well, Greenspring, Sandusky County.
Ripley Bromo Lithia Spring, Ripley, Brown County.
Sandrock Spring, Canton, Stark County.
Spring Grove Lithia Spring, Springfield, Clark County.
Sulphur Lick Spring, Chillicothe, Ross County.
Tallewanda Spring, College Corner, Preble County.
Wheeler Mineral Spring, Youngstown, Mahoning County.
Woods Lithia Spring, Bridgeport, Belmont County.

OKLAHOMA.

According to returns from Oklahoma the output of mineral water during 1913 was 502,439 gallons, valued at $26,231, as compared with 1,015,512 gallons, valued at $32,971, in 1912. This apparent decrease of 51 per cent in quantity and of 20 per cent in value is accounted for chiefly by the omission for 1913 of reports from certain producers hitherto included. The trade in mineral waters therefore really suffered only a slight decline. Mineral-water baths were operated at four springs and considerable water was used in the manufacture of soft drinks.

The record for the last five years is as follows:

Production and value of mineral waters in Oklahoma, 1909–1913.

Year.	Commercial springs.	Quantity sold.	Value.	Average price per gallon.
		Gallons.		*Cents.*
1909	12	563,475	$35,194	6
1910	4	115,000	4,950	4
1911	10	497,074	14,290	3
1912	10	1,015,512	32,971	3
1913	12	502,439	26,231	5

Three new springs reported production for the first time, Excelsior Well, Living Spring, and Snow Mineral Well, all in or near Oklahoma City; the output of one spring for which no report was received was estimated on the basis of figures for 1912.

The 11 springs reporting sales are as follows:

Bromide Spring, Sulphur, Murray County.
Excelsior Well, Oklahoma City, Oklahoma County.
Guthriewell, Guthrie, Logan County.
Hercules Spring, Guthrie, Logan County.
Kalium Spring, Faxon, Comanche County.
Lewis Lithia Wells, Oklahoma City, Oklahoma County.
Living Spring, Oklahoma City, Oklahoma County.
Shanoan Spring, Chickasha, Grady County.
Snow Mineral Well, Oklahoma City, Oklahoma County.
Standard Well, Tulsa, Tulsa County.
Works Excelsior Spring, Comanche, Stephens County.

OREGON.

Sales of mineral water in Oregon amounted in 1913 to 68,413 gallons, valued at $19,409, as compared with 48,351 gallons, valued at $17,503, in 1912, an increase of 42 per cent in quantity and of 11 per cent in value. The average price decreased from 36 to 28 cents a gallon. The output of one spring that failed to report was estimated from the returns of 1912. Five resorts accommodating about 300 guests and five bathing establishments were operated. In addition to the business above reported, about 11,000 gallons was used in the manufacture of soft drinks.

The names of the seven reporting springs are:

Calapooya Spring, London, Lane County.
Cascade Mineral Spring, Cascadia, Linn County.
Colestin Spring, Colestin, Jackson County.
Klamath Spring, Klamath Falls, Klamath County.
Sam-O Spring, Baker City, Baker County.
Selah Spring, Silverton, Marion County.
Wilhoit Spring, Wilhoit, Clackamas County.

PENNSYLVANIA.

The record of the mineral-water trade of Pennsylvania during 1913 indicates practically the same condition as obtained during 1912. The total output amounted to 2,163,931 gallons, valued at

$190,459, as compared with 2,192,106 gallons, valued at $204,906, in 1912. The average price decreased one-half cent and this was accompanied by a decrease of 7 per cent in total value of the output.

The following record of sales during the last five years shows a gradual decline in production since 1910.

Production and value of mineral waters in Pennsylvania, 1909–1913.

Year.	Commercial springs.	Quantity sold.	Value.	Average price per gallon.
		Gallons.		*Cents.*
1909	42	2,177,967	$240,856	11
1910	44	2,536,337	221,685	9
1911	41	2,327,732	216,819	9
1912	41	2,192,106	204,906	9
1913	43	2,163,931	190,459	9

Five new springs were added to the list as follows: Duquesne Vichy, Minnequa, Plymouth Crystal, Quaill Farm, and Summer Hill. The output of two springs that failed to report production was estimated from previous reports and three springs hitherto active were temporarily idle, so that 43 represents the number of commercial springs during 1913. Eleven resorts accommodating 1,650 guests were operated and seven establishments for giving mineral water baths also were maintained. In addition to the water sold 340,000 gallons was used in the manufacture of soft drinks.

The following 41 springs reported sales in 1913:

Bartlett Spring, Cambridge Springs, Crawford County.
Bedford Mineral Springs, near Bedford, Bedford County.
Carnegie Alkaline and Lithia Mineral Spring, Carnegie, Allegheny County.
Chadwick Spring, Cambridge Springs, Crawford County.
Cloverdale Lithia Spring, near Newville, Cumberland County.
Cold Spring, Lotell, Lebanon County.
Colonial Spring, Montgomery County, near Valley Forge.
Colvin White Sulphur Spring, Sulphur Springs, Bedford County.
Crystal-Cray Spring, Warren, Warren County.
De Profundus Spring, Saegertown, Crawford County.
Duquesne Vichy Spring, Swissvale, Allegheny County.
East Mountain Lithia Spring, near Factoryville, Wyoming County.
Franklin Lithia Spring, Cambridge Springs, Crawford County.
Glen Crystal Spring, Harbour Creek, Erie County.
Glen Summit Spring, Glen Summit Springs, Luzerne County.
Gray Mineral Spring, Cambridge Springs, Crawford County.
Harrison Valley Mineral Spring, Harrison Valley, Potter County.
Hutchinson's Spring, East Brook, Lawrence County.
Kecksburg Artesian Mineral Spring, Kecksburg, Westmoreland County.
Keystone Spring, near Taylorsville, Bucks County.
Massassauga Mineral Spring, Erie, Erie County.
Minnequa Spring, Canton, Bradford County.
Mount Laurel Spring, Temple, Berks County.
Original Magnesia Springs, Cambridge Springs, Crawford County.
Pavilion Spring, Wernersville, Berks County.
Petticord Spring, Cambridge Springs, Crawford County.
Plymouth Crystal Spring, Plymouth, Luzerne County.
Pocono Mineral Spring, near Wilkes-Barre, Luzerne County.
Polar Springs, Morrisville, Bucks County.
Prospect Rock Spring, Laurel, Luzerne County.
Pulaski Natural Mineral Spring, Pulaski, Lawrence County.
Puritas Spring, near Erie, Erie County.
Quaill Farm Spring, Bellevue, Allegheny County.
Ross Common Spring, Ross Common, Monroe County.

Sizerville Spring, Sizerville, Cameron County.
Springfield Spring, Springfield Township, Delaware County.
Summer Hill Spring, Pittsburgh, Allegheny County.
Thurston's Carbonate Spring, Meadville, Crawford County.
Tuckahoe Mineral Spring, near Northumberland, Northumberland County.
Unamis Mineral Spring, Unamis, Somerset County.
Whann Lithia Spring, Franklin, Venango County.

RHODE ISLAND.

The mineral-water trade in Rhode Island during 1913 was nearly the same as in 1912. The same springs reported a production of 444,036 gallons, valued at $28,535, as compared with 466,893 gallons, valued at $29,126, in 1912. This water was sold exclusively for table use, and no resorts or bathing establishments were maintained.

The names of the seven springs reporting are as follows:

Berry Spring, Pawtucket, Providence County.
Girard Spring, North Providence, Providence County.
Gladstone Spring, Narragansett Pier, Washington County.
Hermit Spring, East Providence, Providence County.
Holley Mineral Spring, East Woonsocket, Providence County.
Ochee Spring, Johnston, Providence County.
Prophet Spring, Johnston, Providence County.

SOUTH CAROLINA.

The returns for South Carolina indicate a marked decrease in the mineral-water business during 1913. The total sales in 1913 were 261,412 gallons, valued at $49,199; the total sales in 1912 were 360,404 gallons, valued at $70,348; these figures show a decrease of 28 per cent in quantity and of 30 per cent in value. The average price a gallon decreased from 20 to 19 cents. Practically three-fourths of the water is said to be sold for medicinal use. Three new springs were added to the list—Big, Mosely, and Shelton—but three springs active in 1912 were idle in 1913, so that the number of commercial springs remains unchanged. Six resorts, accommodating about 800 guests, and two bathing establishments were maintained. About 130,000 gallons of mineral water also was used in the manufacture of soft drinks.

The following 15 springs reported sales:

Big Springs, Bethune, Kershaw County.
Buffalo Lick Springs, Carlisle, Union County.
Cherokee Springs, Cherokee, Spartanburg County.
Chick Springs, Chick Springs, Greenville County.
Clementia Spring, Clementia Springs, Colleton County.
Crystal Carbon Spring, Spartanburg, Spartanburg County.
Glenn Spring, Glenn Spring, Spartanburg County.
Harris Spring, Harris Springs, Laurens County.
Mosely Spring, Loris, Horry County.
Piedmont Spring, Kings Creek, York County.
Shelton Spring, near Shelton, Fairfield County.
Shivar Spring, Shelton, Fairfield County.
Steele Mineral Spring, Rock Hill, York County.
Turner Magnalithia Spring, Mayo, Spartanburg County.
Verner Spring, Greenville, Greenville County.

SOUTH DAKOTA.

South Dakota reported production from two springs in 1913. The water was sold principally for table use, and a large additional quantity was consumed in the manufacture of soft drinks. The details of production are included with those of other States having less than three active springs. The names of the two springs are:

Culbert Spring, Aberdeen, Brown County.
Minnehaha Springs, Sioux Falls, Minnehaha County.

TENNESSEE.

Returns from Tennessee show a decided gain in the mineral-water trade in 1913 as compared with 1912. The sales amounted to 1,088,034 gallons, valued at $64,905, as compared with 796,568 gallons, valued at $53,560, in 1912. These figures correspond to an increase of 37 per cent in quantity and of 21 per cent in value, the price having decreased from 7 to 6 cents a gallon.

The following table is the record of sales during the last five years:

Production and value of mineral waters in Tennessee, 1909–1913.

Year.	Commercial springs.	Quantity sold.	Value.	Average price per gallon.
		Gallons.		*Cents.*
1909	18	934,912	$76,185	8
1910	18	950,511	71,129	8
1911	19	1,073,115	72,475	7
1912	21	796,568	53,560	7
1913	23	1,088,034	64,905	6

Four new springs are included in the list—Bright Sunrise, Bush Epsom Lithia, Eagle Bluff, and Faulkner—but two springs hitherto active are understood to have been idle in 1913, so that the total number of commercial springs is 23. Fourteen resorts, accommodating 2,300 guests, were operated and the water at four springs is reported to have been used for bathing. A small quantity of water also was used in the manufacture of soft drinks.

The following 23 springs reported sales:

Bright Sunrise Spring, near Ashland City, Cheatham County.
Bush Epsom Lithia Spring, near Nolensville, Williamson County.
Eagle Bluff Springs, near Jacksboro, Campbell County.
Eastbrook Spring, Eastbrook, Franklin County.
Epperson Spring, Macon County, near Westmoreland.
Faulkner Springs, near McMinnville, Warren County.
Galbraith Epsom Lithia Springs, Mooresburg, Hawkins County.
Gammons Spring, near Tate Spring, Grainger County.
Hamilton Spring, near Lebanon, Wilson County.
Horn Springs, Horn Springs, Wilson County.
Idaho Springs, near Clarksville, Montgomery County.
Larkin Spring, Madison, Davidson County.
Neubert Spring, Neubert, Knox County.
Paris Wells, near Paris, Henry County.
Pioneer Lithia Spring, near Nashville, Davidson County.
Red Boiling Springs, Red Boiling Springs, Macon County.
Rhea Springs, Rhea Springs, Rhea County.
Richardsons Lockeland Spring, near Nashville, Davidson County.
Tate Spring, Tate Springs, Grainger County.
Thompson Spring, near Nashville, Davidson County.
Whittle Spring, Whittle Springs, Knox County.
Willow Brook Spring, Craggie Hope, Cheatham County.
Wright's Epsom-Lithia Spring, Mooresburg, Hawkins County.

TEXAS.

Returns from Texas during 1913 indicate a slight decline in the mineral-water trade. The output reported was 1,187,612 gallons, valued at $132,488, as compared with 1,292,992 gallons, valued at $151,395, in 1912. There was thus a decrease of 8 per cent in quantity and of 13 per cent in value of water sold. The average price per gallon dropped one-half cent.

The following table of production during the last five years shows in common with several other States a decline in trade since 1911:

Production and value of mineral waters in Texas, 1909–1913.

Year.	Commercial springs.	Quantity sold.	Value.	Average price per gallon.
		Gallons.		*Cents.*
1909	34	1,033,476	$98,499	10
1910	31	1,241,248	128,549	10
1911	40	1,637,932	158,367	10
1912	34	1,292,992	151,395	12
1913	38	1,187,612	132,488	11

Beauchamp's Well, Hefner Spring, Hanna Springs, Southland Spring, and Wootan Wells reported production for the first time, and the output of one producer who did not report was estimated, so that statistics are included for 38 commercial springs. Practically the entire output is said to be used medicinally. Six resorts, accommodating 600 guests, were operated, exclusive of those at Mineral Wells, and the water of eight springs was used for bathing. Besides this consumption, more than 100,000 gallons of mineral water was used in the manufacture of soft drinks.

The following is the list of the 37 springs reporting sales in 1913:

Aqua Vitae Wells, Nacogdoches, Nacogdoches County.
Austin Well, Mineral Wells, Palo Pinto County.
Beauchamp's Well, Blossom, Lamar County.
Brock Mineral Well, near Denton, Denton County.
Capp's Wells, Longview, Gregg County.
Carlsbad Well, Blossom, Lamar County.
Crazy Well, Mineral Wells, Palo Pinto County.
Crystal Spring, Terrell, Kaufman County.
Dalby Spring, Dalby Springs, Bowie County.
Georgetown Mineral Wells, Georgetown, Williamson County.
Gibson Well, Mineral Wells, Palo Pinto County.
Hanna Springs, Lampasas, Lampasas County.
Hefner Spring, Blossom, Lamar County.
High Island Mineral Well, High Island, Galveston County.
Hubbard Hot Well, Hubbard City, Hill County.
Hume Sour Water Well, Sutherland Springs, Wilson County.
Indian Spring, Mineral Wells, Palo Pinto County.
Lamar Spring, Mineral Wells, Palo Pinto County.
Lonestar Mineral Well, Texarkana, Bowie County.
Mangum Wells, Mangum, Eastland County.
Marlin Hot Wells, Marlin, Falls County.
Maurice Wells, Mangum, Eastland County.
Olympia Well, Mineral Wells, Palo Pinto County.
Orono Spring, Oran, Palo Pinto County.
Overall Mineral Well, Franklin, Robertson County.
Putnam Mineral Well, Putnam, Callahan County.
Riviere Wells, Tyler, Smith County.
Roach Well, near Mount Pleasant, Titus County.

Rosborough Spring, Marshall, Harrison County.
St. Mary's Mineral Well, near Hallettsville, Lavaca County.
Sour Wells, Sulphur Springs, Hopkins County.
Southland Spring, Duffan, Erath County.
Star Well, Mineral Wells, Palo Pinto County.
Texas Carlsbad Spring, Mineral Wells, Palo Pinto County.
Tioga Mineral Wells, Tioga, Grayson County.
Weatherby Spring, Garrison, Nacogdoches County.
Wootan Wells, Wootan Wells, Robertson County.

UTAH.

Only one mineral spring in Utah reported production during 1913 and the production of another was estimated, as no report could be obtained. Statistics regarding them are included with those of other States having less than three operating springs.

The name and location of the spring reporting is:

Deseret Lithia Spring, Deseret, Millard County.

VERMONT.

Returns from Vermont indicate a decline in the mineral-water trade during 1913 of 16 per cent in quantity and of 15 per cent in value. The output was 17,725 gallons, valued at $7,068, as compared with 21,000 gallons, valued at $8,280, in 1912, the average price having increased from 39 to 40 cents a gallon. Practically all the water is sold for table use, and in addition to the reported sales, 31,000 gallons was used in the manufacture of soft drinks. Resorts for nearly 500 guests were operated at three springs and the water of two springs was used for bathing. One new spring, Alburg, was added to the list of active producers, which is as follows:

Alburg Spring, Alburg Springs, Grand Isle County.
Brunswick Mineral Spring, North Stratford, Essex County.
Clarendon Spring, Clarendon Springs, Rutland County.
Equinox Spring, Manchester, Bennington County.

VIRGINIA.

Virginia's output of mineral water during 1913 was slightly greater than that of 1912, but its value was considerably less, chiefly because of decline in the sales of certain high-priced medicinal waters and of increase in the sales of low-priced table waters. Reports from operators in 1913 showed a total output of 2,873,288 gallons, valued at $298,473, as compared with an output of 2,762,319 gallons, valued at $349,255, in 1912. In other words, there was an increase of 4 per cent in quantity but a decrease of 17 per cent in value, and the average price dropped from 13 to 10 cents a gallon.

The following record of the trade during the last five years shows a steady increase in production but notable fluctations in value:

Production and value of mineral waters in Virginia, 1909–1913.

Year.	Commercial springs.	Quantity sold.	Value.	Average price per gallon.
		Gallons.		*Cents.*
1909	49	1,504,530	$203,455	14
1910	40	2,441,923	301,523	12
1911	43	2,474,918	298,701	12
1912	45	2,762,319	349,255	13
1913	49	2,873,288	298,473	10

Five new springs were added to the list of those reporting, as follows: Abbevanna Ponce de Leon, Carter, Coyner's, Eaglewood, and Granite; and the number of springs reporting production has thus been increased to 49, the figure attained in 1909. Resorts accommodating a total of 1,800 guests were reported at 13 springs and the water at 6 springs was used for bathing. In addition to the quantity reported sold, 25,000 gallons was used in the manufacture of soft drinks.

The 49 springs reporting sales are as follows:

Abbevanna Ponce de Leon Spring, Scottsville, Fluvanna County.
Alleghany Spring, Alleghany Spring, Montgomery County.
Bear Lithia Spring, near Elkton, Rockingham County.
Beaufont Spring, near Manchester, Chesterfield County.
Berry Hill Mineral Spring, Elkwood, Culpeper County.
Blue Ridge Springs, near Blue Ridge Springs, Botetourt County.
Alkaline Lithia Spring, near Staunton, Augusta County.
Broad Rock Mineral Spring, near Richmond, Chesterfield County.
Brugh Spring, Nace, Botetourt County.
Buckhead Spring, Buckhead Springs, Chesterfield County.
Buffalo Lithia Spring, Buffalo Lithia Springs, Mecklenburg County.
Burnett Spring, Culpeper, Culpeper County.
Campfield Lithia Well, near Richmond, Chesterfield County.
Carper Lithia Springs, Radford, Montgomery County.
Carter Springs, Danville, Pittsylvania County.
Como Lithia Spring, East Richmond, Henrico County.
Coppahaunk Mineral Springs, Waverly, Sussex County.
Coyner's Spring, near Roanoke, Botetourt County.
Crockett Arsenic Lithia Spring, Crockett Springs, Montgomery County.
Eaglewood Spring, near Danville, Pittsylvania County.
Farmville Lithia Springs, Farmville, Cumberland County.
Fonticello Mineral Spring, near Manchester, Chesterfield County.
Granite Spring, Chesterfield County.
Harris Anti-Dyspeptic Spring, Burkeville, Nottoway County.
Healing Springs, Healing Springs, Bath County.
Jeffress Spring, Jeffress, Mecklenburg County.
Jordan White Sulphur Spring, Stephensons, Frederick County.
Kayser Lithia Springs, Staunton, Augusta County.
Landale Spring, Norfolk, Norfolk County.
Lithia Magnesia Spring, Rocky Mount, Franklin County.
Magee Chlorinated Lithia Spring, Clarksville, Mecklenburg County.
Massanetta Spring, near Harrisonburg, Rockingham County.
Mecklenburg Spring, Chase City, Mecklenburg County.
Mico Well, Alexandria, Alexandria County.
Mulberry Island Artesian Well, Mulberry Island, Warwick County.
Nye Lithia Springs, Wytheville, Wythe County.
Otterburn Lithia Spring, near Amelia, Amelia County.
Paeonian Spring, Paeonian Springs, Loudoun County.
Pickett Spring, Worsham, Prince Edward County.
Rockbridge Alum Springs, Rockbridge Alum Springs, Rockbridge County.
Rubino Healing Springs, Healing Springs, Bath County.
Seawright Spring, near Staunton, Augusta County.
Shoal Bay Iodine Vichy Spring, Smithfield, Isle of Wight County.
Stribling Springs, Stribling Springs, Augusta County.
Trepho Mineral Spring, Claremont, Surry County.
Virginia Etna Springs, Vinton, Roanoke County.
Virginia Magnesian Alkaline Spring, near Staunton, Augusta County.
Wallawhatoola Springs, Millboro, Bath County.
Wyrick Mineral Spring, Crockett, Wythe County.

WASHINGTON.

Washington returns show a slight decrease in the quantity but an increase in value of mineral water sold during 1913. The sales amounted to 150,498 gallons, valued at $18,834, whereas the sales in

1912 amounted to 156,171 gallons, valued at $17,542, these figures representing a decrease of 4 per cent in quantity and an increase of 7 per cent in value. The average price increased from 11 to 13 cents a gallon. Slightly more water was sold for table than for medicinal use.

Solduc Hot Springs reported production for the first time. Private hotels and bathing establishments were maintained at two springs and nearly 25,000 gallons of water was used in the manufacture of soft drinks.

The names of the six reporting springs are:

Diamond Mineral Spring, Auburn, King County.
Klickitat Spring, Klickitat, Klickitat County.
Olympia Hygeian Spring, Tumwater, Thurston County.
Solduc Hot Springs, Soleduck, Clallam County.
Yakima Artesian Mineral Spring, North Yakima, Yakima County.
Yakima Soda Spring, near North Yakima, Yakima County.

WEST VIRGINIA.

Returns from West Virginia for 1913 show a slight increase in the quantity of mineral water sold, but a notable decrease in its value. The total sales were 316,749 gallons, as compared with 309,245 gallons in 1912, an increase of 2 per cent; the value of the production in 1913 was $52,259, as compared with $60,455 in 1912, a decrease of 14 per cent. The average price decreased from 20 to 17 cents a gallon. The decrease occurred especially in the production and value of medicinal waters. Sales were reported for the first time from Madeira Spring, and the output of one spring from which no report could be obtained was estimated on the basis of the figures for 1912. Resorts that accommodated 3,000 guests were maintained at four springs, and the water of two springs was used for bathing, in addition to which a small quantity was used in the manufacture of soft drinks.

The following are the names of the nine commercial springs reporting in 1913:

Borland Springs, Borland, Wood County.
Madeira Spring, Morgantown, Monongalia County.
Man-A-Cea Irondale Spring, Independence, Preston County.
Pence Spring, Pence Springs, Summers County.
Saline-Chalybeate and Vigoro springs, Woodsdale, Ohio County.
Walnut Hill Spring, near Charleston, Kanawha County.
Webster Springs, Webster Springs, Webster County.
White Sulphur Springs, White Sulphur Springs, Greenbrier County.

WISCONSIN.

Wisconsin led the States in value of mineral water sold in 1913 and was second only to New York in quantity of output. The total sales were 6,326,533 gallons, valued at $872,518, and nine-tenths of the output was sold for table use. The sales in 1912 amounted to 6,045,719 gallons, valued at $869,495; thus there was in 1913 an increase of 5 per cent in quantity and of less than 1 per cent in value. The average price decreased about one-half cent a gallon.

The following record of the sales for the last five years indicates a notable annual increase in quantity since 1911:

Production and value of mineral waters in Wisconsin, 1909–1913.

Year.	Commercial springs.	Quantity sold.	Value.	Average price per gallon.
		Gallons.		*Cents.*
1909	34	6,101,882	$1,132,239	19
1910	36	6,400,812	974,366	15
1911	31	5,716,162	955,988	17
1912	31	6,045,719	869,495	14
1913	34	6,326,533	872,518	14

Resorts accommodating 1,600 guests were operated at two springs, but none of the waters was used for bathing. In addition to the quantity reported as sold, 750,000 gallons was used in the manufacture of soft drinks.

Three new springs were added to the list during 1913; Crystal, Deep Rock, and Famous, so that the total number of active springs was increased to 34, as follows:

Allouez Spring, Green Bay, Brown County.
Anderson Spring, Waukesha, Waukesha County.
Arbutus Mineral Spring, Oconto, Oconto County.
Arcadian Spring, Waukesha, Waukesha County.
Bay City Spring, Ashland, Ashland County.
Bethania Spring, Osceola, Polk County.
Bethesda Spring, Waukesha, Waukesha County.
Castalia Spring, Wauwatosa, Milwaukee County.
Chippewa Spring, Chippewa Falls, Chippewa County.
Clysmic Spring, Waukesha, Waukesha County.
Crystal Spring, Sheboygan, Sheboygan County.
Crystal Springs, Waupaca, Waupaca County.
Crystal Rock Springs, Waukesha, Waukesha County.
Darlington Mineral Springs, Darlington, Lafayette County.
Deep Rock Spring, Palmyra, Jefferson County.
Elysian Spring, Prairie du Chien, Crawford County.
Famous Springs, Menominee Falls, Waukesha County.
Fontana Lithia Spring, Fontana, Walworth County.
Glenn Rock Spring, Waukesha, Waukesha County.
Hiawatha Springs, Janesville, Rock County.
Horeb Spring, Waukesha, Waukesha County.
Kusche Spring, Oshkosh, Winnebago County.
Lebenswasser Spring, Green Bay, Brown County.
Maribel Mineral Spring, Maribel, Manitowoc County.
Nee-Ska-Ra Spring, Wauwatosa, Milwaukee County.
Sheboygan Mineral Spring, Sheboygan, Sheboygan County.
Sheridan Mineral Springs, near Lake Geneva, Walworth County.
Silurian Spring, Waukesha, Waukesha County.
Silver Spring, Madison, Dane County.
Solon Springs, Solon Springs, Douglas County.
Waukesha Fox Head Spring, Waukesha, Waukesha County.
Waukesha Roxo Spring, Waukesha, Waukesha County.
White Rock Spring, Waukesha, Waukesha County.
Willnette Spring, Cooper Station, Racine County.

WYOMING.

Four mineral springs in Wyoming reported sales during 1913 amounting to 16,200 gallons, valued at $3,610. More than half this water is said to be used medicinally. The average price per gallon was 22 cents. The water of three springs was used for bathing, and resorts for guests were operated at two springs. In addition to the two springs that reported in 1912, two new ones have been added to the list, the names of the four active springs being as follows:

Big Horn Hot Springs, Thermopolis, Hot Springs County.
De Maris Spring, Cody, Park County.
Paulson Well, Saratoga, Carbon County.
Saratoga Hot Springs, Saratoga, Carbon County.

PUBLISHED ANALYSES OF AMERICAN MINERAL WATERS.

So many requests for information regarding the chemical composition of waters of American springs are received by the United States Geological Survey that the following list of publications has been prepared to meet this demand. The list is not by any means exhaustive, hundreds of analyses of mineral waters having been published elsewhere; it mentions only reports that are notable for the number of analyses of mineral waters in them and reports on especially well-known springs. Those seeking analyses of water that are not mentioned in the following publications are advised to consult published reports of the United States Geological Survey, of State geological surveys, of State boards of health, and of agricultural experiment stations.

Haywood, J. K., Mineral waters of the United States: U. S. Dept. Agr. Bur. Chem. Bull. 91, 1905. Analyses are given of 55 American spring waters, including 13 Saratoga waters.

Skinner, W. W., American mineral waters; The New England States: U. S. Dept. Agr. Bur. Chem. Bull. 139, 1909. This pamphlet contains analyses of New England spring waters and the results of bacteriological examinations of them.

Cohen, S. S. [editor], System of physiologic therapeutics, vol. 9, P. Blakiston's Sons & Co., Philadelphia, 1902. This volume contains a chapter by Dr. A. C. Peale on the classification of mineral waters with special reference to those of the United States, and the composition of many waters is discussed.

Peale, A. C., Geographical distribution of the mineral springs of the United States: Internat. Med. Mag., Nov., 1895.

——— Natural mineral waters of the United States: U. S. Geol. Survey Fourteenth Ann. Rept., pt. 2, pp. 49–88, 1894. This report contains a general discussion of the origin, flow, geologic relations, and utilization of mineral waters, and a list of several hundred American mineral spring resorts. (Out of stock for free distribution; Part II, which includes several other papers, can be purchased from the Superintendent of Documents, Washington, D. C., for $2.10, payable in advance.)

——— Lists and analyses of the mineral springs of the United States: U. S. Geol. Survey Bull. 32, 1886. About 2,800 mineral springs are listed and about 800 analyses are quoted. (Out of print; available for consultation in certain libraries.)

Mineral waters, foreign and domestic, with analyses, use, and source, P. Scherer & Co., New York. Analyses of many foreign and domestic mineral waters are quoted.

Haywood, J. K., Analyses of the waters of the Hot Springs of Arkansas: U. S. Dept. Interior, 1912. (Purchasable from the Superintendent of Documents, Washington, D. C., for 10 cents payable in advance.) Analyses of 46 waters are given. The same report contains a geologic sketch of Hot Springs, Ark., by W. H. Weed.

Gooch, F. A., and Whitfield, J. E., Analyses of waters of the Yellowstone National Park: U. S. Geol. Survey Bull. 47, 1888. The methods of analysis are described and analyses of the waters of the geysers, pools, and hot and cold springs are given. (Out of print; available for consultation in certain libraries.)

Milford, L. R., Analyses of the Saratoga mineral waters: Jour. Ind. and Eng. Chemistry, vol. 4, p. 593, 1912; vol. 5, pp. 24 and 557, 1913; vol. 6, p. 207, 1914. This series of four articles gives new analyses of all the important Saratoga waters.

First bulletin of the commissioners of the State Reservation at Saratoga Springs, Albany, N. Y., October, 1913. Analyses of 20 Saratoga waters are given and the properties of the waters are described.

Waring, G. A., Springs of California: U. S. Geol. Survey Water-Supply Paper 338, 1914. Analyses of practically all California mineral waters are included. (In press.)

Pratt, J. H., The mining industry in North Carolina during 1907 with a special report on the mineral waters: North Carolina Geol. and Econ. Survey Econ. Paper 15, 1908. Analyses of 90 mineral waters are given.

Bailey, E. H. S., Special report on mineral waters: Kansas Univ. Geol. Survey, vol. 7, 1902. Analyses of 115 ground waters are given, including the well-known mineral waters of the State. Analyses of many other noted waters are quoted, among which may be mentioned analyses of Crab Orchard, Hunjadi Janos, Carabana, Kissingen, Sprudel, and Pullna waters. Special chapters deal with the classification of mineral waters and their therapeutic action.

Schweitzer, Paul, A report on the mineral waters of Missouri: Missouri Geol. Survey, vol. 3, 1892. About 80 analyses of Missouri ground waters are given. Analyses of Vichy, Sprudel, Kreutzbrunnen, Spa, St. Moritz, Aix-les-Bains, and other foreign waters are quoted. The classification of mineral waters and their therapeutic action are discussed.

Blatchley, W. S., The mineral waters of Indiana: Indiana Dept. Geol. and Nat. Res. Ann. Rept., vol. 26, pp. 11–158, 1901. Descriptions of more than 100 mineral springs are given and analyses of the waters of many of them are quoted. The same volume (pp. 159–226) contains a discussion of the medicinal properties and uses of Indiana mineral waters by Dr. Robert Hessler.

Hare, R. F., and Mitchell, S. R., Composition of some New Mexico waters: New Mexico Coll. Agr. and Mech. Arts Agr. Exp. Sta. Bull. 83, 1912. In a collection of miscellaneous analyses reports on the composition of the waters of Carlsbad (N. Mex.) Mineral Springs, Mimbres Hot Springs, San Antonio Springs, Aztec Mineral Springs, and some others are given.

Froehling and Robertson, Mineral waters and spring resorts of Virginia: A handbook on the minerals and mineral resources of Virginia, pp. 97–159, Richmond, 1907. This handbook was published for distribution at the Jamestown Exposition, Norfolk, Va., 1907. About 60 resorts are described and analyses of the waters at most of them are quoted.

Bartow, Edward, and others, The mineral content of Illinois waters: Illinois Water Survey Bull. 4, 1908. Analyses of many ground waters are given and special chapters deal with the geological occurrence and classification of the waters and the medicinal springs of Illinois.

Sellards, E. H., A preliminary report on the undergound water supply of central Florida: Florida Geol. Survey Bull. 1, 1908. Analyses of 14 large springs are given.

Shepard, J. H., The artesian waters of South Dakota: South Dakota Agr. Coll. and Exp. Sta. Bull. 41, 1895. Analyses of about 50 deep waters are given.

The United States Geological Survey has issued as water-supply papers and bulletins many reports on the geology and ground-water resources of various parts of the United States, and most of these contain analyses of the spring waters in the territory covered by them. Among these may be mentioned the following water-supply papers, copies of which may be obtained as long as the edition for free distribution lasts by application to the Director, United States Geological Survey, Washington, D. C.:

223, on southern Maine.
233, on the Blue Grass region of Kentucky.
254, on north-central Indiana.
256, on southern Minnesota.
273, on Kansas.
293, on Iowa.

RADIOACTIVITY OF MINERAL WATERS.

By R. B. Dole.

INTRODUCTION.

The radioactivity of mineral waters has attracted much attention during the last decade, and it is now widely believed that the therapeutic value of many waters is largely due to their content of radioactive substances. For many years the beneficial effects attending the use of certain natural waters were attributed to the common mineral ingredients determined by chemical analysis, and several elaborate systems have been devised for classifying such waters on the basis of their chemical composition. Though many natural waters unquestionably cause physiologic reactions because of their great content of common mineral substances, a large proportion of the well-known waters of the United States do not differ essentially in concentration and composition from supplies of city water used daily by thousands of people without apparent physiologic reaction other than that following the use of water itself. Tests have shown that many of these slightly mineralized waters have various degrees of radioactivity, and consequently, as radium compounds have been found to cause marked physiologic reactions, the improvement in health following sojourn at springs has very naturally been attributed to the radioactive properties of the waters. There are yet too few experimental data to settle this point definitely, but it is perhaps not out of place to call attention to the facts that in radiotherapy as in all other branches of medicine the curative agent must be present in a certain strength in order to exert any healing influence, and that most of the radiotherapeutic reactions thus far investigated have been effected by means of radioactive compounds whose strength is far greater than that of natural mineral waters. Therefore owners should not be led into making strong claims for the radiotherapeutic value of the waters of their springs without careful investigation of the subject.

MEASUREMENT OF RADIOACTIVITY.

The radioactivity of water and of the gases contained in water is measured by the effect produced on a charged electroscope by radium emanation (niton), a gas that is given off by radium-bearing minerals in proportion to their content of radium. The general opinion that most spring waters do not contain radium itself but radium emanation derived from contact with radium-bearing minerals is logically based on the fact that nearly all spring waters gradually lose their radioactivity after being removed from the source, whereas a solution of a radium salt, after having once reached equilibrium, continues to give off radium emanation. The sample of water is boiled to drive off the emanation, which is dried and then swept by a current of air into an air-tight electroscope. The latter instrument consists essentially of a jar from the cover of which is suspended a rod supporting at its lower extremity a metal strip and a leaf of aluminum foil. When the system is electrically charged the aluminum foil is deflected from its vertical position, to which it normally returns very slowly as the charge is dissipated. If, however, radium emanation is present in the jar the rate of leakage and consequently the rate of fall of the foil are greatly accelerated. The rate of leakage in the presence of the emanation from a measured quantity of water is therefore observed and compared with the rate of leakage similarly measured on the emanation from a solution of a weighed portion of a mineral whose content of radioactive substance has been determined. From these data the radioactivity of the sample of water can be calculated. The results of such measurements have unfortunately been expressed in a great variety of units, and as a natural consequence it is impossible to compare some reports of radioactivity with others. In England and America it is customary to express radioactivity as an equivalent of radium or of uranium, a radioactive substance; on the Continent it is customary to express the results in electrostatic units. It is quite general, irrespective of the unit, to report the radioactivity per liter of water or per liter of the gas in the water. The quantity of emanation in equilibrium with 1 gram of radium is known as a curie of emanation,[1] but as this is a very large unit estimates are expressed in fractional parts of a curie; thus, 22.9×10^{-9} curie per liter means that one liter of the water contains 229 ten-billionths of the quantity of emanation in equilibrium with 1 gram of radium. The mache unit, frequently encountered in reports of radioactivity, is defined as the saturation ionization current due to the radium emanation, free from decay products, from a liter of water or gas, expressed in electrostatic units (i) multiplied by 1,000;[2] and 1 curie of emanation per liter equals a concentration of 2,670 million mache units.[2]

RADIOACTIVITY OF SOME WELL-KNOWN WATERS.

The following table gives the results of measurements of the radioactivity of several well-known European mineral waters and of a few American waters. Many of these waters also contain radioactive gases. Reports of different observations on the same spring indicate that the waters and the gases in them vary greatly in radioactivity. Because of differences in the methods of measurement and in allowances for disintegration products and also because of the uncertain or arbitrary nature of some of the units of expression the figures have not been reduced to a common unit for direct comparison. The most powerful water listed contains per liter a quantity of emanation equivalent to that in equilibrium with 7×10^{-8} gram of radium, or, to state it differently, 3,800 gallons of the water would contain the quantity of emanation in equilibrium with 1 milligram of radium. The slight strength of the tabulated activities can be comprehended when it is noted that most of the waters are only one-hundredth to one-half as strongly radioactive as the most powerful water.

[d] Moore, R. B., and Whittemore, C. F., Report on the radioactivity of the waters of Saratoga Springs, N. Y.: Unpublished report communicated by the Director, Bureau of Mines.
[e] The cessation of pumping of Saratoga waters since these tests were made has been followed by substantial modification of the flow and hydrostatic head of the springs; consequently it is quite possible that waters have developed that are different from those on which the report here cited was made.

THERAPEUTIC USES OF RADIOACTIVE WATERS.

Radioactive waters are applied to the body in practically every manner that mineral waters have heretofore been used; baths, douches, and local applications of every description are employed, and the waters are also drunk and injected. In addition to these methods of administration, rooms or closets, called inhalatoria and emanatoria, are so arranged that patients may breathe the radium emanation in the gases that escape from the waters. The more completely equipped watering places have arrangements for combination of radium treatment with electric, muscular, aqueous, and other kinds of massage, hot-air baths, mud baths, and X-ray and violet-ray treatment. At some sanatoriums these treatments are given by means of waters, muds, packings, and compresses that have been rendered artificially radioactive. A great variety of diseases are treated, among which may be mentioned especially croupous pneumonia, bronchitis, bronchial asthma, articular rheumatism, tuberculosis, syphilis, gout, diabetes, and obesity. In reference to the physiologic reactions following treatment by the radioactive waters of Bath, Atkins and Harrison are quoted by Low [1] as saying that radium increases diuresis, excretion of uric acid, and exhalation of carbon dioxide; lowers the pressure of the blood and decreases its viscosity; increases the rate of decomposition of uric acid; inhibits inflammation; increases sexual vitality; and has considerable influence over sympathetic affections. As a concluding comment on this topic, it is well to repeat that there is much conflicting testimony on the therapeutic value of radioactive waters and that the physiologic effects of relatively strong solutions of radium salts may not necessarily be duplicated by weakly radioactive natural waters.

[1] Low, T. P., Radium emanation in mineral waters: Lancet, April 20, 1912; abstract in Med. Record, vol. 81, p. 912, 1912.

BIBLIOGRAPHY.

The following list gives the titles and general nature of a few publications on radium, radioactivity, and radiotherapy for the benefit of those who may be sufficiently interested in the subject to pursue it in detail:

Radium.

BASKERVILLE, CHARLES, Radium and radioactive substances, Williams, Brown & Earle, Philadelphia, 1905. This 150-page résumé takes up the phenomenon of radioactivity, the extraction of radium salts, other radioactive substances, the emanations of radium, the theories of radioactivity, and the physical properties and therapeutic applications of radioactive substances.

RUTHERFORD, E., Radioactive transformations, Charles Scribner's Sons, New York, 1906.

MAKOWER, WALTER, and GEIGER, HANS, Practical measurements in radioactivity, London, 1912. The methods and instruments for measuring the radioactivity of minerals, waters, and gases are fully described.

LE RADIUM, a monthly journal published in Paris. It contains chiefly articles of scientific and theoretical interest on the character of radioactive bodies, the effects of radioactive substances, the properties of rays, the theory of electrons, ions, and radiations, and on atomic and cosmic phenomena. The earlier numbers contain references to articles in current literature on the radioactivity of various mineral springs.

Radiotherapy.

LAZARUS, PAUL, and others, Handbuch der Radium Biologie und Therapie, 521 pp., 153 text figs., 2 tables, J. F. Bergmann, Wiesbaden, 1913. This volume contains articles by authorities on the physical, chemical, and biologic properties of the radioactive elements, their general therapeutic uses, and the treatment of special diseases, with a general bibliography including more than a thousand references to articles on radiobiology and radiotherapy.

Comptes rendus de la premier Congrès international pour l'étude de la radiologie et de l'ionization, L. Severeyns, Brussels, 1905. Many papers covering divers phases of radiotherapy and the physical properties of radium are included, among which may be mentioned articles on the physiologic action of very feeble radioactivity, by Dr. E. S. London; medical applications of radium, by Dr. A. Darier; radioactivity applied to the histology of the nervous system, by Prof. Madrid Moreno; and the radioactivity of Austrian thermal waters, by H. Mache and St. Meyer.

BURNHAM, A. C., Radioactive waters in the treatment of gout: Med. Record, vol. 81, p. 117, 1912. The author recommends the use of artificially prepared and tested radioactive waters as the content of American waters is usually insignificant. He outlines the treatment for gout, giving doses.

KOHLRAUCH, F. L., and MAYER, KARL [Radioactive baths]: Zeitschr. exper. Pathologie, vol. 6, p. 186, 1910. The apparatus used in radium-bath treatment is described and clinical observations are given.

HATTON, JOHN [compiler], Notes on the therapeutics of radium in the Bath waters, Bath Corporation, Bath, England. This pamphlet contains the results of investigations of the hot springs of Bath, conducted by Sir William Ramsay; an article by a committee of the Bath branch of the British Medical Association on radioactivity as a factor in the efficacy of the Bath mineral waters; extracts from medical journals on radiotherapy; and a description of the methods of using the radioactive Bath waters.

LONDON, E. S., Das Radium in der Biologie und Medizin, Leipzig, 1911. Contains a bibliography.

ROLLINS, WILLIAM, Some principles involved in the therapeutic applications of radioactivity. Boston Med. Jour., vol. 149, p. 542, 1903.

PERSSON, G. A., Treatment of chronic diseases at spas, particularly with reference to the modern conception of radium emanation: New York Med. Jour., vol. 95, p. 1038, 1912. The author believes that the therapeutic value of treatment at spas is due more to radioactivity than to the mineral content of the waters.

RAYMOND and ZIMMERN [Some facts relating to the therapeutic action of radium]: Acad. méd. Bull., 3d ser., vol. 52, p. 180, 1904.

METZENBAUM, MYRON, Radium, its known medical value: Med. Record, vol. 69, p. 17, 1906.

BERGELL, PETER, and BICKEL, ADOLF [Experimental investigations of the physiologic significance of the radioactivity of mineral waters]: 22. Kong. für inn. Medizin Verh., p. 157, 1905.

LOEWENTHAL, S. [Methods of measurement and units in biologic research with radium]: Deutsche med. Wochenschr., vol. 36, p. 2096, 1910.

Radioactivity of waters.

RAMSAY, SIR WILLIAM, Report on the mineral waters of Bath: Chem. News, vol. 105, p. 133, 1912.

BAMBERGER, MAX, and KRÜSE, KARL [Radioactivity of the mineral springs of the Tyrol]: Monatsh. Chemie, vol. 34, p. 403, 1913. The radioactivity of waters from about fifty localities is given.

SCHWEITZER, A., [Radioactivity of the mineral springs of Switzerland]: Arch. sci. phys. nat., 4th ser., vol. 27, p. 256, 1909. About thirty determinations are reported.

BROCHET, ANDRÉ, [Relation between the radioactivity and the quantity of soluble salts in the thermal waters of Plombières]: Compt. Rend., vol. 150, p. 423, 1910.

HENRICH, F., [Radioactivity of the thermal waters of Wiesbaden]: Zeitschr. anorg. Chemie, vol. 65, p. 117, 1910.

BOLTWOOD, B. B., The radioactive properties of the waters of the springs on the Hot Springs Reservation, Hot Springs, Ark.: Am. Jour. Sci., 4th ser., vol. 20, p. 128, 1905. Waters from 44 hot springs and samples of tufa and gas were examined.

SCHLUNDT, HERMAN, and MOORE, R. B., Radioactivity of the thermal waters of Yellowstone National Park: U. S. Geol. Survey Bull. 395, 1909. The methods and apparatus for measurement of the radioactivity of waters and gases are described and quantitative tests of 80 waters, 40 gases, and 50 solids are reported.

MOORE, R. B., and WHITTEMORE, C. F., The radioactivity of the waters of Saratoga Springs, New York: Jour. Ind. and Eng. Chemistry, vol. 6, p. 552, 1914.

MAGNESITE.

By Charles G. Yale and Hoyt S. Gale.[1]

PRODUCTION.

The magnesite produced and sold or treated in the United States in 1913 was 8.37 per cent less in quantity than in 1912, the total output marketed in 1913 being 9,632 short tons, valued at $77,056, compared with 10,512 tons, valued at $84,096, in 1912.

The only production in this country was from California, as has always been the case, the material having been derived in 1913 from 3 mines—1 in Fresno County, 1 in Riverside County, and 1 in Tulare County. The small output reported in 1912 from the deposit on the Eckert ranch, in Sonoma County, has not been followed by further production; and the deposits on Red Mountain, in Santa Clara County, which yielded a few hundred tons in 1912, were unproductive in 1913.

At the close of the year 1913 there was only 1 productive mine in operation in California, the others having been temporarily closed down. Since the close of the year 6 mining properties have started operations—1 in Alameda County, 1 in Kern County, 1 in Placer County, 1 in Santa Clara County, and 2 in Sonoma County. The mines in Sonoma County are both old ones reopened, but all the others have become productive for the first time, mainly, however, on a small scale. The distribution of the magnesite deposits in California is shown on Plate I.

Protest has been received that the description of the deposit in Placer County, published in Survey Bulletin 540,[2] does not include all the development or exposures represented in that general locality. The outcrops examined were carefully identified both in description and on the map given with the report, so that there can be no mistake as regards the deposits that have been so described; but it is entirely likely that more deposits in the same general vicinity may exist, which were not then examined and are not included in that report. As was there stated, "The area is thickly timbered, and it is possible that not all the known outcrops were found." It is desirable, however, that the matter may be clearly understood, and it is hoped and expected that a further examination of these deposits can be arranged for the field season of 1914, and that the matter may then be put more completely on record.

[1] The statistics concerning domestic production, together with most of the data relating to development in the California fields, have been gathered by Mr. Yale; the statements concerning eastern markets, prices, discussion of imports, uses, cements, and the bibliography are compiled by Mr. Gale.

[2] Gale, H. S., Late developments of magnesite deposits in California and Nevada. U. S. Geol. Survey Bull. 540, pp. 501-503, 1913.

By far the greater part of the domestic product is consumed in calcined form as a digester for wood pulp in paper manufacture. Some, however, is used in making plastic material for flooring, tiles, wainscoting, artificial marble, paint, and fireproofing.

None of the magnesite mined is sold crude, but it is all calcined before shipment from the mines. The California manufacturers of carbon dioxide who have been using limestone for making their gas are making comparative experimental tests with the intention, if desirable, of resuming the use of magnesite as a source of the gas, as was formerly done.

At one of the new mines recently opened in Alameda County a 5-ton calcining furnace has been completed, and the owners have entered into contract with a local steel company to furnish dead-burned refractory material for furnace linings.

In the toilet and bathrooms of the larger buildings of the Panama Pacific Exposition at San Francisco magnesite flooring is being laid, about 5,000 square feet having been put down in each of the main buildings. The domestic product is used in this work. A number of manufacturers in Los Angeles and San Francisco are engaged in work of this class, the magnesite compounds being given different names, such as artolite and litholite. With the near approach of the opening of the Panama Canal, renewed interest is being taken in the investigation and prospecting of the California magnesite deposits, as it is expected that the surplus output above the normal annual consumption of the Pacific coast product may be shipped much more cheaply than is possible at the present time.

A new company, which since the close of 1913 has purchased and is reopening the largest of the Sonoma County deposits, is building a short branch railroad to connect with the main line to tidewater. It is understood that it is the intention of this company to ship its entire output through the canal to New York, where it is reported to have contracts for monthly delivery of several thousand tons of calcined magnesite.

Notwithstanding the fact that California is the only State in which magnesite is produced in commercial quantities, a considerable quantity of imported calcined and ground magnesite is sold in the Pacific coast markets, particularly in California. This magnesite is sold finely ground and in packages of convenient size and form, and it brings a higher price generally than the domestic product, which is equally good, if not superior, because of its freshness, if for no other reason. Generally speaking, the California mine owners sell only carload lots in clacined lump form, and this is shipped in sacks and reduced to powder in the grinding mills at points of greatest consumption, such as Los Angeles and San Francisco. The manufacturers of flooring, tiling, and wainscoting usually buy in small lots of 1 or 2 tons, or even less, in order to fill pending contracts, and thus have to pay higher prices than if they purchased in larger quantities. The importers are able to meet this retail demand by disposing of their product in small wooden packages. Those who grind the domestic material are also following this plan. This domestic calcined and ground magnesite has been selling at an average of about $40 a ton, but as high as $50 and $55 a ton has been paid for the imported material in Los Angeles and San Francisco.

MAP OF A PART OF CALIFORNIA, SHOWING DISTRIBUTION OF MAGNESITE DEPOSITS.

The various magnesite mines and "prospects" in California have been described both in United States Geological Survey bulletins and in those of the California State Mining Bureau. In the opening and development of these mines their nearness to railroad transportation seems to be of more importance than the character or extent of the deposits. Certain deposits, notably in Santa Clara and San Benito counties, are known to be large in extent and of good character of material, but they lie idle owing to the distance the mineral must be hauled to a railroad, while smaller mines close to railroad stations are being worked. Investors looking for deposits of magnesite to be developed are not disposed to investigate even promising mines from which a long haul by team is necessary before the mineral can be placed on the cars.

The following table shows the quantity and value of the domestic output of magnesite from 1891 to 1913, inclusive:

Quantity and value of crude magnesite produced in the United States, 1891–1913, in short tons.

	Quantity.	Value.		Quantity.	Value.
1891	439	$4,390	1903	3,744	$10,595
1892	1,004	10,040	1904	2,850	9,298
1893	704	7,040	1905	3,933	15,221
1894	1,440	10,240	1906	7,805	23,415
1895	2,220	17,000	1907	7,561	22,683
1896	1,500	11,000	1908	6,587	19,761
1897	1,143	13,671	1909	9,465	37,860
1898	1,263	19,075	1910	12,443	74,658
1899	1,280	18,480	1911	9,375	75,000
1900	2,252	19,333	1912	10,512	84,096
1901	3,500	10,500	1913	9,632	77,056
1902	2,830	8,490			

PRICES DURING 1913.

The prices of magnesite of the various classes, and grades of magnesite and magnesia products, have fluctuated somewhat during 1913. The price of Grecian material rose markedly about the middle of the year, owing, it is said, to the scarcity of labor at the mines as a result of the Balkan wars, which limited production for a time. Since the close of the wars the prices have not been reduced to quite their former level.

The following summary represents approximately the wholesale prices per short ton current during 1913 for the products as usually marketed:

New York market:
- Grecian (Eubœan) calcined "caustic," fine-ground (in paper-lined barrels) .... $25 to $35
- Grecian (Eubœan) calcined "caustic," not ground (in sacks) .... $17.50 to $20
- Grecian (Eubœan) crude (bulk) .... $7 to $8
- Austrian, calcined, dead-burned, crushed or fine ground (bulk) .... $16.15 to $16.25

Pacific coast, San Francisco or Los Angeles markets:
- Domestic, calcined "caustic" fine ground (in paper-lined barrels) .... $30 to $35
- Domestic, calcined, not ground, dead-burned (in sacks) .... $20 to $25
- Norwegian, calcined, dead-burned, crushed or fine ground .... $22.50.

The value assigned to the domestic production is based on the figure $17.50 a ton for ordinary run calcined, unground magnesite at the mine or point of shipment, which is assumed to be approximately equivalent to $8 a ton for the raw magnesite.

IMPORTS.

The following statistics concerning imports of magnesite are obtained from the Bureau of Foreign and Domestic Commerce, Department of Commerce. The statistics include imports for consumption for the calendar years 1911 to 1913, inclusive, and also imports for the fiscal years 1910 to 1913, inclusive, under which are two statements relative to the imports of magnesite, calcined not purified—one showing the countries of shipment or nominal origin and the other the ports and customs districts into which imported; there is but one statement with regard to imports of the crude magnesite by the fiscal year, data as to the countries from which imported not being available.

Imports, for consumption, of magnesite into the United States from 1911 to 1913, in pounds.

	1911		1912		1913	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
Magnesia:						
Calcined, medicinal	91,029	$13,694	104,106	$16,326	54,915	$10,034

TARIFF REGULATIONS.

The tariff act of October 3, 1913, contains the following provisions relating to magnesia materials and magnesite:

DUTIABLE LIST.

Schedule A.—Chemicals, oils, and paints. Magnesia: Calcined, 3½ cents per pound; carbonate of, precipitated, 1½ cents per pound; sulphate of, or Epsom salts, $\frac{1}{10}$ cent per pound.

Schedule B.—Earths, earthenware, and glassware. Firebrick, magnesite brick, chrome brick, etc., * * * not glazed, enameled, painted, vitrified, ornamented, or decorated in any manner, 10 per centum ad valorem.

Schedule C.—Metals and manufactures of. * * * Barium, calcium, magnesium, * * * and alloys of which said metals are the component material of chief value, 25 per centum ad valorem.

FREE LIST.

Magnesite, crude or calcined, not purified.

USES OF MAGNESITE.

Magnesite is marketed and used in various forms for different purposes, either raw or crude as mined, or calcined, which results principally in the expelling of the carbon dioxide and moisture of the original carbonate, the residue or calcined magnesite being chiefly the oxide, also known as magnesia.

The calcined magnesites are either the so-called "caustic" or the "dead-burned." The "caustic" magnesite intended for plastic or cement uses is burned at somewhat lower temperatures than the dead-burned, and usually retains a small percentage of carbon dioxide, which permits the material to react with the chloride salts used in cement. The "dead-burned" is roasted beyond the point at which all carbon dioxide would be extracted, heating being carried to incipient fusion, whereby practically all shrinkage is taken up, so that forms moulded of this crushed material and held by a satisfactory binder will shrink but little more with further heating.

The principal uses of magnesite are summarized as follows: (1) Various refractory uses, as brick, furnace hearths, crucibles, etc.; (2) as magnesium sulphite for the digestion and whitening of wood-pulp paper; (3) in crude form for the manufacture of carbon-dioxide; (4) calcined and ground for oxychloride or Sorel cement; (5) miscellaneous applications in crude or calcined form; (6) miscellaneous uses of refined magnesia salts.

Refractory uses.—The refractory uses of calcined magnesite constitute probably its most important application. Made into refractory bricks it finds an important use as the linings of basis steel furnaces. In "dead-burned" calcined form either as brick or as originally burned, the magnesia is used as a refractory lining for open-hearth furnaces and converters in the steel industry, for rotary kiln linings in Portland cement manufacture, for furnace hearths, for crucibles, and for cupels.

It is commonly assumed that the most refractory magnesite is the "dead-burned" product derived from magnesite containing little or no lime, silica, oxide of iron, or alumina. The presence of lime in magnesite bricks used for high temperatures is said to cause them to disintegrate more readily, and in basic steel furnaces the lime is believed "to cause the phosphorus to pass into the hearth instead of the slag, the hearth thereby becoming rotten." Silica, oxide of iron, and alumina are supposed to have a tendency to lower the fusing point. On the other hand, there is a decided preference in refractory uses for the magnesites carrying a certain percentage of iron, as do the Austrian and Hungarian products for use in the manufacture of brick. The iron probably does lower the fusing point but with the result that the shrinkage of the material after calcining is very much less and the bricks made from it are more satisfactorily burned and hold their shape better. It is generally admitted that the whiter and purer grades of magnesite are more refractory, but they require a much greater heat for calcining, in fact it is exceedingly difficult to burn them to a point where they will not shrink further. The calcined, dead-burned Austrian magnesite is reported to contain within a maximum of 3 to 4 per cent silica, 6 to 8 per cent iron, and 4 per cent lime.

Use in the paper-manufacturing industry.—The availability of magnesite in the California deposits has led to its considerable use in the manufacture of wood-pulp paper on the Pacific coast. Magnesia, in the form of the bisulphite, is said to have a more solvent action on the free resins of the wood than lime, and it also has an additional advantage in that the residues left in the paper stock are not afterwards injurious to sizing agents.

The process of making paper [1] in which magnesite is used is known as the sulphite process. The wood (mostly from coniferous trees) is boiled with a disintegrating agent so that it breaks down into a mass of pulp, which is afterward rolled into paper. The disintegrating agent in the sulphite process is sulphurous acid, or common bisulphite of calcium or magnesium. Magnesium bisulphite is more stable and it dissolves the noncellulose matter even more completely than calcium bisulphite. Sodium bisulphite gives a better product than either of the two mentioned, and strong liquors can be made from it, but it is too expensive for general use.

It is known that the greater part of the California magnesite is now used in the manufacture of paper by this process. The Portersville deposits, which have been for years the largest producers, have been worked primarily for the use of paper makers.

Manufacture of carbon dioxide.—The manufacture of carbon dioxide from raw magnesite consists in the decomposition of the magnesium carbonate by roasting with the recovery, purification, and compression of the carbon dioxide gas, the residual magnesia being also available as one of the important products of the process. The operation of this process is described by Hess [2] with a diagram showing details of one of the plants. It is understood that the use of magnesite for this purpose has now been chiefly or wholly abandoned on the Pacific coast, as the gas can be produced more cheaply as a by-product in other processes—as, for instance, as one of the products of a distillery and also from limestone. Carbon dioxide is, however, manufactured in this way from the imported magnesites in the eastern part of the country, in which case the magnesia is sometimes considered as a

[1] Thorp, F. H., Outlines of industrial chemistry, pp. 522–523, 1909.
[2] Hess, F. L., U. S. Geol. Survey Bull. 355, pp. 8, 9, 1908.

by-product in the manufacture of the gas. In other cases, however, the imported product is calcined for the sake of the magnesia alone without any attempt to save the gas.

Oxychloride or Sorel cement.—The use of magnesite for the manufacture of cement is apparently a promising field, and the product is likely to find an increasing use. This product is known as oxychloride or Sorel cement. Its manufacture is based on the fact that a mixture of finely ground calcined magnesite when wet with a solution of magnesium chloride of a certain strength will set as an exceedingly strong cement. This mixture is generally modified by the addition of various filler materials, such as wood flour, cork, talc, silex, asbestos, clay, marble dust, sand, and other materials, besides coloring matter. The cement thus produced is put out under many trade names, espepecially referred to as sanitary flooring. When well laid, magnesite cement flooring has some decided advantages over other cements for this purpose. It produces a smooth, even floor, which when successfully put down may be laid in large areas without cracking. It takes colors advantageously, and is susceptible of good polish by oiling or waxing. It is thus laid in a plastic state on wood, steel, or concrete. Its surface seems to have a resilience not given by ordinary cement, and it does not pulverize or grind to dust. This cement is said to have found a very extensive use abroad as flooring and to be gradually coming into more extended use in this country. It has also found a use in the manufacture of artificial marble and fine tiles.

It appears, however, that there are practical difficulties to be encountered in the manipulation of magnesia cements, which are not yet wholly understood and which have at times led to criticism and dissatisfaction with the material, possibly not always merited. (See review of this subject in subsequent pages.)

Miscellaneous applications in crude or calcined form.—Magnesia finds numerous miscellaneous applications in both crude and calcined form, among which may be mentioned its use in pipe covering as a nonconductor of heat, where it is commonly mixed with asbestos fiber. For this the light carbonate is used which is understood to be obtained from domestic sources, being manufactured from dolomite by a precipitation process. Magnesia, doubtless the light carbonate, is said to be used as an absorbent in the manufacture of dynamite. It is said to be used also as an adulterant in paint, and to prevent scale in boilers in which sulphurous waters are used. It has been tried with some success as a binder for briquetting coal, where it has the disadvantage common to all inorganic binding materials, namely, that they increase the ash without adding to the combustible portion of the fuel.

The use of fine-ground magnesia in a fireproof or fire-retarding paint is also reported to be coming to the fore. Wood or burlap coated with a paint made of magnesia and a magnesium chloride solution are said to resist fire, so that, although they can be burned by direct application of heat and flame, the fire will not spread beyond the areas actually exposed to the flame.

Miscellaneous uses of refined magnesia salts.—Among the miscellaneous uses as refined magnesia salts may be suggested those for medicinal and toilet purposes. The commercial preparation known as magnesia alba is a basic carbonate of slightly varying composition, according to the conditions of production. It is usually prepared by precipitation of either the commercial sulphate or chloride of magnesium with sodium carbonate. Epsom salts (magnesium sulphate) is derived from the deposits at Stassfurt and is imported on a considerable scale; but it is also manufactured by chemical treatment of magnesite. Its principal use is said to be in warp sizing or weighting in cotton mills. Very considerable quantities of magnesium chloride are also imported from the German fields for use in the oxychloride cement and for other purposes. The hydrate is used in sugar manufacture. A considerable quantity of magnesia, quoted as "calcined, medicinal," is imported annually, probably representing a purified product for medicinal or other uses.

UTILIZATION OF THE PRODUCT, DOMESTIC AND FOREIGN.

DOMESTIC.

Although the workable deposits of magnesite in this country are confined to the Pacific coast so far as known, all the important deposits being in the State of California alone, magnesite is very widely distributed throughout the world. Owing to high cost of transportation and possibly to a certain extent to difference in costs of labor in our own country and in foreign lands, the California magnesite has not yet been able to enter the Middle or Eastern States in competition with the imported products. As the largest markets in this country are in the Eastern States the total quantity of the imported product exceeds by many times the home production.

The magnesite of California is consumed principally in the paper-manufacturing trade. There is a limited demand in the West for magnesite for refractory uses, which is partly supplied by importation of foreign products even in that market, and also a limited, though probably growing demand for ground "caustic" magnesite for plastic or cement uses, which now seems to be in a fair way to be supplied by the domestic material as far as the west coast markets are concerned.

FOREIGN.

As suggested, however, the great bulk of the magnesite used in this country passes through our eastern markets and is derived from foreign sources. Ninety-five per cent or more of the magnesite imported into the United States comes from Austria and Hungary and is of the iron-bearing variety used for refractory purposes. This is received chiefly at the port of Philadelphia, where is it delivered in sacks in calcined form and goes into the manufacture of refractory brick. Some of the Grecian magnesite imported raw is calcined and manufactured into refractory brick in a similar way. The greater part of the magnesite that goes into the plastic or cement uses comes from the island of Eubœa, Greece, and is imported in both raw and calcined forms. Much of this product has been shipped raw from the mines to Hamburg and Rotterdam, where the material is calcined and sacked and reexported. Thus most of the product reported as received from Germany and Netherlands is actually Grecian magnesite. According to the statistics given herewith it may be noted that after Austria-Hungary, these are the two largest sources of our imports, each one much exceeding our imports from Greece direct.

A small quantity received from England doubtless comes in the same way. New York is the principal port of receipt of the Grecian material, whence it is distributed by the various importing chemical firms. Of the product thus received in the raw state, a part is used primarily for the manufacture of carbon dioxide, the calcined magnesia (a by-product) being disposed of as a secondary matter, and a part is calcined primarily for the magnesia with no attempt to save the carbon dioxide.

It would seem that there should be a decided advantage in the use of freshly calcined and ground material for the cement trade and that there is room for development along this line. As already stated, the greater part of the Grecian magnesite received here has been shipped raw in bulk from the mines to northern Germany or Holland, there to be calcined and in part ground, and being repacked either in sacks or (if ground) in barrels, is reexported to this country to be again handled by the brokers. In view of the fact that there is a marked tendency in calcined magnesite to deteriorate—especially if, after grinding, it be long kept in storage and particularly if it be exposed at all to dampness—either by absorption of moisture or of carbon dioxide from the air, it would seem that there should be a field for the calcination and grinding in our own country of this material, whether of the raw Grecian rock or of our own product from California. It is possible that the latter may be obtainable shortly at competing rates through the Panama Canal, but this is a matter which is still the subject of speculation. Much dissatisfaction is expressed with the variable quality of the magnesite that is furnished to the magnesia cement trade. Whether this variability is the result of actual differences in the original product, or in its condition of freshness or possible deterioration, or in the manner of the calcining and grinding of the original product has not been determined, and these points are apparently a source of equal uncertainty even within the trade itself. At least one point seems assured, namely, that calcined magnesite does deteriorate markedly with exposure to air and dampness, and that the ground calcined magnesia deteriorates rapidly, so that even with the best of packing in paper-lined boxes or barrels it should not be held in storage long before it is used, probably not more than a year under the most favorable conditions.

A certain quantity of magnesia, in the form of the light carbonate, is made from dolomite in Pennsylvania by precipitation and is used in the preparation of magnesia asbestos fireproofing and insulating materials. This has not been taken into account in the present report.

FOREIGN OCCURRENCES.

A summary of the foreign occurrences is given here chiefly by abstract from the review by Hess.[1]

Foreign occurrences of magnesite.

North America:

Canada: Quebec, in township of Grenville, Argenteuil County. British Columbia, at town of Atlin, in Pine Creek valley, and at 108-mile house on the Cariboo road, 93 miles north of Ashcroft, Lillooet district.

Mexico: Lower California, on island of Santa Margarita and on Cedros Island, in Magdalena Bay.

[1] Hess, F. L., U. S. Geol. Survey Bull. 355, 1908.

South America:
- Venezuela: Island of Margarita.

Europe:
- Austria: Styria (mines at Veitsch).
- Hungary: Nyustya, Jolsva, and Hizsuya, Gomor County; Ochtina, Martonhaza
- Germany: Near Frankenstein, Silesia.
- Greece: On island of Eubœa; near Mariki, close to Thebes (Bœotia); at Hermioni, in Argolis.
- Italy: At Casellette, in Val di Susa, and at several other places in the Turin district; on the island of Elba.
- Macedonia: Near the coast not far from the Greek border, and on the Chalkidike Peninsula.
- Norway: Two fields near Snarum, in the Modums division of Buskerud bailiwick, on the Kroderline, a spur of the Drammen Randsfjord line, 56 kilometers (35 miles) from Drammen, the nearest city or port.
- Russia: In the Uphim Mountain district of the Urals.

Africa:
- Transvaal: Extensive deposits between Kaapumiden and Malelane, 2 miles south of the Pretoria-Delagoa Bay Railway, 87 miles from Lorenzo Marquez, and 300 miles from Johannesburg.
- Rhodesia.

Asia:
- India: Madras, Chalk Hills, 4 miles northeast of Salem, Madras Presidency, in the southern part of the Indian Peninsula. Mysore: Occurrences at a number of points near Mavinhalli and Kadakola, in the south-central part of the Indian Peninsula.
- Ceylon: Hydromagnesite reported.

Australia:
- Queensland: In the Normanton district in the Gulf country; in the Rockhampton district on Dumer, Sawpit, and Stewart creeks; at Stanwell, Islapot, Moonmera, and the Pointer, near Yamba; in other districts at Clermont, Toorwomba, Ipswich, Kilkivan, and Newellton.
- New South Wales: Near Fifield; minor occurrences at other localities.
- South Australia: Large deposits reported.
- Tasmania: At Parson's Hood Mountain; Trial Harbor, in the Meredith Range; Dundas and Hazlewood.
- Victoria: Heathcote.

Oceania:
- New Caledonia: At the north end of the west coast, particularly between Koumac and Voh.

MAGNESIA CEMENT; A REVIEW.

A recent publication [1] on the subject of magnesia cement, generally termed oxychloride or Sorel cement, opens a discussion in this country on a subject which seems involved in a great deal of obscurity. As this paper gives information that will probably be of interest to the magnesite trade generally, the following summary is given, to which are added some other data on this general subject.

The basic idea, namely, the use of finely powdered magnesia and a solution of magnesium chloride to produce a cement, originated with Stanislas Sorel of Paris, who took out patents covering the idea in 1866. This cement has the special distinction as compared with other cements, of a considerable degree of elasticity to which probably may be ascribed its ability to withstand cracking caused by warping in the cement or its foundation, or by expansion or contraction. Its principal use in construction is for adding finishing surface either exterior or interior, but chiefly in the interior, especially for floors. Such surfaces are applied in a plastic form, usually about half an inch thick, which sets in a few hours as a tough seamless

[1] Hooker, H. M., Composition flooring, Eng. Soc. Western Pennsylvania Proc., vol. 29, pp. 305-338, 418-444, 1913.

surface. It has also a very strong bonding power, and will hold firmly to wood, metal, or concrete as a base. It may be finished with a very smooth even surface, which will take a good wax or oil polish. As ordinarily mixed there is added a certain proportion of wood flour, cork, or other filler, thereby adding to the elastic properties of the finished product. Its surface is described as "warm" and "quiet" as a result of the elastic and nonconducting character of the composite material. The cement is usually colored by the addition of some mineral pigment to the materials before mixing as cement. The colors used most commonly are red, buff, or gray. This cement is coming into very general recognition under many trade names, generally with particular reference to what are called its sanitary qualities. Its freedom from cracking where successfully laid favors cleanliness.

The desirable qualities of any flooring material (cost not considered) are listed for purposes of analysis or comparison under 18 heads, as follows: Cleanliness (sanitary qualities), quietness, immunity from abrasion (surface wear), resilience, immunity from slipperiness, appearance, waterproof character, plasticity, warmth (thermal insulation), life (immunity from deterioration with age), acid-proof character, alkali-proof character, fire resistance, elasticity, crushing strength, structural strength (rupture), immunity from expansion and contraction, and lightness. The importance of these various qualities varies with the varying requirements to be met; for instance, in some places, as in hospitals, cleanliness is one of the prime considerations; in other places immunity from abrasion might be one of the principal requisites. However, an attempt is made in the discussion of this subject to estimate quantitatively the values of these different properties and to compare magnesite flooring in this way with many other materials now in common use as flooring. As to most of these qualities the conclusion is reached that the magnesia cement affords one of the most satisfactory flooring materials for many purposes such as in kitchen, laundry, toilet, and bathrooms, corridors, large rooms or halls in public or other buildings, including hospitals, factories, shops, and restaurants.

There is no doubt that the material is steadily coming into more general recognition and favor for these uses. For a few special uses it is more or less disqualified; as an instance, it is not suited for construction of swimming tanks or for conditions of permanent wetness, since under constant immersion it gradually softens, although it is said to withstand intermittent wetting and drying and is recommended for shower baths. Naturally it is not acid-proof and not wholly alkali-proof, which might be a disadvantage in use for laboratory floors and tables; but these are rather special requirements. Its cost per square foot is given as 25 to 33 cents, depending on area, which is estimated to be lower than marble, cork, rubber, clay or mosaic tile, slate, or terrazzo, although more expensive than wood, asphalt, linoleum, or Portland cement.

After the consideration of properties and cost, methods of installation, preparation of foundation, delivery and character of materials are considered, in which the materials are, of course, assumed to be obtained ready prepared from a manufacturer. A feature must be called to attention which has not yet been satisfactorily provided for, namely, that there still remains an element of uncertainty in the practical application of these cement flooring materials which has not yet been successfully obviated. Although the general advantages of the material over most other floorings for many uses may readily be granted, there still exists the element of uncertainty as to whether a floor when laid will be satisfactory or, possibly, will be an entire failure. The real difficulty is that the true causes for the failure are generally not understood, and so can not be readily obviated. Some of these points are brought out in the discussion of Mr. Hooker's paper. It is admitted that in certain cases many floors have had to be replaced. The uncertainty as to what the result would be not only adds to the cost of such floors but acts as a decided deterrent to the more general use of this material.

In the discussion of the subject the causes of failure are ascribed to uncertain climatic changes, lack of uniformity in the mixtures used, lack of care on the part of those handling the materials, possible deterioration of materials used through exposure (either before or after mixing), lack of proper preparation of foundations on which the material is to be laid, and, as a very important factor, experience or nonexperience in the manipulation or actual laying and troweling of the material. Colors used may fade for various reasons, or an efflorescent salt may appear on the floor surface. In summary, the principal point in the argument, as presented for obtaining good results, seems to be in urging dependence on those responsible firms who may gain or have gained a reputation for preparing and laying the materials in a satisfactory way.

The trend of the foregoing argument is obvious. Investigation of the raw materials involved might serve to establish more completely than has yet been done the nature of the chemical reactions involved, and possibly some chemical causes for the failures. Data concerning the percentages of magnesium chloride and of ground calcined magnesia and data concerning the character and quantity of filler and color added to the commercial preparations are naturally guarded as trade secrets by the firms already in the business. A chemical investigation of the finished product, however, would probably not be very satisfactory, as magnesia limestone or dolomite, talc, asbestos, and other inert magnesian fillers are used in the mixture and the magnesia in them could not be readily distinguished from the reacting portion of the cement by ordinary analysis. The examination and standardization of the raw materials used, and of acceptable filler materials, and the establishment of standard proportions for the mixtures would seem to be about the only satisfactory way of attacking such a problem.

Inquiries have been received at the Survey from time to time as to the proportions used in such mixtures for magnesia cement. Of course, there is much variation in the compositions of the natural calcined magnesia to start with, and only certain materials are actually suited for the plastic or cement uses as distinguished from the general refractory and other uses to which magnesite is put. Probably the the best known "caustic" magnesia is the Grecian. The Canadian as well as, locally, the domestic product in our own Western States, is used in this way, although the Canadian is generally reported to contain a high percentage of lime. These magnesites are calcined, but not dead-burned, thereby retaining a small per cent of the original CO_2 in their composition. The condition of their calcination for cement uses is important, as the same material may undoubtedly be very greatly varied in its reacting properties by differing treatment in the kiln. It is generally agreed that the magnesite for cement use must be comparatively free from lime, as lime has a greater tendency to reabsorb water and carbon dioxide than the magnesia, thereby causing swelling. and is therefore not so permanent in the completed cement as a pure magnesia material. The magnesium chloride used is obtained by import from the German potash salt regions in the Stassfurt-Egelen region, where it is produced as a by-product in the potash industry. A limited supply might be, or may be, produced in our own salt refinery business. The fillers used may constitute 10 to 40 per cent of the whole cement, and commonly consist of ground marble, sand, or various sawdust, cork, or other materials. As an example of the formulas used in mixing such cements the following are quoted.[1]

Mixtures for the underlying or coarser layer.

[Parts by weight.]

1. 15 parts magnesia.
   10 parts magnesium chloride solution, 20° Baumé.
   10 parts moist sawdust.
   (Sets in 36 hours.)
2. 10 parts magnesia.
   10 parts magnesium chloride solution, 28° Baumé.
   5 parts sawdust.
   (Sets in 16 hours.)
3. 20 parts magnesia.
   15 parts magnesium chloride solution, 20° Baumé.
   4 parts ground cork.
   (Sets in 24 hours.)
4. 5 parts magnesia.
   3 parts magnesium chloride solution, 20° Baumé.
   5 parts ashes.
   (Sets in 24 hours.)

Mixtures for overlying or surface layers.

[Parts by weight.]

1. 40 parts magnesia.
   33 parts magnesium chloride solution ,19° Baumé.
   10 parts asbestos powder.
   5 parts wood flour.
   1 part red ocher.
   (Sets in 24 hours.)
2. 25 parts magnesia.
   25 parts magnesium chloride, 21° Baumé.
   4½ parts wood flour, impregnated with 4½ parts Terpentinharzlösung.
   15 parts yellow ocher.
   (Sets in 30 hours.)

The magnesite used is, as explained, the fine ground calcined (not dead-burned) of certain specified kinds or place of derivation regularly sold for the plastic purposes. This material commonly comes in paper-lined casks, barrels, or boxes, in which form it is fairly permanent, but it deteriorates by exposure, absorbing carbonic acid and moisture from the air. If carefully handled it can probably be kept unopened a year or more, but it should be used within a few weeks after being opened, even under most favorable conditions.

COKE.[1]

By Edward W. Parker.

INTRODUCTION.

In the manufacture of coke in the United States the cause of conservation has been as signally and materially advanced during the last few years, through the development of retort-oven practice, as has been evinced in any branch of mining and its collateral industries. The new era in coke making had its modest beginning in 1893 in the construction at Syracuse, N. Y., of 12 Semet-Solvay by-product retort ovens which were operated in connection with the chemical works of the Solvay Process Co. Progress at first was slow, for among furnace men a strong prejudice existed against the product of the retort oven which lacked certain physical characteristics, particularly the silvery luster and musical "ring" of the beehive coke, to which for many years they had been accustomed. It required a decade for the young rival of beehive coke to establish a firm hold, for, although production increased each year from the time the first plant was constructed, by 1902 the total quantity of retort coke produced was less than 1,400,000 tons, whereas in the same period the production of beehive coke had increased nearly 15,000,000 tons.

The second by-product coking plant to be erected in the United States was one of 60 Otto-Hoffmann (now known as "United-Otto") ovens built for the Cambria Iron Co. at Johnstown, Pa., in 1895, and it was the enlargement of this plant to 160 ovens in 1899 that probably exercised a considerable influence in convincing furnace men that the luster and ring of beehive coke were not essential qualities in the manufacture of iron.

During the last two or three years the progress in the manufacture of by-product coke has been marked, not only in the number of ovens built and under construction but in the size and capacity of the ovens themselves. The original Semet-Solvay ovens at Syracuse, N. Y., were 30 feet long, 16 inches wide at one end, 17 inches wide at the other, and 5 feet 8 inches high. They had a charging capacity of 4.4 short tons of coal. The original Otto-Hoffmann ovens at Johnstown were 33 feet 6 inches long, 6 feet high, and 17 to 21 inches wide, with a charging capacity of 5.5 tons. Many of the retort ovens constructed at the present time are over 36 feet long and nearly 12 feet high but without much additional width, and they have a charging capacity of from 12 to 16 tons.

The number of retort ovens in the United States in 1902, the end of the first decade in the era of by-product coke manufacture, was

[1] The product obtained from the distillation or partial combustion of bituminous coal in ovens or retorts which constitutes a fuel suitable for the blast furnace or foundry is the only coke considered in this series of reports. "Gas-house" coke is not included.

1,663; in 1912, at the end of the second decade, there were 5,211 such ovens, and in 1913 they numbered 5,688. The increase in the number of retort ovens from 1912 to 1913 was 477, whereas the total number of ovens increased 420, from 102,230 to 102,650. As will be shown later, however, many thousands of the beehive ovens were idle in 1913, more than half of them probably for the whole time, whereas all but 157 of the completed retort ovens were in operation. There were 1,321 new ovens building at the close of 1913, of which 504 were of the by-product type. The output of the by-product ovens in 1913 represented 27.5 per cent of the total coke production of the United States. In 1912 it represented a little more than 25 per cent, and in 1911 22.1 per cent.

The evolution in coke making which is shown to be in process of accomplishment by the figures presented in the following pages is not only in the steady substitution of the retort oven, and its recovery of the valuable contents of the coal other than coke, for the wasteful beehive; it means also the shifting of the coke-making industry from the vicinity of the mines to the centers of manufacture and population, where the gas may be utilized and the other by-products disposed of at a profit. The extent to which this shifting of the coke-making industry has already taken place is evinced by the statistics of production in West Virginia where there are few coke consuming enterprises. From the time the industry was first started in that State the larger part of the product has been shipped to furnaces in other States. The production of coke in West Virginia in 1913 showed an insignificant gain over 1912, and the industry has not only shown no progress during the last 10 years but has materially declined. The quantity of West Virginia coal used in the manufacture of coke, however, has materially increased, but the ovens at which the coal is used are at points in other States, and most of them are of the by-product or retort type. Returns to the Survey for 1913 show that the quantity of West Virginia coal made into coke outside of the State in that year was 7,546,674 tons, or nearly twice as much as the coal made into coke at ovens within the State. Another evidence of this marked change is that of the 17,826 ovens in West Virginia in 1913, 9,129 were idle the entire year and many others for a portion of the year.

In spite of the progress made in the last few years in the manufacture of coke in by-product ovens the United States is still much behind some European countries in this regard. In Germany and Belgium the retort oven is the only one used, the beehive having been discarded years ago. One of the reasons for the somewhat tardy development in the United States is peculiar, being nothing less than the well-grounded apprehension as to the early exhaustion of the Connellsville coal. Because of the limited span of life yet remaining to the Connellsville region, the owners and operators in that district have not felt disposed to throw away the capital already invested in the beehive ovens that have made the Connellsville district notorious and the coke famous.

PRODUCTION.

STATISTICS OF PRODUCTION IN 1913.

The production of coke in the United States in 1913 exceeded all previous records in both quantity and value, and amounted to 46,299,530 short tons, valued at $128,922,273. Compared with 1912, when the production was 43,983,599 short tons, valued at $111,-805,113, the output in 1913 showed an increase of 2,315,931 tons, or 5.3 per cent, in quantity and of $17,117,160, or 15.3 per cent, in value. The statistics for 1913 established a new record not only in quantity and value of output but in the average value per ton for the product. In 1907, when the prolonged strike in the anthracite region of Pennsylvania created a fuel famine in the Eastern States, the prices for coke were advanced and the average value per ton for the year was $2.74, the highest figure reached since this series of reports has been published until 1913, when the average value was $2.78 per ton. The reasons for the higher value in 1913 were two-fold. The first was that the revival which developed in the latter part of 1912 continued into January and contracts for delivery during the rest of the year were made at prices double those at the same period in 1912. The second and more stable reason for the higher value in 1913 was the notable increase in the production of retort oven coke, which, however, for reasons explained later on, does not necessarily involve any increased cost to the consumer. Nor did the higher value in 1913 even for beehive coke represent an equivalent increase of profit to the producers. The total value of the product in 1913, as already stated, showed a gain of $17,117,160 over 1912, and of this amount $6,004,922 was the increase in the value of retort coke. The value of the coal made into coke in 1913 exceeded the value of the coal used in 1912 by $13,642,487, the difference between the value of the coke made in 1913 and the coal used being $3,474,673, and as the increase in the quantity of coke produced was 2,315,931 short tons, it appears that the actual returns to the producers were relatively less in 1913 than in 1912. The value of the coal per ton of coke produced was $1.98 in 1912 and $2.17 in 1913. Of the 46,299,530 tons of coke made in 1913 in the United States, 33,584,830 tons were beehive or "oven" coke, valued at $80,284,421, and 12,714,700 tons, valued at $48,637,852, were by-product or "retort" coke. In 1912 the production of oven coke was 32,868,435 tons, valued at $69,172,183, and that of retort coke was 11,115,164 tons, valued at $42,632,930. From this it appears that nearly 70 per cent of the entire increase in the quantity of coke produced in 1913 was in the output of retort coke.

The increase in the production of retort coke in 1913 was 1,599,536 short tons, or 14.4 per cent; the beehive output increased 716,395 short tons, or 2.2 per cent. The production of beehive coke in 1913, although exceeding that of 1912 by 716,395 short tons and that of 1911 by 5,881,186 tons, was still nearly 1,000,000 tons short of the maximum production in 1910. The output of retort coke in 1913, however, exceeded that of 1910 by over 5,500,000 tons, or nearly 80 per cent.

With the exception of one year (1908) the production of by-product coke has increased each year since the first ovens were completed at Syracuse, N. Y., in 1893. The percentage of by-product coke to the total in 1901 was 5.4; in 1910 it was 17.1; in 1912 it was 25.3; and in 1913 it was 27.5. The value of the oven coke in 1913 exceeded that of 1912 by $11,112,238, or 16.1 per cent, while the increase in the value of the retort coke was $6,004,922, or 14.1 per cent.

The average value per ton for oven coke in 1913 was $2.39 against $2.10 in 1912. The average price for retort coke was $3.82 in 1913 as compared with $3.84 in 1912. As explained in previous reports, the higher value of retort coke is due not to the superior quality of that product but to the fact that the retort ovens are located at considerable distances from the coal mines and at or near the centers of consumption where markets for the gas and other by-products as well as for the coke are available. In such cases the expenses of transportation are borne by the coal and are added to the value of the coal as charged into the ovens. An equivalent value is necessarily added to the coke. The beehive and similar types of ovens are, on the other hand, located in the immediate vicinity of the mines and the expenses of transportation are borne by the coke, and the ultimate consumer pays as much for his beehive coke as for the apparently higher-valued retort coke.

Connellsville coke has for many years been the standard furnace coke of the United States and the Connellsville region is the only one for which weekly reports as to the trade conditions are made to the technical journals. The Connellsville Courier presents each week a comprehensive review of conditions affecting the demand and the prices for the commodity which has been the mainstay of the region. From its weekly reviews the following summary of the trade in 1913 has been extracted.

The year opened with the market quiet but firm, with spot furnace coke quoted at $4 a ton, though a few sales were made early in January at $4.15 and $4.25. Contracts for future delivery were made at $3.25 to $3.50 for the first six months, and at $3 to $3.25 for the second half of the year. Production was heavy during the month, and before the first of February prices for prompt delivery had dropped 50 cents a ton, though contract prices were held firm. Early in February, with a decided dullness in the iron trade in evidence, production was still maintained at high-water mark, and the price for prompt furnace coke dropped to $2.50, a decline of $1.50 in less than a month. Contract purchasers were conspicuous by their absence, though prices for future delivery were quoted nominally at $2.25 to $2.50. Prices for foundry coke were held a little more firmly, though this grade, which early in the year sold at from $4.25 to $4.50 for prompt delivery, was quoted at $3.25 to $3.50 by the end of February. Notwithstanding the declines in price, production held up until the last half of March, when the unprecedented floods in the Ohio Valley caused a sharp reduction in output. In April both spot and contract furnace coke were quoted at $2.25, and foundry coke at $3 to $3.50. In the latter half of April, when the railroads had effected the repairs to their roadbeds and tracks, production returned to normal figures and prices assumed a firmer tone, but without any advances. During May there was a temporary slump in the trade and producers experienced some difficulty in maintaining the price at $2.25 for spot coke; and in June some coke was sold as low as $2.10 while buyers were trying to beat it down to $2. Contract furnace coke was firmly held at $2.50, with foundry coke at $2.75 to $3. During the summer months production was kept down to market requirements and the price for spot furnace coke was maintained at $2.50, contracts for delivery during the last half of the year being made at the same figure until October, when a depression in the iron trade developed which continued through the rest of the year and in sympathy with which coke prices rapidly declined until in November prompt furnace coke was quoted as low as $1.85. From then until the end of the year spot furnace coke was quoted at $1.75 to $2, and producers were fighting as hard for $2 on contracts for delivery in the first half of 1914 as they were six months before for $2.50 on contracts for the last half of 1913.

A considerable proportion of the coke production of the United States is made in ovens or retorts operated by large corporations which not only mine the coal and make the coke but also operate blast furnaces and steel mills, which consume the entire product of the ovens. In such cases the fixing of a value upon the coke and upon the coal consumed in its making is purely arbitrary. By some corporations the coke is charged to the furnace department at cost, while by others a percentage of profit is added or the reported value is based on what it would cost if purchased. As the beehive ovens are gradually replaced by the retorts the proportion of the coke upon which the arbitrary values are fixed will increase, as the retort ovens are for the most part constructed by or for furnace operators and the product of the ovens does not go to the general markets. It must not be considered, therefore, that the values as stated in this and other reports of the series represent the actual selling value of all the coke, but they are sufficiently exact for statistical comparison.

The coal consumed in the manufacture of coke in 1913 was 69,239,190 short tons, valued at $100,561,439, against 65,577,862 short tons, valued at $86,918,952, in 1912. The value of the coke made in 1913 was $128,922,273, the difference between the value of the coal and the coke made from it being $28,360,834, which, less the cost of manufacture and expenses of administration, represents the profit on the coke-making operations. In 1912 the value of the coke was $111,805,113, and the difference between that and the value of the coal was $24,886,160. The difference between 1913 and 1912 of the excess in the value of the coke over the value of the coal used was $3,474,673, but as the quantity of coke produced in 1913 over 1912 was 2,315,931 tons it might be said that the excess in product in 1913 was valued at only about $1.50 per ton, whereas the average value for all the coke produced was $2.78.

At the close of 1912 there were fewer ovens in existence in the United States than at the beginning of that year, the number of ovens abandoned having exceeded the number of new ovens constructed. During that year there were 22 entire plants with a total of 1,529 ovens abandoned, in addition to which there were 2,648 ovens, portions of other plants that were torn down. All but 26 of the 4,177 ovens abandoned in 1912 were of the beehive type. The 26 exceptions were Rothberg ovens, 1 in New York and 25 in Ohio, which were really experimental installations and did not produce satisfactory results. At the close of 1913 there was a net increase of 420 in the total number of ovens in existence, although 2,833 ovens, all of the beehive type, had been abandoned during the year. There were 477 retorts constructed during the year, so that the new installations of the beehive or partial combustion type aggregated 2,776 ovens. These do not include a few small installations which were built in 1913 but not put into blast. The total number of ovens and retorts in operation in the United States increased from 102,230 to 102,650, a net gain of 420. As the retorts show an increase of 477, there was a net decrease of 57 in the number of beehive ovens in existence during 1913 as compared with 1912. Most of the new ovens of the partial combustion type added in 1913 were the Mitchell or rectangular ovens which have met with considerable favor, particularly in the Lower Connellsville district of Pennsylvania. In addition to the ovens abandoned during 1913 (and most of these had been idle for a number of years) there were 30,642 idle, of which 157 were retorts and 30,485 were beehive ovens, most of which had not been in operation for several years. The 30,485 idle beehive ovens included 11,347 which were the entire equipment of 107 idle establishments. All of the idle retorts were portions of plants which were in operation during the year and were idle largely because of the making of necessary repairs and alterations. The statement regarding the number of idle ovens refers only to those which were idle during the entire year. It does not include any ovens which were idle during a portion of the time only and which contributed to the output in 1913. The number of ovens and retorts in blast during the whole or a portion of 1913 was 72,008, as compared with 73,058 active ovens and retorts in 1912. The 72,008 active ovens and retorts in 1913 included 5,531 retorts and 66,477 of the beehive or partial combustion type. As the 5,531 retorts produced a total of 12,714,700 tons of coke, the average production for each retort was therefore practically 2,300 tons. The 66,477 active beehive ovens produced a total of 33,584,830 tons of coke, or an average of 505 tons per oven. In 1912 there were 5,211 retorts which produced an average of 2,133 tons per oven, and 67,847 beehive or partial combustion ovens which produced an average of 484 tons per oven. The average value per oven of the coke produced in active beehive ovens in 1913 was $1,208, and the average value per oven of the coke and by-products produced at retort ovens was $11,854, or nearly 10 times the average value of the beehive production. The new ovens in course of construction at the close of 1913 were 1,321, of which 504 were retorts and 817 beehive.

The tendency to consolidation into larger units is exhibited in the manufacture of coke as in other branches of industry, and the number of coke-making establishments has shown a steady decrease since 1909, when, on December 31, there were 579 coke-making establishments in the United States. At the close of 1910 the number of establishments had decreased to 578, at the close of 1911 to 570, and in 1912 to 559, and a further decrease to 551 on December 31, 1913, is shown. Some of these establishments have been entirely abandoned, and some, fewer in number, have been consolidated with others All of the establishments gone out of existence are relatively small and the ovens have not been in operation in the last few years. There were 6 new plants with a total of 434 ovens under construction at the close of 1913. Three of the new establishments, with a total of 214 ovens, were retort-oven plants.

The statistics of production of coke in 1912 and 1913 are presented, by States, in the following table:

Manufacture of coke, by States, in 1912 and 1913.

1912.

State.	Establishments.	Ovens. Built.	Ovens. Building.	Coal used (short tons).	Yield of coal in coke (per cent).	Coke produced (short tons).	Total value of coke.	Value of coke per ton.

PRODUCTION IN PREVIOUS YEARS.

The earliest use of coke in the United States of which there is any record is reported by the late James M. Swank[1] as having been made in a refinery at Plumsock, Fayette County, Pa., as early as 1817. This

[1] Iron in all ages, p. 201, 1892.

however does not seem to have awakened much interest in coke as a fuel, as in 1835 an offer of a gold medal was made by the Franklin Institute to anyone who would make iron with bituminous coal or coke made from bituminous coal. The medal was never claimed. In 1837 it appears that the manufacture and use of coke was attempted at a number of different but somewhat widely separated points in the United States, namely, by the Creek Coal Co. in the Richmond Basin of Virginia; at Tallmadge in Summit County, Ohio,[1] for use in the blast furnaces at Akron, and at Coke Oven Hollow, Parke County, Ind., for use in local foundries. According to Fulton[2] 100 tons of pig iron were made in the same year with coke as fuel by F. H. Oliphant at Fairchance in Fayette County. Mr. Swank states also that William Fernstone was the first to succeed in making iron with coke at the Mary Ann furnace in Huntingdon County, Pa. Another authority [3] states that the Lonaconing furnace in Maryland in 1837 was the first in the country to use coke with entire commercial success. This furnace continued in operation for many years. In 1841 two carpenters, Provence McCormich and James Campbell, learned that coke might be made from the coal in what is now the Connellsville region. They succeeded in interesting with them John Taylor, a stone mason, who owned a tract of coal land and who was engaged in mining. The three formed a partnership, the mason to build the coke ovens and the two carpenters to build boats to float the coke down the river to Cincinnati, and in the spring of 1842 they with the two arks reached Cincinnati safely with about 40 tons of coke. Here, to their disappointment, they found that the furnacemen were unfamiliar with coke as a furnace fuel and would not use it. The partners traded a large part of their cargo at an unprofitable rate and shipped the remainder by canal boat to Dayton, where Judge Gebhardt used the new fuel and discovered its superiority for iron making.[4] The use of coke did not grow rapidly in favor and did not begin to exert an appreciable influence on the manufacture of pig iron until the latter half of the nineteenth century. The Seventh Census of the United States, 1850, reported 4 establishments engaged in the manufacture of coke, but gave no information regarding the quantity or value of the coke produced. At the Eighth Census in 1860 there were 21 coke-making establishments, and in 1870, according to the Ninth Census, there were 25 establishments, but in neither of these, as at the taking of the Seventh Census, were any figures of production given. Mr. Swank is authority for the statement that it was not until 1875 that the quantity of pig iron made with coke exceeded that made with anthracite, the latter having held the supremacy for 20 years, or since it exceeded charcoal in 1855. At the present time the use of anthracite for blast-furnace fuel is negligible; when used at all it is usually mixed with coke. Some bituminous, also mixed with coke, is used in blast furnaces in Ohio and Indiana, but the quantity compared with the use of coke alone is small. Charcoal is still used to a limited extent for the manufacture of special irons, but even for this purpose its use is steadily decreasing.

[2] Fulton, John, Treatise on coke.
[3] Ninth United States Census, Industry and Wealth, p. 77.
[4] Am. Inst. Min. Eng. Trans., vol. 13, p. 330.

The first record of the quantity of coke made in the United States was in 1880, when, according to the report of the Tenth United States Census, the production is stated to have been 3,338,300 short tons. The annual production since 1880 has been published in this series of reports, the present chapter completing the record of 34 years, which is shown in the following table:

Quantity of coke produced in the United States, 1880–1913, in short tons.

1880	3,338,300	1892	12,010,829	1904	23,661,106
1881	4,113,760	1893	9,477,580	1905	32,231,129
1882	4,793,321	1894	9,203,632	1906	36,401,217
1883	5,464,721	1895	13,333,714	1907	40,779,564
1884	4,873,805	1896	11,788,773	1908	26,033,518
1885	5,106,696	1897	13,288,984	1909	39,315,065
1886	6,845,369	1898	16,047,209	1910	41,708,810
1887	7,611,705	1899	19,668,569	1911	35,551,489
1888	8,540,030	1900	20,533,348	1912	43,983,599
1889	10,258,022	1901	21,795,883	1913	46,299,530
1890	11,508,021	1902	25,401,730		
1891	10,352,688	1903	25,274,281		

Of the 15 coke-producing States for which the statistics may be separately published, there were 9 in which the production increased in 1913 and 6 in which the output decreased. Somewhat more than half the total increase was in Pennsylvania, which showed an increase of 1,314,751 short tons out of a total gain of 2,315,931 tons. The largest percentage of increase in 1913, as in 1912, was in Kentucky, whose output showed a gain of 125,529 short tons, or 65.5 per cent, largely due to the operations of the new plant of Semet-Solvay ovens at Ashland. The second in quantity of increase was Alabama, which gained 348,175 short tons, or 11.7 per cent, and here also the gain was altogether in the output of by-product coke. Virginia, whose production is entirely from beehive ovens, showed a gain of 335,656 short tons, or 34.7 per cent. Second in percentage of increase was the State of Washington, whose production in 1913 showed a gain of nearly 55 per cent over 1912. West Virginia, next to Pennsylvania in the quantity of coking coal produced, barely escaped a decrease in the production of coke in 1913, with a gain over 1912 of 4,766 short tons, or a very small fraction of 1 per cent. The principal decreases in the production of coke in 1913 were shown by Colorado and Ohio, the former being due to labor disturbances in Las Animas County, and the second to floods in the spring and droughts in the summer and early fall.

In the following table is shown the production of coke by States during the last five years, with the increase and decrease in 1913 as compared with 1912:

Quantity of coke produced in the United States, 1909–1913, by States, in short tons, with increase and decrease in 1913.

State.	1909	1910	1911	1912	1913	Increase (+) or decrease (—) in quantity of coke produced.	
						1912-13	Percentage.
Alabama	3,085,824	3,249,027	2,761,521	2,975,489	3,323,664	+ 348,175	+11.7

VALUE OF COKE PRODUCED.

As has already been indicated prices for coke during 1913 averaged higher than in any of the 33 preceding years covered by this series of reports, and values in every State, with the exceptions of Kentucky, Ohio, and Tennessee, showed a large percentage of gain or less percentage of loss than in the quantity of coke produced. There were five States that showed decrease in production in 1913 as compared with 1912, but in two of these, Georgia and New York, the value showed a gain. A part of the larger increase in value in 1913 was due to the larger production of retort coke, notwithstanding that in this item itself there was a slight falling off in the unit value, due to a greater proportionate increase in production from retort ovens nearer the coal mines than from those more distant. Aside from the larger production of retort coke, however, there was a substantial advance in values for beehive coke, particularly during the first part of the year, and, although prices steadily and persistently declined after January, enough coke had been contracted for in that month to make the average for the year the best on record. The average value for beehive coke in 1913 was higher than in any year prior to 1902, or before the output of retort coke began to influence the general averages.

The total value of the coke produced in the United States increased from $111,805,113 in 1912 to $128,922,273 in 1913, a gain of $17,117,-160, or 15.3 per cent. The percentage of increase in production was 5.3. Two-thirds of the total increase in value was made in Pennsylvania, whose production in 1913 was valued at $11,593,609 more than that of 1912. Alabama was second in the amount of increased value, with a gain of $1,528,758, practically all of it being due to the larger production of retort coke. West Virginia, with a negligible increase in quantity, showed a gain of $812,023, or 17.3 per cent, in value. The value of Virginia's production increased $1,024,300, or 56.4 per cent (the largest percentage of gain in value for any of the States); the value of Indiana coke increased $650,000; and Illinois showed a gain of nearly $525,000. Next to Virginia the largest percentage of increase was in the State of Washington, the value of whose coke production in 1913 showed a gain of 55 per cent. Kentucky ranked third in this regard, with a gain of 46.7 per cent. The value of the retort coke produced in 1913 was $48,637,852, a gain of $6,004,922, or 14.1 per cent over 1912, and that of oven, or beehive coke, was $80,284,421, a gain of $11,112,238, or 16.1 per cent. In quantity retort coke showed a gain of 14.4 per cent and oven coke increased 2.2 per cent.

In the following tables are presented statements showing the value of the coke produced in the several States for the last five years, with the amount and percentage of increase and decrease in 1913 as compared with 1912, and the total value of the coke produced in the United States in each year since 1880:

Total value, at the ovens, of the coke made in the United States, 1909–1913, by States, with increase and decrease in 1913.

State.	1909	1910	1911	1912	1913	Increase (+) or decrease (−) in value of coke produced.

1891	20,393,216	1903	66,498,664		

In the following table is shown the average price per ton, by States, during the last five years and the general average price per ton in the United States for each year since 1880. These averages are not the averages of the prices themselves, but are obtained by dividing the total quantity of coke produced into the total value in each State, with the same method for the total for the United States. The figures represent, therefore, the average values obtained rather than the averages of prices, and accordingly represent more accurately the returns obtained by the producers. As has already been explained, the values of the product as reported to the Survey do not always represent actual cash or its equivalent received by the coke producers, as some of the largest operations are carried on in connection with blast furnaces or other manufacturing enterprises, and the placing of value upon the coke produced by them is purely arbitrary. As the same methods of valuation at any one point are, however, employed each year, they would not affect materially the changes due to market conditions, and the statement of value per ton may be accepted as indicating pretty closely the relations of supply and demand.

The average value of coke, by States, from 1909 to 1913, inclusive, is shown in the following table:

Average value per short ton, at the ovens, of the coke made in the United States, 1909–1913, by States.

State.	1909	1910	1911	1912	1913
Alabama	$2.61	$2.82	$2.75	$2.72	$2.90

Average	2.29	2.39	2.37	2.54	2.78

[a] Includes Utah.
[b] Included in other States having less than three producers.
[c] Included with Colorado.

The following table, showing the general average value per ton during a period of 34 years, is of particular interest as indicating the higher values that have obtained since the beginning of the present century. In only three years prior to 1901 did the general average value of coke per ton exceed $2, and one of these was the last year of the nineteenth century. In the other two years the average value per ton exceeded $2 by 1 cent and 2 cents, respectively. On the other hand, in only one year since and including 1901 has the average value of coke per ton fallen below $2 and in five years it has exceeded $2.50 per ton, reaching a maximum of $2.78 in 1913. From 1880 to 1890 the mean average value of coke per ton was $1.71, from 1891 to 1900 it was $1.76, and from 1901 to 1913 it was $2.41.

Average value per short ton, at the ovens, of the coke made in the United States, 1880–1913.

1880	$1.99	1892	$1.96	1904	$1.95
1881	1.88	1893	1.74	1905	2.25
1882	1.77	1894	1.34	1906	2.52
1883	1.49	1895	1.44	1907	2.74
1884	1.49	1896	1.84	1908	2.40
1885	1.49	1897	1.66	1909	2.29
1886	1.63	1898	1.59	1910	2.39
1887	2.01	1899	1.76	1911	2.37
1888	1.46	1900	2.31	1912	2.54
1889	1.62	1901	2.04	1913	2.78
1890	2.02	1902	2.49		
1891	1.97	1903	2.63		

The higher values shown in the later years were due in part, but not entirely, to the influence exerted by the increasing production of retort coke. The average price of beehive coke, which is more of a commercial product than the retort coke, has been much better maintained in the last few years than in the preceding century, and since 1908 the average value for beehive coke has not fallen below $2 per ton. Since 1908 the average value per ton for retort coke has ranged from $1.17 to $1.74 higher than beehive, this difference representing the transportation expenses on the coal from the mines to the ovens. In 1913 for the first time in eight years there was a decline in the average value of retort coke, but the decline was negligible—from $3.84 to $3.82. The average value per ton for beehive coke advanced from $2.10 to $2.39 and the mean average advanced from $2.54 to $2.78.

Comparative average values of beehive (oven) and by-product (retort) coke, 1908–1913, per short ton.

Year.	Beehive.	By-product.	Mean average.
1908	$2.20	$3.44	$2.40
1909	2.10	3.27	2.29
1910	2.17	3.47	2.39
1911	2.05	3.48	2.37
1912	2.10	3.84	2.54
1913	2.39	3.82	2.78

NUMBER OF COKE WORKS AND OVENS IN THE UNITED STATES.

In compiling the statistics of coke manufacture each bank of ovens is considered as a separate establishment, although in many cases these different establishments form a part only of one property and are reported from a central office. Different plants controlled or operated by one company are considered as much separate establishments as are the individual banks of ovens owned and operated by one firm or corporation. In 1913, notwithstanding the largely increased production of coke, the number of establishments and of ovens abandoned exceeded the number of plants and of ovens of new construction. There were 22 establishments abandoned and 14 new plants built, reducing the total number of plants from 559 to 551. The 22 dismantled plants had a total of 1,978 ovens. Most of these plants, it should be stated, had been idle for several years, and as they had an average of less than 90 ovens to a plant they were for the most part small plants. In addition to the 1,978 ovens contained in the 22 abandoned plants, there were 855 ovens, portions of operating plants, that were dismantled, making a total of 2,833 ovens abandoned during 1913. Of the 22 establishments abandoned 7 were in Pennsylvania, 6 in West Virginia, 2 each in Illinois, Kentucky, and Oklahoma, and 1 each in Indiana, Maryland, and Montana. There were 107 establishments with a total of 11,504 ovens that were idle during the year, and 19,138 ovens, portions of other plants, that were not in blast, making a total of 30,642 idle ovens. In 1912 there were 120 idle establishments and a total of 29,172 idle ovens. The number of plants in operation in 1913 was 444 against 439 in 1912, and the number of active ovens was 72,008 against

73,058. The number of active ovens for each plant was 162 in 1913 and 166 in 1912. The 107 idle plants in 1913 averaged 108 ovens to the plant. The 444 active establishments in 1913 produced 46,299,530 tons of coke or an average of a little over 100,000 tons to the plant. The concentration of the coking industry into comparatively large units has progressed markedly in recent years, as indicated by the fact that in 1880 there were 186 establishments which produced a total of 3,338,300 tons, an average of 17,948 tons to an establishment; the average production of each establishment in 1913 was more than six times the average of 1880. In 1880 there were 12,372 ovens in existence, an average of 67 to the establishment; in 1913 the average number of ovens to the establishment, including idle as well as active ovens, was 186. If instead of the number of plants the number of operating firms and corporations were considered as the unit, the concentration would appear to have been even more pronounced. An essential feature, however, in the increase in the average production per establishment and per oven during recent years has been the output from the growing number of by-product plants. In 1913 there were 5,531 active retort ovens in operation, with an average of 2,299 tons of production per oven.

The total number of establishments manufacturing coke in the United States at the end of each decade from 1850 to 1910, and at the end of each year since 1910, is shown in the following table. The numbers reported in 1850, 1860, and 1870 are for the census years; the others are for calendar years.

Number of coke establishments in the United States since 1850.

1850 (census year)	4	1890, Dec. 31	253	1911, Dec. 31	570
1860 (census year)	21	1900, Dec. 31	396	1912, Dec. 31	559
1870 (census year)	25	1910, Dec. 31	578	1913, Dec. 31	551
1880, Dec. 31	186				

The following table shows the number of coke ovens in existence in each State on December 31 for each of the last five years:

Number of coke ovens in each State at close of each year, 1909–1913.

State.	1909	1910	1911	1912	1913

Total	107	11,504	30,642	22	1,978	2,833	6	434	1,321

Number of coke ovens in the United States on Dec. 31 of each fifth year, from 1880 to 1913.

1880	12,372	1900	58,484	1911	103,879
1885	20,116	1905	87,564	1912	102,230
1890	37,158	1910	104,440	1913	102,650
1895	45,565				

A statement of the number of ovens in course of construction at the end of each year since 1907 is shown in the following table. It is not intended by this to show the increase in the number of new ovens from year to year, nor does it include the number of new ovens completed during any one year. It merely exhibits the condition of the industry as shown by plants under construction at the close of each year.

Number of coke ovens building in the United States at the close of each year, 1907–1913.

1907	2,546	1910	2,567	1912	2,783
1908	2,241	1911	2,254	1913	1,321
1909	2,950				

RANK OF COKE-PRODUCING STATES.

The record of coke production in 1913 effected few changes in the relative importance of the States in connection with that industry. Virginia superseded Colorado as sixth in rank, but with that exception the first 12 States held the same position in 1913 as in 1912. Pennsylvania, of course, stands preeminently first, with Alabama second, Indiana third, and West Virginia fourth, but if all the coke made from West Virginia coal were produced in that State it would be well fixed in second place, as by far the larger part of the coke manufactured in Ohio, Indiana, and Illinois is from West Virginia coal. As, however, the production of coke in retort ovens at or near the points of consumption is likely to continue to increase in greater proportion and the beehive ovens to disappear gradually from the mining regions, it is not probable that West Virginia will again assume its former importance as a coke-producing State. The quantity of coke made in West Virginia in 1913 was less than one-half of that made from West Virginia coal in ovens outside the State.

Among the less important States, Ohio gave place to Tennessee as thirteenth in rank, Kentucky advanced from eighteenth to sixteenth place, and Maryland, because of alterations in the plant of the Maryland Steel Co., at Sparrows Point, dropped from sixteenth to eighteenth place. The only other change was the dropping of Kansas from the list. The positions held by the coke-producing States are shown in the following table:

Rank of the States in production of coke, 1909–1913.

State.	1909	1910	1911	1912	1913	State.	1909	1910	1911	1912	1913

COAL CONSUMED IN THE MANUFACTURE OF COKE.

The following tables present a statement of the quantity of coal consumed in the manufacture of coke in the several States during the last five years and the total quantity used each five years since 1880. In former years the determination of the quantity of coal consumed was largely a matter of estimate, and there were few establishments where that factor was accurately ascertained; but in the making of coke, as in other branches of industry, greater exactness is now demanded, and there are relatively few large plants where the coal is not carefully weighed before being charged into the ovens, and the yield thus determined. At the retort ovens it is doubtful if any coal is charged without being first weighed or measured.

A considerable quantity of the coal which is not run directly from the mines to the ovens is crushed and washed before coking. In such cases it has been the practice to ascertain for this report the quantity of cleaned coal obtained from washing operations, and to consider that as the oven charge. As explained in previous reports of this series, the quantity of coal consumed in making coke stated in this chapter is at considerable variance with the quantity reported as made into coke in the chapter on the production of coal. The reason for this discrepancy is that in the chapter on the production of coal the quantity made into coke takes into account only that coal which is coked at the mines. The coal shipped to ovens at a distance is included in the shipments, and not in the quantity made into coke. The total quantity of coal made into coke in 1913 was 69,239,190 short tons. The coal-mine operators reported 49,458,320 tons made into coke at the mines.

The quantity of coal used in the manufacture of coke, as obtained for this report from the several States, from 1909 to 1913, and the quantity used during each fifth year since 1880, are shown in the following tables:

Quantity of coal used in the manufacture of coke in the United States, 1909–1913, by States, in short tons.

State.	1909	1910	1911	1912	1913

[a] Included coal coked in Utah.
[b] Included in other States having less than three producers.
[c] Included with Colorado.

Quantity of coal used in the manufacture of coke in the United States each fifth year, 1880–1913.

	Short tons.		Short tons.		Short tons.
1880	5,237,741	1900	32,113,543	1912	65,577,862
1885	8,071,126	1905	49,530,677	1913	69,239,190
1890	18,005,209	1910	63,088,327		
1895	20,848,323	1911	53,278,248		

VALUE OF COAL USED IN MAKING COKE.

The statistics of coke production presented in the earlier pages of this report show that the value of the coke made in 1913 exceeded that of the preceding year by $17,117,160, or 15.3 per cent, and as the increase in the quantity of coke produced was 2,315,931 short tons, or only 5.3 per cent, it appears at first sight that the industry in 1913 was much more profitable than in 1912. In making these comparisons, however, the value or cost of the coal used should also be given consideration, and when that is done for 1913 the vision of larger profits fades away. The quantity of coal consumed in the manufacture of coke in 1913 was 69,239,190 short tons, valued at $100,561,439, against 65,577,862 tons, valued at $86,918,952, in 1912. The coal used in 1913, therefore, cost the coke producers $13,642,487 more than in 1912, so that the actual gain in the value of the coke over and above the increase in the value of the coal used was only $3,474,673, or at the rate of $1.50 per ton for the amount of increase in coke. The average value per ton of the coal used in 1913 was $1.45, against $1.33 in 1912. The value of the coal per ton of coke produced was $2.17 in 1913, and $1.98 in 1912. The cost of the coal charged into the ovens in 1913 was accordingly 19 cents more per ton of coke produced than it was in 1912, and the average value per ton of coke produced showed a gain of 24 cents, indicating a net gain of 5 cents per ton for the product of 1913.

The total quantity and value of the coal consumed in the manufacture of coke in 1912 and 1913, with the quantity and value of the coal consumed per ton of coke produced, by States, are shown in the following table:

Quantity and value of coal used in the manufacture of coke in the United States in 1912 and 1913, and quantity and value of same per ton of coke, by States.

1912.

State.	Coal used (short tons).	Total value of coal.	Value of coal per ton.	Quantity of coal per ton of coke (short tons).	Value of coal to a ton of coke.

[a] Includes Maryland, Massachusetts, Michigan, Minnesota, Utah, and Wisconsin.

The following table shows approximately the quantity of coal (given in tons and pounds) required to produce a ton of coke in 1880, 1890, 1900, and annually since 1901. It will be observed that up to 1903 the quantity of coal required to produce a ton of coke exceeded 3,100 pounds; from 1904 to 1910, inclusive, it was between 3,000 and 3,100 pounds, and for the last three years it has been less than 3,000 pounds, the lowest figure (2,982 pounds) being in 1912.

Coal required to produce a ton of coke, in tons and pounds.

Year.	Tons.	Pounds.	Year.	Tons.	Pounds.
1880	1.57	3,140	1906	1.531	3,062
1890	1.56	3,120	1907	1.519	3,038
1900	1.57	3,140	1908	1.515	3,030
1901	1.57	3,140	1909	1.510	3,020
1902	1.56	3,120	1910	1.513	3,026
1903	1.56	3,120	1911	1.499	2,998
1904	1.544	3,088	1912	1.491	2,982
1905	1.537	3,074	1913	1.496	2,992

YIELD OF COAL IN COKE.

With the decrease since 1903 in the quantity of coal required to produce a ton of coke, shown in the preceding table, the yield of coal in coke has correspondingly increased. In present practice the quantity of coal required per ton of coke is about 160 pounds, or 5 per cent, less than was necessary 10 or 12 years ago, before the operations of retort ovens began to exert any marked influence on the coke-making industry. The yield of coal in coke, to 1901, was generally less than 64 per cent and reached as high as 65 per cent in one year only. It is, indeed, doubtful if in the earlier years the yield of coal in coke was much, if anything, in excess of 60 per cent, as much of the coal used in making coke, particularly at beehive plants, was not accurately weighed, but was frequently estimated from the cubical contents of the larry used in charging the ovens or by the even less reliably accurate method of the number of mine cars sent to the coking plant. In such cases the operators were quite apt to underestimate rather than overestimate the quantity of coal used. Modern practice in beehive as well as in retort ovens is much more exact, and probably more coal is now actually weighed before charging into the ovens than was previously estimated. At the begining of the present century the production of retort or by-product coke became a factor of some importance in the coke-making industry, and it has continued to exercise an increasing influence each year as the proportion of retort coke to the total output has steadily grown. The increasing yield of coal in coke since 1901 is one of the evidences of the influence of retort coke on the trade. From 1902 to 1904, inclusive, the yield of coal in coke was over 64 per cent; in the next three years another 1 per cent was added to the yield; and since 1908 the yield has been 66 per cent or more. In 1912 it reached its maximum of 67.1 per cent, and in 1913 it was 66.9 per cent. Reports to the Survey as to the source of the coal used in retort ovens indicate that the slightly smaller yield in 1913 was due to a smaller proportion of West Virginia coal and a larger proportion of Illinois or Indiana coal at some of the retort-oven plants in those States.

The effect produced on the yield of coal in coke by the retort ovens already constructed is clearly shown in the following table. The entire output of coke in Illinois, Indiana, Maryland, Massachusetts, Michigan, New Jersey, New York, and Wisconsin is from retort ovens, and the yield of coal in coke in 1913 ranged from 69.4 per cent in Maryland to 77.1 per cent in Indiana, whereas the yield in beehive ovens ranged from 51.5 per cent in Georgia to 66.6 per cent in Pennsylvania. An interesting comparison is also exhibited in the increase in the yield of Alabama coal from 60.7 per cent in 1909 to 64.9 per cent in 1912. In the earlier year 17.3 per cent of Alabama's coke was made in retorts, and in 1913 retort coke constituted 60 per cent of the State's total. The average yield of retort coke in the United States in 1913 was 74.4 per cent, and that from beehive ovens was 64.4 per cent. In 1912 the retort coke yield averaged 75.3 per cent and the beehive, 64.7 per cent.

The following tables show the percentage yield of coal in coke in each State during the last five years; and in the United States in each tenth year since 1880, and annually since 1901:

Percentage yield of coal in coke, 1909–1913, by States.

State.	1909	1910	1911	1912	1913
Alabama	60.7	61.6	62.6	64.9	63.6

1903	64.1	1909	66.2		

CONDITION IN WHICH COAL IS CHARGED INTO THE OVENS.

In the following table is to be found a statement of the condition in which the coal is charged into the ovens in the several States for the last two years and for each of the five-year periods since 1890. In a number of the coking districts the principal oven fuel is the slack coal produced in the mining operations. By far the larger quantity, however, is run of mine, some of which is crushed before being charged into the ovens, as in many cases it is found that a better and more uniform quality of coke is obtained when the coal is crushed before coking. Considerable quantities of both mine-run and slack coal are washed before being coked, in order to remove the impurities, consisting of slate, pyrite, etc. In 1913, 19.8 per cent of all the coal charged into the coke ovens was washed and 80.2 per cent was used without other preparation than, in some instances, crushing. The mine-run coal that is crushed before coking is considered as mine-run coal and not as slack.

In Pennsylvania and West Virginia and in the by-product coke-producing States that draw their coal supplies chiefly from Pennsylvania and West Virginia the larger part of the coal used is unwashed. In West Virginia most of the coal used in making coke is unwashed slack, as a majority of the ovens in that State were constructed for the purpose of utilizing the slack. In Pennsylvania and the other States in which unwashed coal is used the greater part of it is run of mine. In Alabama most of the coal used is washed, and nearly two-thirds of the total coal used in the State is washed slack. All of the coal used in Georgia, New Mexico, and Washington is washed, and in the first two it is slack exclusively. In Colorado the larger part of the coal used is washed run of mine, and in Virginia the quantity of coal is nearly evenly divided between run of mine and slack, all of it being unwashed.

In 1913 the total quantity of coal used for making coke was 69,239,190 short tons, of which 54,359,773 tons (49,566,720 tons unwashed and 4,793,053 tons washed) were run of mine and 14,879,417 tons (5,958,173 tons unwashed and 8,921,244 tons washed) were slack. The total quantity of unwashed coal used was 55,524,893 tons and of washed coal was 13,714,297 tons.

The following table shows the quantity of run-of-mine and of slack coal, unwashed and washed, charged into the ovens in 1912 and 1913, by States, with the percentage of each:

Character of coal used in the manufacture of coke, by States, in 1912 and 1913, in short tons.

1912.

COKE MAKING IN BY-PRODUCT OVENS.

In May, 1913, the by-product branch of the coke-making industry in the United States entered its twenty-first year. The first ovens of the retort or by-product recovery type built in this country comprised a plant of 12 Semet-Solvay retorts with recovery apparatus at Syracuse, N. Y. The initial production of coke from that plant, from May to December, 1893, was 12,850 tons. The second by-product plant constructed was one of 60 Otto-Hoffmann ovens, completed in the latter part of 1895, at Johnstown, Pa. The Semet-Solvay plant at Syracuse, which is operated in connection with the chemical works of the Solvay Process Co., has been enlarged three times, 13 ovens being added in 1896, 5 in 1901, and 10 more in 1903. The plant at Johnstown has also been enlarged three times, to 160 ovens in 1899, to 260 in 1904, and to 372 in 1907. Since the first installations at Syracuse and Johnstown the by-product coking industry has grown steadily, the output each year showing a gain in its percentage to the total quantity of coke produced, and in only one year, 1908, showing a decrease in quantity. The decreased output of retort coke in that exceptional year was less in proportion than the decrease in the production of beehive coke. At the close of 1913 there were 38 by-product coke-making establishments distributed among 14 States and having a total equipment of 5,688 retorts. The production of retort coke in 1913 amounted to 12,714,700 short tons, or 27.5 per cent of the total, an increase of 1,599,536 tons, or 14.4 per cent over 1912, when the output of retort coke was 11,115,164 tons, or 25.3 per cent of the total. As shown in the following table, the percentage of by-product coke to the total in 1893 was 0.01 per cent; in 1901 it was 5.4 per cent; and in 1910 it was 17.1 per cent. In addition to the increase in the number of retorts, the installations of the present day are of much larger dimensions and of greater capacity than formerly. The original ovens at Syracuse, N. Y., were 30 feet long, 16 inches wide at one end, 17 inches wide at the other end, and 5 feet 8 inches in height. Their charging capacity was 4.4 short tons of coal and the time required for coking was 24 hours. Even at that time a gain of 50 per cent in coking time was obtained as compared with beehive practice, which requires 48 hours for the production of furnace coke and 72 hours for the production of foundry coke. The present installations of Semet-Solvay ovens are 36 feet 3 inches long, 20 inches wide at one end and 22 inches at the other, and 11 feet 10 inches high, holding at the average about 16 tons of coal. The exact capacity depends, of course, upon the specific gravity of the coals used. The original 60 Otto-Hoffmann ovens erected at Johnstown, Pa., were 33 feet 6 inches long, 6 feet high, 17 inches wide at one end, expanding to 21 inches at the other. These ovens had a charging capacity of about 5½ tons. The latest installations of United-Otto ovens constructed at Mayville, Wis., in 1912 are 34 feet long, 9 feet 1½ inches high, and 17 to 20 inches wide. They have an average capacity of 10.33 tons of coal. The coking time has been materially reduced, so that excellent furnace coke is now made in 16 to 18 hours. The development of modern mechanical appliances has done much to forward the efficiency of the retort oven and to reduce the labor necessary per unit of output. The same crew of men which was required to handle 25 of the small ovens 20 years ago and which were carbonizing, say, 110 tons of coal a day, is now able, with modern equipment, to handle 50 or more of the larger ovens coking 1,000 tons of coal a day. This represents an increase of about ninefold in the tonnage carbonized per man employed. These developments have been accompanied by marked improvements in by-product recovery, in the manufacture of ammonia, etc. Twenty years ago the only ammonia recovered was in the form of crude liquor running from 12 to 15 per cent ammonia. At the present time coking plants are producing ammonia liquor from crude through the different grades required for the manufacture of flameless powder, etc., to the production of almost chemically pure aqua ammonia at one operation. Other plants are manufacturing sulphate either by the old or indirect process or by some of the more direct processes which have lately come into use where the gas itself is first scrubbed in sulphuric acid to recover ammonia after the tar has been removed. Still another marked development in by-product oven practice is in the adaptation of the surplus gas to the illumination of cities and towns. In the earlier days the ovens produced only a small and irregular quantity of surplus gas, which was also irregular in quality. To-day by-product ovens in the United States are selling from 40,000,000 to 50,000,000 cubic feet of gas per day for illuminating purposes. Almost the entire supply of gas in some cities is from retort ovens. Among these cities may be specially mentioned Boston, Mass.; Camden, N. J.; Indianapolis, Ind.; Hamilton, Ohio; Baltimore, Md.; Duluth, Minn.; South Chicago, Ill.; and Milwaukee, Wis.

The 5,088 retorts in existence in the United States at the close of 1913 consisted of 2,186 United-Otto (including Otto-Hoffmann and Schniewind types), 1,537 Semet-Solvay, 1,361 Koppers, 281 Rothberg, 300 Didier, 22 Klönne, and 1 Roberts-Mass. The one Roberts-Mass oven is an experimental retort built at Gary, Ind., by the American Coal & By-products Coke Co. for the purpose of testing the coking qualities of western coals.

For the first 15 years after the first retorts were built at Syracuse the Semet-Solvay and United-Otto (Otto-Hoffmann) ovens held a practically undisputed field in retort-oven practice, the only other installation being a plant of 282 Rothberg ovens built by the Lackawanna Steel Co. in 1904. In 1908 a new contestant for retort-coke business entered the lists by the construction of 140 Koppers ovens at Joliet, Ill., by the Illinois Steel Co. The patentee of this oven, the H. Koppers Co., has pushed the business with all the vigor of youth, and at the end of the first five years after the first plant was completed there were 1,361 of this type of ovens completed, with 334 under construction. Other uncompleted retorts at the close of 1913 were 152 Semet-Solvay and 18 Wilputte, the latter a modification of United-Otto type.

The eventual total displacement of the wasteful beehive oven by the more conservational retort, with the saving of the valuable by-products, is forecasted by the history of the last 21 years. In 1912 there was an actual decrease of 2,236 ovens of the beehive type, compared with 1911, and although there were 2,576 ovens of the beehive or partial-combustion type built in 1913, there were 2,633 abandoned, so that with an increase of 477 in the total number of retort ovens the net increase in the total number over 1912 was only 420 and the number of beehive ovens decreased by 57. Moreover, of the 96,962 ovens of beehive type in existence in 1913, 30,485, or 31.4 per cent, were idle throughout the entire year, and many (probably more than half) of those might as well be reported abandoned, as it is doubtful if they will ever again be put in blast. A large part of the partial-combustion ovens added in 1913 and building at the close of the year consisted of Mitchell or rectangular ovens, which have achieved considerable popularity in the Lower Connellsville district of Pennsylvania, where the greatest activity in that kind of construction had place. In the rectangular oven the process is the same as in that of the beehive, but the coking chamber, instead of being round is, as the name implies, rectangular in shape and oblong, so that the coke may be pushed, as from a retort oven, and does not have to be drawn, as in the case of the beehive. The rectangular oven is, therefore, included with the beehive type. Some reason exists for the persistence of this type of oven in the Connellsville and the Lower Connellsville regions. The coal is an ideal beehive-oven fuel; the ovens are quickly and cheaply constructed, as compared with the outlay in time and money necessary for the construction of by-product retorts and recovery apparatus; the coking districts are within a short distance of the greatest iron-producing center of the world; and the cost of transportation is not an important factor. Moreover, the life of the Connellsville district proper is drawing to an end, and coke-oven owners are not favorably disposed to the sacrifice of the capital invested in them, nor to undertaking the expense of substituting retorts, for the 25 or 30 years left to the region. With the exception of Alabama, which has shown exceptional progress in the substitution of retort for beehive ovens, most of the by-product oven construction has been at points distant from the mines; and if all of the beehive ovens in the Connellsville district were abandoned, the retorts to take their places would be built at the points of consumption and not at Connellsville.

The increase in the production of retort-oven coke compared with that of beehive coke since 1893 is shown in the following table. In the last 10 years, or from 1903 to 1913, the increase in beehive coke has amounted to 33 per cent; that of retort-oven coke has amounted to 575 per cent.

Production of by-product coke, compared with that of beehive coke, with percentage of quantity and value to the total, 1893–1913.

Of the 5,688 retorts which in 1913 produced coke 157 were idle during the entire year, leaving 5,531 retorts that were in operation a whole or a part of the year. As the total production amounted to 12,714,700 short tons, the average production per oven was 2,299 tons of coke, compared with 2,133 tons in 1912, 1,817 tons in 1911, and 1,762 tons in 1910, which shows that the productive capacity of the ovens has increased regularly during the last four years. The average production per active beehive oven was 505 tons in 1913, 484 tons in 1912, 468 tons in 1911, and 376 tons in 1910. The average production from each retort in 1913 was 4.5 times that of the average production from the beehive type. The value of the coke alone considered, the average yield from each retort in 1913 was $8,794, as compared with $8,143 as the average coke value from each retort oven in 1912, and with $1,208 as the average value of the coke produced in the beehive ovens in 1913. If to the value of the coke is added that of the by-products recovered, the average yield from each retort in 1913 was $11,854, compared with $11,265 in 1912. The average total yield in value from each retort in 1913 was 9.8 times the average value of the yield of coke from beehive ovens in 1913. The quantity of coal consumed in the manufacture of coke in retort or by-product ovens was 17,095,369 short tons, which yielded 12,714,700 short tons of coke, indicating an average yield of coal in coke of 74.4 per cent. This was a slight decrease in the percentage of yield as compared with 1912, and appears to have been owing to a larger proportion of Illinois or Indiana coals used in the ovens in those States in 1913 than in 1912. The usual charge at the plants using principally West Virginia coal is 4 parts of West Virginia coal to 1 part of Illinois or Indiana coal. In 1912 the average yield per ton of coal in coke in retort ovens was 75.3 per cent; in 1911 it was 75.1 per cent; in 1910, 74.9; and in 1909, 74.5 per cent—a steady increase from 1909 to 1912 when, for the reasons stated, it dropped to 74.4 per cent in 1913. The average yield of coal in coke in beehive ovens in 1913 was 64.4 per cent, the difference in favor of the retort ovens being 10 points, or 15.5 per cent. The value of the 17,095,369 short tons of coal consumed in coke retorts in 1913 was $41,511,495, or an average of $2.43 per ton, as compared with $2.41 in 1912. The quantity of coal consumed in beehive ovens in 1913 was 52,143,821 short tons, valued at $59,049,944, an average of $1.13 per ton. The difference in the value of the coal used at retort ovens is due to the location of the plants. In beehive practice the ovens are in the vicinity of the mines, from which the coal is delivered directly to the larries, and no transportation expenses are added to the cost of the coal. The retort-oven plants are located at a distance from the mines and near the points of consumption, so that the transportation expenses are added to the value of the coal charged into the ovens.

The value of the by-product coke produced in 1913 was $48,637,852, or an average value per ton of $3.82. In 1912 the average value per ton of retort coke produced was $3.84. As shown in the preceding paragraph, the cost of the coal consumed advanced from $2.41 per ton in 1912 to $2.43 in 1913, and the average value for the coke declined from $3.84 to $3.82. The value of the coal used per ton of coke produced in retorts in 1913 was $3.28, the difference between the value of the coke produced and the coal used being $0.54 per ton, The value of the coal used in beehive ovens per ton of coke was $1.76. the difference between that and the value per ton of coke produced being $0.63. From this it appears that in 1913 the advantage was with the beehive coke. To the value of the coke produced in retort ovens, however, should be added the value of the by-products recovered. This factor in 1913 amounted to $16,925,941, or 35 per cent of the value of the coke produced. In 1912 the value of the by-products was $14,343,795, or 34 per cent of the value of the coke.

The value of the by-products is nearly $1 per ton of the coal used. The by-products consisted in 1913 of 64,553,941 thousand cubic feet of surplus gas, valued at $5,694,691; 115,145,025 gallons of tar; valued at $2,830,158; ammonia in the form of sulphate, ammoniacal liquor, and anhydrous ammonia to a total value of $7,997,513. In addition there were other by-products, principally coke braize, to the value of $403,579.

The total value of the coke, gas, tar, ammonia, and other products produced at by-product recovery ovens during the last three years is shown in the following table:

Value of products obtained in manufacture of coke in retort ovens in 1911, 1912, and 1913.

Product.	1911		1912		1913

[a] Mainly ammoniacal liquor sold on pound basis of NH_3.

The gas included in the foregoing statement is the "surplus" not consumed in the coking process, which is either used at manufacturing establishments operated in connection with the coke-oven plant or sold. At some plants where the surplus gas is consumed by the producing or an affiliated company both the quantity and the value of the surplus gas become a matter of estimate, but the figures as presented are believed to be sufficiently accurate for statistical purposes. The value of the gas furnished to domestic consumers varies from 10 to 50 cents a thousand cubic feet. When the gas is consumed at industrial works operated in connection with the ovens the value is sometimes placed as low as 3 cents a thousand cubic feet. The average value of all the surplus gas in 1913 was 8.8 cents a thousand cubic feet. The lower value of gas produced since 1909, as compared with the preceding years, is due largely to the operations of ovens connected with iron and steel works at Corey, Woodward, and Ensley, in Alabama, Joliet in Illinois, Gary in Indiana, Ashland in Kentucky, Sparrows Point in Maryland, Buffalo and Solvay in New York, Dunbar, South Sharon, Steelton, and Lebanon in Pennsylvania, and Benwood in West Virginia. This factor represented about 70 per cent of the total production.

At the close of 1912 there were 5,211 retort ovens in operation, and 793 were building. The completed ovens consisted of 2,100 United-Otto ovens (including the Otto-Hoffmann and Schniewind types), 1,443 Semet-Solvay, 281 Rothberg, 1,215 Koppers, 150 Didier, and 22 Klönne ovens. At the close of 1913 there were 5,688 ovens in blast, an increase of 477 over 1912. There were 504 ovens building. The new construction added in 1913 consisted of 54 Semet-Solvay ovens, 66 Koppers, and 150 Didier ovens. There were 200 United-Otto ovens abandoned. The ovens building included 334 Koppers ovens, 152 Semet-Solvay ovens, and 18 Wilputte ovens.

The statistical history of by-product coke making in the United States since the first ovens were completed in 1893 is shown in the table following.

Record of by-product coke making, 1893–1913.

Year.	Ovens.		Production (short tons).	Year.	Ovens.		Production (short tons).
	Built.	Building.			Built.	Building.

NOTE.—Of the 15 active plants of Semet-Solvay ovens in the United States in 1913, 2 were operated by the owners, and the other 13 were operated by the Semet-Solvay Co., the coke produced being turned over to the company whose name appears as owner.

IMPORTS AND EXPORTS.

IMPORTS.

The following table gives the quantity and value of coke imported and entered for consumption in the United States from 1908 to 1913, inclusive. In the reports of the Bureau of Foreign and Domestic Commerce, Department of Commerce, from which these figures are obtained, the quantities are expressed in long tons of 2,240 pounds. These have been reduced to short tons in order to make them conform to the standard unit of this report.

Coke imported and entered for consumption in the United States, 1908–1913, in short tons.

Year.	Quantity.	Value.	Year.	Quantity.	Value.
1908	147,427	$606,294	1911	77,923	$254,455
1909	191,253	736,120	1912	123,614	488,398
1910	172,716	625,130	1913	101,212	435,157

EXPORTS.

The quantity of coke exported from the United States increased steadily from 1900 to 1907. Since 1907 the value of the exports has alternately increased and decreased each year, although, with slight fluctuations, they have remained practically stationary during the last five years. The exports in 1913 were slightly greater than in 1912, which in turn were a little less than those of 1911. The exports during the last six years are shown in the following table, the quantities being reduced to short tons:

Coke exported from the United States, 1908–1913, in short tons.

Year.	Quantity.	Value.	Year.	Quantity.	Value.
1908	695,434	$2,161,032	1911	1,023,727	$3,215,990
1909	1,002,916	3,232,673	1912	912,576	3,002,742
1910	984,618	3,053,293	1913	987,395	3,309,930

IMPORTS OF COAL-TAR PRODUCTS.

It has been contended that the development of the by-product coking industry would have shown more rapid progress if markets for the by-products were assured. This contention pertains principally to the coal tar and its products, as there is no difficulty in disposing of the surplus gas, and there is practically at all times a fair demand for ammonia. The total value of domestic coal tar produced in 1913 from retort coke ovens was $2,830,158. No information is available regarding the quantity and value of the products obtained from this tar, as in going to the distillers it becomes mixed with the coal tar from gas-house retorts, and even if the total quantity and value of coal-tar products were obtainable, it would be practically impossible to differentiate those obtained from retort-oven tar from those obtained from gas-house tar. It is interesting to note, however, that the coal-tar products imported into the United States amount to approximately $10,000,000 annually. In 1913 the total value of coal-tar products imported into the United States was $10,962,828, of which colors and dyes made up nearly 80 per cent. On the entire imports duty was obtained to the amount of $2,323,729, making a total value at the port of entry, exclusive of ocean freights, commissions, and other expenses, of $13,286,557. The value of these importations by the time they are in the hands of the consumer is probably between $18,000,000 and $20,000,000. The kinds of coal-tar products imported, the value thereof, and the amount of duty paid on each during the last five years are shown in the following table:

Coal-tar products imported into the United States, 1909–1913.

Year.	Salicylic acid.		Alizarin and colors or dyes, natural and artificial.		Aniline salts.		Coal-tar colors or dyes, not specially provided for.	
	Value.	Duty.	Value.	Duty.	Value.	Duty.	Value.	Duty.
1909			$1,191,874	Free.	$553,503	Free.	$6,431,767	$1,929,530
1910			430,393	Free.	501,369	Free.	5,867,331	1,760,098
1911	$3,480	$915	996,794	Free.	410,193	Free.	6,444,595	1,933,379
1912	9,543	2,469	1,514,344	Free.	354,226	Free.	7,204,453	2,161,336
1913	2,969	613	1,493,840	Free.	323,420	[a] $4,034	7,253,788	2,176,136

Year.	Coal tar, all preparations, not colors or dyes.		Coal-tar products, not medicinal, not dyes, known as benzol, toluol, etc.		Total.	
	Value.	Duty.	Value.	Duty.	Value.	Duty.
1909	$693,608	$138,768	$960,724	Free.	$9,831,476	$2,068,298
1910	594,252	118,849	962,232	Free.	8,355,577	1,878,947
1911	659,407	131,881	1,128,409	Free.	9,642,878	2,066,175
1912	659,305	131,861	998,767	Free.	10,740,638	2,295,666
1913	702,721	131,268	1,186,090	[b] $11,678	10,962,828	2,323,729

[a] Dutiable on and after Oct. 4, 1913.
[b] All products in this class became dutiable on Oct. 4, 1913, except naphthaline, phenol, and cresol.

PRODUCTION BY STATES.

ALABAMA.

The production of coke in Alabama increased from 2,975,489 short tons, valued at $8,098 412, in 1912 to 3,323,664 tons, valued at $9,627,170, in 1913. The gain was 348,175 tons, or 11.7 per cent, in quantity, and $1,528,758, or 18.9 per cent, in value. All of the increased production, and more, was in the output of retort oven or by-product coke. There are in Alabama four retort oven establishments with a total of 700 ovens, and in 1913 those establishments produced 2,022,959 tons of coke, or a little more than 60 per cent of the total output, whereas 22 active beehive plants with an aggregate of 4,135 ovens in blast produced 1,300,705 tons, or a little less than 40 per cent of the total. The average production per oven in the by-product plants was 2,890 tons, and the average production for each beehive oven was 315 tons.

The increase in the production of by-product coke in 1913 over 1912 was 673,162 tons, or nearly double the total increase. The output of beehive coke decreased 324,987 tons. The value of the by-product coke showed an increase of $1,751,538, or $222,780 more than the total increase, the difference representing the decrease in the value of beehive coke. Moreover, the average yield of coal in coke from the retort ovens was 71.4 per cent, whereas the average yield in the beehive ovens was 54.5 per cent. There is not the marked difference in the values of retort and beehive cokes (and in favor of the former) in Alabama as is shown in some States, for in Alabama the retort ovens, like the beehive, are located near the mines, and the two in that respect are somewhat on a parity, whereas in most of the States where retort coke is made the ovens are at considerable distances from the mines, and the transportation charges assessed against the coal are added to the value of the coke. In fact, the Alabama beehive coke had a higher value per ton in 1913 than the retort coke, the averages per ton being $3.38 for beehive coke and $2.58 for retort coke. The explanation of this seeming inconsistency lies in the fact that all of the retort coke is used by the producers in their own furnaces, and the coke is charged to the furnaces at little more than cost, whereas the greater part of the beehive product is commercial coke, some of it for foundry use, and profits are included in the value.

That the beehive oven has had its day in Alabama and is on the decline is evinced by the facts that no new ovens of that type have been built in the last four years and that 20 establishments, with a total of 3,447 ovens, out of a total of 42 establishments, with 9,584 ovens, were idle in 1913, not counting the ovens out of blast at plants that produced some coke in 1913. There were fewer beehive ovens in existence in Alabama in 1913 than in 1908, five years before. The number of retort ovens increased from 620 in 1912 to 700 in 1913, 80 of the 100 ovens of that type reported as in course of construction at the close of 1912 having been completed and put in blast. The 700 completed ovens include 280 Semet-Solvay ovens (240 at Ensley and 40 at Tuscaloosa) and 420 Koppers ovens (280 at Fairfield, formerly known as Corey, and 140 at Woodward). The only new ovens in course of construction at the close of 1913 were 20 Semet-Solvay ovens which were being added to the Tuscaloosa plant.

The production of coke in Alabama in 1880, 1890, 1900, and annually from 1909 to 1913, is shown in the following table:

Statistics of the manufacture of coke in Alabama, 1880–1913.

Year.	Establishments.	Ovens.		Coal used (short tons).	Yield of coal in coke (per cent).	Coke produced (short tons).	Total value of coke at ovens.	Value of coke at ovens per ton.
		Built.	Building.					
1880	4	316	100	106,283	57.0	60,781	$183,063	$3.01
1890	20	4,805	371	1,809,964	59.0	1,072,942	2,589,447	2.41
1900	30	6,529	690	3,582,547	58.9	2,110,837	5,629,423	2.67
1909	43	10,061	0	5,080,764	60.7	3,085,824	8,068,267	2.61
1910	43	10,132	340	5,272,322	61.6	3,249,027	9,165,821	2.82
1911	44	10,121	280	4,411,298	62.6	2,761,521	7,593,594	2.75
1912	46	10,208	100	4,585,498	64.9	2,975,489	8,098,412	2.72
1913	46	[a]10,284	[b]20	5,218,323	63.6	3,323,664	9,627,170	2.90

[a] Includes 280 Semet-Solvay and 420 Koppers ovens.

[b] Semet-Solvay ovens.

More than 80 per cent of the coal used in the manufacture of coke in Alabama is washed before being charged into the ovens. In 1913, out of a total of 5,218,323 tons of coal made into coke, 4,349,664 tons were washed. Of the washed coal used, 3,665,441 tons were slack and 684,223 tons were mine run. The unwashed mine-run coal used was 868,659 tons. No unwashed slack was used in 1913.

The character of the coal used in the manufacture of coke in Alabama in 1890, 1900, and for the last five years, is shown in the following table:

Character of coal used in the manufacture of coke in Alabama, 1890–1913, in short tons.

Year.	Run of mine.		Slack.		Total.
	Unwashed.	Washed.	Unwashed.	Washed.	
1890	1,480,669	0	206,106	123,189	1,809,964
1900	1,729,882	152,077	165,418	1,535,170	3,582,547
1909	713,992	2,153,801	0	2,212,971	5,080,764
1910	771,931	1,308,085	0	3,192,306	5,272,322
1911	693,135	1,295,109	2,937	2,420,117	4,411,298
1912	747,305	896,421	18,793	2,922,979	4,585,498
1913	868,659	684,223	0	3,665,441	5,218,323

COLORADO.

The production of coke in Colorado decreased from 972,941 short tons, valued at $3,043,994, in 1912 to 879,461 tons, valued at $2,815,134, in 1913. The decrease, which amounted to 93,480 tons, or 9.6 per cent, in quantity and $228,860, or 7.5 per cent, in value, was due entirely to labor troubles among the miners and not to adverse trade conditions. In a struggle to secure recognition of the mine workers' union a strike was called in the latter part of September, 1913, and later developed into a sanguinary conflict which eventually resulted in the calling out of Federal troops to restore order. The principal disturbances were in Las Animas County, the leading coal-producing and coke-making county, and resulted in a decrease in production of coal of nearly a million tons and in the total decrease in the output of coke.

Prior to 1912 it was the custom to include the coke production of Utah with that of Colorado in the reports of this series, as there were only two establishments in the former State, both owned by one company. In the last two years, however, the statistics of Utah's production have been included with other States having less than three establishments, and the figures for Colorado alone are made comparable. There are 15 coke-making establishments in Colorado with a total of 3,588 ovens, all of the beehive type. Six of the establishments, with a total of 726 ovens, were idle throughout the year. In addition to the idle plants, there were 980 idle ovens at plants which made some coke in 1913, so that the total idle ovens numbered 1,706, or nearly one-half of the coking capacity in the State. There were no new ovens in construction at the end of the year.

According to the returns to the Survey, the average value per ton for Colorado coke advanced from $3.13 in 1912 to $3.20 in 1913. In 1911 the average was $3.30. These fluctuations are, however, more apparent than real. A large proportion of the coke produced in Colorado is made in ovens which are parts of plants including in their operations the mining of coal, the making of coke, and the manufacture of iron and steel or the smelting and refining of the precious and base metals. In such establishments the placing of a value on the coke is an arbitrary matter and does not represent market prices. Only about 30 per cent of the total output of Colorado in 1913 was commercial coke:

The statistics of the manufacture of coke in Colorado and Utah in 1880, 1890, 1900, and from 1909 to 1911, inclusive, are shown in the following table. The statistics for 1912 and 1913 are for Colorado alone.

Statistics of the manufacture of coke in Colorado, 1880–1913.

Year.	Establishments.	Ovens.		Coal used (short tons).	Yield of coal in coke (per cent).	Coke produced (short tons).	Total value of coke at ovens.	Value of coke at ovens per ton.
		Built.	Building.					
1880[a]	1	200	50	51,891	49.0	25,568	$145,226	$5.68
1890[a]	8	916	30	407,023	60.0	245,756	959,246	3.90
1900[a]	14	1,692	0	997,861	62.0	618,755	1,746,732	2.82
1909[a]	18	4,700	0	1,984,985	63.1	1,251,805	4,135,931	3.30

1913	15	3,588	0	1,349,743	65.1	879,461	2,815,134	3.20

[a] Includes Utah.

The total quantity of coal consumed in the manufacture of coke in Colorado in 1913 was 1,349,743 tons, of which 1,028,366 tons were mine run and 321,377 tons were slack. All but 13,267 tons of the mine-run coal used and 85 per cent of the slack was washed before being charged into the ovens. The character of the coal used in making coke in Colorado in 1890, 1900, and from 1909 to 1913, inclusive, is shown in the following table:

Character of coal used in the manufacture of coke in Colorado, 1890–1913.

Year.	Run of mine.		Slack.		Total.
	Unwashed.	Washed.	Unwashed.	Washed.	
1890[a]	36,058	0	395,023	0	431,081
1900[a]	229,311	0	316,527	452,023	997,861
1909[a]	117,446	1,155,233	398,762	313,544	1,984,985

1912	680	1,061,917	43,310	367,205	1,473,112
1913	13,267	1,015,099	48,952	272,425	1,349,743

[a] Includes Utah.

GEORGIA.

Portions of two counties in the extreme northwest corner of the State, Dade and Walker, are underlain by the coal measures of the Appalachian province. Coal has been mined and coke has been made in both counties, but the Dade County mines and ovens have been idle the last few years and all the production at the present time is from Walker County. The sole operator in that county is the Durham Coal & Coke Co., of Chattanooga, Tenn. The statistics of its production of coke, as of coal, are published with the express permission of the company.

The production of coke at the one plant in Walker County in 1913 amounted to 42,747 short tons, valued at $186,304, compared with 43,158 short tons, valued at $161,842, in 1912. These figures indicate a slight decrease (411 tons) in quantity in 1913 but a gain in value of $24,462. Coke making, notwithstanding, or possibly because of, the smaller quantity produced, appeared to be more remunerative in 1913 than coal mining, for the average value per ton of the coal produced declined from $1.49 to $1.41, whereas the average value per ton of coke advanced from $3.75 in 1912 to $4.35 in 1913.

The two establishments in Georgia have a total coke-making equipment of 251 ovens, of which 100 were idle in 1913. All of the ovens are of the beehive type, the wasteful character of which is shown in the theoretical and practical yield of the Walker County coal in coke. The mine-run coal has a high content of fixed carbon (80 per cent), whereas the yield during the last few years has averaged less than 55 per cent, and in each of the last three years has been less than 52 per cent. The recovery is less than two-thirds of the possible yield.

The screened coal from Walker County makes a high-grade steam fuel and is in favor in the bunker trade. The screenings (or slack) only are used for coke making, and as most of the impurities in the coal pass through the screens with the slack, the latter is washed before being charged into the ovens.

The period of greatest activity in the coal mines and coke ovens of Georgia was during the first six or seven years of the present century, when the mines were operated by convicts leased by the State. The convict-lease system was abolished in 1908, and as the operators have been unable to supply this deficiency with free labor, the production of both coal and coke has been much reduced. The quantity of coal mined in the last six years has averaged less than 60 per cent of the production for an equal number of years just preceding.

The statistics of the manufacture of coke in Georgia in 1880, 1890, 1900, and from 1909 to 1913, inclusive, are shown in the following table:

Statistics of the manufacture of coke in Georgia, 1880–1913.

Year.	Establishments.	Ovens.		Coal used (short tons).	Yield of coal in coke (per cent).	Coke produced (short tons).	Total value of coke at ovens.	Value of coke at ovens per ton.
		Built.	Building.					
1880	1	140	40	63,402	60.0	38,041	$81,789	$2.15
1890	1	300	0	170,388	60.0	102,233	150,995	1.48
1900	2	480	0	140,988	52.4	73,928	210,646	2.85
1909	2	350	0	86,290	53.8	46,385	159,334	3.44
1910	2	350	0	80,019	54.8	43,814	173,049	3.95
1911	2	225	0	72,677	51.7	37,553	135,190	3.60
1912	2	251	0	87,300	50.0	43,158	161,842	3.75
1913	2	251	0	82,871	51.5	42,747	186,304	4.35

ILLINOIS.

All of the coke made in Illinois is the product of retort ovens, the Hemingway experimental ovens at Chicago and 24 beehive ovens at Gallatin having been permanently abandoned in 1913. They have not been in operation for several years. The retort-oven plants are at South Chicago, Joliet, and Waukegan, but they draw most of their coal from West Virginia or Pennsylvania mines. A common practice is to mix the West Virginia coal with Illinois coal in the proportion of 4 to 1. The mixture is ground fine and has been found to make an entirely satisfactory coke, with a yield of coal in coke of approximately 75 per cent. There are four establishments with a total of 568 ovens, all of which were in operation during the year. There were 58 new ovens in construction at the end of the year, 40 at South Chicago and 18 at Joliet, both installments being additions to plants already established.

The production of coke in Illinois increased from 1,764,944 short tons, valued at $8,069,903, in 1912 to 1,859,553 tons, valued at $8,593,581, in 1913, the gain in quantity amounting to 94,609 tons, or 5.4 per cent, and in value to $523,678, or 6.5 per cent. The increase in the value of the coke, however, was less than the increase in the value of the coal used in its manufacture. In 1912 the coal consumed in the coke ovens of Illinois amounted to 2,316,307 tons, valued at $6,568,003; in 1913 the coal used was 2,481,198 tons, and it was valued at $7,225,925, the difference being $657,922, or $134,244 more than the increase in the value of the coke made from it. But in Illinois, as elsewhere, a large part of the by-product coke is consumed by the producing or allied interests and the fixing of the values is an arbitrary matter and not indicative of market conditions.

The statistics of the manufacture of coke in Illinois during the last seven years is shown in the following table:

Statistics of the manufacture of coke in Illinois, 1907–1913.

Year.	Establishments.	Ovens.		Coal used (short tons).	Yield of coal in coke (per cent).	Coke produced (short tons).	Total value of coke at ovens.	Value of coke at ovens per ton.
		Built.	Building.					
1907	5	309	280	514,983	72.3	372,697	$1,737,464	$4.66
1908	6	430	140	503,359	72.0	362,182	1,538,952	4.25
1909	5	468	40	1,682,122	75.9	1,276,956	5,361,510	4.20
1910	5	508	0	1,972,955	76.8	1,514,504	6,712,550	4.43
1911	6	506	48	2,087,870	77.1	1,610,212	6,390,251	3.97
1912	6	594	40	2,316,307	76.2	1,764,944	8,069,903	4.57
1913	4	[a] 568	[b] 58	2,481,198	74.9	1,859,553	8,593,581	4.62

[a] Includes 253 Semet-Solvay and 315 Koppers ovens.
[b] Includes 40 Semet-Solvay and 18 Wilputte ovens.

INDIANA.

As in the neighboring State of Illinois, all the coke made in Indiana is the product of retort ovens and most of the coal used is brought from West Virginia. The State assumed importance in the manfuacture of coke in 1911, when a portion of the United States Steel Corporation plant at Gary was completed and put in blast. The entire plant was completed in 1912, and Indiana, from a relatively low place in the rank of coke-producing States in 1910 (seventeenth) advanced to third place in 1912 and 1913, outranking West Virginia, upon whose mines the ovens in Indiana depend for the greater part of their coal. The United States Steel Corporation's plant at Gary consists of 560 Koppers ovens, which in 1913 produced 90 per cent of the entire output of coke in the State. Prior to the completion of this plant, the Citizens Gas Co. at Indianapolis had built, in 1909, 50 United-Otto ovens, which plant was doubled in size by 50 additional ovens, completed in 1913. In 1912 the Central Indiana Gas Co. completed 22 Klönne ovens at Muncie; the Inland Steel Co. began the construction of 66 Koppers ovens (completed in 1913), and the construction of 41 Semet-Solvay ovens, which were still incomplete at the close of 1913, was begun at Indianapolis. One Roberts-Mass oven, an experimental installation, was built at Gary in 1913 by the American Coal & By-Products Coke Co. The total number of ovens in the State at the close of 1913 was 749, with 41 under construction. Ten beehive ovens at Black Creek were abandoned.

The production of retort coke in Indiana in 1913 was 2,727,025 short tons, valued at $13,182,136, against 2,616,339 tons in 1912, valued at $12,528,685. The increase in 1913 was 110,686 tons, or 4.2 per cent in quantity, and $653,451, or 5.2 per cent, in value. The average value per ton advanced from $4.79 to $4.83. The increase in the value of the coke was, however, only a little more than half of the increase in the value of the coal used, which in 1913 was $11,006,033, against $9,689,756 in 1912, the difference being $1,316,277. The 749 ovens had an average production in 1913 of 3,670 tons of coke, and an average yield of coal in coke of 77.1 per cent. In 1912 the average production per oven was 4,140 tons, and the average yield was 81.8 per cent. The lower averages in 1913 were probably due to a larger proportion of Illinois coal used in the oven charge.

The statistics of the manufacture of coke in Indiana in 1912 and 1913 are shown in the following table:

Statistics of the manufacture of coke in Indiana, 1912 and 1913.

Year.	Establishments.	Ovens.		Coal used (short tons).	Yield of coal in coke (per cent).	Coke produced (short tons).	Total value of coke at ovens.	Value of coke at ovens per ton.
		Built.	Building.					
1912	4	642	169	3,198,874	81.8	2,616,339	$12,528,685	$4.79
1913	5	*a* 749	*b* 41	3,535,136	77.1	2,727,025	13,182,136	4.83

a Includes 626 Koppers, 100 United-Otto, 22 Klönne, and 1 Roberts-Mass ovens.
b Semet-Solvay ovens.

KANSAS.

Kansas dropped out of the list of coke producers in 1913. The industry has never been of much importance in the State, and the largest production was 20,902 short tons in 1902. That product was made in ovens operated in connection with zinc works and was used in the zinc retorts. "Dead" coal mined in the State, and so called because of its absolutely noncoking quality, is used raw by the zinc smelters and takes the place of the coke. A small quantity of coke was made in 1910, 1911, and 1912 in underground ovens at Lansing, the coal being from the mines operated by the State penitentiary, but these were not used in 1913.

The statistics of the manufacture of coke in Kansas in 1880, 1890, 1900, and in 1909–1913 are shown in the following table:

Statistics of the manufacture of coke in Kansas, 1880–1913.

Year.	Establishments.	Ovens.		Coal used (short tons).	Yield of coal in coke (per cent).	Coke produced (short tons).	Total value of coke at ovens.	Value of coke at ovens per ton.

a Included with other States having less than 3 producers.

KENTUCKY.

Kentucky is the only one of the United States whose coal supplies are drawn from any two of the great fields. The eastern counties of the State are underlain by the coal measures of the Appalachian region, and the southern extremity of the eastern interior, or Illinois-Indiana field, is worked extensively in the western part of Kentucky. Coke has been made from coal mined in both the eastern and the western parts of the State, but although the coals of the eastern counties are in large part among the high-grade coking coals of the Appalachian field, most of the coke, until the last two years, has been made in the western district. The building of ovens has followed, however, upon recent extensive coal-mining developments in the Elkhorn district of Pike and Harlan counties; the principal coking activities have shifted to the eastern part of the State; and Kentucky is now assuming some importance as a coke-manufacturing State. The production has increased from less than 50,000 tons in 1909 to 191,555 tons in 1912 and to 317,084 tons in 1913. During the last year a plant of 54 Semet-Solvay ovens was completed for the Kentucky-Solvay Co., at Ashland, and added materially to the increased production. Fifty new beehive ovens were also added, and, by a coincidence, 104 ovens were abandoned, so that the total number in existence at the close of 1913 was the same (1,049) as at the close of 1912. The Wisconsin Steel Co., which completed 300 beehive ovens at Benham, in Harlan County, in 1912, had 100 additional ovens in course of construction at the end of 1913.

The 1,049 ovens are distributed among 9 establishments, 2 of which, with a total of 220 ovens, were idle in 1913.

The quantity of coal used in the manufacture of coke in 1913 was 512,245 short tons, of which 440,480 tons were unwashed run of mine and 71,765 tons were washed slack. All the latter was used in the western district.

The following table gives the statistics of production in Kentucky in 1880, 1890, 1900, and for the last five years:

Statistics of the manufacture of coke in Kentucky, 1880–1913.

Year.	Establishments.	Ovens.		Coal used (short tons).	Yield of coal in coke (per cent).	Coke produced (short tons).	Total value of coke at ovens.	Value of coke at ovens per ton.
		Built.	Building.					
1880	5	45	0	7,206	59.0	4,250	$12,250	$2.88
1890	9	175	103	24,372	51.0	12,343	22,191	1.80
1900	5	458	3	190,268	50.2	95,532	235,505	2.47
1909	6	495	0	89,083	52.0	46,371	101,257	2.18
1910	6	495	0	104,103	51.7	53,857	120,554	2.24
1911	8	577	300	118,255	55.9	66,099	134,862	2.04
1912	9	1,049	291	307,162	62.4	191,555	513,734	2.68
1913	9	[a] 1,049	100	512,245	61.9	317,084	753,897	2.38

[a] Includes 54 Semet-Solvay and 150 rectangular ovens.

MONTANA.

Some of the coals found in Montana possess coking quality, but so far the attempts to use them for that purpose have not been entirely successful. Four plants, with a total of 451 ovens, have been built, but none of them have been in active operation for the last three years, and one establishment of 100 ovens was abandoned in 1913. All of the ovens are of the beehive type.

In the following table are given the statistics of production of coke in Montana in 1884, when the first production was reported, and in 1890, 1900, and since 1909:

Statistics of the manufacture of coke in Montana, 1884–1913.

Year.	Establishments.	Ovens.		Coal used (short tons).	Yield of coal in coke (per cent).	Coke produced (short tons).	Total value of coke at ovens.	Value of coke at ovens per ton.
		Built.	Building.					
1884	3	5	12	165	46.0	75	$900	$12.00
1890	2	140	0	32,148	45.0	14,427	125,655	8.71

1913	3	351	0	0	0	0	0	0

[a] Included with other States having less than 3 producers.

NEW MEXICO.

All of the coke made in New Mexico is from coal mined from the Raton field in Colfax County. This field is the southern part of the Raton Mountains coal region, which consists of the Raton field in northeastern New Mexico and the Trinidad field in Colorado. The coal measures are continuous, but the producing areas are separated by a high divide near the Colorado-New Mexico line. A bank of 50 ovens at Waldo, in Santa Fe County, has not been in operation for several years. Slack coal is used in the manufacture of coke, and as over 25 per cent of the total output of the mines yielding coking coal goes into slack, an ample supply of fuel for the coke ovens is available.

There are 4 coking establishments in the State, including the one of 50 ovens at Waldo, which has been idle during the last four years.

The total number of ovens in the State has not changed since 1909, there being altogether 1,030. Deducting the 50 idle ovens there were 980 that made coke in 1912 and 1913. There has been no new construction work started during the last five years. All of the ovens in the State are of the beehive type. At Dawson, however, 446 out of a total of 570 ovens, although of beehive type in construction, are provided with underflues through which the gases are conveyed to a large flue back of the ovens and thence to the power house. The heat obtained from the oven gases renders the use of other fuel in the power plant unnecessary. The power plant, in addition to furnishing power for the operation of the mines, for ventilation, electric haulage, the coal crusher, washery, etc., furnishes also steam heat to the offices, commissary, hotel, hospital, and theater, and electric light for the city of Dawson.

The quantity of coke made in New Mexico in 1913 was 467,945 short tons, valued at $1,548,536, the maximum record both in quantity and in value. Compared with 1912 the output in 1913 showed an increase of 54,039 tons, or 13 per cent, in quantity and of $191,590, or 14.4 per cent, in value. All of the coal used is washed slack from the mines at Dawson, Koehler, and Gardiner. The quantity used in 1913 was 788,172 tons. The yield of coal in coke was 59.4 per cent.

The statistics of production in 1882, 1890, 1900, and from 1909 to 1913 are shown in the following table:

Statistics of the manufacture of coke in New Mexico, 1882–1913.

Year.	Establishments.	Ovens.		Coal used (short tons).	Yield of coal in coke (per cent).	Coke produced (short tons).	Total value of coke at ovens.	Value of coke at ovens per ton.
		Built.	Building.

NEW YORK.

All of the coke made in New York is from coal mined in Pennsylvania, and it is all made in retort ovens. There are 4 establishments in the State with a total of 555 ovens, 188 of which are Otto-Hoffmann (or United-Otto, as they are now called), 281 Rothberg, and 86 Semet-Solvay. The United-Otto and Rothberg ovens are operated by the Lackawanna Steel Co., at Buffalo; 40 of the Semet-Solvay ovens are located at Solvay, near Syracuse, and 46 at the Empire Coke Works at Empire. Although New York lies entirely outside the coal-producing area, it has the distinction of being the first State in which by-product ovens were built, the first 12 Semet-Solvay ovens constructed in the United States having been erected in 1893 at Solvay. This plant was increased to 25 ovens in 1896 and to 40 ovens in 1903.

All of the 4 establishments were in operation in 1913, but the production decreased from 794,618 tons in 1912 to 758,486 tons in 1913. The value, however, increased from $3,203,133 in 1912 to $3,301,400 in

1913. The decrease in quantity was 36,132 tons, or 4.5 per cent, and the increase in value was $98,267, or 3.1 per cent. The quantity of coal used in 1913 was 1,067,207 short tons, valued at $2,640,679, or an average of $2.47 per ton. The yield of coal in coke was 71.1 per cent. Nearly all of the coal used for coke making in New York is mine-run. In 1913, 1,057,964 tons of the coal used was mine-run, of which 835,600 tons were unwashed and 222,364 tons were washed. The slack coal used consisted of 6,259 tons of unwashed and 2,984 tons of washed coal.

The statistics of the manufacture of coke in New York since 1910 are shown in the following table:

Statistics of the manufacture of coke in New York, 1910–1913.

Year.	Establishments.	Ovens.		Coal used (short tons).	Yield of coal in coke (per cent).	Coke produced (short tons).	Total value of coke at ovens.	Value of coke at ovens per ton.
		Built.	Building.					
1910	4	555	0	910,293	71.7	652,459	$2,635,873	$4.04
1911	4	555	0	955,067	71.8	686,172	2,883,990	4.20
1912	4	555	0	1,095,198	72.6	794,618	3,203,133	4.03
1913	4	a 555	0	1,067,207	71.1	758,486	3,301,400	4.35

a Includes 188 United-Otto, 281 Rothberg, and 86 Semet-Solvay ovens.

OHIO.

The coals of Ohio belong to the Appalachian province, and most of the beds are correlated with those of Pennsylvania and West Virginia to the east and southeast. But although the bituminous and semi-bituminous coals of Pennsylvania and West Virginia include the highest grade coking coals in the United States, and although those two States are first and second in rank as coal producers, the coals seem to lose their coking qualities as the beds extend westward, and a large part of the coke made in Ohio is from coal brought from West Virginia to by-product retort ovens at Kokotto, near Cincinnati, and at Cleveland. The principal beehive operations are those of the United Iron & Steel Co. at Cherry Valley, in Columbiana County, and the coal for these ovens is brought from Pennsylvania mines. On the other hand, some of the coal mined in Ohio makes a satisfactory blast-furnace fuel in the raw state, but when so used, at the present time, it is usually mixed with coke. At one time raw bituminous coal was an important factor in the iron industry of Ohio.

Ohio ranks fourth among the States as a producer of coal, but stands somewhat far down in the list of coke producers, being fourteenth in this respect in 1913. It is believed, however, that coke making is bound to become a much more important industry in the State. Ohio is second among the States in the manufacture of pig iron, and blast furnaces have been supplied largely by Connellsville coke; but, as in Illinois and Indiana, the future blast-furnace fuel in Ohio will be the product of retort ovens located at or near the points of consumption. The first installation of this kind was a bank of 50 Otto-Hoffmann ovens near Hamilton built in 1901 by the Hamilton-Otto Coke Co. A second installation of the same number of ovens was completed in 1909, and, in 1910, 49 Semet-Solvay ovens were completed at Cleveland. This plant is now being increased to 100 ovens, construction of the additional 51 ovens having been begun in 1912. In 1913 construction work also was begun on 68 Koppers ovens at Youngstown for the Republic Iron & Steel Co.

The production of coke in Ohio in 1913 was 351,846 short tons, valued at $1,231,554, against 388,669 tons, valued at $1,365,905 in 1912, a decrease in 1913 of 36,823 short tons, or 9.5 per cent in quantity and of $134,351, or 9.8 per cent in value. The decreased production in 1913 is attributed to the floods in the early part of the year and the prolonged drought in the summer and early fall.

The plant under construction at Youngstown included, there were 8 establishments in the State in 1913, with 471 ovens completed and 119 buildings at the end of the year. Of the 471 completed ovens, 29 were idle throughout the year. The active ovens consisted of 149 retort ovens and 293 beehive. The retort coke in 1913 amounted to 236,032 tons, or an average of 1,584 tons per oven, and the beehive coke to 115,814, or an average of 439 tons per oven.

The statistics of the production of coke in Ohio in 1880, 1890, 1900, and for the last five years are shown in the following table:

Statistics of the manufacture of coke in Ohio, 1880–1913.

Year.	Establishments.	Ovens.		Coal used (short tons).	Yield of coal in coke (per cent).	Coke produced (short tons).	Total value of coke at ovens.	Value of coke at ovens per ton.
		Built.	Building.					
1880	15	616	25	172,453	58.0	100,596	$255,905	$2.54
1890	13	443	1	126,921	59.0	74,633	218,090	2.92
1900	8	369	50	115,269	62.5	72,116	194,042	2.69
1909	7	447	49	340,735	65.4	222,711	683,155	3.07
1910	8	496	0	413,059	68.3	282,315	911,987	3.23
1911	8	496	0	456,222	68.2	311,382	961,904	3.09

1913	7	[a] 471	[b] 119	507,417	69.3	351,846	1,231,554	3.50

[a] Includes 100 United-Otto and 49 Semet-Solvay ovens.
[b] Includes 51 Semet-Solvay and 68 Koppers ovens.

Most of the coal used for coke making in Ohio is unwashed run of mine. In 1913 the total quantity of coal carbonized was 507,417 short tons, of which 479,286 tons were unwashed mine-run, 7,726 tons were washed mine-run, and 7,414 tons were unwashed slack, and 12,988 tons were washed slack.

The character of the coal used in the manufacture of coke in Ohio in 1890, 1900, and from 1909 to 1913 is shown in the following table:

Character of coal used in the manufacture of coke in Ohio since 1890, in short tons.

Year.	Run of mine.		Slack.		Total.
	Unwashed.	Washed.	Unwashed.	Washed.	
1890	34,729	0	54,473	37,719	126,921

1913	479,286	7,726	7,417	12,988	507,417

OKLAHOMA.

No coke has been made in Oklahoma since 1910, and of 536 ovens in existence in 1909 more than half (276) have been abandoned.

The following table gives the statistics of the manufacture of coke in Oklahoma (Indian Territory) in 1880, 1890, 1900, and from 1909 to 1913:

Statistics of the manufacture of coke in Oklahoma (Indian Territory), 1880–1913.

Year.	Establishments.	Ovens.		Coal used (short tons).	Yield of coal in coke (per cent).	Coke produced (short tons).	Total value of coke at ovens.	Value of coke at ovens per ton.
		Built.	Building.					
1880	1	20	0	2,494	62.0	1,546	$4,638	$3.00
1890	1	80	0	13,278	50.0	6,639	21,577	3.25

a Included with other States having less than 3 producers.

PENNSYLVANIA.

The quantity of coke produced in Pennsylvania in 1913 amounted to 28,753,444 short tons, valued at $67,929,864, against 27,438,693 tons, valued at $56,336,255, in 1912. The production in 1913, both in quantity and in value, was the maximum record for the State, and represented an increase over 1912 of 1,314,751 short tons, or 4.8 per cent, in quantity and of $11,593,609, or 20.6 per cent, in value. The features of interest in 1913 were the marked increase in value as compared with the increase in production, the decreased output in both the Connellsville and the Lower Connellsville districts, and the relative gain on the Connellsville district made by its younger neighbor the Lower Connellsville. The latter district opened in 1900 and entered its "teens" in 1913. For a number of years it has been the second coke-producing district not only in Pemmsylvania but in the United States, and is now within 25 per cent of equaling the Connellsville district as a coke producer. In 1913 the Lower Connellsville district produced 78 per cent as much coke as the Connellsville, and 31 per cent of the total output of the State.

Prices in 1913 ruled considerably higher than in 1912, quotations for Connellsville coke at the first of the year being more than double what they were at the beginning of 1912; but conditions in the two years were reversed. In 1912 there was a steady advance with the demand gradually overtaking and finally exceeding the supply, and finally almost a famine, particularly in foundry coke. In 1913, on the other hand, with a strong opening in January there was a somewhat irregular falling off in business, with a gain in supply over demand, culminating in a slump in the iron trade in October, and prices declined until in December they were down to the low level of the beginning of 1912. A study of the table of prices on page 512 would give the impression that the average for 1913 was about the same as in 1912, but it must be remembered that the larger part of the product is delivered on contracts made several months before, and most of the coke delivered in 1912 was on the low-contract basis of the early part of that year. In 1913, on account of the higher prices at the opening, contract buyers were less anxious to close and less contract coke was sold during the year; but sufficient quantities were contracted for to make the total returns for 1913 much more satisfactory to the producers than had been the case for many years. The average value per ton for Connellsville coke in 1913 was $2.23 as compared with $1.90 in 1912, whereas the averages of the higher contract monthly prices were $2.40 in 1912 and $2.42½ in 1913.

For the first time in three years there was in 1913 an increase in the number of coke ovens in operation, as compared with the preceding year, although there was a net decrease of 1 in the number of establishments. Seven establishments were abandoned during 1913, and 6 new ones were completed. The net increase in the number of ovens in 1913 as compared with 1912 was 1,302. There were 740 ovens abandoned and 2,042 new ovens constructed. Most of the new construction was in the Pittsburgh district, where 825 ovens, all of them of the Mitchell or rectangular type, were built. The Lower Connellsville district showed an increase of 211 ovens, and 224 new ovens (150 of them Didier) were added to the miscellaneous plants included under "Other districts." The number of ovens in the Connellsville district has decreased in each of the last three years, and there were 30 fewer ovens in this district in 1913 than in 1912. As noted in the report for 1912 the period of expansion in the Connellsville coke trade proper is ended, and its supersession as the leading coke-producing district in the United States at no late date is to be expected. The area of the Connellsville Basin proper is limited, and the drains upon it during the last three decades of marvelous expansion in our iron and steel industries have exhausted the most of the supply of Connellsville coal. By some authorities it is estimated that in another generation the manufacture of coke in the Connellsville district will be largely a matter of history. This reason is assigned as the principal one for the continuance of beehive-oven practice in the district, the expense of substituting retort ovens for beehive not being warranted by the short life ahead of the Connellsville coal field. This, however, was hardly true 20 years ago and is not true of the Lower Connellsville district, where the beehive or its equally wasteful companion, the rectangular oven, continues to be built. It is indeed to be hoped that with the continued construction of by-product ovens at other points, the beehive type of ovens in the Connellsville districts will be abandoned more rapidly than the coal is exhausted and that Connellsville coal will become for a while at least an important fuel for the retort ovens.

The total number of ovens in Pennsylvania increased from 53,756 in 1912 to 55,058 in 1913. Of these ovens 9,432 were idle throughout the year, nearly half of them in the Connellsville district, where 1,895 were the entire equipment of 19 establishments. There were 257 establishments that made coke in 1913, a gain of 1 over 1912, when 21 plants were idle. The 257 active establishments had 45,626 ovens in operation during the year and produced 28,753,444 tons of coke, an average of 111,881 tons of coke to each establishment and of 630 tons per oven. The 45,626 active ovens in 1913 included

1,467 of the by-product type. The active by-product ovens constituted 3.2 per cent of the total active number, and produced 2,628,680 tons of coke, or 9.1 per cent of the total output. The average production for each active retort oven was 1,792 tons of coke, and the yield of coal in coke was 75.3 per cent. The 44,159 active beehive ovens produced an average of 592 tons of coke, and the yield of coal in coke was 65.8 per cent.

At the close of 1913 there were 582 ovens in course of construction, 512 of them rectangular and 70 beehive. Eighty per cent of the new ovens (all of them rectangular) were building in the Lower Connellsville district, where this type of oven has achieved considerable popularity. The chief advantage possessed by the rectangular oven over the beehive is that the coking chamber being long and narrow like the retort oven, the coke may be pushed from it and does not have to be drawn as is the case with the beehive oven. The process of carbonization is the same—that of partial combustion.

The statistics of the production of coke in Pennsylvania for the years 1880, 1890, 1900, and for the last five years are shown in the following table:

Statistics of the manufacture of coke in Pennsylvania, 1880–1913.

Year.	Establishments.	Ovens.		Coal used (short tons).	Yield of coal in coke (per cent).	Coke produced (short tons).	Total value of coke at ovens.	Value of coke at ovens per ton.
		Built.	Building.					
1880	124	9,501	836	4,347,558	65.0	2,821,384	$5,255,040	$1.86
1890	106	23,430	74	13,046,143	65.6	8,560,245	16,333,674	1.91
1900	177	32,548	2,310	20,239,966	66.0	13,357,295	29,692,258	2.22
1909	283	54,506	2,072	36,983,568	67.3	24,905,525	50,377,035	2.02
1910	288	55,656	1,334	39,455,785	66.7	26,315,607	55,254,599	2.10
1911	279	54,904	1,271	32,875,655	66.7	21,923,935	43,053,367	1.96
1912	277	53,756	1,887	41,268,532	66.5	27,438,693	56,336,255	2.05
1913	276	[a]55,058	[b] 582	43,195,801	66.6	28,753,444	67,929,864	2.36

[a] Includes 932 United-Otto, 360 Semet-Solvay, 150 Didier, and 5,059 rectangular ovens.
[b] Includes 512 rectangular ovens.

By far the larger part of the coal used in coke making in Pennsylvania is unwashed run of mine. The coal mined in the Connellsville districts is an ideal coking coal, and requires no preparation for the coke oven, though some of it is crushed before being charged. Of the 43,195,801 short tons of coal used in 1913 for coke making in Pennsylvania, 36,621,183 tons were unwashed run of mine and 1,199,859 tons were unwashed slack. The washed coal used consisted of 2,191,944 short tons of mine run and 3,182,815 tons of slack.

The character of the coal used in the manufacture of coke in Pennsylvania in 1890, 1895, 1900, 1905, and from 1909 to 1913, has been as follows:

Character of coal used in the manufacture of coke in Pennsylvania since 1890, in short tons.

Year.	Run of mine.		Slack.		Total.
	Unwashed.	Washed.	Unwashed.	Washed.	
1890	11,788,625	303,591	630,195	323,732	13,046,143
1895	13,618,376	34,728	440,869	117,594	14,211,567
1900	17,692,623	647,045	1,300,796	599,502	20,239,966
1905	26,148,696	1,335,631	2,436,621	1,109,397	31,030,345
1909	31,712,482	2,278,927	1,016,576	1,975,583	36,983,568
1910	32,688,029	2,372,115	1,275,348	3,120,293	39,455,785

1912	35,344,633	2,493,661	1,098,392	2,331,846	41,268,532
1913	36,621,183	2,191,944	1,199,859	3,182,815	43,195,801

Pennslyvania stands preeminent among the States in the production of coal and in the manufacture of coke. As a producer of coke Pennsylvania is relatively of greater importance than as a producer of coal, for, whereas, including the production of anthracite, Pennsylvania contributes less than half the entire output of coal in the United States, nearly two-thirds the total production of coke is made within that State. In 1913 the two principal coking districts of Pennsylvania—the Connellsville and the Lower Connellsville districts—both included in the two counties of Fayette and Westmoreland, produced 45 per cent of the coke product of the United States. Ever since coke became the principal fuel in the manufacture of iron (it superseded anthracite for this purpose in 1875) the Connellsville district has been the chief source of supply. What is known as the Lower Connellsville district came into existence in 1900, and in its 13 years of life has exhibited a rapidity in development that has outrivaled any coke-making district in the world. The Connellsville Basin proper is included in both Westmoreland and Fayette counties; the Lower Connellsville Basin is entirely in Fayette County, lies southwest of the southern end of the Connellsville Basin, and is separated from it by the Greensburg anticline. The Lower Connellsville district is now the second coke-producing district in the United States and will probably in a few years rival its older neighbor for first place. In both the Connellsville and the Lower Connellsville districts all but a very small quantity of the coke is made in beehive ovens or in rectangular ovens, in which the process is one of partial combustion, as in the beehive ovens, and without recovery of by-products or utilization of the heat generated in the coking process. With the exception of 110 Semet-Solvay ovens in the Connellsville district, all the by-product recovery ovens in Pennsylvania are outside of the coking-coal mining districts.

PRODUCTION BY DISTRICTS.

In previous chapters of this series of reports it has been customary to consider the production of coke in Pennsylvania according to certain well-defined districts. These divisions are based to some extent upon geographic boundaries, but also upon the quality of the coal mined and the coke produced. Each district has been more fully described in some of the preceding volumes, but the following brief statement regarding the territory included in the different coking districts is repeated here for the sake of convenience.

The Allegheny Mountain district includes the ovens along the line of the Pennsylvania Railroad from Gallitzin eastward over the crest of the Alleghenies to a point beyond Altoona. The Allegheny Valley district formerly included the coke works of Armstrong and Butler counties and one of those in Clarion County, the other ovens in the latter county being included in the Reynoldsville-Walston district. All but two of the Allegheny Valley plants have been abandoned, and the production is combined with that of the Allegheny Mountain district. What was previously known as the Beaver district included the ovens in Beaver and Mercer counties, but all the ovens in Beaver County have been abandoned, those formerly operated by the Semet-Solvay Co. in Mercer County have been abandoned, and the operations of the one establishment of United-Otto ovens at South Sharon are now included in the Pittsburgh district. The Blossburg and the Broadtop districts embrace the Blossburg and the Broadtop coal fields. The ovens of the Clearfield-Center district are chiefly in the two counties from which it derives its name. The Connellsville district is the well-known region of western Pennsylvania in Westmoreland and Fayette counties, extending from just south of Latrobe to Fairchance. The Lower Connellsville region is entirely in Fayette County and southwest of the Connellsville Basin proper, from which it is separated by the Greensburg anticline. It embraces the important developments in the vicinity of Uniontown and is now the second producing district of the State. The Greensburg, Irwin, Pittsburgh, and Reynoldsville-Walston districts include the ovens near the towns which have given the names to these districts. The Upper Connellsville district, sometimes called the Latrobe district, is near the town of Latrobe. The Semet-Solvay ovens at Chester, Steelton, and Lebanon, the 300 Didier ovens at South Bethlehem, and the United-Otto ovens at Lebanon are in what has been designated as the Lebanon-Schuylkill district.

Coke production in Pennsylvania in 1912 and 1913, by districts.

1912.

a Includes 372 United-Otto ovens.
b Includes 110 Semet-Solvay and 1,132 rectangular ovens.
c Includes 2,271 rectangular ovens.
d Rectangular ovens.
e Includes 332 United-Otto and 1,135 rectangular ovens.
f Includes 210 rectangular ovens.
g Includes 72 rectangular ovens.
h Includes 250 Semet-Solvay, 228 United-Otto, 300 Didier, and 311 rectangular ovens.

Connellsville district.—The Connellsville district of Pennsylvania continues to be the most important coke-producing district of the world, though in the last few years it has been gradually losing its relatively exalted position in the coke production of the United States. This relative retrogression may be expected to continue as this wonderful portion of the great Pittsburgh bed approaches exhaustion, an eventuality which, according to conservative estimates, is only three or four decades distant. The beginning of the decline may have already begun, for in 1913, when for the greater part of the year prices were exceptionally high and when production for the State as a whole showed a gain of practically 5 per cent, the output in the Connellsville district decreased nearly 250,000 tons.

There were fewer ovens in the Connellsville region in 1913 than in any year since 1905, and the number has been decreasing steadily for the last three years from the maximum of 24,481 ovens in 1910. In 1913 there were 22,189 ovens in the Connellsville region, 30 fewer than in 1912. There were only 148 ovens building at the close of 1912, and only 60 ovens at the close of 1913. The number of establishments has decreased with the number of ovens, there being 106 coke-making plants in the Connellsville district in 1913 against 109 in

1912. Of the 106 plants, with 22,189 ovens, in existence at the close of 1913, 1 plant, with 42 ovens, was idle throughout the year, in addition to which there were 4,264 idle ovens at plants portions of which were in operation. Altogether there were 17,883 ovens in the Connellsville district making coke in 1913. They produced a total of 11,566,778 tons of coke, or an average of 647 tons per oven. In 1912 there were 18,151 active ovens, producing 11,814,588 tons of coke, or an average of 651 tons per oven. The average value per ton for coke made in Pennsylvania was $2.05 in 1912 and $2.36 in 1913. The average value of Connellsville coke was $2.23 in 1913, against $1.90 in 1912. The apparent lower value for Connellsville coke is due to including in the total production the output from a number of by-product plants located at distances from the mines, where the expense of transportation of the coal is added to the cost thereof, and is naturally reflected in the higher prices for the coke at the ovens. The total quantity of retort-oven coke in Pennsylvania was 2,628,680 short tons, valued at $8,238,924, or an average of $3.13 per ton, which had the effect of increasing the average value per ton of all the coke produced in the State. Of the 22,189 ovens in the Connellsville district, only 110 are of the by-product recovery type. These are Semet-Solvay ovens operated by the Semet-Solvay Co. at Dunbar. A few rectangular, or Mitchell, ovens have been constructed in the district but in them, as in the beehive ovens, the process is one of partial combustion and not of distillation.

In the following table are presented the statistics of the manufacture of coke in the Connellsville district in 1880, 1890, 1900, and from 1909 to 1913:

Statistics of the manufacture of coke in the Connellsville region, Pennsylvania, 1880–1913.

Year.	Establishments.	Ovens.		Coal used (short tons).	Yield of coal in coke (per cent).	Coke produced (short tons).	Total value of coke at ovens.	Value of coke at ovens per ton.
		Built.	Building.					
1880	67	7,211	731	3,367,856	65.5	2,205,946	$3,948,643	$1.79
1890	28	15,865	30	9,748,449	66.3	6,464,156	11,537,370	1.94
1900	98	20,981	686	14,946,659	67.0	10,020,907	22,383,432	2.23
1909	117	24,422	370	17,581,899	66.9	11,769,758	23,379,149	1.99

1913	106	[a]22,189	60	17,379,314	66.6	11,566,778	25,830,382	2.23

[a] Includes 110 Semet-Solvay by-product and 922 rectangular ovens.

The following table, compiled by the Courier, of Connellsville, Pa., shows the shipments of coke, by months, from the Connellsville and the Lower Connellsville districts. The figures are given in cars and tons, with the average number of cars shipped each working day of the month, and include shipments from the Lower Connellsville district as well as from the Connellsville district proper. This authority gives the shipments in 1913 at 20,078,679 short tons, whereas the combined production of the Connellsville and Lower Connellsville district as reported to the Geological Survey amounted to 20,543,559 tons. It will be noted that in the first seven months of 1913, with one exception—April—the shipments exceeded those of 1912. The falling off in the demand for coke following the slump in the iron trade in October is exhibited in these statistics for 1913 by a decrease of 90,000 tons in the shipments for October, 260,000 tons in the shipments for November, and of nearly 400,000 tons in the shipments for December. The heaviest shipments in 1913 were in the month of January, 1,867,336 tons; in 1912 the largest shipments were in October, 1,793,432 tons. The average of the daily records of shipments in 1913 was 1,950 cars; in 1912 the average daily shipments were 1,911 cars. The highest average daily shipments were in February, 2,114 cars, and the smallest daily car record was made in December, 1,365 cars. The largest shipment of cars in any month during the last three years occurred in January of 1913, 55,148 cars; the smallest number was in December of 1913, 35,506 cars.

The monthly shipments from this region from 1909 to 1913, inclusive, reported by the Courier, are given in the following table:

Monthly shipments of coke from the Connellsville and Lower Connellsville regions, 1909–1913, in short tons.

Month.	1909	1910	1911	1912	1913
January	1,205,650	1,952,406	1,194,047	1,575,198	1,867,336
February	1,143,487	1,787,164	1,302,098	1,583,567	1,716,525
March	1,185,814	1,922,575	1,621,301	1,750,944	1,777,977
April	1,144,751	1,754,654	1,419,369	1,710,417	1,707,727
May	1,235,044	1,527,515	1,343,879	1,778,860	1,823,674
June	1,429,289	1,544,964	1,299,295	1,621,004	1,687,486
July	1,605,937	1,446,294	1,257,820	1,565,126	1,717,683
August	1,641,287	1,464,060	1,355,774	1,690,681	1,690,636
September	1,704,919	1,390,140	1,394,752	1,553,246	1,622,630
October	1,821,444	1,450,717	1,424,232	1,793,432	1,703,438
November	1,835,745	1,252,797	1,385,627	1,736,938	1,473,484
December	1,832,465	1,196,436	1,335,974	1,672,862	1,289,983
Total	17,785,832	18,689,722	16,334,168	20,032,275	20,078,579

The total shipments in cars for the last 26 years, the total number of cars in 1912 and 1913, the daily car average, and the total number of tons shipped, as reported by the Courier, are shown in the following tables:

Total and daily average shipments in cars, 1888–1913.

Year.	Daily average.	Total cars.	Year.	Daily average.	Total cars.	Year.	Daily average.	Total cars.

As Connellsville coke is recognized as the standard for the United States and governs largely the prices for the product of other districts, the following table is given showing the prices for furnace and foundry coke, by months, during the years 1911 to 1913. These prices are quoted from The Iron Age and are for strict Connellsville coke. "Main Line" and "outside" cokes are usually quoted from 15 to 20 cents below the strict Connellsville.

During the last three years there seems to have been some disposition to get away from the buying of coke on six months' contract for delivery, and accordingly two sets of statistics for prices have developed—one for spot coke and one for contract, usually made for six months at a time. As a general thing the contract prices are higher than spot, the latter being frequently made on unsold coke which happens to be thrown upon the market, but not always so. During 1911 the prices for Connellsville coke were low. Spot coke ranged steadily below contracts. In the latter part of 1912, however, and in January of 1913 spot coke was in active demand and famine prices were realized, from $4.25 to $4.50 being obtained for spot coke, while a portion of the deliveries were on contracts made the previous summer, when prices were from $2.40 to $2.50 per ton. The steady advance in prices in 1912 and the almost equally steady decline in 1913 are clearly exhibited in this statement. The high average of the spot furnace coke in 1912 was $3.85 to $4 in November, and the high average for 1913 was in January, $3.50 to $4.15. The average value per ton for Connellsville coke was $1.90 in 1912 and $2.23 in 1913, from which it appears that the price quotations do not exactly harmonize with the actual receipts by the producers.

Prices of Connellsville furnace and foundry coke per short ton at ovens, 1911–1913, by months.

Lower Connellsville district.—This district is now the second in importance among the coke-making districts of the United States. It bids fair to rival the Connellsville district within a few years. The first ovens were built in 1900, so that at the close of 1913 the district was only a little more than 13 years old. The production in 1912 was 9,023,371 short tons and in 1913 it was 8,976,781, indicating a slight decrease. The value, however, increased from $17,166,837 in 1912 to $19,868,322, the average price per ton rising from $1.90 in 1912 to $2.21 in 1913.

There was a gain of 211 in the total number of ovens in existence at the close of the year, as against a decrease of 30 ovens in the Connellsville district, and there were 440 ovens building at the close of the year in contrast with only 60 building in the Connellsville district. The number of establishments in the Lower Connellsville district increased from 74 to 75. There were 2 idle establishments with a total of 86 ovens, and 1,377 additional ovens idle belonging to plants operated for a portion of the year. The rectangular or Mitchell ovens have found their greatest favor in the Lower Connellsville district, there being 2,271 of this type in existence at the close of the year and 430 building. There are no by-product recovery ovens in the district.

The record of coke production in the Lower Connellsville district in 1900, 1905, and from 1909 to 1913 is as follows:

Statistics of the manufacture of coke in the Lower Connellsville district, Pennsylvania, 1900, 1905, and 1909–1913.

Year.	Establishments.	Ovens.		Coal used (short tons).	Yield of coal in coke (per cent).	Coke produced (short tons).	Total value of coke at ovens.	Value of coke at ovens per ton.
		Built.	Building.					
1900	12	2,033	1,112	579,928	66.5	385,909	$792,886	$2.05
1905	45	7,484	1,145	5,666,812	68.3	3,871,310	7,532,382	1.95
1909	70	14,215	1,036	9,781,803	69.1	6,761,335	12,490,518	1.85
1910	73	14,805	668	12,130,425	67.8	8,219,492	16,048,675	1.95
1911	71	14,857	654	10,771,495	68.3	7,354,736	12,998,192	1.77
1912	74	15,525	422	13,456,074	67.1	9,023,371	17,166,837	1.90
1913	75	[a]15,736	[b]440	13,498,088	66.5	8,976,781	19,868,322	2.21

[a] Includes 2,271 rectangular ovens. [b] Rectangular ovens.

The combined production of the Connellsville, Upper Connellsville, and Lower Connellsville districts in 1913 amounted to 21,363,751 tons, as compared with 21,600,659 tons in 1912. All the other coke-producing districts in Pennsylvania, including the by-product ovens at Lebanon, Steelton, South Bethlehem, and Chester, amounted to 7,389,693 short tons, valued at $20,419,807. The three Connellsville districts produced 74 per cent of the total for Pennsylvania.

TENNESSEE.

The eastern part of Tennessee is crossed, in a northeast-southwest direction, by the coal measures of the Appalachian province. Coal is mined in 17 counties and coke is made in 8. The counties in which coke is made are Campbell, Grundy, Hamilton, Marion, Morgan, Rhea, Roane, and Sequatchie. The larger part of the workable coal in the State occurs in three basins, the Wartburg, the Walden, and the Sewanee. (See report on production of coal, 1910.) Each of these basins contains a number of workable coal beds, as many as seven having been noted in the Walden Basin. Nearly all of the Tennessee coals possess coking qualities, but not all to the same degree, as is attested by the number of idle ovens during the last six years. There are 15 establishments in the State with a total of 2,427 ovens (157 less than in 1912), of which 6 with a total of 768 ovens were idle. In addition to the idle plants there were 370 idle ovens at establishments which operated some of their ovens during the year. The 1,289 active ovens, all of which are of the beehive type, produced 364,578 tons of coke in 1913, a decrease of 5,498 tons as compared with 1912, when 370,076 tons were produced by 1,466 active ovens. The value decreased from $951,853 to $925,430. There were no new ovens in course of construction in either 1912 or 1913.

The statistics of the manufacture of coke in Tennessee in 1880, 1890, 1900, and from 1909 to 1913, are shown in the following table:

Statistics of the manufacture of coke in Tennessee, 1880–1913.

Year.	Establishments.	Ovens.		Coal used (short tons).	Yield of coal in coke (per cent).	Coke produced (short tons).	Total value of coke at ovens.	Value of coke at ovens per ton.
		Built.	Building.					
1880	6	656	68	217,656	60.0	130,609	$316,607	$2.42
1890	11	1,664	292	600,387	58.0	348,728	684,116	1.96
1900	14	2,107	340	854,789	55.6	475,432	1,269,555	2.67

1913	15	2,427	0	694,085	52.5	364,578	925,430	2.50

Nearly all of the coal used for coke making in Tennessee is washed before being charged into the ovens. In 1913 the total quantity of coal used was 694,085 tons, of which 669,758 tons (202,014 tons of mine-run and 467,744 tons of slack) were washed. The unwashed coal was 24,327 tons of slack.

Character of coal used in the manufacture of coke in Tennessee, 1890, 1900, and 1909–1913, in short tons.

Year.	Run of mine.		Slack.		Total.
	Unwashed.	Washed.	Unwashed.	Washed.	
1890	255,359	0	273,028	72,000	600,387

VIRGINIA.

All the coking coals of Virginia are contained in a few counties lying in the extreme southwestern portion of the State and within the coal fields of the Appalachian province. The development of this region began in 1883 with the completion of the New River division of the Norfolk & Western Railway, and for 10 years the manufacture of coke, as well as the production of coal, in Virginia was almost entirely from Tazewell County. Ten years from the opening of the district, or in 1893, the Norfolk & Western Railway completed a branch up the Clinch Valley and opened in Wise County what is now the most important coking-coal district in the State. During 1906 and 1907 extensive developments in what is known as the Black Mountain field in Lee County followed the construction into that district of the Black Mountain Railway, now operated jointly by the Southern Railway and the Louisville & Nashville Railroad.

The principal coke-making activities are in Wise County, which now produces nearly 90 per cent of the total coke output of the State and considerably more than that proportion of the coal used in its manufacture. The coal for the ovens in Tazewell County is drawn from mines whose workings extend across the State boundary line into West Virginia, and a part of the coal, probably the greater part, comes from the West Virginia side of the line. The ovens at Low Moor and Covington draw their supplies of coal from the New River district of West Virginia.

There are 18 establishments in the State, with a total of 5,695 ovens. Coke was made at all 18 plants in 1913, but 2,406 ovens, more than 40 per cent of the total number, were idle. The production, however, increased from 967,947 short tons, valued at $1,815,975, in 1912 to 1,303,603 tons, valued at $2,840,275, in 1913. The gain amounted to 335,656 tons, or 34.7 per cent, in quantity and to $1,024,300, or 56.4 per cent, in value. In two earlier years, 1909 and 1910, the output exceeded that of 1913, but in the value of the product 1913 exceeded all previous records. The output in 1910 was larger than that of 1913 by 190,000 tons, but fell below the value of the later year by more than $100,000.

The statistics of the manufacture of coke in Virginia in 1883, when the first operations were begun, and in 1890, 1900, and from 1909 to 1913, are shown in the following table:

Statistics of the manufacture of coke in Virginia, 1883–1913.

Year.	Establishments.	Ovens.		Coal used (short tons).	Yield of coal in coke (per cent).	Coke produced (short tons).	Total value of coke at ovens.	Value of coke at ovens per ton.
		Built.	Building.					
1883	1	200	0	39,000	65.0	25,340	$44,345	$1.75
1890	2	550	250	251,683	66.0	165,847	278,724	1.68
1900	7	2,331	300	1,083,827	63.2	685,156	1,464,556	2.14
1909	19	5,469	100	2,060,518	65.1	1,347,478	2,415,769	1.79

1912	18	5,408	0	1,555,969	62.2	967,947	1,815,975	1.88
1913	18	5,695	100	2,015,259	64.7	1,303,603	2,840,275	2.18

All the coal used in the manufacture of coke in Virginia is of exceptionally high grade, and none of it requires preparation other than crushing before being charged into the ovens. The character of the coal used is nearly evenly divided between run of mine and slack. The total quantity of coal consumed in the manufacture of coke in 1913 was 2,015,259 short tons, of which 916,808 tons were mine run and 1,098,451 tons were unwashed slack.

The following table shows the character of the coal used in coke making in Virginia in 1890, 1900, and from 1909 to 1913:

Character of coal used in the manufacture of coke in Virginia, 1890–1913, in short tons.

Year.	Run of mine.		Slack.		Total.
	Unwashed.	Washed.	Unwashed.	Washed.	
1890	98,215	0	153,468	0	251,683
1900	620,207	0	463,620	0	1,083,827

WASHINGTON.

Washington is the only Pacific coast State possessing coal of coking quality, but the coking industry is restricted to a limited area in Pierce County. The coal mined in the northern part of the Roslyn field in Kittitas County (the only coal field in Washington east of the Cascades) is of coking grade, but no attempt at producing coke from it commercially has been made. There are 6 establishments in the State, with a total of 331 ovens; but 3 of the plants, 1 of 50 ovens and 2 of 25 ovens each, have been idle for several years, the entire production being from 3 establishments in the Wilkeson-Carbonado field of Pierce County. The production in 1913 was the largest in the history of the State, amounting to 76,221 short tons, valued at $432,770, and exceeding that of 1912 by 26,961 tons, or 54.7 per cent, in quantity and $153,665, or 55 per cent, in value. Most of the coke is consumed by the smelter at Tacoma. All of the coal used for making coke in 1913 was washed run of mine.

The first ovens were built in Washington in 1885, but 400 tons of coke were made in pits the preceding year.

The statistics of production in 1884, 1890, 1900, and from 1909 to 1913 are as follows:

Statistics of the manufacture of coke in Washington, 1884–1913.

Year.	Establishments.	Ovens.		Coal used (short tons).	Yield of coal in coke (per cent).	Coke produced (short tons).	Total value of coke at ovens.	Value of coke at ovens per ton.
		Built.	Building.					
1884	1	0	0	700	57.0	400	$1,900	$4.75
1890	2	30	80	9,120	64.0	5,837	46,696	8.00

WEST VIRGINIA.

The manufacture of coke in West Virginia is far from keeping pace with the progress shown by that State in the mining of coal, in spite of the fact that, next to Pennsylvania, West Virginia possesses more wealth in supplies of high-grade coking coals than any other State in the Union. The production of coal in West Virginia in 1913 exhibited an increase over 1912 of 4,523,295 short tons, and reached a total of 71,308,982 tons, whereas the output of coke showed an insignificant gain of 6,766 tons, or only a little more than one-fourth of 1 per cent. The coke production in 1913 in this State was but 5 per cent larger than in 1900 and was less than the output of either 1909 or 1910 by more than one-third. The reasons assignable for this actually stationary and relatively retrogressive condition are found in the almost entire absence of an iron industry in the State and the now somewhat rapid shifting of the coke-making activities from the coal-mining regions to the consuming centers, as the beehive ovens are being replaced by the more economical by-product retorts. But while no advance is being made by West Virginia in the manufacture of coke, larger quantities of West Virginia coal are being used for coke making in other States, most of the retort ovens in Ohio, Indiana, and Illinois drawing their coal supplies from West Virginia mines. The quantity of coal made into coke in West Virginia in 1913 was 4,034,251 short tons, whereas inquiries as to the source of the coal made into coke in retort ovens outside of the coking-coal regions developed the information that 7,546,674 tons, or nearly twice as much as that consumed in West Virginia, were from the mines of that State.

In coke making, as in coal mining, West Virginia is handicapped by having relatively little home consumption for her products. As a coal producer this State ranks second only to Pennsylvania and has in a number of years held the same rank in the manufacture of coke, but has now fallen behind both Alabama and Indiana. Only a small proportion of either product is consumed within the State, fully 80 per cent of the coal mined and nearly all of the coke produced being shipped to consumers in other States, usually at prices to the producers much below those obtained for lower grades from other districts.

The quantity of coke made in West Virginia in 1913 was 2,472,752 short tons, valued at $5,504,416, against 2,465, 986 tons, valued at $4,692,393, in 1912. The increase in quantity was only 6,766 tons, but the increase in value amounted to $812,023, or 17.3 per cent, and was due to the general advance in the prices of coke which prevailed during the early part of the year.

With the exception of 120 Semet-Solvay ovens at Benwood, near Wheeling, all the ovens in West Virginia are of the beehive type. It is to be noted that the average yield of coal in coke in West Virginia is only about 61 per cent, notwithstanding the fact that a large part of the coal used for making coke in the State contains only from 15 to 20 per cent of moisture and volatile matter. The coal should yield about 80 per cent in coke. The difference in actual results is due to the necessity of burning off at least one-fourth of the fixed carbon in the beehive oven in order to secure the heat necessary to produce a high-grade cellular coke. When it is considered that in the retort ovens to which West Virginia coal is shipped the theoretical yield is practically obtained, the shifting of coking activity from the mining districts of West Virginia to the industrial centers of the Middle West is not difficult to understand.

The number of coke-making establishments decreased from 129 in 1912 to 124 in 1913. Six plants with a total of 964 ovens were abandoned, and 1 new plant was added to the Upper Monongahela district, notwithstanding more than half the plants and ovens in the district were idle. The total number of ovens abandoned in 1913 was 1,342 and the net decrease in the number of ovens in the State was 1,238, reducing the total from 19,064 in 1912 to 17,826 in 1913. Of the 1,342 ovens abandoned in 1913, 381 were in the Pocahontas district, 149 were in the New River district, and 807 were in the upper Potomac district. Of the 17,826 ovens in existence in 1913, considerably more than half, or 9,129, were idle. The greatest percentage of idleness was in the Tug River district, where out of a total of 2,151 ovens 1,493 were idle. Nearly half of the ovens in the Pocahontas district and a little over half each in the Kanawha, the New River, and the Upper Potomac districts were idle.

In the following table will be found the statistics of the manufacture of coke in West Virginia in 1880, 1890, 1900, and for the last five years:

Statistics of the manufacture of coke in West Virginia, 1880–1913.

Year.	Establishments.	Ovens.		Coal used (short tons).	Yield of coal in coke (per cent).	Coke produced (short tons).	Total value of coke at ovens.	Value of coke at ovens per ton.
		Built.	Building.					
1880	18	631	40	230,758	60.0	138,755	$318,797	$2.30
1890	55	4,060	334	1,395,266	60.0	833,377	1,524,746	1.83
1900	106	10,249	1,306	3,868,840	60.9	2,358,499	4,746,633	2.01
1909	138	20,283	126	6,361,759	62.0	3,943,948	7,525,922	1.91
1910	135	19,912	230	6,226,234	61.1	3,803,850	7,354,039	1.93
1911	138	19,876	130	3,754,561	60.4	2,291,049	4,236,845	1.85
1912	129	19,064	0	4,061,702	60.7	2,465,986	4,692,393	1.90
1913	124	[a]17,826	35	4,034,251	61.3	2,472,752	5,504,416	2.23

[a] Includes 120 Semet-Solvay ovens at Benwood.

The larger part of the coal used in coke making in West Virginia (nearly 70 per cent) is slack. In 1913, out of a total of 4,034,251 short tons of coal consumed in coke-making operations, 2,879,048 tons were slack. Of that quantity 2,525,919 tons were unwashed and 353,129 tons were washed. The total quantity of mine-run coal used was 1,155,203 tons, of which 916,068 tons were unwashed and 239,135 tons were washed coal. The total quantity of coal washed, including mine-run and slack, was 592,264 short tons, or 14 per cent of the total quantity of coal consumed in the manufacture of coke in the State.

The character of the coal used in the manufacture of coke in West Virginia in 1890, 1900, and from 1909 to 1913 is shown in the following table:

Character of coal used in the manufacture of coke in West Virginia, 1890–1913, in short tons.

Year.	Run of mine.		Slack.		Total.
	Unwashed.	Washed.	Unwashed.	Washed.	
1890	324,847	0	930,989	139,430	1,395,266
1900	509,960	8,000	3,140,064	210,816	3,868,840
1909	2,282,403	32,285	3,644,271	402,800	6,361,759
1910	2,088,553	234,484	3,462,927	440,270	6,226,234
1911	925,460	158,308	2,408,299	262,494	3,754,561
1912	1,146,620	143,309	2,433,229	338,544	4,061,702
1913	916,068	239,135	2,525,919	353,129	4,034,251

PRODUCTION BY DISTRICTS.

It has been customary in the preceding reports of this series to consider the coke production by the districts into which the State has been divided. These districts are known, respectively, as the Upper Monongahela, the Upper Potomac, the Kanawha, the New River, and the Flat Top. The first two are in the northern part of the State and are named from the rivers, the Monongahela and the Potomac, by whose headwaters they are drained. The other three districts are in the southern part of the State. The New River district includes the ovens along the line of the Chesapeake & Ohio Railway and its branches from Quinnimont to Hawks Nest, near which point the coals of the New River region go below water level. The Kanawha district embraces all of the ovens along Kanawha River and its tributaries from Mount Carbon to the western limit of the coal fields. The ovens of the Gauley Mountain Coal Co. at Ansted are included in the New River district, although the Ansted coal belongs in realty to the coal series of the Kanawha district and lies about 1,000 feet above the New River coals. The Flat Top region is drained by the upper portions of New, Guyandotte, and Big Sandy Rivers, and includes the ovens in West Virginia, which belong to the Pocahontas coal field. The Flat Top district is by far the most important and bears the same relation to the production of West Virginia that the Connellsville district bears to that of Pennsylvania. Since 1900 the statistics of production of the Flat Top district have included the new operations along Tug River lying west of and continuous with the Flat Top district. The output from the Flat Top-Tug River district averages somewhat more than 50 per cent of the total coke production of the State.

The statistics of the production of coke in West Virginia, by districts, in 1912 and 1913 are shown in the following table:

Production of coke in West Virginia in 1912 and 1913, by districts.

1912.

District.	Establishments.	Ovens.		Coal used (short tons).	Yield of coal in coke (per cent).	Coke produced (short tons).	Total value of coke at ovens.	Value of coke at ovens per ton.
		Built.	Building.					
Flat Top [a]	53	11,280	0	2,094,283	56.6	1,185,978	$2,057,456	$1.73
Kanawha	10	1,628	0	499,085	62.2	310,350	515,508	1.66
New River	20	1,709	0	290,805	62.0	180,190	426,475	2.37
Upper Monongahela	33	2,873	0	887,612	66.6	591,243	1,326,661	2.24
Upper Potomac and Tygarts Valley	13	1,574	0	289,917	68.4	198,225	366,293	1.85
Total	129	19,064	0	4,061,702	60.7	2,465,986	4,692,393	1.90

1913.

District.	Establishments.	Ovens.		Coal used (short tons).	Yield of coal in coke (per cent).	Coke produced (short tons).	Total value of coke at ovens.	Value of coke at ovens per ton.
		Built.	Building.					
Flat Top [a]	52	10,952	0	2,047,926	58.8	1,203,690	2,543,953	2.11
Kanawha	10	1,628	0	533,035	61.8	329,618	700,559	2.12
New River	19	1,561	0	322,070	60.1	193,418	489,071	2.53
Upper Monongahela	34	[b] 2,918	0	793,508	64.9	515,189	1,279,614	2.48
Upper Potomac and Tygarts Valley	9	767	35	337,712	68.4	230,837	491,219	2.12
Total	124	17,826	35	4,034,251	61.3	2,472,752	5,504,416	2.23

[a] Includes Tug River district.

[b] Includes 120 Semet-Solvay ovens.

OTHER STATES.

In the following table are presented statistics of the production of coke in those States in which there are three or less establishments, and for which permission to give separate publication has not been granted. Permission has been given to give separate publication for the operations of the Camden Coke Co.'s plant, and New Jersey, therefore, is not included in "Other States" in the present report. Kansas, which was also included in "Other States" in 1912, is dropped this year because all the ovens have been idle, and, in fact, have been practically abandoned. Six States are therefore included in the report for 1913 against 8 in 1912. The 6 States included are Maryland, Massachusetts, Michigan, Minnesota, Utah, and Wisconsin. These 6 States have 9 establishments with a total of 2,005 ovens, all but those of Utah being of the by-product recovery type. The total production for the 6 States included in this table in 1913 was 2,345,329 short tons, valued at $9,354,765, or an average of $3.99 per ton. Of the 6 States, Maryland, Michigan, Minnesota, and Wisconsin obtain their coal from mines in other States, Massachusetts obtains its supply from Nova Scotia and West Virginia; the Utah ovens are supplied from mines within the State.

Statistics of coke production from 1900 to 1905 and from 1909 to 1913 in States having only one or two establishments.

Year.	Establishments.	Ovens.		Coal used (short tons).	Yield of coal in coke (per cent).	Coke produced (short tons).	Total value of coke at ovens.	Value of coke at ovens per ton.
		Built.	Building.					
1900	10	832	594	708,295	71.5	506,730	$1,454,029	$2.87
1905	12	1,666	145	2,222,723	74.7	1,660,857	5,500,337	3.31
1909	20	2,553	563	3,427,732	73.3	2,509,306	9,129,282	3.64
1910	29	2,878	563	4,903,129	75.1	3,684,276	14,509,072	3.94
1911	23	2,850	95	4,002,047	75.6	3,023,607	10,989,538	3.63
1912	11	2,006	174	3,623,019	69.8	2,530,018	9,386,978	3.71
1913	9	[a] 2,005	[b] 210	3,299,345	71.1	2,345,329	9,354,765	3.99

[a] Includes 495 Semet-Solvay and 752 United-Otto ovens.
[b] All Koppers ovens.

BORAX.

By Charles G. Yale and Hoyt S. Gale.

PRODUCTION AND VALUE OF CRUDE BORATE MATERIALS IN 1913.

In 1913 the production of crude borate materials in the United States was 58,051 short tons, valued at $1,491,530, as compared with 42,315 tons in 1912, valued at $1,127,813. This is an increase of 37.19 per cent in the total quantity produced. All of this material consists in various degrees of purity of the mineral colemanite (calcium borate), which is derived from several mines in southern and southeastern California. The value of the product as here given is fixed on a basis of $1 per unit per cent of anhydrous boric acid (boron trioxide, B_2O_3) in the raw material as shipped, which is approximately the present price at the mine or point of shipment.

The statistics of production of borate ores in California from 1895 to 1913, inclusive, are given in the following table:

Production of borate of lime, or colemanite, in California, 1895–1913.

Year.	Quantity.	Value.	Year.	Quantity.	Value.
	Short tons.			Short tons.	
1895	[a] 5,959	$595,900	1905	[b] 46,334	$1,019,154
1896	[a] 6,754	675,400	1906	[b] 58,173	1,182,410
1897	[a] 8,000	1,108,000	1907	[b] 52,850	1,121,520
1898	[a] 8,000	1,120,000	1908	[b] 25,000	975,000
1899	[a] 20,357	1,139,882	1909	[b] 41,434	1,534,365

1904	[b] 45,647	698,810			

[a] Refined product. [b] Crude product.

REVIEW OF CONDITIONS OF INDUSTRY.

Source of domestic material.—All the borax in the United States continues to be produced from ores derived from California (see Pl. II), mainly from a few mines in Inyo and Los Angeles counties, though small quantities were produced in 1913 in Ventura County. During 1913 the Russell Borate Co., in Ventura County, ceased operations and the mine was sold to a San Francisco firm, operations as conducted having been unprofitable. In the same county the National Borax Co. also closed its mine and plant, and the property reverted to the United States Borate Co. through failure to meet payments.

This is the old Columbus or Calm Bros. mine, and the National Borax Co. was organized as a holding company to finance the United States Borate Co. Since the close of 1913 the extensive holdings of F. M. Smith in the Pacific Coast Borax Co. have been sold to the Borax Consolidated (Ltd.), of London, England, the transaction involving payment of about $4,000,000. The sale includes the famous Lila C. borax mine in the Death Valley region of Inyo County.

Thus far there has been no output of borax from the potash properties in the Searles Lake region, San Bernardino County, where the promoters expect to obtain borax as a by-product of the potash mining operations.

An unconfirmed report of new deposits near Kramer, Kern County, Cal. (sec. 22, T. 11 N., R. 8 W. San Bernardino meridian), appeared in the San Francisco newspapers in October, 1913. The reported deposits have not been examined by any member of the Survey, nor has any direct information concerning them been obtained.

Price.—According to price quotations in the trade journals the prices of borax and boric acid have not fluctuated or changed noticeably from those obtaining in recent years. They are as follows:[1] Borax, crystals, in bags, 3¾ to 4½ cents a pound; borax, crystals, in barrels, 4 to 4½ cents a pound. Boric acid, crystals, 7 to 7½ cents a pound; boric acid, powdered, 7 to 7½ cents a pound.

Tariff.—The tariff act, as passed and approved October 3, 1913, reads as follows:

DUTIABLE LIST.

Schedule A.—Chemicals, oils and paints:
Boric acid, ¾ cent per pound.
Soda, borate of, or borax refined, ½ cent per pound.

FREE LIST.

Borax, crude and unmanufactured, and borate of lime, soda, and other borate material, crude and unmanufactured, not otherwise provided for in this section.

IMPORTS.

The following table shows the imports of borax and borates into the United States from 1902 to 1913, inclusive:

Imports for consumption of borax and borates into the United States, 1902–1913, in pounds.

Year.	Borax.		Borates, calcium and sodium (crude) and refined sodium borate.		Boric acid.	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.

MAP SHOWING BORAX DEPOSITS IN THE UNITED STATES.

HISTORY OF THE BORAX INDUSTRY.

The history of the borax industry has been repeatedly reviewed and summarized, and accounts of the occurrence of borate minerals in various parts of the world have appeared from time to time. In the following bibliography is to be found about as complete an account of this history and of the occurrence of these materials as can at present be given in summary. For further study of the subject reference may be had to the originals cited.

BIBLIOGRAPHY.

By Hoyt S. Gale.

The following bibliography of publications relating to borax and borates is arranged in order of publication.

1844.

Hayes, A. A., Hydrous borate of lime; Am. Jour. Sci., 1st ser., vol. 47, p. 215, 1844.
Quotes an early analysis of borate of lime from Iquique, Chile, where it was associated with gypsum, magnesia alum, sodium iodate, and glauberite.

1857.

Veatch, J. A. (under date of June 28, 1857), quoted in report on the Mineral Resources of the States and Territories west of the Rocky Mountains, Washington, pp. 178–185, 1867.
An interesting narrative account of the first recognition of borax and boric acid in natural waters on the Pacific coast and the steps then taken for the further investigation and development of these resources. Borax crystals were first observed by Dr. Veatch forming in the residue from the evaporation of waters from Lick Springs in Tehama County, Cal., on January 8, 1856. They were recognized as borax by the crystal form, the determination being later confirmed by chemical test. Dr. Veatch describes his visit to and examination of Clear Lake, Borax Lake, and Sulphur Bank, and the later finding of the crystals of borax in the mud on the bottom of Borax Lake.

1859.

Veatch, J. A., Occurrence of boracic acid in the sea water of the Pacific (paper read before the society Jan. 17, 1859); California Acad. Sci. Proc., vol. 2, pp. 7–8, 1863.
Dr. Veatch mentions that he had in the month of January, 1856, discovered borate of soda in solution in the water of a mineral spring in Tehama County, Cal., and that prosecuting the research he had found traces of boric acid in the form of borates in nearly all the mineral springs with which the State of California abounds. He relates how he found boric acid also in salt derived from solar evaporation of the sea water along the Pacific coast, and following this, showed the presence of appreciable quantities of boric acid in the sea water off the coast—a maximum near San Diego and in diminishing quantity northward, until barely perceptible in specimens of water brought from beyond Oregon. This peculiarity seems to extend to no great distance seaward; no trace found 30 or 40 miles out.

1861.

Forbes, David, On the geology of Bolivia and southern Peru: Geol. Soc. London Quart. Jour., vol. 17, p. 7, 1861. (Read Nov. 21, 1860.)
Describes salines near Iquique and also occurrences scattered over the whole arid portion of the west coast. These are defined as post-Tertiary. A list of saline minerals found is given, which are ascribed to a marine origin supposed to be the desiccated products of lagoons of sea water elevated by crustal movement. The origin of nitrates and borates is particularly referred to. (It may be added by way of comment on this paper that the list of saline minerals given is probably capable of other interpretation, as the minerals, common salt, thenardite, glauberite, gypsum, and probably most of the others mentioned, characterize continental as well as marine salines.

How, H., Natro-boro-calcite and another borate occurring in the gypsum of Nova Scotia: Am. Jour. Sci., 2d ser., vol. 32, p. 9, 1861. (See also Philos. Mag., 4th ser., vol. 35, p. 31, 1868; vol. 41, p. 270, 1871.)

In the gypsum beds of Windsor, Nova Scotia, ulexite, howlite, and cryptomorphite are found, associated with anhydrite, selenite, mirabilite, salt, aragonite, and calcite.

Veatch, J. A., Boracic acid in the sea water of the Pacific on the coast of California: Chem. News, July 13, p. 16, 1861.

Notes boric acid in sea water of Pacific coast in July, 1857. In January of 1856 discovered borate of soda and other borates in solution in the water of a mineral spring in Tehama County. (This may be a quotation from the California Acad. Sci. Proc.)

1863.

Forbes, David, On the chemical composition of some Chilian minerals: Philos. Mag. and Jour. Sci., 4th ser., vol. 25, London, pp. 113–114, 1863.

Finding a calcium borate (hayesine), either ulexite or bechilite, actually in process of deposition at the hot springs of Banos del Toro, in the Cordilleras of Coquimbo, Chile, the author believes volcanic origin of borate minerals to be confirmed.

1865.

Whitney, J. D., Geological survey of California, vol. 1, p. 96, 1865.

Describes Clear Lake, about 65 miles northwest of Suisun Bay, and 36 miles from the Pacific, the volcanic evidences, the hot springs, and the relations to them of Borax Lake, which occupies a depression on the east side of the narrow arm of Clear Lake. An analysis of water from Borax Lake collected in September, 1863, is quoted, showing 2,401.56 grains of solid matter per gallon, of which about one-half is NaCl, one-fourth Na_2CO_3, and 281.48 grains of anhydrous biborate of soda (=535.08 crystallized borax). Contains notes as to the occurrence of distinct borax crystals imbedded in the muds at the bottom of Borax Lake. Also describes the "Sulphur Banks" near by.

1866.

Whitney, J. D., On borax in California: Am. Jour. Sci., 2d ser., vol. 41, pp. 255–258, 1866.

Quotation from Geological survey of California, vol. 1, p. 96, with additional note from the San Francisco papers quoting production from the Borax Lake locality.

1867.

Browne, J. R., Mineral resources of the States and Territories west of the Rocky Mountains, pp. 178–187, 1867.

Consists chiefly of the quotation from J. A. Veatch already referred to (1857), but includes notes as to foreign sources of borax at that time, the production in California, and the process of working at Borax Lake in Lake County. The mud was taken from the lake bottom through cofferdams which could be moved from place to place and then bailed out. The fine crystals were formed in the upper layer of soft mud to a depth of about 6 feet, which were separated by solution in hot water and redeposited by cooling. Below the top stratum was a stiff blue mud containing the largest crystals which were picked out by hand, the mud being too stiff to be treated by washing. It was, of course, recognized that a great deal of borax was also present in solution in the waters of the lake

1873.

Chase, A. W., On the Oregon borate of lime: Am. Jour. Sci., 3d ser., vol. 5, p. 287, 1873.

Describes mineral afterward named priceite, in what appears to be a unique deposit at Chetco, Curry County, Oreg. When found it lay as an outcrop of a white substance like chalk in the banks of a little stream 500 yards from the sea and about 20 feet above it. Upon mining it was shown to be in the form of distinct bowlders or rounded masses imbedded in a tough blue clay.

Silliman, B., Mineralogical notes on Utah, California, and Nevada, with a description of priceite, a new borate of lime: Am. Jour. Sci., 3d ser., vol. 6, pp. 128–133, 1873.

Adds further notes and analyses of the mineral priceite, on the occurrence of ulexite in the Western States and of borax from "the eastern slope of the Sierra Nevada, not far from Walker's Pass" [probably China Lake or Searles Lake.]

1877.

DIEULAFAIT, L., Annales chim. et phys., 5th ser., vol. 12, p. 318, 1877.

Boric acid exists in the waters of all the oceans and contrary to chemical expectation it is concentrated in the last mother liquor.

KING, CLARENCE, U. S. Geol. Expl. 40th Par., vol. 2, pp. 594, 744, 1877.

In the Humboldt River valley above Osino Canyon, saline incrustations yielded on analysis 52 per cent soluble alkaline salts, chiefly carbonate of soda, 4½ per cent of the water-soluble part being borax.

Near Brown's station, opposite Humboldt Lake, a quantity of saline incrustation found covering the ground was collected, mixed with the fine impalpable soil of the valley. Analysis showed the salts to be about one-half sodium chloride, a considerable proportion of sulphate and carbonate of soda, and 11.3 per cent borax.

PHILLIPS, J. A., The alkaline and boracic lakes of California: Pop. Sci. Rev., vol. 16 (2d ser., vol. 1), pp. 153–164, London, 1877; Kansas City Rev., vol. 1, pp. 225–235, 1878.

A very interesting account (for this date) of Owens and Mono lakes, with the earliest recorded analysis of the water of the former. Contains descriptions as a result of a visit made in 1866 to the two borax lakes near Clear Lake, Lake County, Cal., of the occurrence of the borax crystals in the mud on the lake bottom and the method of recovering same by means of cofferdams. Notes the manipulation at Little Borax Lake of ulexite brought from Wadsworth, Nev., to be treated here on account of the presence of carbonate of sodium and the cheapness of fuel. Notes an occurrence of borax in the bed of an ancient lake near Walker's Pass, mentions "similar deposits in Panamint and Death valleys in lower Nevada; but these desolate tracts have not as yet received so careful an examination as they deserve." Ulexite in the Cane Spring district, and at the Hot Springs in northwestern Nevada are also referred to. Finally notes as to the purification of crude borax (tincal) are added, with the remark that recent discovery of large quantities of borates in Nevada "will, no doubt, eventually to some extent affect the Tuscan producers of boric acid."

1878.

SCHLAGINTWEIT, H. VON, München Acad. Sitzungsb., vol. 8, p. 518, 1878.

Describes the great borax deposits of the Puga Valley, in Ladak, in northern British India, where the mineral covers the ground over a large area to an average depth of 3 feet. The borate is a deposit from hot springs, which issue more than 15,000 feet above sea level, at a temperature ranging from 54° to 58° C. The saline mass contains free boric acid and sulphur, with lesser quantities of salt, ammonium chloride, magnesium sulphate and alum, and there is much gypsum in the vicinity. No ulexite was found.

1880.

KYLE, J., J. J., La boronatrocalcita de la Provincia de Salta (Argentina): Soc. cient. argentina Anales, vol. 10, p. 169, 1880.

Describes ulexite associated with glauberite from the Province of Salta and refers to its existence in Catamarca.

LOCK, C. G. W., Pandermite, a new boracic mineral: Soc. Arts Jour., vol. 28, pp. 767–768, Aug. 6, 1880.

Pandermite, named from its port of shipment, Panderma, was found on the Tchinar-son, a small stream feeding Rhyndacus River, whose outlet is in the Sea of Marmora, about 40 miles (English) from Panderma, on the Asiatic shore. The field is situated in a region of Tertiary rocks, including granite, trachyte, and columnar basalt, also characterized by hot and mineral springs. The pandermite occurs as a stratum at the bottom of an enormous bed of gypsum, 60 to 150 feet in thickness, the borate mineral occurring in the form of closely packed nodules of irregular size and shape and weighing as much as a ton. The mineral resembles a snow-white fine-grained marble. The material has for some time been shipped to Europe as a source of borax and boric acid.

1882.

AYERS, W. O., Borax in America: Pop. Sci. Monthly, vol. 21, pp. 350–361, July, 1882.
A good description from personal observation of the workings for borax at Borax Lake and Hachinhama in the vicinity of Clear Lake, Cal., and also of the occurrence of borax and ulexite at Columbus Marsh, Nev. This account records the discontinuance of the crystal borax washings at Borax Lake (1864–1868), "when it ceased, not from failure of the supply, but simply from mismanagement of the work." The other locality, Hachinhama, on the southern side of Clear Lake, about 4 miles west of Borax Lake, was then operated. Here no borax had already crystallized, and only the solution in the lake water was available. This was concentrated by boiling and the borax crystallized by cooling. Later, as this small, shallow lake became more nearly or quite dry, the surface efflorescence of salts was scraped and was purified by resolution and crystallization as before. This process was continued until the spring of 1872, when the ulexite from the Nevada marsh deposits began to be brought in, and was used to increase the yield from the Hachinhama waters. This continued until 1874, when the large supply of borax from Nevada fields made the work in these California lakes unprofitable. Then follows a description and discussion of the deposits at Columbus Marsh, Nev.

DARTON, N. H., On a new locality for hayesine and its novel occurrence: Am. Jour. Sci., 3d ser., vol. 23, pp. 458–459, 1882.
Describes a mineral from Bergen Hill, N. J., identified as hayesine, with the formula $CaB_2O_7+3H_2O$ calculated from an analysis. It occurs with datolite and calcite in cavities in trap rock, as an asbestos-like, soft, fibrous mass.

1883.

HANKS, H. G., Report on the borax deposits of California and Nevada: California State Min. Bur. Third Ann. Rept., pt. 2, pp. 1–102, 1883.
An extended review of the subject of borax, including its ancient history, its early production and refining, the history of its discovery in the United States, many quotations concerning these subjects and reports of occurrences, together with a map of localities in California and Nevada. Besides the description of the discovery and workings near Clear Lake in California, accounts are given of Searles Lake (p. 26), the Death Valley fields, the discovery of colemanite in the Calico district, and the Desert or Cane Springs deposits. Descriptions of Nevada localities are given as follows: Columbus Marsh, Sand Springs, Teels Marsh, Rhodes Marsh, Fish Lake Valley, and Pyramid Lake. The use of a hand spectroscope in a test for boric acid is described, as also other chemical methods for its detection and determination. A review of the methods of recovery from the Tuscan fumaroles is also given by quotation. Statistical data are followed by descriptions of borate minerals and salts.

ANON., Borax: U. S. Geol. Survey Mineral Resources, 1882, pp. 566–577, 1883.
A short and general review of the whole field, including the history of the development of the industry in this country, presumably by abstract from previous publications; a short description of Fish Lake Marsh, Columbus Marsh, Rhodes Marsh, Teels Marsh; and references to borax workings at Sand Springs, at Hot Springs on the Central Pacific Railroad, at Soda Lake near Ragtown in Nevada, and to developments at Slate Range Marsh (Searles Lake), at Furnace Creek in Death Valley, and at Resting Springs in California. Mention is made of reported discovery of borax in Soda Lake, the sink of Mohave River. Statistics of production from 1873–1882 are quoted. Price of borax in New York is quoted as 13½ cents a pound for refined and 10½ to 11 cents for crude. The tariff is quoted as 5 cents a pound on refined borax and boric acid, ranging to 4 cents and 3 cents on other materials carrying boric acid.

1884.

HANKS, H. G., California minerals: California State Min. Bur. Fourth Ann. Rept., pp. 80–93, 311–314, and 391–394, 1884.
Mineralogical descriptions of borax, priceite, pandermite, colemanite, ulexite, contained in a list of California minerals, including description of tests, etc.; reference to history of production, largely by abstract from the report of the preceding year, but with some additional data.

JACKSON, A. W., On colemanite, a new borate of lime: Am. Jour. Sci., 3d ser., vol. 28, p. 447, 1884.

A new borate of lime recently determined by J. T. Evans, of the California Acad. Sciences, as $2CaO.3B_2O_3.5$ aq., and differing from pandermite in containing 5 instead of 3 molecules of water; gives crystallographic determination on specimens. Short note. No locality references.

1885.

DIEULAFAIT, L., Nouvelle contribution à la question de l'origine de l'acide borique; eaux de Montecatini (Italie): Compt. Rend., vol. 100, pp. 1240–1243, 1885.

Boric acid with lithium and strontium occur in the waters of Montecatini, and as these rare minerals signalize the sea-water solution particularly, the belief is expressed that these salines of Montecatini are derived from formations which have been derived from ancient lakes or lagoons, the unusual association being naturally concentrated in the last mother liquors of sea waters.

EVANS, J. T., The chemical properties and relations of colemanite: California Acad. Sci. Bull. 2, January, 1885.

Deduces the formula $2CaO.3B_2O_3.5H_2O$ and compares formulas of pandermite, $2CaO.3B_2O_3+3H_2O$, and priceite, $3CaO.4B_2O_3+6H_2O$.

JACKSON, A. W., On the morphology of colemanite: California Acad. Sci. Bull. 2, p. 3, 1885.

A crystallographic description of colemanite. Statement is made that colemanite was discovered by R. Neuschwander in October, 1882, in southern California, and named after W. T. Coleman, of San Francisco.

ANON., Borax: U. S. Geol. Survey Mineral Resources, 1883–84, pp. 859–863, 1885.

Contains an announcement of the discovery of new deposits of borates in Death Valley, Inyo County, at Desert Springs, Kern County, and in the eastern part of the Calico district, San Bernardino County, Cal. A decline in the price of borax until it reached 8½ cents in New York and 8 cents in San Francisco is recorded, including mention of a new tariff bill which had temporarily raised the price. Statistics of production are quoted. A description of the methods of working in Fish Lake Valley, Nevada, taken from a Candelaria newspaper, reviews the apparatus and operations in some detail.

1886.

ANON., Borax: U. S. Geol. Survey Mineral Resources, 1885, pp. 491–493, 1886.

Continued decline in the price of borax is noted, the San Francisco selling price being 6 to 8 cents per pound. Statistics of production are given, and also statement of imports. The condition of the industry is summarized in the statement: "Only the practice of the strictest economy has enabled existing companies to continue operations till the present time."

1887.

GOOCH, F. A., A method for the separation and estimation of boric acid, with an account of a convenient form of apparatus for quantitative distillations: U. S. Geol. Survey Bull. 42, pp. 64–72, 1887.

ANON., Borax: U. S. Geol. Survey Mineral Resources. 1886, pp. 678–680, 1887.

Statistics of production and imports. Price in San Francisco May, 1887, was 5 to 6 cents for concentrated or refined borax.

1888.

ANON., Senate Rept. No. 2332, pt. 2, 50th Cong., 1st sess., pp. 205–218 [June 18, 1888].

BECKER, G. F., Geology of the quicksilver deposits of the Pacific coast: U. S. Geol. Survey Mon. 13, pp. 265, 347–349, 440, 1888.

Incidental to the main subject of the monograph, Borax Lake, Lake County, Cal., is described and a very complete analysis of its waters given (p. 265), which shows 5 grams per liter of borax in solution (about 6¼ per cent of the total salts, the dissolved constituents amounting to about 8 per cent of the original solution). The relation of this district to former volcanic activity is pointed out.

A very complete analysis of the water from Steamboat Springs, Nev., is given (p. 347), showing water that contains borax to the amount of about 11 per cent of the total dissolved salts, the water, however, being dilute, carrying only about 0.28 per cent dissolved salts.

Reference is made (p. 440) to the probable ultimate source of borax in these natural waters, ascribing as a rational explanation a source in volcanic emanations from some deep-seated positions.

Biddle, H. J., Notes on the surface geology of southern Oregon: Am. Jour. Sci., 3d ser., vol. 35, p. 476, 1888.
Incidentally mentions occurrence of ulexite in Warner Valley, Oreg., observed in summer of 1887.

Anon., Borax: U. S. Geol. Survey Mineral Resources, 1887, pp. 4–9, 1888.
Statistics of production.

Witting, F., Die Boraxfabrication aus Boronatrocalcite: Zeitschr. angew. Chemie, vol. 17, pp. 483–487. (The manufacture of borax from boronatrocalcite.)
Discusses the manufacture of borax in Germany from the crude boronatrocalcite obtained in the north of Chile, at Maricunga, Pedernal, and at Ascotan. Process consists of the following steps: Boiling of the borate of lime with soda; working up the residual mud; fine crystallization; and working up the lyes. The process is reviewed in some detail.

Witting, F., On the manufacture of borax from boronatrocalcite: Soc. Chem. Ind. Jour., vol. 7, p. 748, 1888.
Review in English of paper in Zeitschr. angew. Chemie, pp. 483–487. 1888.

1889.

Hake, C. N., An account of a borax lake in California: Soc. Chem. Ind. Jour., pp. 854–857, 1889.
The borax works at Borax [Searles] Lake, San Bernardino County, Cal., are described as a result of a visit of a month or six weeks, while work on these deposits was in progress. A sketch of the Searles Basin and salt deposits with small map of the salt and borax deposits is included. The data given are mostly observations of a general nature, but include some analyses, descriptions of methods of working for borax, etc.

Hanks, H. C., On the occurrence of hanksite in California: Am. Jour. Sci., 3d ser., vol. 37, p. 63, 1889.
Some general notes as to Searles Lake [Borax Lake] in San Bernardino County, Cal., with special reference to the occurrence there of the mineral hanksite.

Whitfield, J. E., Analyses of natural borates and borosilicates: U. S. Geol. Survey Bull. 55, pp. 56–59, 1889.
Analyses and descriptions of minerals: Colemanite from Death Valley, Cal.; priceite from Curry County, Oreg.; pandermite from the island of Panderma, in the Black Sea; and ulexite from Rhodes Marsh, Nev.

1890.

Chatard, T. M., Natural soda; its occurrence and utilization: U. S. Geol. Survey Bull. 60, 1890.
Incidental to the discussion of the general topics of the paper, notes borate content of waters of Owens and Mono lakes, which show B_4O_7 0.32 per cent of the dissolved salts, the latter being 5.1 per cent of the weight of the original water sample.

Crossman, J. H., Borax: California State Min. Bur. Ninth Ann. Rept., p. 225, 1890.
A single paragraph concerning developed fields in California.

De Groot, H., The Searles borax marsh, California: California State Min. Bur. Tenth Ann. Rept., pp. 534–539, 1890.
The plant, property, and operations of the San Bernardino Borax Co. at Searles Lake, Cal., with a review of the history and the general features of the desert basin; a quotation of the old Searles deep well log to a depth of 230 feet; an account of the origin of the salts and the minerals found there; description of the methods of manufacture of borax.

Mather, J. W., and others, Borax and its products; tariff hearings before the Committee on Way and Means; 51st Cong., 1st sess., Misc. Doc. 176, p. 361, 1890.
Statements as to the importance of the borax industry in the United States and argument for more stringent regulations for the imposition of duty on foreign borate products. The law of 1883 is said to have made duty on refined borax and boric acid 5 cents a pound, on commercial boric acid 4 cents, and 3 cents on crude orax, borate of soda, and borate of lime, but that boracic acid had been on free list until then.

Anon., Borax: U. S. Geol. Survey Mineral Resources, 1888, p. 5, 1890.
Contains only a brief statement of production and price—6 cents a pound.

1891.

Soc. Chem. Ind. Jour., p. 367, 1891.

An English patent (No. 2526, Feb. 17, 1890) "deals with the manufacture of borax from pandermite. It has not been accomplished by heating this mineral with soda, probably because the lime and boric acid therein are not in the right proportions for conversion into borax."

Witting, F., Borax from boronatrocalcite: Zeitschr. angew. Chemie, p. 367 1891.

1892.

Anon., The history of borax in the United States: Eng. and Min. Jour., vol. 54, pp. 247–248, 1892.

Review of the history of the industry, including the discovery and working of the colemanite deposits in the Calico district, California.

Kemp, J. F., Borax: Eng. and Min. Jour., vol. 53, p. 8, 1892.

A short review of the boron minerals; localities of occurrence; manufacture and uses.

Scheuer, ——, Überblick über die Industrie der Borsäure und des Borax [Review of the boric acid and borax industry]: Zeitschr. angew. Chemie, pp. 241–248, 1892.

In 1870 Germany took up the borax and boric acid industry, and now produces enough to cover home consumption. Review of uses of borax and boric acid, also of the sources of these materials.

Stassfurt boracite (stassfurtite) occurs in the salt mines as roundish white nodules, from the size of a barleycorn to that of a bead, imbedded in the salt. Its composition is approximately expressed $2Mg_3B_8O_{15}+MgCl_2$. Stassfurtite is decomposed by sulphuric acid, yielding boric acid and magnesium sulphate which are recovered by crystallization.

The conditions governing the conversion of boric acid into borax are summarized. (See review, Soc. Chem. Ind. Jour., vol. 2, pp. 683–685, 1892.

Spears, J. R., Illustrated sketches of Death Valley and other borax deserts of the Pacific coast, pp. 13–226, Rand, McNally & Co., 1892.

A popularized account of the historical record of Death Valley and vicinity; the discovery of borax minerals; the location of Searles Lake for borax; the early history of the Nevada borax marshes, etc.

Yale, C. G., Borax: U. S. Geol. Survey Mineral Resources, 1889 and 1890, pp. 494–506, 1892.

This chapter again reviews the history of the discovery and development of the industry in California and Nevada, giving notes on most of the localities of production or attempted production. Reference is made to the attempted workings at Soda Lake near Ragtown, at Sand Springs, and at Hot Springs, Nev. De Groot's article (1890) on Searles Lake, Cal., is quoted. The Calico colemanite deposits discovered in 1883 are noted as being actively worked, and Rhodes Marsh, Columbus Marsh, Nev., the Chetco deposits in Oregon, and in Saline Valley in California are described and production noted. The price for these years is reported as 6½ to 7 cents a pound.

1893.

Storms, W. H., Mineral resources of San Bernardino County, Cal.: California State Mining Bur., Eleventh Ann. Rept., pp. 345–348, 1893.

Describes deposits of colemanite at Borate in the Calico mining district near Daggett, Cal., and offers an explanation as to their origin. This statement is probably the first advocating a lacustrine origin for the colemanite in the tuffs, sandstones, and clays.

Anon., Borax: U. S. Geol. Survey Mineral Resources, 1891, pp. 587, 588, 1893.

A brief review of conditions of the borax industry, with statistics of production. The price of borax is stated as 6½ to 7½ cents a pound.

U. S. Geol. Survey Mineral Resources, 1892, p. 5, 1893.

Contains merely a statement of production of borax for the year.

1894.

Anon., Borax: U. S. Geol. Survey Mineral Resources, 1893, pp. 734–736, 1894.

Contains a statement of production and imports of borax.

1895.

U. S. Geol. Survey Sixteenth Ann. Rept., pt. 4, Mineral Resources, 1894, p. 13, 1895.
Statement of production of borax for the year 1894.

U. S. Geol. Survey Eighteenth Ann. Rept., pt. 5, continued, Mineral Resources, 1896, pp. 14–15, 1897.
Statement of production of borax for the year 1896.

1898.

U. S. Geol. Survey Nineteenth Ann. Rept., pt. 6, continued, Mineral Resources, 1897, p. 9, 1898.
Statement of production of borax for the year 1897.

1899.

U. S. Geol. Survey Twentieth Ann. Rept., pt. 6, continued, Mineral Resources, 1898, pp. 16–17, 1899.
Statement of production of borax for the year 1898.

1901.

Buttgenbach, H., Gisements de borate des Salinas Grandes de la République Argentine; propriétés optiques de l'ulexite; Soc. géol. Belgique Annales, vol. 28, M, p. 99, 1901.
Ulexite formed at Salinas Grandes, Province of Jujuy, Argentina, is described in some detail. Analyses of ulexite given. The boric acid of the ulexite is regarded as of volcanic origin. Microscopic study of ulexite; distinction of ulexite from hayesine; general observations concerning the mode of origin of the deposits.

U. S. Geol. Survey Twenty-first Ann. Rept., pt. 6, continued, Mineral Resources, 1899, pp. 18–19, 1901.
Statement of production of borax for the year 1899.

U. S. Geol. Survey Mineral Resources, 1900, p. 21, 1901.
Statement of production of borax for the year 1900.

Newton, William, A new system for the manufacture of borax and nitrates: Soc. Chem. Ind. Jour., vol. 20, pp. 324–325, 1901. London.
Refers to difficulties encountered in usual methods of heating for evaporation of solutions of crude borates and nitrates, evidently from the Chilean deposits. Suggests a method of evaporation and stirring by direct application of all the hot combustion gases from the furnace by passing them through the liquid under pressure.

1902.

Bailey, G. E., The saline deposits of California: California State Min. Bur. Bull. 24, pp. 33–90, 1902.
Contains general review of history of the borax industry; fluctuations in market price; statistics of production in California and of imports until 1902. Review of the California localities by counties; short descriptions of localities at Bennetts Wells, Confidence, Furnace Creek, Mount Blanco, Owens Lake, Resting Springs, Saline Valley, Salt Wells Valley, Tecopa, and Amargosa Canyon in Inyo County; Buckhorn Springs, China Lake, Indian Springs, Cane Springs, and El Paso Wells in Kern County; Borax Lake and Lake Hachinhama, and other borate springs in Lake County; Colorado Desert in Riverside and San Diego counties; Calico district, Cave Springs, China Lake, Coyote Holes or Willow Springs Lake, Lone Star, Lone Willow, Soda Lake, the sink of Mohave River, Owl Springs, Palma Lake, Saratoga Springs, Searles Lake, and other playas and springs in San Bernardino County; the Lick or Tuscan Springs in Tehama County, and the colemanite deposits of Ventura County. A list of springs reported or possibly containing borates and a short review of processes of manufacture of refined borax are given.

CAMPBELL, M. R., Reconnaissance of the borax deposits of Death Valley and Mohave Desert: U. S. Geol. Survey Bull. 200, 23 pp., 1902.

Presents in the form of an itinerary a summary of observations on the occurrence of lake beds and of borate minerals and other geologic data along a route traversed by the author in the year 1900. The trip constituted a large circuit crossing the Mohave Desert and passing through Death Valley and Panamint and Owens valleys. The colemanite deposits were at that time generally regarded as products of the dessication of ancient extinct lakes, and it was assumed that general study of the lake beds might lead to the discovery of borate deposits elsewhere than were then known. The observations recorded along the route form an interesting commentary for further study of the geology and physiography of the region.

CAMPBELL, M. R., Reconnaissance of the borax deposits of Death Valley and the Mohave Desert: Eng. and Min. Jour., vol. 74, pp. 517–519, 1902.

An account covering much the same ground as U. S. Geol. Survey Bull. 200.

DENNIS, W. B., A borax mine in southern Oregon: Eng. and Min. Jour., vol. 73, pp. 581–582, 1902.

Describes marsh borax deposits in Harney County, Oreg., said to cover 10,000 acres of lowland immediately south of Lake Alvord. The crude salt incrustation said to show 5 to 20 per cent boric acid, which was then (April 25, 1902) being worked with an annual production of 400 tons, shipped by mules 130 miles to Winnemucca, Nev.

EAKLE, A. S., Colemanite from southern California; a description of the crystals and of the method of measurement with two-cycle goniometer: California Univ. Dept. Geology Bull., vol. 3, No. 2, pp. 31–50, 1902.

Detailed crystallographic description of colemanite from various localities including crystal measurements and drawings.

STRUTHERS, JOSEPH, Borax: U. S. Geol. Survey Mineral Resources, 1901, pp. 869–872, 1902.

A short review of the borax industry by Joseph Struthers, containing statements of production and imports, and notes concerning operations in this country and abroad. Announcement is made of the installation of the refining plants at Daggett, Cal., during 1901, to work the low-grade colemanite-bearing shales ("mud" deposits), of continued production from the colemanite deposits at Borate north of Daggett, and of the development and production from the colemanite mines in Ventura County, Cal. Notes concerning the marsh deposits in Harney County, Oreg., then producing. The foreign borate fields in Argentina, Chile, Russia, Turkey, are briefly mentioned. The price of borax during 1901 was reported as 7 to 7¾ cents a pound.

VERNADSKY, W. S., and POPOFF, S. P.: Zeitschr. prakt. Geologie, p. 79, 1902.

On the peninsula of Kertch, near the sea of Azov, Crimea, south Russia, borax occurs among the erupted substances of the so-called mud volcanoes. It effloresces on the surface of the dried mud, and is more or less mixed with salt and soda.

1903.

CAMPBELL, M. R., Borax deposits of eastern California: U. S. Geol. Survey Bull. 213, pp. 401–405, 1903.

An abstract of material presented in Bulletin 200 relating particularly to the noted occurrences and developments of borate minerals.

GILES, W. B., Bakerite (a new borosilicate of calcium) and howlite from California: Mineralog. Mag., vol. 13, pp. 353–355, 1903.

The discovery and naming of a new mineral, bakerite, a borosilicate of calcium ($8CaO.5B_2O_3.6SiO_2.6H_2O$), is announced, and the occurrence noted of this and of howlite, another borosilicate of calcium ($4CaO.5B_2O_3.2SiO_2.5H_2O$) previously recorded only from Nova Scotia, at the California borax mines near Daggett, where the latter is said to occur in immense quantities. Analyses of specimens from this locality are given.

HART, EDWARD, Death Valley, Cal., and its borax industry: Am. Ceramic Soc. Trans., vol. 5, pp. 64–73, 1903.

An interesting narrative, with map and pictures, of a trip from Daggett to Saratoga Springs and Morrisons, made during the time when borax operations were at their maximum at Daggett.

MAGUIRE, D., American borax mines: Mines and Minerals, pp. 298–300, February, 1903.

A popular account of the history of borate discoveries and developments (cf. California State Mining Bur. Third Ann. Rept., 1883).

Spurr, J. E., Descriptive geology of Nevada south of the fortieth parallel and adjacent portions of California: U. S. Geol. Survey Bull. 208, pp. 189-190, 1903.

Reference to the colemanite deposits on Furnace Creek as interbedded in the Tertiary sedimentary series, deposited by the evaporation of waters of an inclosed lake which is supposed to have been of great dimensions. Discussion of geologic relations of the Tertiary and other terranes.

1904.

Stafford, O. F., Mineral resources and mineral industry of Oregon for 1903: Oregon Univ. Bull., new ser., vol. 1, No. 4, p. 6, 1904.

Brief quotations from Mineral Industry concerning the borate deposits south of Lake Alvord, Harney County, and the priceite deposit near Chetco in Curry County.

Bailey, G. E., The desert dry lakes of California: Min. and Sci. Press, vol. 89, pp. 138, 161, 174, 192-193, 205-206, 222-223, 241-242, 255, 1904.

Popularized magazine accounts, made up chiefly from former publications, much by direct quotation.

Cortese, Emilio, A quicksilver deposit: Eng. and Min. Jour., vol. 78, pp. 741-742, Nov. 10, 1904.

Describes three centers of solfataric emanation similar to the soffioni of Tuscany, the waters of which contain saline compounds, together with boric acid, ammonium, chloride, etc., in the Chaguarama Valley, Venezuela, noting also the occurrence of cinnabar in sandstone.

Herrick, C. L., Lake Otero, an ancient salt lake basin in southeastern New Mexico: Am. Geologist, vol. 34, pp. 174-192, 1904.

A general description and map of the Otero basin. Refers to the occurrence of borax in the salines in the playas.

Struthers, Joseph, Borax: U. S. Geol. Survey Mineral Resources, 1902, pp. 891-896, 1904.

Short review containing brief references to general abandonment of operations on the marsh deposits and production from the "bedded" deposits of colemanite. Statistics of production and of imports from 1864 and 1868 to 1902 are quoted. The review of the industry for 1902 contains reference to deep-mining operations about Daggett, developments in Ventura County, and smaller production from marshes in California, Nevada, and Oregon. The prices quoted range from 6¾ to 7¼ cents a pound for refined borax. A table of world's production is accompanied by notes on foreign producing localities: Argentina, Bolivia, Chile, Italy, Peru, and Turkey.

Yale, C. G., Borax: U. S. Geol. Survey Mineral Resources, 1903, pp. 1017-1028, 1904.

Summary review of history of borax, quoting statistics of production, imports, and world's production, with a statement of the industry for the year in the various fields—Ventura County, San Bernardino County, Inyo County, Cal.; and review of the uses of borax and of technology of its manufacture.

Morgan, W. C., and Tallmon, M. C., A peculiar occurrence of bitumen and evidences as to its origin: Am. Jour. Sci., 4th ser., vol 18, pp. 363-377, 1904.

A peculiar occurrence of the mineral colemanite within a fossil egg, which was found inclosed within a larger pebble embedded in placer gravels on Gila River in Arizona, and which is described and figured in detail.

Wiley, H. W., Results of borax experiment: U. S. Dept. Agr. Bur. Chemistry Circ. No. 15, pp. 1-27, 1904.

Report of the results and conclusions derived from experimental investigation of the effects of borax on foods and on the general state of health of individuals to whom various doses are regularly administered. The conclusion is reached that small doses given for a long period or large quantities for a short period create disturbances of appetite, of digestion, and of health.

1905.

Yale, C. G., Borax: U. S. Geol. Survey Mineral Resources, 1904, pp. 1017-1028, 1905.

A review similar in form to that of preceding year, with notes as to developments for the year and a more detailed review of the Blumenberg process for treatment of the shale deposits near Daggett.

1906.

Reichert, F., Chem. Zeitung, vol. 30, p. 150, 1906.

Describes eight of the Argentine "borateras" and gives analyses of their products. His complete report, Los yacimientos de boratos, is in Anales del Ministerio de Agricultura, Buenos Aires, 1907. For an abstract, see Zeitschr. Kryst. Min., vol. 47, p. 205, 1909.

——— The mineral production of Chile in 1903; Borax: Min. Jour., London, vol. 80, pp. 411-412, Mar. 31, 1906.

An abstract and translation from Estadística minera de Chile en 1903, p. 321, Santiago de Chile, 1905, with a mining map of the country and a geologic map of Atacama.

The yield of borates in 1903 is given as 18,605½ short tons, about 92 per cent of which was controlled by the Borax Consolidated Co.

The principal borax deposits of Chile are found as in Peru, Bolivia, and Argentina, on the high plateaus of the Andes, in Chile, at altitudes ranging from 11,500 to over 13,000 feet, and at distances of 125 to 150 miles from the coast. The borates appear to have been derived from the evaporation of ancient lakes as they lie in more or less marshy depressions where they are mixed with other saline substances. They resemble the saline marshes of California and Nevada. The only borax mineral reported is ulexite, which has a tendency to be localized near the margins of the saline deposits. Since the year 1852 borates have been obtained from these fields, in Tarapaca, Antofagasta, etc. Quotations from a British consular report published in 1896 are given describing the Maricunga, Chilcaya, and Ascotan deposits. The main shipping port is Antofagasta.

Bailey, G. E., The borax deposits of California: Mining World, vol. 24, pp. 4-5, 1906.

Generalized statements as to borax of California desert deposits illustrated by several views of the borate beds and workings at Daggett, saline crusts in the Mohave Desert, etc.

Yale, C. G., Borax: U. S. Geol. Survey Mineral Resources, 1905, pp. 1091-1096, 1906.

A short statement of conditions in the borax industry for the year 1905. Contains notes of late developments, record of fall in market price to 6½ to 6¾ cents a pound for refined borax.

Spurr, J. E., Ore deposits of the Silver Peak quadrangle, Nevada: U. S. Geol. Survey Prof. Paper 55, pp. 21, 158-165, 1906.

Chapter headed "Borates and salt." Playas or alkali flats of Fish Lake Valley, Clayton Valley, and Big Smoky Valley described by quotation from H. W. Turner, with several analyses of playa deposits showing borate content. Section on the genesis of the deposits, including reference to colemanite in the Tertiary sediments, the borate minerals said to be chemically precipitated deposits a result of evaporation of Tertiary alkaline lakes. The borates in the playas are believed to have originated in part at least from the concentration of the saline constituents of hot-spring waters, and the localization of the borate deposits is in part explained by the variation in the constituents of the different hot-spring waters, which in turn have presumably derived their borate salts in some way from volcanic exhalations.

Taft, H. H., Notes on Inyo County, Cal.: Eng. and Min. Jour., vol. 81, pp. 704-705, Apr. 14, 1906.

Some rather general notes relating to borax deposits, Death Valley, Owens Lake Valley, etc.

Taft, H. H., Notes on southern Nevada and Inyo County, Cal.: Am. Inst. Min. Eng. Trans., vol. 37, pp. 178-197, 1906.

In a general account of the country incidental mention is made of a little borax in the spring waters at Ash Meadows, Nevada (p. 184), and two paragraphs are devoted to borax deposits in general (pp. 191-192).

Willey, D. A., Borax mining in California: Eng. and Min. Jour., vol. 82, pp. 633-634, 1906.

Description and views of the mine at Borate, in the Calico district north of Daggett, Cal.

1907.

Ball, S. H., A geologic reconnaissance in southwestern Nevada and eastern California: U. S. Geol. Survey Bull. 308, pp. 41, 198, 1907.

In discussing geologic history of the desert region reference is made to the deposition of limestone, gypsum, and boron minerals by the desiccation of the hypothetical "Pahute" Lake; and later (p. 198) in description of the Death Valley

region reference is made to colemanite and other chemical precipitates interbedded with the other deposits (which) were laid down during periods of unusual evaporation—evidently based on the acceptance of a desiccated alkaline lake hypothesis for the origin of these minerals.

JOCHAMOWITZ, A., Yacimiento de borax de la Laguna de Salinas: Cuerpo Ing. Minas Perú Bol. 49, Lima, 24 pp., 1907. Abstract in Min. Jour., London, vol. 82, p. 247, Aug. 24, 1907. Quoted in Eng. and Min. Jour., vol. 84, p. 780, 1907.

A dry lake basin, carrying borates and other saline salts, is known as Lake Salinas, 12 leagues east of Arequipa City on the line separating the Departments of Areguipa and Moquegua. It lies at an altitude of 14,200 feet. The crust consists of chloride and sulphate of soda and fine sand, 10–14 centimeters, gravel 6 centimeters, sand with layers of borate 20–50 centimeters, fine sand, thin bed, borate of variable thickness, usually 40 centimeters to maximum of 1 meter. The borate is the mineral ulexite. Ulexite of Laguna de Salinas is regarded as of volcanic origin. The original text contains topographic maps of the salinas and of the general region showing by contours the topography of adjacent mountains, also good views of the deposit.

YALE, C. G., Borax: U. S. Geol. Survey Mineral Resources, 1906, pp. 1059–1062, 1907.

Review containing usual statistics and notes of developments in various fields.

1908.

YALE, C. G., Borax: U. S. Geol. Survey Mineral Resources, 1907, pt. 2, pp. 631–635, 1908.

Notes sudden drop in market price during 1907, which resulted in closing all but the largest producing operators in the field. Price of borax fell to 4½ to 5½ cents a pound. Quotes usual statistics of production and imports. Notes opening of the Lila C. mine in Inyo County, Cal., and abandonment of the mines at Borate, near Daggett, San Bernardino County, Cal.; also the discovery of important colemanite deposits near Lang in Los Angeles County, Cal., in November, 1907.

MUNROE, C. E., Borax industry in the United States: Census Bur. Bull. 92, pp. 36–37, 1908.

Borax industry discussed chiefly by quotation from California State Mining Bur. Bull. 24.

1909.

ANON. The borate field of Chile: Chem. Trade Jour., vol. 45, pp. 380–382, 1909.

The mineral found principally in the borate fields in Chile bordering on Bolivia is an impure borate of lime containing in the crude state about 36 per cent boric acid, 35 per cent water, some sodium borate, silicates, etc. The silicates and calcium sulphate are difficult impurities to separate. By calcining, part of the water is driven off, and the product shipped from the mines contains about 45 per cent boric acid.

KEYES, C. R., Borax deposits of the United States: Am. Inst. Min. Eng. Bull. 34, pp. 867–903, 1909.

A dissertation dealing with surface features, geologic formations, and borate occurrences in Death Valley, Mohave Desert, and elsewhere in southern California, with considerable theorizing based on the assumption that the borate minerals are interbedded deposits, formed under conditions of an arid climate in a great shallow arm of the Pacific Ocean that had been cut off by the upheaval of the mountains along the coast.

KEYES, C. R., American borax deposits: Eng. and Min. Jour., vol. 88, pp. 826–827, Oct. 23, 1909.

An account of the development of the colemanite ores in southern California, a statement as to the character of the Tertiary rocks with which they are associated, and of the ores and methods of mining.

YALE, C. G., Borax: U. S. Geol. Survey Mineral Resources, 1908, pt. 2, pp. 603–605, 1909.

A brief statement for the year, with the usual statistics.

WAINWRIGHT, W. B., Borate deposits of California: Inst. Min. Eng. [London] Trans., vol. 37, pt. 1, pp. 156–162, 1909; Manchester Geol. and Min. Soc. Trans., vol. 31, pt. 4, pp. 60–66, 1909.

A compilation of notes concerning the occurrence of mining and manufacture of borates in California.

WILSON, E. B., Boron: Mines and Minerals, vol. 30, pp. 168–170, October, 1909.
A list of minerals in which boron occurs, a review in some detail of the methods of test for and analysis of boron minerals, and a few notes on the borax localities in the United States.

1910.

ANON., India Geol. Survey Records, vol. 41, p. 168, 1910.
Brief statistical review as follows: "Although borax is not produced in India, but in Tibet, most of the output probably comes to this country for export and distribution. The amount exported during 1910 rose to 6,272 hundredweight."

BOEKE, H. E., The borates of the potash deposits: Leipzig, Centralbl. Mineralogie, pp. 531–539, 1910.
A brief description of heintzite, pinnoite, ascharite, boracite, the identity of which with stassfurtite is reaffirmed, and sulfoborite.

DUPONT, F. M., The borax industry: Jour. Ind. and Eng. Chem., vol. 2, pp. 500–503, 1910.

Review of paper published in Argentina Minist. Agr. Anales, 1907.

STRONG, A. M., Borax deposits of the United States: Am. Inst. Min. Eng. Bull. 38, pp. 167–171, February, 1910.
Discussion of C. R. Keyes's paper, objecting to suggestion by Keyes of marine origin of borates and borate-bearing beds, calling attention to evidence of fresh-water deposition within this series, as of the occurrence of fresh-water mollusks, fish, and plants, as well as coal beds. Reports colemanite within Saline Valley drainage.

SURR, G., The origin and commercial value of borates: Min. World, vol. 33, pp. 1137–1138, Dec. 17, 1910.
Speculations of a general character concerning the origin of borates and boric acid in natural occurrences.

WHITFIELD, J. E., Analyses of borates: U. S. Geol. Survey Bull. 419, p. 300, 1910.
Analyses of colemanites from Death Valley, Cal.; priceite from Curry County, Oreg.; and pandermite from Island of Panderma, Black Sea. The pandermite from the original described locality agrees very closely in composition with the priceite from its original locality. An analysis of ulexite from Rhodes Marsh, Nevada, is also given.

1911.

BAKER, C. L., Notes on the later Cenozoic history of the Mohave Desert in southwestern California: California Univ. Dept. Geology Bull., vol. 6, No. 15, pp. 333–383, 1911.
Describes the "Rosamond series," including various occurrences of the "borate member" in southern California, and discusses the genesis of borate deposits (p. 358).

CLARKE, F. W., The data of geochemistry, 2d ed.: U. S. Geol. Survey Bull. 491, pp. 231–240; also pp. 14, 110, 150, 165, 1911.
The general distribution of boron (p. 14); its occurrence in sea water (p. 110); its occurrence in Mono and Owens lakes, California; Harney Lake, Oregon; Big Lake, Track Lake, Red Lake, otherwise known as Laramie or Union Pacific lakes of Wyoming (pp. 150–152); and a general discussion of borates (pp. 231–240), their relation to volcanism, referring especially to the relation between boric acid and ammonium in hot-spring waters of evident volcanic relations. The literature relating to borates in various parts of the world is reviewed, an abstract of these references being incorporated in this bibliography.

EAKLE, A. S., Neocolemanite, a variety of colemanite, and howlite from Lang, Los Angeles County, Cal.: California Univ. Dept. Geology Bull., vol. 6, No. 9, pp. 179–189, 1911.
A careful study of the supposed colemanite from the deposits north of Lang, Los Angeles County, Cal., has revealed a mineral of somewhat distinct optical and crystallographic properties, although identical with colemanite in chemical composition and general physical properties. To the new mineral the name neocolemanite is given. Crystallographic measurements are given, and a few paragraphs describing the manner or occurrence, and also an associated borate mineral, howlite.

YALE, C. G., Borax: U. S. Geol. Survey Mineral Resources, 1909, pt. 2, pp. 631-632, 1911.
Brief statement containing the usual statistics.
——— U. S. Geol. Survey Mineral Resources, 1910, pt. 2, pp. 701-702, 1911.
Brief statement containing usual statistics. Virtually entire product of borax in the United States then derived from two mines, one in Inyo County and one in Los Angeles County, both in California.
WEINTRAUB, E., On the properties and preparation of the element boron: Jour. Ind. and Eng. Chem., vol. 3, pp. 299-300, 1911.
Artificial production of the element boron, its properties, especially the influence of temperature on its electrical resistance, on which some of its principal industrial applications are likely to be based.

1912.

CHAMBERLIN, R. T., The physical setting of the Chilean borate deposits: Jour. Geology, vol. 20, pp. 763-768, November-December, 1912.
A description of the salinas, or dry saline lake beds, characteristic of Chile, Bolivia, and Peru, with views of Ascotan, Borax Lake, and a similar borax lake near Cellobar. The relations of these areas of interior drainage to volcanoes are pointed out—suggesting a direct volcanic source of the boron salts they contain. The boron occurs almost entirely as a single compound, the mineral ulexite. The material is so free from other salts that it is only necessary to dry it before shipping it to Europe, where it is later manufactured into the commercial salts.
YALE, C. G., and GALE, H. S., Borax: U. S. Geol. Survey Mineral Resources, 1911, pt. 2, pp. 857-866, 1912.
Review of the borax industry, containing usual statistics. Market price of refined borax remains low, 3½ to 4 cents a pound. Contains historical review and map of known borax localities. An account and map of the Lila C. borax mine at Ryan, Cal., and a bibliography of publications relating to borax, by Hoyt S. Gale.

1913.

BAXERES DE ALZUGARAY, Borates and consumption of boron compounds: Min. and Eng. World, Jan. 8, 1913, p. 99.
New uses for boron compounds, such as in extension and improvement in the making of enamels for the lining of iron, steel, and other metallic vessels; the use of alkali perborates as bleaching agents highly recommended, and also as powerful oxidizers in disinfecting, where the perborates have the advantage that they may be stored without deteriorating. In metallurgy of iron and steel, boron alloys resistant to acids may become of value. The use of boric acid and borates in tanning and bleaching of leather and as general mordants in dyeing of fabrics, in soap making and treating of fatty acids, as an antiseptic and as a wood preserver, and in paper making, etc., is referred to.
GALE, H. S., Borate deposits in Ventura County, Cal.: U. S. Geol. Survey Bull. 540 (chapter A, published separately, 1913), pp. 434-456, 1914.
Describes geology of the colemanite deposits in Ventura County, a district which has yielded crude colemanite valued at approximately a million dollars.
——— Salt, borax, and potash in Saline Valley, Inyo County, Cal.: U. S. Geol. Survey Bull. 540 (chapter N, published separately, 1913), pp. 416-421, 1914.
Brief summary of production of borax in the "marsh" form of deposits from this valley in the early days of the industry in the country.
——— The origin of colemanite deposits: U. S. Geol. Survey Prof. Paper 85 (chapter A, published separately, 1913), pp. 3-9, 1914.
Reviews former hypotheses as to the origin of colemanite as a product of desiccation of Tertiary alkaline waters; notes the evidence and argument to show that colemanite is not a desiccation deposit at all, but is a vein deposit, in part at least, of the replacement type.
YALE, C. G., and GALE, H. S., Borax: U. S. Geol. Survey Mineral Resources, 1912, pt. 2, pp. 839-846, 1913.
Review of statistics and conditions, similar to that of preceding year, with a republication of the bibliography relating to borax, somewhat enlarged.

ASPHALT.

By David T. Day.

INTRODUCTION.

The use of asphalt is increasing. Oil asphalt obtained as a residue from the distillation of asphaltic oils is becoming more and more available from Mexican, Gulf, and California oils, and even from those of the Middle West. There is correspondingly less interest in the development of new sources of natural asphalt. No new sources of supply have entered into the trade.

PRODUCTION.

NATURAL ASPHALT.

The production of natural asphalt, including all the varieties of natural asphalt, asphaltic sandstone, and limestone, amounted in 1913 to 92,604 short tons, valued at $750,713. This was a decline from 95,166 short tons, valued at $865,225, in 1912. This decline in natural products was undoubtedly due to the fact not only that oil asphalt dominates the industry but that its relative importance is increasing at the expense of the natural varieties. Thus 354,344 short tons of manufactured or oil asphalt was produced in 1912, and in 1913 the production was 436,586 short tons, with corresponding increase in value from $3,755,506 to $4,531,657. Of the total of 529,190 short tons of asphalt products of the United States in 1913 only 17.5 per cent was natural asphalt, including asphaltic limestone and sandstone. This large supply of oil asphalt is only for such purposes as street paving, road binders, and roofing, and has no bearing on the demand of asphalt for varnish and many other high-grade uses, for which such natural asphalt as gilsonite and other hard asphalts are needed.

Production of natural asphalt and bituminous rock, 1882–1913, in short tons.

Year.	Quantity.	Value.	Year.	Quantity.	Value.
1882	3,000	$10,500	1898	76,337	$675,649
1883	3,000	10,500	1899	75,085	553,904
1884	3,000	10,500	1900	54,389	415,958
1885	3,000	10,500	1901	63,134	555,335
1886	3,500	14,000	1902	84,632	461,799
1887	4,000	16,000	1903	55,068	483,282
1888	50,450	187,500	1904	64,167	420,701
1889	51,735	171,537	1905	62,898	305,242
1890	40,841	190,416	1906	73,052	674,934
1891	45,054	242,264	1907	85,913	938,381
1892	87,680	445,375	1908	78,565	517,485
1893	47,779	372,232	1909	99,061	572,846
1894	60,570	353,400	1910	98,893	854,234
1895	68,163	348,281	1911	87,074	817,250
1896	80,503	577,563	1912	95,166	865,225
1897	75,945	664,632	1913	92,604	750,713

MANUFACTURED OR OIL ASPHALT.

The following table shows the production of manufactured or oil asphalt since 1902, inclusive:

Production of manufactured or oil asphalt, 1902–1913, in short tons.

Year.	Quantity.	Value.	Year.	Quantity.	Value.
1902	20,826	$303,249	1908	119,817	$1,540,396
1903	46,187	522,164	1909	129,594	1,565,427

TOTAL PRODUCTION BY CLASSES AND BY STATES.

The changes in production in the different classes of asphalt are detailed for five years in the table which follows:

Production of asphalt, 1909–1913, by varieties, in short tons.

Variety.	1909		1910		1911	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
Bituminous rock	55,376	$205,756	64,554	$400,557	[a] 42,654	[a] $159,670
Maltha	652	8,047	1,252	12,742	8,574	125,966
Wurtzilite (elaterite)	220	1,400			610	30,500
Gilsonite	[b] 38,889	[b] 323,406	[b] 33,087	[b] 440,935	30,236	486,114
Grahamite	3,894	32,737			5,000	15,000
Ozokerite and tabbyite	30	1,500				
Total	99,061	572,846	98,893	854,234	87,074	817,250
Manufactured or oil asphalt [c]	129,594	1,565,427	161,187	2,225,833	277,192	3,173,859
Total	228,655	2,138,273	260,080	3,080,067	364,266	3,991,109

Variety.	1912		1913	
	Quantity.	Value.	Quantity.	Value.
Bituminous rock	[a] 54,762	[a] $173,018	57,549	$173,764
Maltha	474	3,518		
Wurtzilite (elaterite)	[d] 8,452	[d] 115,620	35,055	576,949
Gilsonite	31,478	573,069		
Grahamite	([e])	([e])		
Total	95,166	865,225	92,604	750,713
Manufactured or oil asphalt [c]	354,344	3,755,506	436,586	4,531,657
Total	449,510	4,620,731	529,190	5,282,370

[a] Includes small output of mastic.
[b] Includes gum.
[c] This item includes material previously referred to as refined bitumen.
[d] Includes grahamite.
[e] Included in wurtzilite.

The following table shows the production of natural asphalt, by States in 1909–1913:

Production of natural asphalt, by States, 1909–1913, in short tons.

State.	1909		1910		1911	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
California	43,825	$218,625	41,299	$165,954	36,481	$220,580

Total	95,166	865,225	92,604	750,713

a Included in Oklahoma.
b Includes West Virginia.
c Includes Kentucky.
d Included in Oklahoma.
e Includes Texas.
f Included in Kentucky.

CONDITIONS AND PRODUCTION IN THE CHIEF PRODUCING STATES.

California.—An interesting development of the year 1913 in the production of oil asphalt in California was the acquisition by the larger companies of a number of the smaller asphalt refineries and the vigorous efforts of the larger companies to control the market, with the result that as many as 11 of the smaller companies disappeared from the market and others showed greatly reduced activity and production while the larger companies showed proportionate increase.

The only natural asphaltic material produced in California in 1913 was the bituminous sandstone from the well-developed deposits near Santa Cruz in Santa Cruz County and from San Luis Obispo County. The low cost of production for local use allows this industry to persist in spite of the encroachments of oil asphalt, which reduced the output from 36,741 short tons in 1912 to 27,870 short tons in 1913. The average price declined from $2.73 at the quarries in 1912 to $2.51 in 1913.

Kentucky.—Kentucky produces only bituminous rock. The production showed an increase for 1913, due partly to an increase in the Texas product, which is included with Kentucky to avoid disclosing individual returns.

Oklahoma.—The product of Oklahoma includes grahamite, bituminous sandstone, and bituminous limestone. The total output and its value was greater in 1913 than in any previous year, the apparently larger production in 1911 being due to combining the production of Kentucky with that of Oklahoma.

L. C. Snyder, of the Geological Survey of Oklahoma, has published a comprehensive account of the occurrence of asphalt in Oklahoma, in Circular 52 of that survey, together with a detailed description of the deposits in the Wichita Mountains, in Stephens and Jefferson counties, in the Ardmore district, in the Arbuckle Mountains, in the Ouachita Mountains, and in the Red River district. He has also given a valuable review of the uses to which the asphalt is put for paving, etc., with prices.

Utah.—The production of hard asphalts, gilsonite, and elaterite from Utah fills a demand which is fairly steady; nevertheless the output in 1913 was slightly less than in 1912 and the average price per short ton received at the mines declined from $19.47 in 1912 to $17.01 in 1913.

Philippines.—Consul General George E. Anderson, at Hongkong, reports, in the Daily Consular and Trade Report of June 9, 1914, the discovery of a vein of asphalt of high quality and of large extent in the Philippine Islands. He thinks the material is likely to have a marked influence on street paving in cities in the Far East. It lies in the province of Leyte, barrio of Campopoc, on the northwestern peninsula of the island of Leyte, about 10 miles from the shore.

The vein is about 4 feet thick and can be readily followed for 160 yards along the side of the hill. Analysis made in Europe shows that it is of a quality suitable for the highest uses. The material is also being used for roofing and similar purposes. The Far East is just commencing to use asphalt for paving and roofing, the supply coming at present largely from the west coast of the United States.

PRODUCTION IN PRINCIPAL COUNTRIES.

The following table shows the production of asphalt in the principal producing countries from 1904 to 1913, inclusive:

Production of asphalt and bituminous rock in the principal producing countries, 1904–1913, in short tons.

Year.	United States.		Trinidad.[a]		Germany.

1913	....	....	....	....	[d] 83,825	[f] 400,000

[a] Only about 7 per cent of the quantity given represents asphalt, the remainder being bituminous sandstone and limestone.
[b] In addition 6,306 tons of bituminous rock were produced, no value being reported.
[c] Ozokerite only; quantity of asphalt not available.
[d] Exports.
[e] Not available.
[f] Estimated.

IMPORTS.

The following table shows the imports, for consumption, of asphalt, by calendar years, from 1908 to 1913, inclusive:

Asphalt imported for consumption into the United States, 1908–1913, in short tons.

Year.	Crude.		Dried or advanced.		Bituminous limestone.		Total.	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
1908	137,808	$532,297	7,642	$67,364	6,224	$20,758	151,674	[a] $624,979
1909	128,109	511,631	10,087	94,146	6,409	18,440	144,605	[a] 633,205
1910	162,435	588,206	20,180	178,704	3,696	9,301	186,311	[a] 785,963
1911	167,681	572,198	20,461	184,954	8,180	23,468	196,322	789,236
1912	193,645	726,345	20,707	177,992	3,976	15,808	218,328	921,145
1913	[b] 207,033	738,452	[c] 14,750	133,336	6,395	38,823	228,178	910,611

[a] Imports for 1908 include $4,560 of manufactures; 1909, $8,988; 1910, $9,752.
[b] Includes dried or advanced asphalt for last three months of 1913.
[c] Last three months of 1913 included in crude asphalt.

The ozokerite imported amounted to 4,472,708 pounds, valued at $388,461, in 1911. This increased to 6,352,003 pounds in 1912, valued at $488,894. The import price declined from 8.7 cents a pound in 1911 to 7.7 cents a pound in 1912. In 1913 the quantity imported rose to 7,141,514 pounds, valued at $549,992.

The following table shows the imports, by countries, of asphalt into the United States for the fiscal years 1909 to 1913:

Asphalt imported into the United States during the fiscal years ending June 30, 1909 to 1913, by countries, in long tons.

Tariff.—Under the law which became effective October 4, 1913, all asphalt, except manufactured products, is imported free of duty. The duty provided by the former law, that of June 1, 1912, was $1.50 a ton on crude asphalt, $3 a ton on that dried or advanced, and $0.50 a ton on limestone-rock asphalt.

EXPORTS.

Exports of domestic asphalt in fiscal years 1907 to 1913 are shown in the following table:

Value of asphalt exported from the United States during the fiscal years 1907–1913, in short tons.

Year.	Unmanufactured.	Manufactures of.	Total.
1907	(a)	(a)	$374,476

UNITED STATES GEOLOGICAL SURVEY PUBLICATIONS ON ASPHALT.

The following list comprises the more important papers relative to asphalt published by the United States Geological Survey or by members of its staff. The Government publications, except those to which a price is affixed, can be obtained free by applying to the Director, United States Geological Survey, Washington, D. C. The folios may be purchased from the Geological Survey; the other priced publications from the Superintendent of Documents, Government Printing Office, Washington, D. C.

Anderson, Robert, An occurrence of asphaltite in northeastern Nevada: Bull. 380, pp. 283–285, 1909. 40 cents.

Boutwell, J. M., Oil and asphalt prospects in Salt Lake basin, Utah: Bull. 260, pp. 468–479. 1905. Exhausted.

Branner, J. C., Newsome, J. F., and Arnold, Ralph, Geological Atlas, Santa Cruz folio (No. 163), 1909. Exhausted.

Clarke, F. W., The data of geochemistry, 2d ed.: Bull. 491, pp. 686–689, 1911. 70 cents.

Day, D. T., Asphalt, related bitumens, and bituminous rock: Mineral Resources, 1909, pt. 2, pp. 731–733 (75 cents), 1910; idem, 1910, pt. 2, pp. 833–839, 1911 ($1.25); idem, 1911, pt. 2, pp. 1003–1021, 1912 (exhausted); idem, 1912, pt. 2, pp. 997–1000, 1913; idem, 1913, pt. 2, pp. 537–544, 1914.

Day, W. C., The coal and pitch coal of the Newport mine, Oregon: Nineteenth Ann. Rept., pt. 3, pp. 370–376, 1899. Exhausted.

CLAY-WORKING INDUSTRIES.

By Jefferson Middleton.

INTRODUCTION.

The present report deals with the products of the clay-working industries, with the exception of the section on clay mining; hence the tables are made up to show the products of clay manufactured and not the production of clay.

The year 1913 in the clay-working industries was on the whole one of progress. The total value of all clay products marketed in the year—the principal criterion in judging the status of the industry—was $181,289,132, compared with $172,811,275 in 1912, an increase of $8,477,857, or 4.91 per cent. Compared with 1908, the year of general business depression, the increase was $48,091,370, or 36.11 per cent, and compared with 1903, it was $50,226,711, or 38.32 per cent.

Of the two great divisions of the industry (1) brick and tile and (2) pottery, the former showed the larger increase, both actual and proportionate. The increase in the brick and tile industry was $6,989,646, or 5.13 per cent; the increase in the pottery industry was $1,488,211, or 4.08 per cent.

The most prominent features in the industries in 1913 were the large decrease in the production and value of common brick in the region supplying the New York market and in the value of architectural terra cotta, and the large increase in the value of vitrified brick, sewer pipe, fireproofing, and fire brick. The engineering and refractory products, vitrified brick, draintile, sewer pipe, fire brick, and stove lining, showed an increase of $7,257,428, and the structural materials showed a net decrease of $521,315 in 1913. The growing use of hollow tile not only in fireproof construction in the larger buildings, but also in dwelling houses and other small structures, is shown in the large and continued increase in the value of this material, the making of which seems destined to be an important branch of the industry. The vitrified paving brick industry had probably the most satisfactory year it has yet experienced, there being a large increase in its production, value, and average price per 1,000. The effect of the educational work of the several associations devoted to the increased use of vitrified brick as a paving material, not only for city streets but as the most satisfactory, enduring, and economical material for country roads, is being felt, and this industry no doubt has a bright future.

In the brick and tile industry decrease was shown in the quantity and value of common brick, and in the value of fancy or ornamental brick and of architectural terra cotta. The decrease in the quantity of commom brick was 466,448,000, or 5.45 per cent, but owing to the higher prices prevailing in 1913 the proportionate decrease in value was less—3.21 per cent. Increase was recorded in the quantity and value of vitrified paving brick, of front brick, and of fire brick; in the value of enameled brick, sewer pipe, drain tile, stove lining, fireproofing, and tile, not drain. Vitrified brick, enameled brick, fire brick, sewer pipe, fireproofing, and tile, not drain, reached their maximum value in 1913, as also did the total value for brick and tile products.

The largest increase in value recorded was fire brick—$2,749,493, or 15.38 per cent, and the largest decrease was in common brick—$1,661,509, or 3.21 per cent.

In the pottery industry every variety of ware as classified in this report except one showed an increase, and the year was one of notable progress in every way. The new tariff law which will have a much greater influence on the pottery industry than on the brick and tile industry, both in raw material and on the finished product, went into effect so late in the year that it had little or no apparent result. For the information of those interested the old and the new tariff acts, so far as they relate to pottery, are given on another page of this report. The value of pottery imports, which were principally of high-grade ware, showed a considerable increase in 1913 over 1912—$621,921, or 6.51 per cent—but with the exception of 1912 was the lowest recorded in 11 years. The exports of high-grade domestic pottery, though small, increased, but the exports of low-grade pottery decreased over 60 per cent, and the value of all exports decreased.

In statements to the Geological Survey quantities are reported for common brick, front brick, vitrified paving brick, fire and silica brick, but not for fancy or ornamental brick or enameled brick. The average price per 1,000 increased in 1913 in every case, except front brick, which was the same in both years—$11.62. The increase in the price of common brick was 15 cents, of vitrified paving brick 68 cents, of clay fire brick 72 cents, and of silica brick 34 cents.

A notable feature of the clay-working industries in the last few years has been the concentration of the industry into fewer and larger units, principally by the elimination of the smaller temporary plants, though considerable consolidation has also been going on. This concentration is shown by the fact that the average value of output per operator has increased from $21,451 in 1904 to $44,598 in 1913.

There were no strikes of great importance in the clay-working industries in 1913, though there were some local labor disturbances that had no serious effect. The pottery industry was threatened with labor troubles for a time, but serious consequences were avoided. In Chicago there were strikes, not in the clay-working industries, but in the building trades, which affected the use of clay products; but these appear to have been settled in a manner to insure more permanent peace than has been enjoyed there for some years. The scarcity of labor and the legislative restrictions concerning the employment of women and children in some States have affected the industries. On the whole, however, the year was an important one in development of the industries, and constant efforts are being made to introduce economies in manufacture and improvement in the wares.

ACKNOWLEDGMENTS.

The writer again desires to thank the clay workers of the country on behalf of the Geological Survey for their cooperation, without which this report would be impossible.

The State geological surveys of Alabama, Florida, Georgia, Illinois, Iowa, Kansas, Maryland, Michigan, Missouri, New Jersey, New Mexico, North Carolina, Oklahoma, Oregon, Pennsylvania, Virginia, Washington, and Wisconsin have cooperated in the collection of the statistics in these States, the completeness of the returns and the earlier publication of the results being due largely to their efforts.

Thanks are also extended to the clay-working press for its support and appreciation and to the officials who have supplied information concerning the building operations of the various cities of the country.

PRODUCTION.

PRODUCTION BY STATES.

In the following table will be found a statement of the value of the clay products in the United States in 1912 and 1913, by States:

Value of the products of clay in the United States in 1912 and 1913, by States and Territories.

State or Territory.	1912			1913		
	Brick and tile.	Pottery.	Total.	Brick and tile.	Pottery.	Total.
Alabama	$1,912,966	$22,213	$1,935,179	$2,071,423	$20,158	$2,091,581

Percentage of total	78.88	21.12	100.00	79.04	20.96	100.00

[a] Included in "Other States."

This table shows that the brick and tile products as classified in this report continue to constitute approximately four-fifths and the pottery products one-fifth of the total value.. These approximate proportions have been maintained for many years. Every State is a producer of burned clay. Of the Territories, Alaska and Hawaii reported none for 1913. A small production was reported from the District of Columbia and from Porto Rico. In Nevada and Rhode Island there was not a sufficient number of producers reporting to permit the publication of State totals without disclosing individual returns, so that statistics for these States have been combined with those of contiguous States.

Value of the clay products of the United States, by States and Territories, in 1912 and 1913, showing increase or decrease, with percentage of increase or decrease.

State or Territory.	1912	1913	Increase (+) or decrease (—) in 1913.	Percentage of increase(+) or decrease(—) in 1913.
Alabama	$1,935,179	$2,091,581	+ $156,402	+ 8.08
Arizona	178,564	218,542	+ 39,978	+22.39
Arkansas	462,605	529,624	+ 67,019	+14.49

Georgia	2,806,541	2,692,619	— 113,922	— 4.06
Idaho and Nevada	176,108	150,701	— 25,407	—14.43
Illinois	15,210,990	15,195,874	— 15,116	— .10
Indiana	7,935,251	8,498,646	+ 563,395	+ 7.10
Iowa	4,522,326	5,573,681	+1,051,355	+23.25
Kansas	2,036,500	1,919,910	— 116,590	— 5.73
Kentucky	2,443,740	2,914,276	+ 470,536	+19.25
Louisiana	523,643	638,491	+ 114,848	+21.93
Maine	534,101	661,573	+ 127,472	+23.87
Maryland	1,865,753	1,917,500	+ 51,747	+ 2.77
Massachusetts	1,767,166	1,814,875	+ 47,709	+ 2.70
Michigan	2,545,498	2,674,125	+ 128,627	+ 5.05
Minnesota	1,611,040	1,781,017	+ 169,977	+10.55
Mississippi	601,799	641,271	+ 39,472	+ 6.56
Missouri	6,412,861	6,602,076	+ 189,215	+ 2.95
Montana	314,017	456,897	+ 142,880	+45.50
Nebraska	805,398	886,166	+ 80,768	+10.03
New Hampshire	492,096	462,534	— 29,562	— 6.01
New Jersey	19,838,553	19,705,378	— 133,175	— .67
New Mexico	185,575	176,528	— 9,047	— 4.88
New York	12,058,858	11,469,476	— 589,382	— 4.89
North Carolina	1,465,653	1,614,406	+ 148,753	+10.15
North Dakota	231,245	262,580	+ 31,335	+13.55
Ohio	34,811,508	38,388,296	+3,576,788	+10.27
Oklahoma	535,318	573,371	+ 38,053	+ 7.11
Oregon	734,226	771,795	+ 37,569	+ 5.12
Pennsylvania	21,537,221	24,231,482	+2,694,261	+12.51
Porto Rico	14,294	6,359	— 7,935	—55.51
South Carolina	704,563	583,241	— 121,322	—17.22
South Dakota	41,496	46,685	+ 5,189	+12.50
Tennessee	1,501,016	1,493,085	— 7,931	— .53
Texas	2,886,068	3,049,349	+ 163,281	+ 5.66
Utah	724,978	708,906	— 16,072	— 2.22
Vermont	79,266	94,773	+ 15,507	+19.56
Virginia	1,874,174	1,705,651	— 168,523	— 8.99
Washington	2,388,870	2,390,226	+ 1,356	+ .06
West Virginia	4,775,874	5,208,270	+ 432,396	+ 9.05
Wisconsin	1,044,486	1,020,728	— 23,758	— 2.27
Wyoming	45,103	61,678	+ 16,575	+36.75
Other States	[a] 684,442	[a] 793,549	+ 109,107	+15.94
Total	172,811,275	181,289,132	+8,477,857	+ 4.91

[a] Includes pottery products which could not be separately classified without disclosing individual figures.

Of the States and Territories represented in this table, 29 showed increase as compared with 1912 and 19 showed decrease, the same numbers as for 1912. Ohio showed the largest increase, $3,576,788, or 10.27 per cent. This State also showed the largest increase in 1912 over 1911—$2,147,613, or 6.57 per cent. The largest proportionate increase was in Montana, 45.5 per cent. The largest decrease was in New York, $589,382, or 4.89 per cent. The largest proportionate decrease was in Porto Rico, 55.51 per cent. The State increases or decreases were not confined to any one section of the country. Of the 19 States that showed decrease 2 were in New England—Connecticut and Rhode Island (taken together) and New Hampshire; 3 in the middle Atlantic region—District of Columbia, New Jersey, and New York; 5 in the Southern States—Florida, Georgia, South Carolina, Tennessee, and Virginia; 2 in the Central States—Illinois and Wisconsin; 1 in the Western States—Kansas; 4 in the Rocky Mountain region—Colorado, Idaho and Nevada (taken together), New Mexico, and Utah; 1 on the Pacific coast—California; and Porto Rico. Six of the States that showed decrease in 1913 also showed decrease in 1912, namely: Colorado, District of Columbia, Idaho and Nevada (taken together); Kansas, Porto Rico, and Wisconsin. Four of the first 10 States in value of production—New Jersey, Illinois, New York, and California—showed decrease in 1913.

Value of the products of clay in the United States in 1912 and 1913, with increase or decrease.

Product.	1912	1913	Increase (+) or decrease (—) in 1913.	Percentage of increase(+) or decrease(—) in 1913.
Common brick	$51,796,266	$50,134,757	—$1,661,509	— 3.21
Vitrified paving brick or block	10,921,575	12,138,221	+ 1,216,646	+11.14
Front brick	9,455,297	9,614,138	+ 158,841	+ 1.68
Fancy or ornamental brick	225,367	109,703	— 115,664	—51.32
Enameled brick	1,027,314	1,225,708	+ 198,394	+19.31
Draintile	8,010,250	8,558,320	+ 548,070	+ 6.84
Sewer pipe	12,147,677	14,872,103	+ 2,724,426	+22.43
Architectural terra cotta	8,580,436	7,733,306	— 847,130	— 9.87
Fireproofing	7,174,148	8,620,216	+ 1,446,068	+20.16
Tile (not drain)	5,809,495	6,109,180	+ 299,685	+ 5.16
Stove lining	516,874	535,667	+ 18,793	+ 3.64
Fire brick	17,877,629	20,627,122	+ 2,749,493	+15.38
Miscellaneous	2,764,783	3,018,316	+ 253,533	+ 9.17
Total brick and tile	136,307,111	143,296,757	+ 6,989,646	+ 5.13
Total pottery	36,504,164	37,992,375	+ 1,488,211	+ 4.08
Grand total	172,811,275	181,289,132	+ 8,477,857	+ 4.91

This table shows that 10 of the brick and tile items showed increase and only 3 showed decrease in 1913. The decrease was entirely in the structural materials, the engineering and refractory products showing large increases. In 1912, 8 of these items showed increase and 5 decrease. The increases were large in that year and the decreases small, so that the net gain in 1912 was larger than that of 1913.

The greatest of all clay products in point of value and geographic distribution, common brick, which showed decrease in 1910 and 1911, and increase in 1912, fell back and showed a large decrease in 1913—$1,661,509, or 3.21 per cent. This was considerable more than one-half of the total decrease.

Vitrified paving brick, which suffered a decrease of $194,167, or 1.75 per cent, in 1912, rallied in 1913 and showed a large increase—$1,216,646, or 11.14 per cent.

Sewer pipe, which has increased steadily in value since 1909, showed the second largest increase, $2,724,426, in 1913 and the largest proportionate increase, 22.43 per cent. This increase was due, in part, at least, to the floods in the Ohio valley during 1913.

Draintile, which showed the largest decrease in 1912, $816,064, or 9.25 per cent, showed a considerable gain in 1913—$548,070, or 6.84 per cent—in spite of the unusually dry season in the Middle West.

Front brick only slightly more than held its own, showing an increase of $158,841, or 1.68 per cent, over 1912. In 1912 it increased $806,420, or 9.32 per cent, over 1911.

Fireproofing, which showed a gain of $1,513,976, or 26.75 per cent, in 1912, showed another large gain in 1913, namely, $1,446,068, or 20.16 per cent.

The manufacture of tiles other than drain tiles is a growing industry in the United States. The value of these tiles increased $299,685, or 5.16 per cent, in 1913. These tiles, which have been used chiefly in the construction of the better class of buildings, are now being used extensively as a sanitary material even in the smallest modern residences. In 1912 this class showed an increase over 1911 of $453,311, or 8.46 per cent.

Architectural terra cotta, which showed the largest gain in 1912 over 1911—$2,562,635, or 42.58 per cent—was one of the three brick and tile products to decrease in value in 1913. This decrease was $847,130, or 9.87 per cent, and was principally in Illinois.

Fire brick, which in 1912 made a large increase—$1,802,943, or 11.22 per cent—continued to gain in value of production, and in 1913 increased $2,749,493, or 15.38 per cent, over 1912. For 1913 silica brick was reported to the value of $3,815,806, which should be deducted from the figures here given to arrive at the value of the clay fire brick.

The total increase in the brick and tile products in 1913 was $9,613,949; the total decrease was $2,624,303—a net increase of $6,989,646, or 5.13 per cent. The pottery production showed an increase of $1,488,211, or 4.08 per cent, the total net increase for both industries being $8,477,857, or 4.91 per cent. In 1912 the brick and tile production increased in value $8,589,490, or 6.73 per cent, and pottery production increased $1,985,604, or 5.75 per cent, the net increase in that year being $10,575,094, or 6.52 per cent.

The following table shows the value of the production of clay in the United States from 1903 to 1913, inclusive, by varieties of products, together with the total for each year, and the number of active firms reporting:

Products of clay in the United States, 1903–1913, by varieties.

Year.	Number of active firms reporting.	Common brick.			Vitrified paving brick.		
		Quantity (thousands).	Value.	Average price per thousand.	Quantity (thousands).	Value.	Average price per thousand.
1903	6,034	8,463,683	$50,532,075	$5.97	654,499	$6,453,849	$9.86
1904	6,108	8,665,171	51,768,558	5.97	735,489	7,557,425	10.28
1905	5,925	9,817,355	61,394,383	6.25	665,879	6,703,710	10.07

a Stove lining is included in fire brick in 1903; in miscellaneous in 1904.

This table shows the growth of the clay-working industries during 11 years. Considering a 10-year period for comparative purposes, the total value of these products ranged from $131,023,248 in 1904 to $181,289,132 in 1913. The increase of 1913 over 1904 was $50,265,884, or 38.36 per cent. In three years, within the 10-year period, 1907, 1908, and 1911, there were decreases. The greatest decrease was in 1908—$25,744,607, or 16.2 per cent, and the greatest increase was in 1909—$33,123,451, or 24.87 per cent. The maximum value was reached in 1913 in six brick and tile products, vitrified paving brick, enameled brick, fire brick, sewer pipe, fireproofing, and tile, not drain. The total value of brick and tile products was also the greatest yet attained. Pottery also reached its maximum value in 1913.

The maximum quantity of common brick was reached in 1906 and the maximum value in 1905. The production in 1913 was less than the maximum output by 1,938,249,000 brick, or 19.33 per cent, and less than the maximum value by $11,259,626, or 18.34 per cent. The average price per 1,000 ranged from $5.73 in 1908 to $6.25 in 1905. The average price in 1913 was 15 cents higher than that of 1912, and within 5 cents of the maximum.

Vitrified paving brick reached its maximum quantity in 1909 and its maximum value in 1913. The output of 1913 was 64,974,000 brick, or 6.35 per cent, less than that of 1909, but its value in 1913 was $868,635, or 7.71 per cent, greater than that of 1909. The output in 1913 was 46,811,000 brick, or 5.13 per cent, greater than that of 1912, and the value in 1913 was $1,216,646, or 11.14 per cent, greater. The average price per 1,000 ranged in the 10-year period from $10.07 in 1905 to $12.66 in 1913.

Front brick reached its maximum quantity in 1913 and its maximum value in 1909. The output of 1913 was 13,658,000 brick, or 1.68 per cent, greater than that of 1912, and the value of the 1913 output was $98,081, or 1.01 per cent, less than that of 1909. The average price per 1,000 was the same, $11.62, in both 1912 and 1913, and was the lowest in 10 years. The highest average price was in 1905—$13.12.

Enameled brick reached its maximum value in 1913—$1,225,708. This was an increase of $186,843, or 17.99 per cent, over 1911, the year of maximum value prior to 1913. The production of 1913 was valued at more than twice as much as that of 1904.

Fire brick showed a very large increase and attained its maximum value in 1913. This was $2,515,648, or 13.89 per cent, greater than that of 1910, the next highest value, and was nearly twice as large as that for 1908, the year of minimum value in the 10-year period.

Draintile, after a steady increase for 10 years, showed a large decrease in 1911 and 1912, but in 1913 rallied and showed a considerable increase, so that the value of 1913 was but $1,831,502, or 17.63 per cent, less than that of 1910, the year of maximum value.

Sewer pipe made large increase in 1913, and attained its maximum. The value of sewer pipe in 1913 was $5,684,680, or 61.87 per cent, greater than that of 1904, the year of minimum value in the 10-year period.

Architectural terra cotta was the only product that showed a decrease in 1913, after reaching its maximum value in 1912. This decrease in 1913 is probably due to the falling off of building operations in some of the larger cities, which are the largest consumers of architectural terra cotta. With the exception of 1912, however, the value of architectural terra cotta in 1913 was the highest reported. Its value in 1913 was $3,625,833, or 88.27 per cent, greater than that of 1904.

Fireproofing, including hollow building tile or block, again showed a large increase and in 1913 attained its maximum value. This product has increased steadily in value since 1908, the year of minimum value in the 10-year period and in 1913 its value was $5,452,179, or 172.1 per cent, greater than that of 1908.

Tile, not drain, which embraces all kinds of tile except drain tile, has varied considerably. It showed a large increase in 1909, a small decrease in 1910, and increases in 1911, 1912, and 1913, reaching its maximum value in 1913. Its value in 1913 was $3,085,752, or 102.06 per cent, greater than that of 1904.

The number of active firms reporting continues to decrease—from 4,284 in 1912 to 4,065 in 1913. There has been a steady decrease in the number of active operators reporting since 1904, the net decrease in this period being 2,043, or 33.45 per cent. This condition is partly due to the consolidation of companies, but the principal cause is undoubtedly the elimination of the smaller plants. It should be borne in mind, however, that no attempt is made to show the number of yards or plants, or even the number of operators, but merely the number of operators reporting sales of products during the year. The number of plants is considerably larger than the number of firms reporting business during the year, as many operators have more than one plant and some as many as 20 or more, and many were idle or reported no sales.

RANK OF STATES.

The following table shows the rank of States in the value of clay products, the number of operating firms reporting, and the percentage of the total value produced in each State in 1912 and 1913:

Rank of States, value of output, and percentage of total value of clay products in 1912 and 1913.

State or Territory.	1912				1913			
	Rank.	Number of active firms reporting.	Value.	Percentage of total products.	Rank.	Number of active firms reporting.	Value.	Percentage of total products.

a Undistributed pottery products.

The value of clay products ranged by States in 1913 from $6,359 in Porto Rico to $38,388,296, or 21.18 per cent of the total, in Ohio. For 1912 Ohio reported 20.14 per cent of the total. Ohio has been the leading State in the value of clay products since figures were first compiled by the Geological Survey in 1894. It is likely to maintain this position for many years, as its output in 1913 was valued at $14,156,814, or 58.42 per cent more than that of Pennsylvania, the second State whose output was valued at $24,231,482, or 13.37 per cent of the total. For 1912 Pennsylvania reported 12.46 per cent of the total. New Jersey was the third State in both years. There was no change in the relative rank of the first seven States. Iowa, which was tenth in 1912, was eighth in 1913, and California, which was eighth in 1912, was ninth in 1913, and West Virginia, which was ninth in 1912, was tenth in 1913. There were but slight changes in the relative ranks of the other States. Kentucky rose from fourteenth in 1912 to twelfth in 1913; Virginia fell from eighteenth in 1912 to twenty-first in 1913; Maine rose from thirty-third in 1912 to thirtieth in 1913, exchanging places with South Carolina; and the District of Columbia fell from fortieth in 1912 to forty-third in 1913. The first 10 States reported for 1913 wares valued at $140,218,137, or 77.35 per cent of the total; for 1912 the same States reported wares valued at $133,015,892, or 76.97 per cent of the total. The first 5 States reported wares in 1913 valued at $108,990,506, or 60.13 per cent of the total, as compared with $103,457,130, or 59.87 per cent of the total in 1912.

BRICK AND TILE.

PRODUCTION.

PRODUCTION BY STATES.

The following tables show the output and value of the building brick and other structural products of clay, and of the fire brick, paving brick, and other clay products used in engineering work, the rank of the State in these products, and the percentage of the total value of each State in 1912 and 1913:

Brick and tile products in the United States in 1912.

[a] Including adobes, bake-oven tile, burnt-clay ballast, charcoal furnaces, chemical brick and tile, chimney pipe and tops, condensers, conduits, crucibles, flue pipe and lining, furnaces for heating irons, gas logs, glasshouse supplies, grave and lot markers, muffles, radial chimney brick and block, retorts, saggers, scorifiers, silo blocks, sundials, vases, and wall coping.

[b] Included in "Other States."

[c] Includes all products made by less than 3 producers in 1 State.

[d] The total of "Other States" is distributed among the States to which it belongs, in order that they may be fully represented in the totals.

[e] Including the following values: Floor tile, $2,483,082; wall tile, $1,763,992; roofing tile, $1,130,286; and faience tile, $731,820.

[f] In the total quantity and total value of fire brick are included, respectively, 174,246,000 silica brick, valued at $3,815,806, of which 132,042,000, valued at $2,608,940 was produced by Pennsylvania, and the remainder, 42,204,000, valued at $1,206,866, by Alabama, California, Colorado, Idaho, Illinois, Indiana, Missouri, Montana, New Jersey, Ohio, and Utah.

Common brick, as its name implies, is the most widely distributed of the clay products, being reported from every State and Territory except Alaska and Hawaii. There were 8,088,790,000 common brick reported for 1913, valued at $50,134,757, or $6.20 per 1,000, a decrease of 466,448,000 brick, or 5.45 per cent, from 1912. In 1912 there was an increase over 1911 of 79,961,000 brick, or 0.94 per cent. The value showed a decrease in 1913 of $1,661,509, or 3.21 per cent. In 1912 the value increased $1,911,004, or 3.83 per cent. Nineteen States showed increase in both quantity and value in 1913; 23 States showed decrease in both quantity and value; and 6 States—Illinois, Iowa, Kentucky, Massachusetts, Minnesota, and Missouri—showed decrease in quantity and increase in value.

In 1913 Illinois was the largest producer of common brick, displacing New York, which has been first for several years, and reporting 1,155,480,000 brick, valued at $6,445,821, or $5.58 per 1,000. This was a decrease of 55,019,000 brick, or 4.55 per cent, in quantity but an increase of $8,490, or 0.13 per cent, in value compared with 1912. New York was the second State in 1913, reporting 1,068,516,000 brick, valued at $6,029,103, or $5.64 per 1,000, a decrease in quantity of 205,125,000 brick, or 16.11 per cent, and in value of $1,282,572, or 17.54 per cent. The cause of the decrease in production of common brick in New York was the lessened activity in the building operations in New York City, the principal market in that State. The third State in rank in the production of common brick in 1913 was Pennsylvania, which reported 704,493,000 brick, valued at $4,772,229, or $6.77 per 1,000, an increase of 7,470,000 brick, or 1.07 per cent, in quantity and of $181,445, or 3.95 per cent, in value. Ohio was fourth in the production of common brick in 1913, displacing New Jersey, and reporting 407,685,000 brick, valued at $2,523,014, or $6.19 per 1,000, an increase of 11,849,000 brick in quantity, or 2.99 per cent, and of $108,532, or 4.50 per cent, in value. New Jersey was fifth in 1913, reporting 401,702,000 brick, valued at $2,391,287, or $5.95 per 1,000, a decrease of 27,607,000 brick, or 6.43 per cent, in quantity and of $200,804, or 7.75 per cent, in value. Of the Illinois production 717,682,000 brick, or 62.11 per cent, was from Cook County, and of the output of New York, 779,773,000, or 72.98 per cent, was from the Hudson River region. The average price per 1,000 in 1913 for common brick ranged from $4.42 in Kansas to $10.76 in Wyoming, the average for the entire country being $6.20, an advance of 15 cents over the average for 1912. These same States reported for 1912 the extremes in average price of $4 and $9.98. In Illinois there was an advance of 26 cents per 1,000; in New York there was a decline of 10 cents per 1,000, in Pennsylvania an advance of 18 cents, in Ohio an advance of 9 cents, and in New Jersey there was a decline of 9 cents.

Vitrified paving brick was reported from 29 States for 1913, an increase of 2—Oregon and Virginia, which reported none for 1912. Ohio, as for several years, was the leading State, reporting 304,391,000 brick, valued at $3,308,975, or $10.87 per 1,000. This was an increase of 36,120,000 brick, or 13.46 per cent, in quantity and of $478,666, or 16.91 per cent, in value over 1912. Ohio reported 31.75 per cent of the total production and 27.26 per cent of the total value in 1913. Pennsylvania was second in quantity but third in value, and Illinois was second in value and third in quantity in 1913. Pennsylvania reported 140,407,000 brick, valued at $1,814,833, or $12.93 per 1,000, an increase of 28,035,000 brick, or 24.95 per cent, in quantity and of $403,737, or 28.61 per cent, in value over 1912. Illinois reported 133,938,000 brick, valued at $1,883,199, or $14.06 per 1,000. This was a decrease of 2,770,000 brick, or 2.03 per cent, in quantity and an increase of $43,478, or 2.36 per cent, in value as compared with 1912. West Virginia was fourth in production and value; Washington was seventh in quantity and fifth in value, and Indiana fifth in quantity and sixth in value. The average price per 1,000 ranged in 1913 in the important producing States from $10.19 in Kansas to $16.42 in Washington, with a general average of $12.66.

Next to the common-brick industry, that of the front or face brick branch is most widely spread, production being reported from 43 States in 1913, the same as for 1912. In 1913 Pennsylvania, as for many years, was the leading front-brick producing State, reporting 214,734,000 brick, valued at $2,325,201, or $10.83 per 1,000. This was a decrease in quantity of 2,594,000 brick, or 1.19 per cent, but an increase in value of $3,722, or 0.16 per cent, compared with 1912. Pennsylvania's output in 1913 was 25.94 per cent of the total quantity and 24.19 per cent of the total value. Ohio was second in rank, Indiana third, and New Jersey fourth. The average price per 1,000 for front brick in 1913 ranged from $8.52 in Kansas to $25.56 in Oregon, with a general average of $11.62.

Draintile was reported from 38 States, or 1 less than for 1912, Oklahoma and Vermont reporting none for 1913, and New Mexico reentering the list of producers. Iowa, Indiana, Ohio, Illinois, and Michigan were the leading States in production in the order named in 1913, as for several years. These 5 States together reported draintile valued at $7,543,403, or 88.14 per cent of the total, in 1913; for 1912 these States reported draintile valued at $7,075,030, or 88.32 per cent of the total. Of these leading States Indiana and Ohio showed a decrease in 1913; Iowa showed an increase of $505,732, or 22.05 per cent; Illinois, $35,280, or 2.96 per cent; and Michigan, $27,598, or 7.11 per cent.

Sewer pipe was reported from 28 States in 1913, the same as for 1912. Ohio was the leading State in 1913, as for many years, and reported production valued at $5,159,548, an increase of $1,137,470, or 28.28 per cent, over that of 1912. Ohio's production constituted 34.69 per cent of the total for the country. Pennsylvania was second, displacing Missouri, which was third in 1913, and California, which was third in 1912, was fourth in 1913. These 4 States reported 58.71 per cent of the total for 1913. Sewer pipe constituted in 1912, 10.38 per cent of the value of all brick and tile products and 8.20 per cent of all clay products.

Architectural terra cotta was reported from 12 States for 1913, a decrease of 1, Oregon reporting none. In only 7 States were there a sufficient number of producers to permit the publication of figures without disclosing individual returns. Every one of these States, except New Jersey, showed a decrease in the value of production. New Jersey was the leading State in 1913, displacing Illinois, its output being valued at $2,388,293; this was an increase of $58,228, or 2.5

per cent. Illinois was second with an output valued at $1,908,399, a decrease of $576,613, or 23.2 per cent. New York was third, as in 1912, reporting production valued at $1,110,726, a decrease of $28,565, or 2.51 per cent. These 3 States reported 69.92 per cent of the total.

Fireproofing, including hollow building tile or block, was reported from 34 States in 1913, an increase of 3. Louisiana, North Carolina, North Dakota, and South Carolina, which reported no fireproofing for 1912, entered the list of producing States in 1913, and Arkansas dropped out. Ohio was the leading State in 1913, displacing New Jersey by a small margin—$23,491. The output of Ohio was valued at $2,115,861, an increase over 1912 of $365,146, or 20.86 per cent. New Jersey's output increased in value $61,020, or 3 per cent. These 2 States produced 48.82 per cent of the total. Iowa was third, Indiana fourth, and Illinois fifth in value of output in 1913. Fireproofing composed 6.02 per cent of the value of brick and tile products in 1913 and 4.75 per cent of all clay products, compared with 5.26 per cent and 4.15 per cent, respectively, in 1912.

"Tile, not drain," includes roofing, floor, wall, and art tile. These were reported from 19 States for 1913, a decrease of 2 States. Alabama, Iowa, and Montana, which reported no product for 1912, entered the list of producers in 1913, and Nebraska, Oregon, South Dakota, Utah, and Washington dropped out for 1913. Ohio, as for many years, was the leading State, reporting wares valued at $2,492,380, or 40.8 per cent of the total. This was an increase of $70,597, or 2.92 per cent, over 1912. New Jersey was second, as in 1912, reporting production valued at $1,308,787, or 21.42 per cent of the total, an increase of $53,541, or 4.27 per cent, over 1912. These 2 States, therefore, reported nearly two-thirds of the total production.

Fire brick in 1913, as for many years, was second only to common brick in value. It was reported from 33 States, a decrease of 4 States, as Kansas, Louisiana, North Carolina, and Oklahoma, which reported fire brick for 1912, reported none for 1913. The quantity reported, including silica brick, increased from 913,681,000 9-inch equivalent brick in 1912 to 1,017,299,000 brick in 1913, an increase of 103,618,000 brick, or 11.34 per cent. The total value was $20,627,122 in 1913, as compared with $17,877,629 in 1912, an increase of $2,749,493, or 15.38 per cent. The average price per 1,000 in 1913 for all fire brick was $20.28, compared with $19.57 in 1912. The total number of clay 9-inch equivalent fire brick reported for 1913 was 843,053,000, valued at $16,811,316, or $19.94 per 1,000. This was an increase of 64,950,000 brick, or 8.35 per cent, in quantity and $1,856,861, or 12.42 per cent, over 1912. Pennsylvania continues to be the leading producer of both clay and silica fire brick, reporting 42.89 per cent of the total quantity of clay fire brick reported for 1913 and 42.2 per cent of its value, and 75.78 per cent of the silica fire brick and 68.37 per cent of its value. If clay fire brick and silica fire brick be considered together, Pennsylvania produced 48.52 per cent of the quantity of fire brick and 47.04 per cent of its value. Ohio was second in quantity of fire brick in 1913 and third in value; Missouri was third in quantity and second in value; Kentucky was fourth in quantity and value; and New Jersey was fifth in both. All of the first 5 States, except New Jersey, showed increases in quantity and value over 1912. These 5 States reported 82.88 per cent of the production and 82.5 per cent of the value of all clay fire brick in 1913. The average price per 1,000 ranged in the important States for clay fire brick from $8.83 in West Virginia to $41.57 in New York.

The production of silica fire brick in 1913 was 174,246,000 9-inch equivalent brick, valued at $3,815,806, or $21.90 per 1,000, compared with 135,578,000 brick, valued at $2,923,174, or $21.56 per 1,000, in 1912. This was an increase of 38,668,000 brick, or 28.52 per cent, in quantity and of $892,632, or 30.54 per cent, in value over 1912.

Fire brick composed 14.39 per cent of the value of all brick and tile products in 1913 and 11.38 per cent of all clay products.

Pennsylvania was in 1913, as for many years, the leading State in the value of brick and tile products, reporting wares valued at $22,185,383, or 15.48 per cent of the total, an increase of $2,776,702, or 14.31 per cent, over 1912. Ohio, as in 1912, was second with products valued at $21,868,407, or 15.26 per cent of the total, an increase of $2,565,634, or 13.29 per cent. Illinois continued to be third, reporting wares valued at $14,280,611, or 9.97 per cent of the total, an increase of $1,572, or 0.01 per cent. New Jersey was fourth, reporting 7.58 per cent of the total; New York was fifth with 6.02 per cent of the total; Indiana was sixth and Missouri seventh; Iowa was eighth, displacing California, which was ninth, and Texas was tenth.

TILE, NOT DRAIN.

For the first time an effort was made to obtain figures for the various varieties of tile embraced under the head "Tile, not drain." The result of this effort is shown in the following table. There are a number of subdivisions and trade names under these varieties, but owing to the small number of producers of some of these subdivisions it has been thought best to classify them simply as floor, wall, roofing, and faïence tile, the latter class embracing art tile.

Value of the tile, not drain, production in the United States, in 1913, by varieties.

Variety.	Value.	Number of firms reporting each variety.
Floor	$2,483,082	39
Wall	1,763,992	15
Roofing	1,130,286	24
Faïence	731,820	23
Total	6,109,180	....

This table shows that floor tile is the variety of greatest value, $2,483,082, or more than 40 per cent of the total. This variety of tile was reported by 39 operators in California, Illinois, Indiana, Kentucky, Massachusetts, Montana, New Jersey, New York, Ohio, Pennsylvania, Rhode Island, and West Virginia. Ohio was the leading producer, reporting this ware to the value of $1,017,240, or more than 40 per cent of the total. New Jersey was second, with a value of $719,651.

Wall tile was reported by 15 operators to the value of $1,763,992, or nearly 29 per cent of the total of all tile, not drain. Ohio was the leading producer of wall tile, reporting $838,860, made entirely in Muskingum County, and New Jersey was second, with a value of $293,704. It was also made in California, Indiana, Kentucky, Massachusetts, Missouri, and Pennsylvania.

Roofing tile was third in value, $1,130,286 being reported by 24 operators in Alabama, California, Colorado, Georgia, Illinois, Iowa, Kansas, Kentucky, Michigan, Missouri, Ohio, Pennsylvania, and West Virginia. Here again Ohio was the leading State, with a production valued at $470,905, or more than 41 per cent of the total. Kansas was second and California was third.

Faïence, including art tile, was the variety of smallest value, being reported by 23 operators to the value of $731,820. New Jersey was the leading State, reporting this tile to the value of $295,432, or more than 40 per cent of the total.

HUDSON RIVER REGION.

New York City is the leading common brick market in the United States, many millions of brick being used there annually. The principal source of this supply is the Hudson River region, extending from New York to Cohoes on both sides of the river. Bergen County, N. J., has also contributed largely to this market, and within the last two years the Raritan River region, located in Middlesex County, N. J., has sent the larger portion of its output of common brick to the New York market. For this reason it is included in the table showing the output of the Hudson River region. Connecticut also is at times a factor in the New York brick market.

The water transportation enjoyed by the Hudson River yards and those located in the Hackensack and Raritan districts, however, gives them a great advantage, and it is only when prices are high—above $7 per 1,000—that Connecticut brick can profitably enter the New York City market. As prices were unusually low in 1913, few, if any, Connecticut brick were shipped to New York during that year.

The year 1913 was notable in this region principally for the large decrease in production—16.86 per cent—and the still greater decrease in value—20.99 per cent. The principal use of the brick made in this region is, and probably always will be, in the building industry of New York. Notwithstanding that the cost of the building operations in New York City decreased about 35 per cent in 1913 from 1912, the marketed brick decreased less than one-half as much, thus showing that the use of brick in building is expanding and that they are also being used more extensively than ever before for sewers, subways, and possibly for other purposes. Probably both of these conditions prevail. The back-to-brick campaign is apparently having its effect, not only in the common-brick industry, but in the higher grades of building brick and other clay products, such as hollow building tile and terra cotta, and it is confidently believed that the prospects for the structural branches of the clay-working industries, especially in the East, are bright, and that the consumption of clay products in the building industries in the future will be larger than during the last few years.

The following table shows the production and value of common brick along the Hudson River and in portions of New Jersey from 1901 to 1913, with the number of operating firms reporting and the average price received per thousand:

Production of common brick in the Hudson River district from 1901 to 1913, inclusive.

Year.	Number of active firms reporting.	Quantity.	Value.	Average price per thousand.
		Thousands.		
1901	127	830,154	$3,880,215	$4.67
1902	127	833,065	3,683,379	4.42
1903	115	844,500	3,973,316	4.70
1904	119	987,644	5,810,114	5.88
1905	129	1,297,389	9,063,753	6.99
1906	135	1,274,372	7,672,639	6.02
1907	132	1,064,892	5,515,585	5.18
1908	123	875,979	4,107,382	4.69
1909	127	1,313,760	6,438,642	4.90
1910	135	1,142,284	5,544,600	4.85
1911	125	926,072	4,717,633	5.09
1912 [a]	136	1,233,187	7,133,177	5.78
1913 [a]	132	1,025,308	5,636,061	5.50

[a] Includes Raritan district, New Jersey.

This table shows that the number of brick marketed in this region in 1913 was 1,025,308,000, valued at $5,636,061, as compared with 1,233,187,000, valued at $7,133,177, in 1912. This was a decrease of 207,879,000 brick, or 16.86 per cent, in quantity, and of $1,497,116, or 20.99 per cent, in value.

In the New York and Bergen County portions of the region, the production, 830,617,000 brick, in 1913, was the smallest since 1902, when it was 833,065,000 brick, and the value, $4,515,508, was the smallest since 1908, when it was $4,107,382. The average value per thousand, $5.44, was 30 cents lower than in 1912, but considerably higher than in any year from 1907 to 1911. Compared with the year of maximum production, 1909, there was a decrease of 483,143,000 brick, or 36.78 per cent, in 1913; and compared with the maximum value in 1905, there was a decrease of $4,548,245, or 50.18 per cent.

The average price per thousand for the region was $5.50, as compared with $5.78 in 1912. The maximum average price was $6.99 in 1905, and the minimum average price was $4.42 in 1902. The number of active firms reporting has varied in the New York and Bergen County portion of the region from 115 in 1903 to 135 in 1906 and 1910. In 1913 in this portion of the region there were 121 active firms reporting, a decrease of 5 from 1912. The number of active firms reporting for the whole region decreased from 136 in 1912 to 132 in 1913. As in other branches of the clay-working industry, the number of active firms reporting is not equivalent to the number of yards, as some of the operators have more than one yard.

The following table shows the production of common brick in the Hudson River district in 1912 and 1913 by counties:

Production of common brick in the Hudson River district (from Cohoes to New York City) and in Raritan district, New Jersey, in 1912 and 1913, by counties.

County.	1912				1913			
	Number of active firms reporting.	Common brick.		Average price per thousand.	Number of active firms reporting.	Common brick.		Average price per thousand.
		Quantity.	Value.			Quantity.	Value.	
		Thousands.				*Thousands.*		
Albany	12	71,600	$436,626	$6.10	12	61,792	$363,964	$5.89
Columbia	7	70,866	354,589	5.00	6	58,593	300,624	5.13
Dutchess	18	129,860	765,788	5.90	18	113,120	610,457	5.40
Greene	6	34,708	196,888	5.67	5	24,214	118,845	4.91
Orange	9	116,304	660,089	5.68	9	98,493	525,887	5.34
Rensselaer	5	15,760	85,797	5.44	5	14,076	87,063	6.19
Rockland	27	207,796	1,221,428	5.88	25	163,612	890,188	5.44
Ulster	24	259,480	1,458,554	5.62	24	194,125	1,026,870	5.29
Westchester	8	62,390	363,098	5.82	7	51,748	297,504	5.75
Total for New York portion of district	116	968,764	5,542,857	5.72	111	779,773	4,221,402	5.41
Bergen County, N. J.	10	50,495	307,913	6.10	10	50,844	294,106	5.78
Raritan district (Middlesex County), N. J.	10	213,928	1,282,407	5.99	11	194,691	1,120,553	5.76
Grand total	136	1,233,187	7,133,177	5.78	132	1,025,308	5,636,061	5.50

New York's portion was 76.05 per cent of the quantity of brick and 74.9 per cent of the value of the region. This portion, consisting of 779,773,000 brick in 1913, showed a decrease of 188,991,000 brick, or 19.51 per cent, from 1912. The value of New York's portion of the region was $4,221,402, a decrease of $1,321,455, or 23.84 per cent.

Of the counties included in the New York portion of this region in 1913, Ulster, as for many years, was first in output and value, reporting 194,125,000 brick, valued at $1,026,870, a decrease in quantity of 65,355,000 brick, or 25.19 per cent, and in value of $431,684, or 29.6 per cent. Rockland was second with 163,612,000 brick, valued at $890,188, a decrease of 44,184,000 brick, or 21.26 per cent, and of $331,240, or 27.12 per cent. Dutchess County was third, with 113,120,000 brick, valued at $610,457, a decrease of 16,740,000 brick, or 12.89 per cent, and of $155,331, or 20.28 per cent. Every county showed a decrease in production, and every county except Rensselaer—the smallest producing county in the region—showed a decrease in value. The increase in value in Rensselaer County was slight, $1,266, or less than 1½ per cent. The highest average price per thousand in 1913 was in Rensselaer County—$6.19, an increase of 75 cents over 1912. In 1912 the highest average price was attained in Albany County—$6.10. The lowest average price in 1913, $4.91, was in Greene County, a decrease of 76 cents. In 1912 the lowest average price, $5, was in Columbia County. The average for New York's portion of the region was $5.41 for 1913, compared with $5.72 in 1912 and with $5.06 in 1911.

New Jersey's portion of the production of this region is comparatively small, being 245,535,000 brick in 1913, or 23.95 per cent of the output of the region, and $1,414,659, or 25.1 per cent of the value. Bergen County showed a small increase in production in 1913 over 1912, 349,000 brick, or less than 1 per cent. The average price per thousand decreased in this county 32 cents from 1912, and the total value decreased $13,807, or 4.48 per cent. The Raritan district showed a decrease in both production and value in 1913 from 1912, the former 19,237,000 brick, or 8.99 per cent, and the latter $161,854, or 12.62 per cent.

The average price per thousand in New Jersey's portion of the region was $5.76, or 35 cents higher than that for New York's portion and 26 cents higher than that for the whole region.

Middlesex County, N. J., showed the largest production and value in the region in 1913, 194,691,000 brick, valued at $1,120,553. The production of this county in 1913 exceeded in quantity by 566,000 brick, or 0.29 per cent, and in value by $93,683, or 9.12 per cent, the production of Ulster County, the leading county of New York's portion of the region.

The number of active firms reporting decreased 5 in the New York portion ot the region and increased 1 in the New Jersey portion.

POTTERY.

INTRODUCTION.

The following tables show the status of the pottery industry in 1912 and 1913 and the production, imports, and exports of pottery from 1901 to 1913, inclusive. The figures indicate that the industry was in a prosperous condition in 1913. The year opened with bright prospects and sufficient business to keep the potteries busy, and throughout the spring and summer and well into the fall business was generally reported as unusually good. There resulted the largest production in the history of the industry. The underlying cause of this prosperity is no doubt the improved character of the American product in texture, finish, color, decoration, and prevention of crazing, some of the higher grades of American pottery equaling if not surpassing some of the best imported ware.

Although the pottery industry has been singularly free from labor troubles, the year 1913 was more or less disturbed by strikes, none of which were general and none of which were of a very grave character. The scarcity of labor, however, which was severely felt in 1913, and the legal restrictions concerning the employment of children and women in some States have affected the expansion of the industry. The year 1914 will have the largest kiln capacity ever known in the industry, about 47 new kilns having been added during 1913 or early in 1914.[1]

The value of all domestic pottery marketed in 1913 was $37,992,375, an increase of $1,488,211, or 4.08 per cent. The imports, which comprise almost exclusively the higher grades of ware, increased $621,921, or 6.51 per cent. In 1912 the imports of pottery decreased $1,083,086, or 10.18 per cent. The proportion of domestic production to consumption in 1913 was 79.86 per cent, a slightly less proportion than for 1912, when it was 81.45 per cent.

Every product as classified in this report, except stoneware and yellow and Rockingham ware, participated in the increase of 1913. The most important variety in value, white earthenware (valued at $15,066,811 in 1913), showed an increase of 1.6 per cent, and reached its maximum value. Other important products showing a large increase were sanitary ware and porcelain electrical supplies.

---

[1] Report of committee on statistics, United States Potters Association, December, 1913.

Tariff.—The imports of pottery have always been more or less interesting. For many years the value of imported pottery exceeded the value of that made at home, but about the close of the nineteenth century domestic production caught up with imports and since that time has greatly exceeded them, the production of 1913 being nearly four times as great in value as the imports. The imports for 1913 are especially interesting in view of the tariff act of that year, which lowered the duties on all varieties of pottery products. The new law went into effect so late in the year that but little can be judged as to its effect on the industry. The law is at least very definite in its classification of pottery, and has created a separate class—earthenware and crockery composed of a nonvitrified absorbent body. This ware was imported to the value of $605,781 from October 4, when the law went into effect, to December 31, 1913. The classification of pottery and the rates of duty under the old and the new tariffs are as follows:

Act o fAugust 5, 1909.

92. Common yellow, brown, or gray earthenware, plain, embossed, or salt-glazed common stoneware, and earthenware or stoneware crucibles, all the foregoing not decorated in any manner, 25 per centum ad valorem; yellow earthenware, plain or embossed, coated with white or transparent vitreous glaze but not otherwise ornamented or decorated, and Rockingham earthenware, 40 per centum ad valorem.

93. China, porcelain, parian, bisque, earthen, stone, and crockery ware, including clock cases with or without movements, pill tiles, plaques, ornaments, toys, charms, vases, statues, statuettes, mugs, cups, steins, and lamps, all the foregoing wholly or in chief value of such ware; painted, colored, tinted, stained, enameled, gilded, printed, or ornamented or decorated in any manner; and manufactures in chief value of such ware not specially provided for in this section, 60 per centum ad valorem.

94. China, porcelain, parian, bisque, earthen, stone, and crockery ware, plain white, plain brown, including clock cases with or without movements, pill tiles, plaques, ornaments, toys, charms, vases, statues, statuettes, mugs, cups, steins, and lamps, all the foregoing wholly or in chief value of such ware, not painted, colored, tinted, stained, enameled, gilded, printed, or ornamented or decorated in any manner; and manufactures in chief value of such ware not specially provided for in this section, 55 per centum ad valorem.

Act of October 3, 1913.

78. Common yellow, brown, or gray earthenware made of natural unwashed and unmixed clay; plain or embossed, common salt-glazed stoneware; stoneware and earthenware crucibles; all the foregoing, not ornamented, incised, or decorated in any manner, 15 per centum ad valorem; if ornamented, incised, or decorated in any manner and manufactures wholly or in chief value of such ware, not specially provided for in this section, 20 per centum ad valorem; Rockingham earthenware, 30 per centum ad valorem.

79. Earthenware and crockery ware composed of a nonvitrified absorbent body, including white granite and semiporcelain earthenware, and cream-colored ware, and stoneware, including clock cases with or without movements, pill tiles, plaques, ornaments, toys, charms, vases, statues, statuettes, mugs, cups, steins, lamps, and all other articles composed wholly or in chief value of such ware; if plain white, plain yellow, plain brown, plain red, or plain black, not painted, colored, tinted, stained, enameled, gilded, printed, ornamented, or decorated in any manner, and manufactures in chief value of such ware not specially provided for in this section, 35 per centum ad valorem; if painted, colored, tinted, stained, enameled, gilded, printed, or ornamented or decorated in any manner, and manufactures in chief value of such ware not specially provided for in this section, 40 per centum ad valorem.

80. China and porcelain wares composed of a vitrified nonabsorbent body which when broken shows a vitrified or vitreous, or semivitrified or semivitreous fracture, and all bisque and parian wares, including clock cases with or without movements, plaques, ornaments, toys, charms, vases, statues, statuettes, mugs,

cups, steins, lamps, and all other articles composed wholly or in chief value of such ware, if plain white, or plain brown, not painted, colored, tinted, stained, enameled, gilded, printed, or ornamented or decorated in any manner; and manufactures in chief value of such ware not specially provided for in this section, 50 per centum ad valorem; if painted, colored, tinted, stained, enameled, gilded, printed, or ornamented or decorated in any manner, and manufactures in chief value of such ware not specially provided for in this section, 55 per centum ad valorem.

PRODUCTION.

The following table shows the statistics of the production of pottery in the United States from 1901 to 1913:

Value of pottery products in the United States, 1901–1913, by varieties.

Year.	Number of active firms reporting.	Red earthenware.	Stoneware and yellow and Rockingham ware.	White ware, including C. C. ware, etc.	China, bone china, delft, and belleek ware.	Sanitary ware.	Porcelain electrical supplies.	Miscellaneous.	Total.
1901	535	$703,698	$2,855,638	$11,608,898	$1,392,864	$2,877,650	$1,141,362	$1,883,750	$22,463,860
1902	518	735,386	3,383,678	12,371,111	1,219,293	3,555,662	1,350,255	1,512,068	24,127,453
1903	546	698,175	3,658,836	12,493,012	1,757,502	3,362,263	1,464,980	2,001,284	25,436,052
1904	556	756,625	3,701,844	11,924,404	1,512,115	3,585,375	1,431,452	2,246,455	25,158,270
1905	533	780,637	3,969,016	12,809,414	1,558,730	4,580,145	2,253,061	1,967,891	27,918,894
1906	540	909,262	4,193,884	14,152,503	1,787,776	5,098,310	2,838,284	2,460,865	31,440,884
1907	509	845,465	4,280,601	13,913,680	1,930,669	4,863,222	2,613,771	1,696,066	30,143,474
1908	497	757,900	3,518,841	11,474,147	1,581,020	4,373,590	2,009,005	1,421,052	25,135,555
1909	466	805,906	3,993,859	13,728,316	[a]1,766,766	5,989,295	3,047,499	[a]1,717,800	31,049,441
1910	463	854,196	3,796,688	14,780,980	1,962,126	6,758,996	3,794,153	1,837,539	33,784,678
1911	449	893,678	4,120,608	14,366,251	2,057,985	7,031,458	4,232,101	1,816,479	34,518,560
1912	434	958,270	3,919,778	14,829,431	2,177,305	7,902,255	4,927,316	1,789,809	36,504,164
1913	426	1,000,529	3,683,567	15,066,811	2,424,060	8,214,838	5,737,741	1,864,829	37,992,375

[a] China, bone china, delft, and belleek ware for Ohio is included in miscellaneous.

This table shows that the value of the pottery products of the United States in 1913 was $37,992,375, the largest yet reported, exceeding that of 1912 by $1,488,211, or 4.08 per cent, and that of 1911 by $3,473,815, or 10.06 per cent. In 1913, as in 1912, only one variety decreased in value—stoneware—which declined $236,211, or 6.03 per cent. With the exception of stoneware, every product reached its maximum value in 1913, the variety showing the largest gain, both proportionate and actual, being porcelain electrical supplies, which increased $810,425, or 16.45 per cent.

The value of white ware, including china, but excluding sanitary ware and porcelain electrical supplies, was $17,490,871 in 1913, as compared with $17,006,736 in 1912, an increase of $484,135, or 2.85 per cent. These articles constituted 46.04 per cent of all pottery products in 1913 and 46.59 per cent in 1912. If the value of sanitary ware and porcelain electrical supplies be added, the total for 1913 would be $31,443,450, or 82.76 per cent of all pottery products, an increase of $1,607,143, or 5.39 per cent, over the corresponding value for 1912.

Chinaware production showed an increase in value of $246,755, or 11.33 per cent. This product has increased in value almost steadily since 1902, the value in 1913, the highest recorded, being nearly twice as great as it was in 1902.

Red earthenware showed an increase of $42,259 over 1912, or 4.41 per cent; white ware, $237,380, or 1.6 per cent; and sanitary ware, $312,583, or 3.96 per cent.

The total value of the pottery products of the United States in 1913 was $6,551,491, or 20.84 per cent, greater than in 1906, $7,848,901, or 26.04 per cent, greater than in 1907, and $12,856,820, or 51.15 per cent, greater than in 1908. The value of these products has increased steadily during each year of the period covered by the table with the exception of 1904, 1907, and 1908.

In the following tables will be found the statistics of the production of pottery in the United States in 1912 and 1913 by States and varieties, the former year being given for comparison.

Value of pottery products in 1912, by varieties of products, by States.

Rank of State.	State.	Number of active firms reporting.	Red earthenware.	Stoneware and yellow or Rockingham ware.	White ware, including C. C. ware, white granite, semiporcelain ware, and semivitreous porcelain ware.	China, bone china, delft, and belleek ware.

[d] Included in [e] ($793,549).
[e] Made up of State totals of Connecticut, Kansas, Louisiana, Maine, Minnesota, Montana, Nebraska, New Hampshire, Oregon, Porto Rico, Utah, Virginia, and Washington.

The number of States reporting for 1913 ware classed as pottery in this report was 38, an increase of 1, Nebraska being added to the list of pottery-producing States. The important producing States, especially those reporting production of the higher grades of ware are few. White ware was reported from 10 States, a decrease of 1; china was reported from 4 States, the same number as for 1912; sanitary ware from 8 States, the same number as for 1912; and porcelain electrical supplies from 10 States, a decrease of 1, California reporting none.

Red earthenware, the commonest of pottery products, was reported from 31 States in 1913, an increase of 1, Nebraska and Porto Rico entering the list of producers of red earthenware, and Louisiana reporting none. Ohio was the leading State in 1913, as for several years, reporting red earthenware valued at $236,883, a decrease of $26,202, or 9.96 per cent. Pennsylvania was second, displacing Massachusetts, which became third. In 1913 the value of the output of Pennsylvania increased $25,488, or 15.72 per cent. Massachusetts, Ohio, and Pennsylvania together reported about 60 per cent of the total value of this product in 1913, 61.38 per cent in 1912, and 60.71 per cent in 1911. Red earthenware was reported by 147 producers in 1913, by 145 in 1912, and by 160 in 1911. It constituted 2.63 per cent of the total value of pottery in 1913 and 1912.

Stoneware, including yellow and Rockingham ware, was reported from 28 States in 1913, a decrease of 1, Utah reporting none. Ohio, in 1913, as for many years, was the leading State, reporting an output valued at $1,649,186, or 44.77 per cent of the total. This was a decrease of $183,080, or 9.99 per cent. Illinois, as for some years, was second, showing a decrease of $51,050, or 7.56 per cent, in 1913. These 2 States reported 61.72 per cent of the total value of this variety of ware in 1913. The number of producers reporting stoneware continues to decrease, 154 reporting for 1913, as compared with 163 for 1912 and with 175 for 1911. Stoneware constituted 9.70 per cent of the value of pottery in 1913, 10.74 per cent in 1912, and 11.94 per cent in 1911.

These tables show that the pottery products of greatest value are embraced under the heading white ware, which represents the general household wares. These wares were reported from but 10 States in 1913, a decrease of 1, California and Michigan reporting none for 1913, and Kentucky entering the list of producers. Ohio has been the leading producer of these wares for many years, and reported for 1913 white ware valued at $10,548,628, an increase of $579,137, or 5.81 per cent. Ohio's production in 1913 was 70.01 per cent of the value of the entire output, as compared with 67.23 per cent in 1912 and with 66.91 per cent in 1911. West Virginia was second, as for several years, and reported wares valued at $2,024,104, a decrease of $27,883, or 1.36 per cent. Pennsylvania was third in 1913, displacing New Jersey, which has been third for several years, by a narrow margin—$5,122. The value of these wares in 1913 in Pennsylvania showed a decrease of $62,747, or 6.95 per cent. New Jersey's production decreased $255,967, or 23.47 per cent. White ware constituted 39.66 per cent of all pottery products in 1913, 40.62 per cent in 1912, and 41.62 per cent in 1911. The number of producers reporting white ware in 1913 was 55, as compared with 63 in 1912 and with 61 in 1911.

China production was reported from 4 States in 1913, as in 1912. New Jersey was the leading State, as for many years, and reported china valued at $1,239,453, an increase of $83,687, or 7.24 per cent. The production of New Jersey constituted 51.13 per cent of the entire production. New York was second. The production of china is still comparatively unimportant, though it has been steadily increasing, showing a considerable gain in 1913 over 1912, and will no doubt in time constitute an important branch of the industry in this country. The value of the china output reported for 1913 was only 6.38 per cent of the total pottery production for the country, as compared with 5.96 per cent in 1912 and 1911. The number of operators reporting china in 1913 was 14, a decrease of 2 from 1912.

Production of sanitary ware was reported from 8 States in 1913, the same as for 1912. New Jersey was the leading State, reporting ware for 1913 valued at $5,238,013, an increase of $38,735, or 0.75 per cent. New Jersey's output was 63.76 per cent of the total for 1913. West Virginia was second, as in 1912, reporting sanitary ware valued at $1,146,205, a decrease of $10,273, or 0.89 per cent. Indiana was third, as for 1912, reporting ware valued at $719,103, which was an increase of $85,525, or 13.5 per cent. The number of producers reporting sanitary ware in 1913 was 44, as compared with 40 in 1912 and with 36 in 1911. Sanitary ware composed 21.62 per cent of the value of pottery products in 1913, 21.65 per cent in 1912, and 20.37 per cent in 1911.

Porcelain electrical supplies were reported from 10 States in 1913, 1 less than in 1912, California reporting no production for 1913. Ohio is the largest producer of porcelain electrical supplies, reporting for 1913 an output valued at $2,184,201, or 38.07 per cent of the total. This was an increase of $356,911, or 19.53 per cent. New York was second and New Jersey third, as in 1912. New York's output increased in value $291,762, or 22.99 per cent over that of 1912, and New Jersey's increased $43,981, or 3.84 per cent. The other seven States were comparatively unimportant producers, their combined output constituting but 13.98 per cent of the total value. The number of producers reporting porcelain electrical supplies for 1913 was 36, an increase of 2 over 1912. This variety constituted 15.1 per cent of the value of all pottery in 1913, 13.5 per cent in 1912, and 12.26 per cent in 1911.

Ohio is the leading pottery-producing State of the Union, reporting for 1913 wares valued at $16,519,889, or 43.48 per cent of the total, an increase of $1,011,154, or 6.52 per cent, over 1912. Ohio's principal pottery product is white ware, which constituted 63.85 per cent of the value of Ohio's entire pottery output in 1913. The second in importance is porcelain electrical supplies. Ohio produced every variety of pottery as classified in this report but one—china. New Jersey is the second largest pottery-producing State. For 1913 New Jersey reported wares valued at $8,838,545, or 23.26 per cent of the total, a decrease of $97,375, or 1.09 per cent. The principal pottery product of New Jersey is sanitary ware, which constituted 59.26 per cent of the State total for 1913. West Virginia is third in rank among the pottery-producing States, reporting for 1913 ware valued at $3,424,887, or 9.01 per cent of the total, an increase of $59,721, or 1.77 per cent. New York was fourth, as for several years, and Pennsylvania fifth, the former reporting 7.48 per cent of the total value and the latter 5.39 per cent. Indiana and Illinois maintained their relative ranks of sixth and seventh, reporting 3.12 per cent and 2.41 per cent, respectively. The first five States—Ohio, New Jersey, West Virginia, New York, and Pennsylvania—reported 88.63 per cent of the total production in 1913; in 1912 these States reported 88.61 per cent of the total, and in 1911, 88.04 per cent.

In considering the rank of States it should be borne in mind that the small number of producers in many of them in 1913, which prevents the publication of State totals without disclosing individual returns, makes the rank of all but the first few the relative and not the actual rank.

CONSUMPTION.

The pottery imported into the United States in 1913 was valued at $10,177,451 and the production at $37,992,375, a total of $48,-169,826. After deducting exports—domestic, $559,163, and foreign, $34,816—the net apparent consumption was valued at $47,575,847, of which the domestic production was 79.86 per cent. In 1912 this percentage was 81.45; in 1911 it was 78.93; in 1910 it was 77.08; and the next highest was in 1902, when it was 72.91.

POTTERY INDUSTRY BY STATES.

Alabama.—The pottery industry of Alabama is of comparatively little importance. Production was reported for 1913 by 9 operators, a decrease of 6. The output was valued at $20,158, a decrease of $2,055. The product consists of red earthenware and stoneware. There were 5 idle potteries in Alabama in 1913.

Arkansas.—In Arkansas there were 4 active potters in 1913, who reported wares valued at $19,757, a decrease of $9,200 from 1912. The product consists of stoneware, art pottery, and red earthenware. There was 1 idle pottery in Arkansas in 1913.

California.—Pottery products of California were reported by 11 operators for 1913, a decrease of 1 from 1912. The value of the products in 1913 was $290,255, an increase of $70,602, or 32.14 per cent, over 1912. The product of greatest value was sanitary ware, made in Contra Costa County. There were 4 idle works, and 1 new plant that had not begun operations at the close of the year.

Colorado.—Colorado's pottery production for 1913 was reported by 5 operators, the same number as in 1912, and was valued at $46,501, an increase of $5,254. Colorado's leading pottery product is stoneware made in Denver County. Red earthenware, art pottery, and "fireproof china" cooking utensils are also reported from this State. All of Colorado's potteries were active in 1913.

Connecticut.—The principal pottery product of Connecticut is porcelain electrical supplies made at Hartford. Red earthenware and stoneware are also made in Connecticut in small quantities.

District of Columbia.—There were 3 operators in the District of Columbia in 1913, all of whom reported red earthenware only.

Georgia.—Georgia's pottery products in 1913 were valued at $28,528, an increase of $9,471 over 1912. These consist entirely of red earthenware and stoneware. There were 6 idle works in the State in 1913.

Illinois.—Twenty-three operators reported production in Illinois for 1913, a decrease of 1, with products valued at $915,263, a decrease of $16,688. This loss was principally in stoneware, which decreased $51,050, or 7.56 per cent, every other variety of pottery showing an increase. The miscellaneous items showed a decrease also. Stoneware is the pottery product of chief value in Illinois, comprising 68.2 per cent of the total output, and is made in Brown, Green, La Salle, McDonough, Tazewell, and Warren counties. White ware in small, though increasing quantities, is also made in this State, as are filter stones, clay pipes, and art pottery. One new plant started operations in Illinois in 1913, and 2 were idle.

Indiana.—Indiana is the sixth State in rank in value of pottery products, reporting wares for 1913 valued at $1,186,706, an increase of $109,604, or 10.18 per cent. Indiana's principal pottery product is sanitary ware, which increased in value $85,525, or 13.5 per cent over 1912. This ware (60.6 per cent of the total value for the State in 1913) was reported from Howard and Vanderberg counties. There were 11 active operators in the State in 1913, an increase of 1, and 3 were idle.

Iowa.—The pottery industry of Iowa is of comparatively little importance. The total value of pottery in 1913 was $20,698, a decrease of $9,443. The principal pottery product was stoneware. There were 4 active firms reporting and 1 idle works in 1913 in Iowa.

Kansas.—There were 2 pottery works in Kansas in 1913, 1 of which was idle. The only pottery product reported from Kansas in 1913 was stoneware. Business was reported poorer in 1913 than in 1912.

Kentucky.—Seven operators reported pottery products from Kentucky for 1913. The output was valued at $102,118, a decrease of $12,086. A new company at Dayton began the production of semi-porcelain ware in 1913. The other pottery products reported from Kentucky were red earthenware and stoneware.

Louisiana.—Louisiana is the home of the Newcomb pottery, located at New Orleans, where the famous Newcomb art ware is made. Owing to the fact that there were less than 3 operators in Louisiana reporting pottery products for 1913, separate figures of production can not be published.

Maine.—Stoneware is the only pottery product of Maine. There being only 1 producer, separate figures can not be published.

Maryland.—The value of Maryland's pottery products in 1913 was $155,034, a decrease of $29,677. The principal pottery product of Maryland is white ware. Red earthenware, stoneware, and clay smoking pipes were also made in the State in 1913. Six operators were active and 1 plant was idle in 1913.

Massachusetts.—The principal pottery product of Massachusetts is red earthenware, of which it was the third largest producer in 1913. Stoneware, white ware, porcelain electrical supplies, art pottery, porcelain shuttle eyes and thread guides are also made there. The value of the pottery products in Massachusetts in 1913 was $231,345, a decrease of $20,754 from 1912. There were 11 active operators in 1913, a decrease of 1, and 1 plant was idle.

Michigan.—Michigan's pottery products in 1913 were valued at $222,883, an increase of $27,991. The principal pottery product of the State is porcelain electrical supplies, with red earthenware second. Art pottery is also produced. There were 6 active operators in the State in 1913, the same number as in 1912, and no idle plants.

Minnesota.—The only pottery product of Minnesota is stoneware, made at Red Wing, Goodhue County. There being but one operator reporting for 1913 separate figures of production are not published. There are two other plants in the State, both of which were idle.

Mississippi.—Mississippi's pottery products, red earthenware and stoneware, were valued at $17,451 in 1913, an increase of $4,745 over 1912. There were 8 operators in 1913, an increase of 2, and 1 idle plant.

Missouri.—Missouri is the leading Southern State in the production of clay wares, but its pottery industry is of minor importance. The value of the pottery output in 1913 was only $3,412, a decrease of $103 from 1912. Five operators reported for 1913, an increase of 1, and 4 plants were idle.

Montana, Nebraska, and New Hampshire.—There was only 1 pottery plant in each of these States in 1913, so that statistics of production are not published separately.

New Jersey.—New Jersey is the second largest pottery-producing State, reporting wares valued at $8,838,545 for 1913, or 23.26 per cent of the total for the United States, a decrease of $97,375, or 1.09 per cent, from 1912. New Jersey's leading product is sanitary ware, valued at $5,238,013, or 59.26 per cent of the State total in 1913, though every variety of pottery, as classified by the Survey, and in addition, chemical ware, smoking pipes, door knobs, hardware trimmings, souvenirs, and art pottery were reported from this State for 1913. Mercer County, in which Trenton is located, reported 89.36 per cent of the value of the pottery of the entire State—$7,898,474, a decrease in this county from 1912 of $171,220, or 2.12 per cent. No red earthenware or stoneware was made in 1913 in Mercer County. Middlesex County was the second largest pottery-producing county in the State, reporting wares (principally sanitary ware) valued at $370,026, an increase of $16,741 over 1912. There were 51 active potters in New Jersey in 1913, a decrease of 1; 6 were idle.

New York.—New York was the fourth State in 1913 in value of pottery produced, 23 operators reporting wares valued at $2,841,658, or 7.48 per cent of the total. This was an increase of $436,126, or 18.13 per cent over 1912. New York's principal pottery product in 1913 was porcelain electrical supplies manufactured chiefly in Schenectady and Ontario counties, and also in Kings, Livingston, and Onondaga counties. These were valued at $1,560,870, or 54.93 per cent of the total value of pottery for the State. China production was second in importance, being valued at $763,322 and constituting 26.86 per cent of the total. The principal china-making center is in Onondaga County. In addition to these wares, the manufacture of every other variety of pottery as classified in this report, and of art pottery, smoking pipes, chemical stoneware, and hardware trimmings was reported for 1913. Three pottery plants were idle in 1913.

North Carolina.—North Carolina had a comparatively large number (23) of active operators reporting for 1913, but the industry is of little importance, though the value of the product is increasing. The value of the pottery products of the State in 1913 was $13,683, an increase of $4,733. Red earthenware and stoneware and art pottery were the only wares made in the State. There were three idle pottery plants in North Carolina in 1913.

Ohio.—Ohio is the leading State in the production of pottery. The value of the output in 1913 was $16,519,889, or 43.48 per cent of the value for the entire country. This was an increase of $1,011,154, or 6.52 per cent, over 1912. Every variety of pottery as classified in this report, except china, was reported for 1913, and in addition, pins, stilts and spurs, saggers, porcelain filter tubes, art pottery, gas-mantle supplies, gas burners, toy marbles, umbrella stands, and chemical stoneware. White ware was the variety of chief value ($10,548,628 in 1913), constituting 63.85 per cent of the total for the State. This was an increase of $579,137, or 5.81 per cent, over 1912. Columbiana is the leading county (reporting a value of $6,664,682, or 63.18 per cent of the State total for this variety). Mahoning County was second, reporting white ware valued at $2,126,857, or 20.16 per cent of the State total. Porcelain electrical supplies was the variety of second importance in 1913—being valued at $2,184,201, or 13.22 per cent of the total value of pottery for the State. Stoneware and yellow and Rockingham ware (taken together) were third in importance in 1913, being reported to the value of $1,649,186, or 9.98 per cent of the State total.

Columbiana is the leading pottery-producing county of the State, reporting wares valued at $8,248,654, or 49.93 per cent of the total for the State. Mahoning County is second in importance, reporting wares for 1913 valued at $2,243,487, or 13.58 per cent of the State total. Mahoning's principal pottery product is white ware. Muskingum was the third county in importance, reporting for 1913 wares valued at $1,365,432, or 8.27 per cent of the State total. East Liverpool, Columbiana County, is the principal pottery center of the State, its wares being valued in 1913 at $6,683,007. There were 105 active and 8 idle operators in Ohio in 1913.

Oklahoma.—No production of pottery from Oklahoma was reported for 1913. Plans to erect a stoneware pottery in Oklahoma in 1914 were under consideration.

Oregon.—In Oregon only 2 potters reported production in 1913, so that the figures can not be published separately without disclosing individual operations. Red earthenware and stoneware are the only pottery products made in this State.

Pennsylvania.—Pennsylvania was the fifth State in value of pottery products in 1913, its output being valued at $2,046,099, a decrease of $82,441, or 3.87 per cent. This decrease was chiefly in white ware, which declined $62,747, though stoneware, sanitary ware, and porcelain electrical supplies also showed decrease. Only 2 varieties, red earthenware and china, showed increase. White ware, valued at $839,838, was Pennsylvania's leading pottery product in 1913, this variety constituting 41.05 per cent of the total value of pottery for the State. Twenty-seven active operators reported for 1913, a decrease of 2 from 1912. Three plants were idle in Pennsylvania in 1913, and 1 only operated in an experimental way.

Porto Rico.—Two potters located in Ponce district reported from Porto Rico in 1913.

South Carolina.—The pottery industry of South Carolina is of minor importance. There were 5 operators reporting wares valued at $9,782, an increase of $3,021 over 1912. Red earthenware and stoneware are the only products made.

Tennessee.—Eight firms reported pottery production in Tennessee in 1913. The principal product is turpentine cups, made in Hamilton County. The output of Tennessee pottery was valued at $145,100 in 1913, a decrease of $28,066.

Texas.—Though the kaolin beds of Texas are conceded to be equal if not superior to any others in the country, its pottery products are confined to the lowest grades of ware—red earthenware and stoneware. The total value of Texas pottery in 1913 was $80,374, a decrease of $66,230. This decrease may be more apparent than real, as it seems probable from reports received for 1913 that for 1912 some of the operators unintentionally duplicated figures. The Survey at this date, however, is unable to determine the extent of duplication, if there were any. Fourteen active operators reported for 1913, an increase of 2 over 1912, and 4 plants were idle in 1913.

Utah.—There were only 2 potters in Utah who reported production for 1913, so that no figures can be published. Red earthenware is the only pottery ware made in the State.

Virginia.—In Virginia only 2 potters reported production for 1913. Tobacco pipes was the only product reported.

Washington.—Washington pottery products are confined to red earthenware and stoneware and are comparatively unimportant.

West Virginia.—West Virginia was third in the value of pottery produced in 1913. This State is rapidly increasing in importance as a pottery-producing State, notwithstanding the small increase in value of pottery products in 1913 over 1912—$59,721, or 1.77 per cent. The new works mentioned as in contemplation in the last report were erected in 1913, but were not put in operation in time to affect the production for that year. West Virginia's pottery product of chief value is white ware, of which it was the second largest producer in the country. The value of the white ware made in 1913 in West Virginia was $2,024,104, or 59.1 per cent of the value of the pottery output of the State, a decrease of $27,883, or 1.36 per cent. This product is made principally in Hancock County, opposite East Liverpool, Ohio. The pottery products of this county in 1913 were valued at $1,894,682, or 55.32 per cent of the total for the State. Sanitary ware was second in value in this State in 1913, being valued at $1,146,205, a decrease of $10,273, or 0.89 per cent. Fourteen operators reported production from this State, the same number as in 1912.

Wisconsin.—Wisconsin's pottery production in 1913—red earthenware only—was valued at $7,700, a decrease of $200 from 1912. Three potters reported for 1913, the same number as for 1912.

IMPORTS AND EXPORTS.

The following tables show the imports and exports of clay products from 1901 to 1913:

Value of earthenware, china, brick, and tile imported and entered for consumption in the United States, 1901–1913.

Year.	Pottery.						Brick, fire brick, tile, etc.	Grand total.
	Brown earthen and common stone ware.[a]	Earthenware and crockery composed of a nonvitrified absorbent body.		China and porcelain.		Total.		
		Not decorated.	Decorated.	Not decorated.	Decorated.			
1901....	$51,551	....	....	$1,094,078	$8,385,514	$9,531,143	$150,268	$9,681,411
1902....	58,926	....	....	1,016,010	8,495,598	9,570,534	235,737	9,806,271
1903....	95,890	....	....	1,234,223	9,897,588	11,227,701	228,589	11,456,290
1904....	81,951	....	....	1,329,146	9,859,144	11,270,241	218,170	11,488,411

[a] Including Rockingham ware.
[b] Figures cover period from Oct. 4 to Dec. 31.
[c] Including wares classified under the act of 1913 as china and porcelain wares composed of a vitrified nonabsorbent body: Not decorated, $244,933; decorated, $2,204,851.

The value of imports of all clay products in 1913 increased $683,219, or 6.99 per cent; in 1912 there was a decrease from 1911 of $1,076,673, or 9.93 per cent. The total value for 1913 was, however, $393,454, or 3.63 per cent, less than that for 1911 and $3,356,804, or 24.31 per cent, less than that of 1907, the year of maximum value. Of the imports for 1913, 97.35 per cent was pottery and 2.65 per cent brick and tile. The pottery imports in 1913 increased in value $621,921, or 6.51 per cent, over 1912, but were $3,408,161, or 25.09 per cent, less than in 1907 and $461,165, or 4.33 per cent, less than in 1911. The brick and tile imports in 1913 increased in value $61,298, or 28.46 per cent, over 1912. The imports of brick and tile are, however, of relatively little importance. Of the pottery imports, 97.73 per cent was of the high-grade wares and 2.27 per cent of the low-grade wares.

Value of exports of clay wares of domestic manufacture from the United States, 1905–1913.

[a] Building brick only.
[b] Includes all brick, other than building brick.
[c] Figures cover period from July 1 to Dec. 31.

The exports of domestic clay products in 1913 decreased in value $212,656, or 4.25 per cent, from 1912. In 1912 there was an increase of $1,335,175, or 36.42 per cent, over 1911. Of these exports in 1913, 11.68 per cent was pottery and 88.32 per cent was brick and tile. In 1912, 23.55 per cent was pottery and 76.45 per cent was brick and tile. Brick and tile exports increased in 1913 over 1912, $405,965, or 10.61 per cent, and pottery exports decreased $618,621, or 52.52 per cent. The increase in the exports of brick and tile was general, every item, except the one covering miscellaneous products, showing increase. The decrease in the pottery exports was entirely in earthen and stone ware, these wares decreasing in value $627,755. China exports are small, but have shown a steady growth since 1908, increasing in 1913, $9,134. Of the pottery exports 73.3 per cent was earthen and stone ware and 26.7 per cent was china.

CLAY PRODUCTS BY STATES.

In the following pages the statistics of the clay-working industry from 1909 to 1913, inclusive, are given for some of the more important States. Owing to the changes in the classification of the products in some of the minor items, the figures do not always represent solely the value of the products named, though the classification as given in the tables is sufficiently correct for comparative analysis. The item "Miscellaneous" under each State includes all products not otherwise classified and those that could not be published separately without disclosing individual returns. For details concerning the production of pottery in the several States, the reader is referred to the section of this report on pottery.

ALABAMA.

Alabama is rich in clays, but its rank as a clay-working State is not high. In 1913 it was sixteenth among the States, with products valued at $2,091,581, or 1.15 per cent of the total for the country. This was an increase over 1912 of $156,402, or 8.08 per cent. In 1913 Alabama was ninth in the production and value of vitrified brick, and ninth in production and eleventh in value of fire brick. The principal product is common brick, valued in 1913 at $730,148, and representing 34.91 per cent of the value of all of Alabama's clay products in that year. Front brick, fireproofing, and tile, not drain, were reported to the value of $258,130, so that the structural materials represent nearly one-half of Alabama's clay products in 1913. The engineering products, vitrified paving brick, draintile, sewer pipe, and fire brick were reported to the value of $1,057,059, or more than 50 per cent of the total. Pottery clays are abundant in the State, but this branch of the industry has not been developed extensively, the value of pottery production in 1913 being only $20,158.

Jefferson County is the principal clay-working county, reporting a production valued at $1,313,432, or 62.8 per cent of the total value for 1913, an increase of $178,093 over 1912. No pottery was reported from this county. All of the fire brick produced in the State comes from Jefferson County, and fire brick is its principal product. Vitrified brick was reported only from Jefferson and St. Clair counties, the former being the leading county with 22,710,000 brick, valued at $339,615. The leading counties in the value of common brick in 1913 were, in the order of their importance, Montgomery, Talladega, and Jefferson.

CALIFORNIA.

California is an important clay-working State, being ninth in value of production in 1913. It was fourth in the value of fancy and enameled brick, sewer pipe, and architectural terra cotta; sixth in the value of front brick and fire brick; and seventh in the value of common brick, fireproofing, and tile, not drain. There were 91 active operators reporting for 1913, the same number as for 1912.

The total value of all of California's clay products in 1913 was $5,344,958, a decrease of $567,492, or 9.6 per cent, from 1912. California's principal clay product—common brick, made chiefly in Los Angeles and Contra Costa counties—was valued in 1913 at $1,699,426, or 31.79 per cent of all clay products in the State, but a decrease of $498,877 from 1912. The average price per 1,000 in 1913 was $5.75, a decline of 53 cents from 1912. Sewer pipe, made principally in Los Angeles and Alameda counties, is second in importance among the clay products of California, being reported at $1,032,094 for 1913, a decrease of $104,335 from 1912. Architectural terra cotta, made principally in Placer County, was the product of third importance; this also decreased in 1913—$21,534. The only products to show increases in 1913 were enameled brick, fire brick, fireproofing, tile, not drain, stove lining, and pottery. Pottery production was valued at $290,255, an increase over 1912 of $70,602.

Los Angeles, the principal common brick producing county, reported 161,398,000 brick, valued at $836,372, or 54.58 per cent of the total quantity and 49.21 per cent of value for the State in 1913.

The principal product of Los Angeles County was common brick, with sewer pipe second, these two constituting more than half the value of the county's clay products in 1913. Fire brick, fireproofing, and front brick are also produced in this county in considerable quantities. Los Angeles was also the leading clay-working county, reporting wares valued at $2,387,658, or 44.67 per cent of the State's total. This was an increase over 1912 of $109,273.

COLORADO.

The total value of Colorado's clay products in 1913 was $1,293,511, a decrease of $143,883, or 10.01 per cent, from 1912. In 1913 Colorado's clay product of chief value was fire brick, displacing common brick, which was second. Fire brick was reported to the value of $306,843 in 1913, an increase of $5,163; common brick decreased 21,423,000 brick in quantity and $116,315 in value.

Denver County is the chief producer of common brick, reporting 18,162,000 brick, valued at $106,862. This was a decrease of 18,887,000 brick in quantity and of $101,324 in value from 1912. Denver County is the principal clay-working county, reporting wares valued at $654,612, or more than half the State's product. It is the leading county in the production of all clay products except enameled brick, tile, not drain, and refractory wares. Pueblo County is the principal producer of refractory wares. The pottery production of the State was valued at $46,501 in 1913.

CONNECTICUT AND RHODE ISLAND.

There being but two producers in Rhode Island it is impossible to publish figures for the State, and they are combined with those of Connecticut. The value of the clay products of these States in 1913 was $1,372,234, a decrease of $92,766, or 6.33 per cent, from 1912. Connecticut's products are common brick, stove lining, fire brick, and tile, not drain. Rhode Island makes common, vitrified, front, and fancy brick and tile, not drain. Common brick composed 91.25 per cent of the total value of the clay products of these two States in 1913, but decreased in value $125,330. Hartford is the leading county in Connecticut, reporting wares valued at $784,146, or more than half the value of the entire State. It reported more than one-half of the value of the common brick in 1913. New Haven and Middlesex counties are also large producers of common brick. Fire brick is made only in New Haven County.

GEORGIA.

The total value of all clay products in Georgia in 1913 was $2,692,619, a decrease of $113,922, or 4.06 per cent, from 1912. In 1913 Georgia was seventh in the production and ninth in the value of common brick, and seventh in the value of sewer pipe. The principal product is common brick, which was valued at $1,464,322, a decrease of $170,348 from 1912; the quantity decreased 36,972,000 brick. The value of common brick was 54.38 per cent of the value of all clay products. Sewer pipe is second in importance, its production being valued at $634,478, an increase of $11,851 over 1912. Bibb County is the leading producer of common brick and of sewer pipe, and reported 90,481,000 brick, valued at $453,513, or nearly a third of the output and value of the State. Richmond and Fulton counties are also large producers of common brick. Architectural terra cotta was reported only from Fulton County, and tile, not drain, from Liberty County. Pottery production was valued at $28,528. Bibb County was the leading clay-working county of the State, reporting wares for 1913 valued at $776,076, an increase of $71,659 over 1912.

ILLINOIS.

Illinois, which makes every variety of clay product as classified in this report except china and stove lining, was the leading State in 1913 in the production and value of common brick, third in the production and second in the value of vitrified paving brick, third in the value of enameled brick, sixth in the production and seventh in the value of front brick and fire brick, fourth in the value of draintile, fifth in the value of sewer pipe and fireproofing, and second in the value of architectural terra cotta.

The total value of the clay products of Illinois in 1913 was $15,195,874, a decrease from 1912 of $15,116, or 0.1 per cent. The principal product of the State is common brick, the production of which was 1,155,480,000 brick, valued at $6,445,821, compared with 1,210,499,000 brick, valued at $6,437,331, in 1912, a decrease of 55,019,000 brick in quantity, but an increase of $8,490 in value. Common brick constituted 42.42 per cent of the value of all clay products of the State in 1913. Of the common-brick production, Cook County reported 717,682,000 brick, valued at $3,569,134, which was 62.11 per cent of the quantity and 55.37 per cent of the value of common brick for the State, and a decrease from 1912 of 48,163,000 brick in quantity and of $122,985 in value. This is the largest brick-making county in the country, and is the second largest common-brick making region of the United States, being surpassed only by the Hudson River region of New York, which embraces nine counties. The average price per 1,000 for common brick in 1913 in Illinois was $5.58, or 26 cents higher than that of 1912. The average price in Cook County was $4.97, or 15 cents higher than in 1912. Second in importance is architectural terra cotta, which was valued in 1913 at $1,908,399, or 12.56 per cent of the total value. This was a decrease of $576,613, or 23.2 per cent. The third product in point of value was vitrified brick, of which 133,938,000 were reported for 1913, valued at $1,883,199. Knox was the leading county in the production of vitrified brick, with Livingston County second. Madison County led in the value of front brick. Enameled brick was reported only from Kankakee County. La Salle led in the production of draintile, fireproofing, and fire brick, and sewer pipe was produced chiefly in McDonough County. Cook County was the largest producer of architectural terra cotta as well as of common brick. Pottery to the value of $915,263, principally stoneware, was reported for 1913.

Cook County, owing to the large local market, was the leading clay-working county in 1913, reporting products valued at $5,529,785, or 36.39 per cent of the total for the State in 1913, a decrease of $651,866 from 1912. Knox County was second, with a production valued at $1,094,564, or 7.2 per cent of the State's total. The principal clay products of this county are vitrified paving brick and sanitary ware.

Illinois has been fourth among the States in the value of clay products for a number of years, and reported 8.38 per cent of the total value of the whole country for 1913.

There were 281 active operators reporting for 1913, and 301 for 1912. Compared with 1909 there were 98 less active operators in 1913, but the value of production was nearly $1,000,000 greater, and the average output per active operator increased from $37,848 in 1909 to $54,078 in 1913.

INDIANA.

Indiana is one of the most important clay-working States, ranking sixth in value and reporting 4.69 per cent of the total. It reported for 1913 every variety of clay wares as classified in this report except fancy brick, enameled brick, and china. It was second in 1913 in the production of draintile, third in the production and value of front brick and in the production of tile, not drain, fourth in the production of fireproofing, and sixth in the production of sewer pipe and in the value of vitrified brick.

a Included in "Miscellaneous."

The total value of Indiana's clay products in 1913 was $8,498,646, an increase of $563,395, or 7.1 per cent, over 1912. Draintile is Indiana's principal clay product, which was reported to the value of $1,595,290 in 1913, and constituted 18.77 per cent of the total for the State. Madison was the principal draintile producing county in 1913 with a value of $186,105, an increase of $12,360, over 1912.

Common brick is the clay product of second importance, 208,500,000 brick, valued at $1,268,710, being reported for 1913, or 14.93 per cent of the value of the State's clay products. This was an increase of 6,444,000 brick in quantity, and of $64,216 in value over 1912. Lake County is the principal one in the production of common brick and is the second county in the value of all clay products. Clay is the principal clay-working county, reporting for 1913 wares valued at $1,329,075, or 15.64 per cent of the State's total. The value of the pottery production of the State in 1913 was $1,186,706. Sanitary ware is the principal pottery product of Indiana, and was valued at $719,103 in 1913.

There were 257 active operators reporting for 1913, compared with 278 in 1912 and with 348 in 1909. The average value of production per operator reporting was $33,069 in 1913, compared with $28,544 in 1912 and with $21,969 in 1909.

IOWA.

Iowa ranked eighth in the value of clay products in 1913 and tenth in 1912. The total value of Iowa's clay products in 1913 was $5,573,681, an increase of $1,051,355, or 23.25 per cent, over 1912. Iowa is the leading State in the production of draintile, the principal clay product of the State. In 1913 Iowa was the third State in the production of fireproofing and ninth in the production of sewer pipe. Draintile was valued at $2,798,816 and constituted 50.21 per cent of the value of Iowa's clay products, an increase of $505,732 over 1912. Common brick is the clay product of second importance in Iowa, and was valued at $1,052,036 in 1913, or 18.88 per cent of the total, an increase of $34,909 over 1912. The quantity of common brick decreased 5,209,000 brick. Fireproofing is third in point of value among Iowa's clay products, being valued at $762,563, an increase of $227,309 over 1912.

Cerro Gordo County is the leading producer of draintile, reporting a value of $1,043,440, or more than one-third the production of the entire State, an increase of $422,216 over 1912. Webster County, the second county, reported draintile to the value of $631,726. Woodbury County is the leading producer of common brick.

Cerro Gordo, owing to its large production of draintile in 1913, was the leading county in the State in value of all clay products (displacing Webster County, which was second), and reported wares valued at $1,401,015, or 25.14 per cent of the State's total, an increase of $516,678 over 1912. Webster County, whose principal product also is draintile, was second, reporting wares valued at $1,077,059, or 19.32 per cent of the total value. The pottery production of Iowa in 1913 was valued at $20,698.

There were 186 active operators reporting for 1913, compared with 200 in 1912 and with 247 in 1909. The average value of production per active operator reporting was $29,966 in 1913 and $19,833 in 1909.

KANSAS.

The total value of clay products in Kansas in 1913 was $1,919,910, a decrease of $116,590, or 5.73 per cent, from 1912. The low prices of brick in this State mentioned in the last report as the principal feature of the clay-working industry in the State, prevailed also in 1913, though there was an advance in the average price of each variety. Vitrified brick is the leading clay product of Kansas, closely followed by common brick, the difference between the value of these products in 1913 being only $2,188—$543,929 for vitrified brick, against $541,741 for common brick. Vitrified brick showed the large decrease of $262,498 in value in 1913, and common brick showed a decrease of $42,532. On the other hand, front brick, sewer pipe, fireproofing, and tile, not drain, increased in value. Vitrified brick constituted 28.33 per cent of the value of Kansas clay products in 1913 and common brick 28.22 per cent of its value.

The principal vitrified brick-producing counties in Kansas in 1913, given in the order of the value of production, were Montgomery, Wilson, and Crawford. These three counties reported vitrified brick valued at $484,166, or 89.01 per cent of the State's total. Wilson County was the largest producer of common brick in 1913, reporting 49,378,000 brick, valued at $179,068, with Allen County second, and Montgomery County third.

Montgomery County was the leading clay-working county in 1913, its products being valued at $564,413, or more than one-fourth of the State's total, but a decrease of $114,078 from 1912. Vitrified brick is the principal clay product of the county, though front brick, and tile, not drain, are also important products. Wilson County is second in importance, the principal products of this county in 1913 being front brick and common brick.

KENTUCKY.

The value of Kentucky's clay products in 1913 was $2,914,276, an increase of $470,536, or 19.25 per cent, over 1912. Kentucky was fourth in the production and value of fire brick in 1913 and fifth in the production of tile, not drain. Kentucky's leading clay product is fire brick, which was valued at $1,428,938 in 1913, an increase of $428,882. The quantity of 9-inch equivalent fire brick marketed in Kentucky in 1913 was 79,342,000, an increase of 26,180,000 brick over 1912. The value of fire brick constituted 49.03 per cent of the value of Kentucky's clay products in 1913. Common brick was second in importance, being valued at $681,727. The clay product of third importance in the State was tile, not drain, valued at $301,094. Kentucky's pottery production in 1913 was valued at $102,118.

Carter County is the chief producer of fire brick, reporting 41,802,000 nine-inch equivalent fire brick, valued at $818,378, or over half the output and value of the State. This was an increase of 13,893,000 brick in quantity and of $267,806 in value over 1912. Fire brick was the only clay product made in Carter County in 1913. Jefferson County is second in the manufacture of fire brick and the leading county in the production of common brick, reporting 21,173,000 common brick, valued at $152,598, for 1913.

Carter County was the leading county in the value of clay products in 1913, Jefferson County being second with wares valued at $694,042. These two counties reported more than one-half of the value of the clay products of the State for 1913. Kenton County was third with products valued at $268,816, principally tile, not drain.

MARYLAND.

Maryland's clay products were valued at $1,917,500 in 1913, an increase of $51,747, or 2.77 per cent over 1912. In 1913 Maryland was the tenth State in the production and value of fire brick, though its principal clay product is common brick, 153,053,000 of the latter valued at $1,004,146, being reported for 1913, a decrease in quantity of 1,507,000 common brick and in value of $49,189. The average value per 1,000 for common brick declined 26 cents in 1913. Common brick constituted 52.37 per cent of the value of Maryland's clay products in 1913. Fire brick is Maryland's second clay product in point of value, 14,444,000 9-inch equivalent brick being reported for 1913, valued at $295,707. This was an increase in quantity of 458,000 brick and in value of $32,890 over 1912. Maryland's pottery production, mostly of the higher-grade wares, was valued at $155,034 in 1913.

The chief center of production of common brick was in the city of Baltimore and in Baltimore County. These two localities reported 111,894,000 common brick, valued at $725,435, or 73.11 per cent of the quantity and 72.24 per cent of the value of the State, respectively. This was a decrease of 7,231,000 brick in quantity and of $21,402 in value from 1912. Frederick County was also a large producer of common brick, reporting 11,366,000 brick in 1913, valued at $77,133. Allegany County was the leading fire brick-producing county, reporting 13,059,000 9-inch equivalent brick, valued at $248,795, which was

90.41 per cent of the production and 84.14 per cent of the value of fire brick for the State, and an increase of 302,000 brick in quantity and $17,525 in value over 1912.

Baltimore City and Baltimore County, whose chief product is common brick, but which also report high-grade pottery, constituted the principal clay-working center of the State, reporting production valued at $1,207,574, or 62.98 per cent of the total for 1913, an increase of only $7,437 over 1912. Baltimore County was the leading county in 1913, reporting wares valued at $717,819, and Baltimore City was second, with wares valued at $489,755.

MASSACHUSETTS.

The value of clay products in Massachusetts in 1913 was $1,814,875, an increase of $47,709, or 2.7 per cent over 1912. The chief clay product of Massachusetts is common brick. There were 153,818,000 brick reported for 1913, valued at $1,106,437, a decrease in quantity of 3,709,000 brick but an increase in value of $10,853, compared with 1912. The average price per 1,000 increased 24 cents to $7.19. The value of common brick constituted 60.96 per cent of the value of all clay products in Massachusetts in 1913. Stove lining was second in value, being reported at $179,980 in 1913, an increase of $6,724 over 1912. Massachusetts is the leading State in this variety of clay product, reporting 33.6 per cent of the total for the country. Pottery production to the value of $231,345 was reported for 1913.

Middlesex County was the leading county in the value of common brick in the State in 1913, with Hampden second and Plymouth third. These 3 counties reported more than half the production and value of common brick in the State. Bristol County reported practically all of the stove lining of the State. This county was also the leading fire-brick producing county.

Middlesex County is the leading clay-working county reporting a production valued at $439,356, or nearly one-fourth of the production for the State and an increase of $16,894 over 1912. Bristol County was second and Hampden third.

MICHIGAN.

The value of Michigan's clay products in 1913 was $2,674,125, an increase of $128,627, or 5.05 per cent over 1912. In 1913 Michigan ranked fifth among the States in the value of drain tile and eighth in the production and value of common brick. Michigan's leading clay product is common brick, 273,571,000 brick valued at $1,626,287 being reported for 1913, an increase in quantity of 2,382,000 brick and in value of $34,004 over 1912. The value of common brick constituted 60.82 per cent of the value of all clay products in Michigan in 1913. Draintile is second in importance in Michigan, and was reported to the value of $415,543 for 1913, an increase of $27,598 over 1912. Michigan's pottery production in 1913 was valued at $222,883.

Wayne County, in which Detroit is located, was the leading common brick producing county, reporting 215,534,000 brick valued at $1,270,639, or 78.79 per cent of the quantity and 78.13 per cent of the value of common brick for the entire State in 1913. This was an increase of 9,748,000 brick in quantity and of $77,041 in value over 1912. This county was also the leading clay-working county, reporting for 1913 a total value of $1,553,119, or 58.08 per cent of the total value for the State and an increase of $114,329 over 1912. Eaton County, the second in value of all clay products, is the principal draintile producing county, and draintile is its chief product.

MINNESOTA.

The value of clay products in Minnesota in 1913, exclusive of pottery, was $1,781,017, an increase of $169,977, or 10.55 per cent, over 1912. Minnesota was eighth among the States in the production of sewer pipe in 1913. The principal clay product is common brick, of which 129,261,000 brick, valued at $800,441, were reported, a decrease of 343,000 brick in quantity and an increase of $39,458 in value, compared with 1912. The average price per 1,000 increased 32 cents to $6.19 in 1913. The value of the common brick constituted 44.94 per cent of all of Minnesota's brick and tile products in 1913. Sewer pipe is second among Minnesota's clay products, but as it was made by less than three producers, figures of production are not published. Fireproofing is third, this product being valued at $170,214 in 1913, an increase of $9,410 over 1912.

Carver County was the largest producer of common brick in 1913, and reported 38,965,000 brick, valued at $239,500, or 30.14 per cent of the production and 29.92 per cent of the value of common brick in the State. This was a decrease of 2,035,000 brick in quantity, but an increase of $12,000 in value, compared with 1912.

Goodhue County was the leading clay-working county in the State; Hennepin was second, and Carver third.

b The value of pottery products for Minnesota could not be included in the State totals without disclosing the operations of individual establishments.

MISSOURI.

Missouri is one of the most important clay-working States of the country and is the leading Southern State. It reported for 1913 every variety of brick and tile products as classified in this report and was the seventh State in the value of clay products. In 1913 it was the second State in the value of enameled brick and of fire brick, third in the output of fire brick, third in the value of fancy brick and of sewer pipe, fifth in the value and seventh in quantity of front brick, sixth in the value of architectural terra cotta, and tenth in the production and value of vitrified paving brick.

The total value of the clay products of Missouri in 1913 was $6,602, 076, an increase of $189,215, or 2.95 per cent, over 1912. Fire brick was the product of chief value. There were 104,728,000 9-inch equivalent clay fire brick reported from Missouri for 1913, valued at $2,138,368, or $20.42 per 1,000, an increase of 6,977,000 brick in quantity and of $197,021 in value The value of fire brick constituted 32.39 per cent of the value of clay products of the State in 1913. Common brick was second in value, closely followed by sewer pipe. There were 185,872,000 common brick, valued at $1,270,581, reported for 1913, a decrease of 2,624,000 brick but an increase of $27,511 in value. The average price per 1,000 increased 25 cents to $6.84 in 1913.

Sewer pipe was third in the value of products, $1,213,889 being reported as its value for 1913, an increase of $35,407 over 1912. Architectural terra cotta was fourth, the output for 1913 being valued at $480,372, a decrease of $173,791. Pottery production to the value of only $3,412 was reported for 1913.

The leading producer of fire brick in 1913 was St. Louis City, which reported 39,979,000 9-inch equivalent fire brick, valued at $967,676, an increase of 6,986,000 brick in quantity and of $167,534 in value over 1912. St. Louis County was second, with 37,185,000 9-inch equivalent brick, valued at $685,438, a decrease of 1,800,000 brick in quantity and of $45,847 in value compared with 1912. These two localities reported 73.68 per cent of the quantity and 77.31 per cent of the value of the fire brick for the State. They are also the leading localities in the production of common brick. St. Louis City reported 81,379,000 common brick, valued at $571,822, a decrease of 4,123,000 brick in quantity but an increase of $32,353 in value compared with 1912, the average price per 1,000 increasing 71 cents in 1913. St. Louis County reported 37,664,000 common brick, valued at $246,764, a decrease of 5,770,000 brick in quantity and of $52,350 in value from 1912. These two localities reported 64.05 per cent of the total quantity and 64.43 per cent of the total value of the common brick of the State, and constitute the fourth largest common brickmaking center of the country. St. Louis City is also the leading producer of every other variety of brick and tile products and is the only place in the State where fancy or ornamental brick, enameled brick, tile, not drain, and silica brick are made.

a Included in "Miscellaneous."

St. Louis City is the leading clay-working district in the State. It reported for 1913 clay products valued at $3,918,805, or 59.36 per cent of the value for the entire State, an increase of $192,199 over 1912. St. Louis County was next, reporting production valued at $934,739, a decrease of $100,289 from 1912. Jackson County was third, with wares valued at $464,571, Audrain fourth ($312,788), and Henry fifth. St. Louis County and St. Louis City reported together 73.52 per cent of the value of clay products of the State in 1913.

The number of active operators reporting in 1913 was 105, compared with 110 in 1912 and with 156 in 1909. The average output per active operator was $62,877 in 1913 and $47,693 in 1909.

NEW JERSEY.

New Jersey ranks third in the value of clay products. It reported every variety of product as classified in this report for 1913, except vitrified paving brick. It is second in the value of pottery products and fourth in the value of brick and tile products. In 1913 it was first in the value of china and sanitary ware, enameled brick, and architectural terra cotta; second in the value of fireproofing and of tile, not drain; third in the value of porcelain electrical supplies; fourth in the production and value of front brick and in the value of white ware; and fifth in the production and value of common and fire brick.

The value of New Jersey's clay products in 1913 was $19,705,378—brick and tile $10,866,833, and pottery $8,838,545, a decrease of $133,175, or 0.67 per cent, from 1912. This decrease was principally in pottery—$97,375. New Jersey's leading clay product is sanitary ware, which was reported to the value of $5,238,013, an increase of $38,735 over 1912, and which constituted 26.58 per cent of the value of all of New Jersey's clay products in 1913. Common brick was second, closely followed by architectural terra cotta. There were 401,702,000 common brick reported for 1913, valued at $2,391,287, a decrease of 27,607,000 brick in quantity and of $200,804 in value, compared with 1912. The value of common brick was 12.14 per cent of the value of all clay products of New Jersey in 1913. Architectural terra cotta ranks third in value among New Jersey's clay products. It was valued at $2,388,293 (or 12.12 per cent of the State's total) in 1913, an increase of $58,228 over 1912. New Jersey was the only one of the important States to show an increase in value of this product in 1913. Fireproofing was New Jersey's fourth clay product in 1913. It was valued at $2,092,370, which was an increase of $61,020 over 1912. The value of this product was 10.62 per cent of New Jersey's clay products in 1913. Tile, not drain, is also an important product in this State, being reported to the value of $1,308,787, an increase of $53,541 over 1912.

Mercer County, in which Trenton is located, is the most important clay-working county in the State, and its leading product is sanitary ware, of which the value reported was $4,620,330 in 1913, or 88.21 per cent of the State's total for this variety—a decrease of $42,438 from 1912. The value of all of the Mercer County clay products in 1913 was $8,618,496, or 43.74 per cent of the State's total, a decrease of $154,551 from 1912. Middlesex County, second in importance as a clay-working county, its production being valued at $8,451,232, or 42.89 per cent of the State's total in 1913, was the principal producer of common brick, reporting 194,641,000 brick, valued at $1,120,553. This county is the leading producer of every variety of brick and tile product, except fancy or ornamental brick, of which it produced none, and it was the only producer in 1913 of enameled brick, stove lining, and silica brick. Middlesex County reported for 1913 architectural terra cotta valued at $2,084,137, or 87.26 per cent of total value for the State; fireproofing to the value of $1,864,623, and tile, not drain, to the value of $718,210, or 89.12 per cent of the State total of the former and 54.88 per cent of the latter. Its production of clay fire brick was 35,934,000 9-inch equivalent brick, valued at $1,031,159. Bergen County was second in the manufacture of common brick, with 50,844,000 brick, valued at $294,106 in 1913. The principal market for Bergen County common brick (its only clay product) is Greater New York.

In value of brick and tile products Middlesex County was first with products valued at $8,081,206, and Mercer second, with products valued at $720,022. In value of pottery Mercer was first with products valued at $7,898,474, and Middlesex second with $370,026.

There were 149 active operators in New Jersey reporting for 1913 compared with 155 in 1912 and 165 in 1909. The average value of production per operator in 1913 was $132,251 and $104,173 in 1909.

NEW YORK.

New York is the fifth State in the value of clay products and reported for 1913 every variety as classified in this report, except enameled brick and silica brick. It was the fifth State in the value of brick and tile products and fourth in pottery. Its most interesting feature is the remarkable production of common brick along Hudson River, the largest brick-producing region in the country and probably in the world. New York was the second State in 1913 in the production and value of common brick, Illinois being first, by reason of the large decrease in the Hudson River region. It was also second in the value of china and porcelain electrical supplies, third in the value of terra cotta and stove lining, fifth in the value of white ware, and eighth in the production and value of vitrified paving brick.

The value of clay products in New York in 1913 was $11,469,476—$8,627,818 brick and tile and $2,841,658 pottery, a decrease of $589,382, or 4.89 per cent, from 1912. Common brick is New York's principal clay product. For 1913 there were 1,068,516,000 brick reported, valued at $6,029,103, a decrease of 205,125,000 brick, or 16.11 per cent, in quantity, and of $1,282,572, or 17.54 per cent, in value. The decrease in production was principally in the Hudson River region—188,991,000 brick—and the decrease in value was entirely in the Hudson River region, the decrease there being $1,321,455. The average price per 1,000 in 1913 for the whole State was $5.64, a decrease of 10 cents. In the Hudson River region the average price declined 31 cents per 1,000. The value of common brick constituted 52.57 per cent of the value of all of New York's clay products in 1913. Next to common brick in value are porcelain electrical supplies, which were valued in 1913 at $1,560,870, an increase of $291,762 over 1912; third, terra cotta, valued at $1,110,726, a decrease of $28,565; and china fourth with a value of $763,322 in 1913, an increase of $72,257 over 1912.

Ulster County was the leading county in the production of common brick, reporting 194,125,000 brick in 1913, valued at $1,026,870. Rockland County was second with 163,612,000 brick, valued at $890,188. The only clay product made in these counties is common brick.

Onondaga was the leading county in the value of clay products in 1913. It reported wares valued at $1,074,727—pottery $934,575 and brick and tile $140,152. This was an increase over 1912 of $128,206—pottery $114,863 and brick and tile $13,343. For 1912 Onondaga County was third and Ulster first and Rockland second. For 1913 Ulster County was second and Erie County third with a production valued at $1,005,359. Schenectady and Ontario counties are the principal producers of porcelain electrical supplies, reporting together a production valued at $1,025,296, or nearly two-thirds of the State total for this variety, an increase of $166,451 over 1912.

There were 215 active operators reporting for 1913, 219 for 1912, and 243 for 1909. The average value of production per operator in 1913 was $53,346, compared with $50,030 in 1909.

NORTH CAROLINA.

The value of clay products in North Carolina in 1913 was $1,614,406, an increase of $148,753, or 10.15 per cent, over 1912. The clay product of chief value is common brick, of which there were 204,097,000 reported, valued at $1,354,062, an increase of 11,039,000 brick in quantity and of $117,619 in value over 1912. The value of common brick constituted 83.87 per cent of all clay products in North Carolina in 1913. Front brick and draintile were made in small quantities. Sewer pipe was made in considerable quantity by one operator; hence the figures are not published. The production of pottery was valued at $13,683 in 1913.

Wayne County is the principal common-brick producing county, and reported 33,300,000 brick, valued at $230,000 for 1913, an increase of 9,700,000 brick in quantity and of $68,600 in value over 1912. Wake is the second county in quantity of common brick, but was third in value, and Craven County was second in value and third in quantity.

Guilford is the principal clay-working county in the State, reporting for 1913 products valued at $281,542, an increase of $13,080 over 1912. Common brick, draintile, sewer pipe, and fireproofing were reported from this county for 1913. Wayne County was second in the value of all clay products in 1913.

OHIO.

Ohio is the leading State of the Union in the value of clay products. For 1913 it reported every variety of brick and tile products as classified in this report, except terra cotta, and all of the pottery products except china. It was the leading State in 1913 in the production of vitrified paving brick, sewer pipe, fireproofing, tile, not drain, red earthenware, stoneware, white ware, and porcelain electrical supplies. It was second in the production and value of front brick and in the value of fancy brick, and second in the production and third in the value of fire brick and of draintile; fourth in production and value of common brick, and in value of sanitary ware.

The value of its clay products in 1913 was $38,388,296, or 21.18 per cent of the total for the country. This was an increase of $3,576,788, or 10.27 per cent over 1912, and was the largest increase reported by any State for 1913. Ohio's brick and tile production in 1913 was valued at $21,868,407, and its pottery production at $16,519,889. Ohio's principal clay product is white ware, which was reported to the value of $10,548,628 in 1913, an increase of $579,137, or 5.81 per cent, over 1912. The value of white ware constituted 27.48 per cent of the value of all of Ohio's clay products in 1913. Sewer pipe was the second product, being reported to the value of $5,159,548, an increase of $1,137,470 over 1912. Vitrified brick, Ohio's third product, increased 36,120,000 in quantity and $478,666 in value in 1913. The fourth product in value in 1913 was common brick, of which 407,685,000 were reported, valued at $2,523,014, or $6.19 per 1,000. This was an increase of 11,849,000 brick in quantity and of $108,532 in value over 1912. Common brick was closely followed in value by tile, not drain, which was reported to the value of $2,492,380, an increase of $70,597 over 1912.

Columbiana County, the most important clay-working county in Ohio, is the principal producer of white ware. The clay products for the county in 1913 were valued at $8,920,853, or 23.24 per cent of the State's total, an increase of $640,026 over 1912. The value of the white ware produced in this county in 1913 was $6,664,682, or 63.18 per cent of this product for the State, an increase of $219,042 over 1912. Sewer pipe is produced most largely in Summit County, which reported it to the value of $1,707,911 for 1913; Jefferson County was second, reporting sewer pipe to the value of $1,603,802; and these two counties reported 64.19 per cent of the total of this product for the State. The leading county in the value of vitrified paving brick in 1913 was Stark; and Athens County was third in production and second in value and Cuyahoga County second in production, but third in value in 1913. Cuyahoga County was the leading common brick producing county in the State in 1913, reporting 107,796,000 brick, valued at $640,023, or 26.44 per cent of the quantity and 25.37 per cent of the value for the entire State, an increase of 1,650,000 brick in quantity and of $34,271 in value over 1912. The city of Cleveland furnishes the principal market for this output. Lucas County was second, reporting 36,690,000 brick valued at $215,012, a decrease of 10,036,000 brick in quantity and of $65,614 in value from 1912.

Muskingum County, the second county in the State in the value of all clay products, reported wares valued at $3,615,605, or 9.42 per cent of the State's total. This was an increase of $131,443 over 1912 in spite of the loss in business caused by the flood of March, 1913. Of the value of Muskingum's clay products in 1913, $2,250,173 was brick and tile, principally tile, not drain, and $1,365,432 was pottery, principally stoneware. Summit County was third in importance, reporting clay products valued at $3,387,018, an increase of $364,640 over 1912. Of this total, $2,286,926 was brick and tile and $1,100,092 was pottery. Summit county's principal brick and tile product is sewer pipe ($1,707,911 in 1913), and its principal pottery product is porcelain electrical supplies ($549,324 in 1913). Jefferson County, fourth in the value of clay products, reported for 1913 wares valued at $2,930,707, of which $2,523,098 was brick and tile and $407,609 was pottery. Jefferson County's principal brick and tile product is sewer pipe ($1,603,802 in 1913), and its principal pottery product is white ware.

There were 563 active operators reporting for 1913, compared with 596 in 1912 and with 685 in 1909. The average value of production per active operator was $68,185 in 1913, and $44,301 in 1909.

PENNSYLVANIA.

Pennsylvania is the second State in the value of clay products, reporting for 1913 every variety of ware as classified in this report, except enameled brick. In 1913 it was first in the value of brick and tile products and fifth in the value of pottery; it was the leading producer of front, fancy, and fire brick, reporting over one-fourth of the front brick and nearly one-third of the fancy brick, and over two-fifths of the clay fire brick production; second in the production of vitrified paving brick (but third in its value), sewer pipe, stove lining, and red earthenware; third in the production and value of common brick and in the value of white ware and china; fourth in the value of tile, not drain, and porcelain electrical supplies; and fifth in the value of terra cotta.

Pennsylvania's clay products in 1913 were valued at $24,231,482, an increase of $2,694,261, or 12.51 per cent, over 1912. This total was 13.37 per cent of the value of all clay products of the country. Its brick and tile production was valued at $22,185,383 and its pottery production at $2,046,099. Its principal brick and tile product is fire brick, and its chief pottery product is white ware.

Pennsylvania's clay product of greatest value is fire brick. Including silica fire brick, Pennsylvania reported 493,590,000 9-inch equivalent brick for 1913, valued at $9,703,734, or $19.66 per 1,000, an increase of 56,940,000 brick in quantity and of $1,574,156 in value over 1912. Of the clay fire brick, Pennsylvania reported 361,548,000, valued at $7,094,794, or $19.62 per 1,000, an increase of 26,494,000 brick and of $915,924 over 1912. Pennsylvania reported 42.88 per cent of the quantity of clay fire brick of the entire country for 1913, and 42.2 per cent of its value. It reported 132,042,000 9-inch equivalent silica fire brick for 1913, valued at $2,608,940, or $19.76 per 1,000. This was an increase of 30,446,000 brick in quantity and of $658,232 in value over 1912. The value of all fire brick production in Pennsylvania in 1913 composed 40.05 per cent of the State's total for all clay products. Pennsylvania's second clay product in value is common brick. The quantity reported for 1913 was 704,493,000 brick, valued at $4,772,229, or $6.77 per 1,000. This was an increase of 7,470,000 brick in quantity and of $181,445 in value over 1912. Its third product is front brick, the quantity of which reported for 1913 decreased 2,594,000 brick from 1912, but the value increased slightly—$3,722. The average value per 1,000 increased 15 cents—to $10.83.

Philadelphia County, the third largest common brick producing center of the country, with the city of Philadelphia for a market, is the principal producer of common brick, reporting 186,131,000 brick for 1913, valued at $1,353,620, an increase of 8,987,000 brick in quantity and of $94,489 in value over 1912, and Allegheny County, the home of "Greater Pittsburgh," is second with 92,430,000 brick valued at $620,724 in 1913, an increase of 3,229,000 brick in quantity and of $59,811 in value over 1912. Vitrified paving brick was produced most largely in Lawrence County in 1913, with Beaver County second and McKean County third; in value of product, however, McKean was second and Beaver third. Front brick is made chiefly in Armstrong County, 70,494,000 brick, valued at $806,196, or about one-third of the production and value for the State being reported for 1913, a decrease of 5,911,000 brick in quantity and of $49,295 in value from 1912. Clearfield County is the largest producer of clay fire brick and reported 101,141,000 9-inch equivalent brick, valued at $2,209,062, or more than one-fourth of the production and value of all clay fire brick for the State, an increase of 3,582,000 brick in quantity and of $340,656 in value over 1912. Huntingdon County is the largest producer of silica fire brick and reported 70,287,000 9-inch equivalent brick, valued at $1,433,255, or over one-half of the production and value for the State, an increase of 12,137,000 brick in quantity and of $289,809 in value over 1912.

Clearfield County is the most important clay-working county in the State, reporting wares valued at $2,612,191 in 1913, an increase of $361,208 over 1912. Clearfield's principal product is fire brick, though considerable quantities of vitrified and front brick are made there also. Allegheny County was second in importance by a small margin, $6,497, in 1913, displacing Philadelphia County, which was third. Allegheny County's clay products were valued at $2,193,642 in 1913, an increase of $486,373 over 1912, the chief product being clay fire brick ($815,044). Philadelphia County's clay products in 1913 were valued at $2,187,145, an increase of $9,554 over 1912. The principal product of this county is common brick, though architectural terra cotta and fire brick are important products.

There were 377 active operators reporting for 1913, compared with 393 for 1912 and with 457 for 1909. The average value of production per active operator was $64,274 in 1913 and $46,360 in 1909.

TENNESSEE.

The total value of all of Tennessee's clay products in 1913 was $1,493,085, a decrease of $7,931, or 0.53 per cent, from 1912. The principal product was common brick. There were 151,072,000 brick reported for 1913, valued at $902,832, or $5.98 per 1,000. This was practically the same output as for 1912, there being a decrease of only 3,139,000 brick in quantity and of $200 in value. The value of common brick constituted 60.47 per cent of the value of all clay products of the State in 1913. Front brick was second in importance in 1913, there being 16,085,000 brick reported, valued at $154,681, an increase of 4,967,000 brick in quantity and of $53,106 in value over 1912.

Davidson County was the largest producer of common brick in 1913, reporting 32,396,000 brick, valued at $187,131. Shelby County was second in the value of common brick ($143,450), although Hamilton County's production (28,471,000 brick) was larger than Shelby's output (19,354,000 brick) in 1913.

Hamilton County was the principal clay-working county of the State, its production being valued in 1913 at $440,981, or 29.53 per cent of the State's total. Davidson was second with production valued at $278,870. This was a decrease of $26,531 in Hamilton County and an increase of $5,049 in Davidson County, as compared with 1912. Hamilton County's chief clay products in 1913 were common brick, front brick, sewer pipe, and turpentine cups. Davidson's principal clay products in 1913 were common brick and front brick.

TEXAS.

The value of clay products in Texas in 1913 was $3,049,349, an increase of $163,281, or 5.66 per cent, over 1912. In 1913 Texas was the ninth State in the production of common brick, and sixth in its value; it was eighth in the production of front brick and ninth in value, and eleventh in the value of sewer pipe reported. The principal product is common brick. There were reported for 1913, 248,271,000 brick, valued at $1,826,793, an increase of 5,523,000 brick in quantity and of $235,833 in value over 1912. The value of common brick constituted 59.91 per cent of the value of all clay products of the State. Sewer pipe was the second product, front brick third, and fireproofing fourth. Pottery production was valued at $80,374 in 1913.

Ellis County was the largest producer of common brick for 1913, reporting 90,481,000 brick, valued at $612,391, an increase of 14,221,000 brick in quantity and of $170,532 in value. Sewer pipe was reported from Wilson and Bowie counties in considerable quantities, but there being less than three producers figures are not published. Fireproofing showed a large increase—$72,330. Ellis County is the leading clay-working county in the State. It reported nothing but common brick for 1913.

Clay products of Texas, 1909–1913.

VIRGINIA.

The total value of Virginia's clay products in 1913 was $1,705,651, a decrease of $168,523, or 8.99 per cent from 1912. In 1913 Virginia was the tenth State in the production and value of common brick, and it was ninth in the production of and tenth in the value of front brick reported. Virginia's principal clay product is common brick from the Coastal Plain region. There were 217,408,000 brick reported, valued at $1,409,798 in 1913, a decrease of 27,133,000 brick in quantity and of $103,540 in value. This product constituted 82.65 per cent of the value of the State's clay products in 1913. Front brick is the only other clay product of importance in Virginia. In 1913 it was valued at $247,142, a decrease of $66,409 from 1912. The average price per 1,000 for common brick increased 29 cents to $6.48, and that for front brick decreased 71 cents from $14.41.

Henrico County was the leading common brick producing county in 1913, reporting 44,326,000 brick, valued at $284,531, or $6.42 per 1,000, a decrease of 8,906,000 brick in quantity and of $49,577 in value from 1912. Alexandria County, which was first in quantity and second in value in common brick in 1912 was second in both quantity and value in 1913, showing a decrease of 23,944,000 brick in quantity and of $114,728 in value from 1912. The average price per 1,000 for common brick in this county in 1913 was $6.05, an increase of 56 cents over 1912. These two counties are the principal sources of supply of common brick of Richmond, Va., and Washington, D. C., respectively, and the decline in building operations in these cities probably accounts for the decrease in production in these counties, though some of the clays of Alexandria County have been worked out. Front brick was made most largely in Alexandria County, and it is that county's principal clay product.

Alexandria County was the leading clay-working county in the State in 1913, with production valued at $423,563.

Clay products of Virginia, 1909–1913.

WASHINGTON.

The total value of the clay products of Washington in 1913 was $2,390,226, an increase of $1,356, or 0.06 per cent, over 1912. In 1912 there was a large decrease in this State—$451,502, or 15.9 per cent, principally in common brick, vitrified brick, and sewer pipe. In 1913 there was a further decrease in common brick, but vitrified brick and sewer pipe showed an increase. In 1913 Washington was the seventh State in the production and fifth in the value of vitrified paving brick; it was seventh in the value of architectural terra cotta and tenth in the value of sewer pipe. Washington's principal clay product is vitrified paving brick, which in 1913 constituted 29.35 per cent of the value of Washington's clay products. Sewer pipe is the product of second importance; it was valued at $501,102 in 1913, a slight increase—$4,602—over 1912, and constituted 20.96 per cent of the total State value. Common brick, the third product in value, showed a decrease of 10,565,000 brick in quantity, and of $71,187 in value from 1912. Architectural terra cotta, the next product in importance, showed a decrease of $48,481 from 1912.

King County, with Seattle and Tacoma for markets, is the principal producer of common brick, and reported 30,812,000 brick, or 45.69 per cent of the State's total, for 1913, valued at $207,955, or 43.7 per cent of the total. This was a decrease of 5,889,000 brick in quantity and $43,095 in value from 1912. This county is also the leading clay-working county, and reported wares valued at $1,517,307, or 63.48 per cent of the State's total, an increase of $195,329 over 1912. Spokane County, whose principal product in 1913 was sewer pipe, was second, with production valued at $254,474.

WEST VIRGINIA.

West Virginia was the tenth State in the value of clay products in 1913, reporting products valued at $5,208,270—pottery, $3,424,-887, or 65.76 per cent of the total, and brick and tile $1,783,383, or 34.24 per cent of the total—an increase in 1913 of $432,396, or 9.05 per cent. This increase was principally in the brick and tile products—$372,675, pottery increasing only $59,721. In 1913 West Virginia was second in value of white ware and of sanitary ware, fourth in the production and value of vitrified paving brick, sixth in the value of tile, not drain, and eighth in the production and twelfth in the value of fire brick. West Virginia's principal clay product is white ware; for 1913 it was reported to the value of $2,024,104, or 38.86 per cent of the State's total. Next in importance is sanitary ware, which in 1913 was valued at $1,146,205, or 22.01 per cent of the State's total. The principal brick and tile product of West Virginia is vitrified brick, which in 1913 was valued at $795,555, an increase in value of $161,846 and in quantity of 6,528,000 brick over 1912. The average price per 1,000 increased $1.41, to $13.55. Common brick also increased 7,926,000 brick in quantity and $82,384 in value in 1913. The average price per thousand of common brick increased 45 cents in 1913, to $6.93.

Hancock County is the leading producer of vitrified brick, and reported for 1913, 50,050,000 brick, valued at $689,263, or 85.22 per cent of the quantity and 86.64 per cent of the value for the entire State. This was an increase of 6,111,000 brick in quantity and of $152,733 in value over 1912. Hancock County is the leading clay-working county of the State, its production in 1913 being valued at $2,839,864, or 54.53 per cent of the State's total, an increase of $208,994. Of this production $1,894,682 was pottery, principally white ware, and $945,182 was brick and tile, principally vitrified brick. West Virginia was the third State in production of pottery in 1913.

There were 58 active operators reporting for 1913, compared with 54 in 1912 and with 50 in 1909. The average value of production per active plant in 1913 was $89,798, and in 1909 it was $70,202.

WISCONSIN.

The total value of Wisconsin's clay products in 1913 was $1,020,728, a decrease of $23,758, or 2.27 per cent. Wisconsin's principal clay product is common brick, of which 116,534,000 were reported for 1913, valued at $815,461. This was a decrease of 6,376,000 brick in quantity and of $15,312 in value from 1912. The average price per 1,000 increased 24 cents in 1913, to $7. The value of common brick constituted 79.89 per cent of the total value of Wisconsin's clay products in 1913. Pottery production in Wisconsin in 1913, which was entirely red earthenware, was valued at $7,700.

Milwaukee was the leading clay-working county with products in 1913 valued at $278,243, nearly all of which was common brick. This county alone reported 38,133,000 common brick, valued at

$268,943, or 32.72 per cent of the quantity and 32.98 per cent of the value of this product for the State, an increase of 782,000 brick in quantity and of $11,976 in value over 1912. There was an increase of $11,976 in the value of Milwaukee County's clay product in 1913 over 1912. Dunn County, whose principal product is front brick, was second with a total value of $217,011 in 1913.

CLAY.

INTRODUCTION.

Clay available for the manufacture of clay products is one of the most widely spread of our minerals. Hence, there are clay-working plants scattered over every State and Territory in the Union. Miners of the lower-grade clays are usually also the manufacturers, but as the higher grades of ware are reached, the rule is that fewer and fewer manufacturers are also miners, until in the highest grades of ware the rule is that the manufacturer buys and does not mine the clays he uses. The figures given in the following tables represent clay that is mined and not manufactured by the miner, but is sold as clay. The clay thus sold is small in quantity compared with the total production and includes mainly clay used for high-grade pottery and tile, for paper making, and for refractory products.

The clay-mining industry in 1913 made considerable progress and showed its maximum production and value. Only two varieties decreased in production and value, slip clay (5,437 tons and $3,068) and brick clay (70,416 tons and $66,528); and two varieties, paper clay and fire clay, reached their maximum quantity and value. The miscellaneous item showed an increase in quantity and a decrease in value in 1913. In 1912, two varieties showed decrease in quantity and value, kaolin and stoneware clay, and ball clay showed decrease in output. Kaolin, which is the purest form of clay, and in some respects the most important of our clays, showed a small increase in quantity and value; paper clay and fire clay also showed increase in quantity and value in 1913, as did ball clay and stoneware clay. The average price per ton for five of the varieties of clay increased in 1913, and for two varieties and the miscellaneous item it decreased. The general average increased 2 cents per ton.

Imports of clay showed increase in both quantity and value, though in less proportion than those of the domestic production, and kaolin imports decreased in 1913.

PRODUCTION.

The following table shows the production of clay in 1912 and 1913, by varieties:

Production of clay in the United States in 1912 and 1913, by varieties, in short tons.

Variety.	1912			1913		
	Quantity.	Value.	Average price per ton.	Quantity.	Value.	Average price per ton.
Kaolin	25,852	$220,747	$8.54	28,834	$235,457	$8.17
Paper clay	119,857	522,924	4.36	126,377	567,977	4.49
Slip clay	16,339	27,573	1.69	10,902	24,505	2.25
Ball clay	64,939	227,545	3.50	67,134	237,672	3.54
Fire clay	1,695,337	2,363,357	1.39	1,820,379	2,592,591	1.42
Stoneware clay	124,409	115,522	.93	153,353	143,587	.94
Brick clay	229,306	204,504	.89	158,890	137,976	.87
Miscellaneous	254,226	263,848	1.04	282,120	240,694	.85
Total	2,530,265	3,946,020	1.56	2,647,989	4,180,459	1.58

This table shows that the total quantity of clay mined and sold as such in 1913 was 2,647,989 short tons, as compared with 2,530,265 tons in 1912, an increase of 117,724 tons, or 4.65 per cent; and that the value was $4,180,459, or $1.58 per ton, as compared with $3,946,-020, or $1.56 per ton, in 1912, an increase of $234,439, or 5.94 per cent. Every variety except slip clay and brick clay showed an increase in production and every variety except slip clay, brick clay, and the miscellaneous item showed increase in value. Fire clay showed the largest increase in quantity, 125,042 tons, or 7.38 per cent; stoneware clay increased 28,944 tons, or 23.27 per cent; kaolin increased 2,982 tons, or 11.53 per cent; and paper clay increased 6,520 tons, or 5.44 per cent. Brick clay decreased 70,416 tons, or 30.71 per cent, and slip clay decreased 5,437 tons, or 33.28 per cent. Fire clay showed the largest increase in value, $229,234, or 9.7 per cent; and paper clay showed an increase of $45,053, or 8.62 per cent. Fire clay in 1913, as for many years, was the principal variety, constituting 68.75 per cent of the quantity and 62.02 per cent of the value of all clay marketed as such. Paper clay was the second in value of production, its value constituting 13.59 per cent of the value of all clay mined and sold. The average price per ton varied but little in 1913 compared with 1912, the general average increasing only 2 cents per ton. The greatest change was in slip clay, which advanced 56 cents per ton. Kaolin declined 37 cents a ton, and paper clay advanced 13 cents a ton.

Clay mined and sold in the United States, 1905–1913, in short tons.

[a] Included in "Miscellaneous" in 1905 and 1906.

This table shows that the maximum quantity and value of clay mined and sold in the period covered were attained in 1913. The production rose steadily, except in 1908 and 1911, from 1,806,133 short tons in 1905 to 2,647,989 tons in 1913, and in value from $2,768,006 to $4,180,459. This was an increase in production of 841,856 tons, or 46.61 per cent, and in value of $1,412,453, or 51.03 per cent. Kaolin reached its maximum production and value in 1906, and its minimum in quantity in 1912 and its minimum in value in 1908. Paper clay and fire clay reached their greatest quantity and value in 1913. Ball clay reached its maximum quantity and value in 1910.

Clay mined and sold in the United States in 1912, by States, in short tons.

(a) Including bentonite, modeling clay, pipe clay, terra-cotta clay, and shale.
(b) Included in "Other States."
(c) Included in (f) (61,512 tons, valued at $192,701).
(d) Paper clay for Maryland is included in "Maryland miscellaneous."
(e) Includes all products made by less than 3 producers in 1 State.
(f) Made up of State totals of Florida, Idaho, Minnesota, North Dakota, Oregon, Utah, Vermont, and Wyoming.

Clay mined and sold in the United States in 1913, by States, in short tons.

[a] Including bentonite, modeling clay, pipe clay, terra cotta clay, and clay for medicinal use. [b] Included in "Other States." [c] Included in f (62,309 tons, valued at $197,451).
[d] Paper clay for Maryland is included in Maryland miscellaneous. [e] Includes all products made by less than three producers in one State.
[f] Made up of State totals of Connecticut, Florida, Idaho, Minnesota, Mississippi, North Dakota, Oregon, Vermont, and Wyoming.

Thirty-seven States reported sales of clay for 1913, an increase of 2, Connecticut and Mississippi, over 1912. The leading clay-producing State in both quantity and value was Pennsylvania. For 1913 the production of Pennsylvania was 479,548 short tons, valued at $836,916. This was an increase over 1912 of 16,943 tons in quantity, or 3.66 per cent, and of $95,432, or 12.87 per cent, in value. Pennsylvania reported 18.11 per cent of all clay sold in 1913 and 20.02 per cent of the total value. Of Pennsylvania's total clay production in 1913, fire clay was 87.95 per cent of the quantity and 78.48 per cent of the value. New Jersey was the second State, as for 1912, reporting 448,135 short tons of clay, valued at $769,689. This was an increase over 1912 of 9,252 tons, or 2.11 per cent, in quantity and of $67,681, or 9.64 per cent, in value. New Jersey's production was 16.92 per cent of the total clay mined in 1913 and 18.41 per cent of its value. In this State fire clay was also the leading variety, 73.01 per cent of the quantity of clay mined in the State and 74.96 per cent of the value being of this variety. Ohio, the leading clay-manufacturing State, was third in quantity and fifth in value of clay marketed, and Missouri was fourth in quantity and third in value. In 1912 Ohio was third in quantity and fourth in value, and Missouri was fourth in quantity and third in value. In 1913 Ohio showed an increase of 27,877 tons, or 7.82 per cent, in quantity and of $14,700, or 5.59 per cent, in value over 1912. In 1913 Missouri showed decrease in both production and value of clay, the former decreasing 57,669 tons, or 19.5 per cent, and the latter $92,029, or 16.37 per cent. Illinois was fifth in production and sixth in value of clay marketed in 1913, and Georgia was sixth in quantity and fourth in value. Both of these States showed substantial increases in production and value of clay marketed in 1913 over 1912. These six States—Pennsylvania, New Jersey, Ohio, Missouri, Illinois, and Georgia—reported 1,901,351 tons, or 71.8 per cent, of the total quantity, and $2,883,045, or 68.96 per cent, of the total value.

Of the remaining 22 States for which totals are given 10 showed increase in quantity of clay marketed and 12 showed decrease; 14 showed increase in value and 8 showed decrease. Nine States showed increase in production and value and 7 showed decrease in both. Delaware, Maryland, Michigan, West Virginia, and Wisconsin showed decrease in production and increase in value, and North Carolina showed increase in production and decrease in value. Georgia showed the largest increase in production, 80,559 tons, or 106.26 per cent. Pennsylvania showed the largest increase in value. Missouri showed the largest decrease in 1913 in both production and value. In 1912 Pennsylvania showed the largest increase in both production and value, and Kentucky showed the largest decrease in both quantity and value.

In 1913 Pennsylvania was the leading State in the production and value of fire clay, reporting 421,751 tons, valued at $656,825. New Jersey was second, reporting 327,175 tons, valued at $576,957. Ohio was third in production and fourth in value, and Missouri was fourth in production and third in value, and Illinois was fifth in both quantity and value. In 1912 Pennsylvania was first in production and second in value, Missouri was first in value and third in production, and New Jersey was second in quantity and third in value. The average price per ton of fire clay in these States in 1913 was: Illinois,

$1.18; Missouri, $1.98; New Jersey, $1.76; Ohio, $0.82; and Pennsylvania, $1.56. In 1912 the corresponding prices of fire clay were: $1.19, $1.92, $1.72, $0.82, and $1.44, respectively. These 5 States reported 1,340,751 tons, or 73.65 per cent, of the total quantity of fire clay, valued at $2,030,566, or 78.32 per cent, of the total value of fire clay in 1913.

Kaolin was reported from 6 States for 1913, an increase of 1 State. Maryland and Pennsylvania, which reported none for 1912, reentered the list of producers and California dropped out. North Carolina was the leading State, reporting 16,332 tons, or 56.64 per cent, of the total quantity, valued at $139,629, or 59.3 per cent, of the total value.

IMPORTS.

The following table shows the imports of clay from 1907 to 1913:

Classified imports of clay for consumption, 1907–1913, in short tons.

Year.	Kaolin or china clay.			All other clays.						Total.

The imports of clay, except for kaolin or china clay and the clay designated as "common blue," but which is high-grade fire clay, are unimportant. In 1913 of the clay imported 79.46 per cent of the quantity and 80.93 per cent of the value was kaolin or china clay.

The quantity imported increased 3,468 short tons, or 1.04 per cent, and the value increased $54,539, or 2.79 per cent. Every variety except kaolin showed increase in quantity and value. The imports of kaolin, which in 1912 showed a large increase, showed a decrease of 9,610 tons, or 3.45 per cent, in quantity and of $5,112, or 0.31 per cent, in value in 1913. The average price per ton of imported kaolin in 1913 increased 19 cents.

Tariff.—The tariff act of 1913 reduced the duty on clay 50 per cent. It went into effect late in the year and had, apparently, no effect on imports.

BUILDING OPERATIONS.

The following tables show the building operations of some of the leading cities of the country. Efforts were made to obtain detailed information for all cities of 35,000 or more inhabitants—157 in number. For 108 cities sufficient detail was received to include these cities in a table; for 39 cities only the totals for permits and cost of buildings could be obtained; and for 10 cities no data were procured. In some cases the data furnished were apparently inconsistent and considerable editing of reports was necessary.

The first table shows a comparison between 1912 and 1913 in 48 cities, also the increase or decrease in the cost of building operations. Used as an index of prosperity, the figures here given show that in the building trades it was sporadic in 1913. New York City, the largest building center of the country, showed a large decrease, while Newark, only a few miles away, showed a large increase over 1912. Chicago, which showed the largest decrease in 1912, rallied and showed the largest increase in 1913. Most of the cities that showed increase in 1912 showed decrease in 1913, and a few—9 altogether—that showed decrease in 1912 showed increase in 1913. None of these, except Chicago and Pittsburgh, were of the larger cities. On the whole, therefore, the building industries can not be considered as having been in a very prosperous condition in 1913. Where an exact comparison can be made, there was a decrease in 1913 of 10.75 per cent from 1912 and of 4.07 per cent from 1911. Various causes are assigned for the changes. Many cities ascribe the decrease in 1913 to the fact that in 1912 the structures erected were unusually costly; others to labor troubles; others to financial stringency; and some to overbuilding in previous years. The large increase in Cambridge, Mass., was caused by the erection of college buildings, and that in Grand Rapids, Mich., by the erection of one large building, costing nearly one-third of all operations in that city.

The total cost of building operations in these 48 cities in 1913 was $659,515,746, compared with $738,989,710, in 1912. Of the 48 cities included in this table 20 showed increase in the cost of buildings and 28 showed decrease. The total decrease was $114,985,805; the total increase $35,511,841, a net decrease of $79,473,964, or 10.75 per cent from 1912. In 1912, 31 of these cities showed increase and 17 showed decrease, the net increase being $51,482,749, or 7.49 per cent. Compared with 1911, there was a decrease of $27,991,215, or 4.07 per cent in 1913. The greatest decrease in 1913 was in New York City, $56,414,655, or 34.5 per cent. The greatest proportionate decrease was in Atlanta, 47.86 per cent. The largest increase was in Chicago, $6,492,527, or 7.81 per cent. The largest proportionate increase was in Cambridge, Mass., 123.61 per cent. In 1912, New York City showed the largest increase, $27,815,647, so that the building operations in that city cost very much less in 1913 than in 1911. The city showing the greatest decrease in 1912 was Chicago, $20,096,100.

Building operations in a number of the leading cities of the United States in 1912 and 1913.

Of the 48 cities included in this table, 11 showed increase in both 1912 and 1913; Buffalo, Cambridge, Cleveland, Columbus, Detroit, Indianapolis, Los Angeles, Newark, New Orleans, St. Paul, and Seattle. Eight cities showed decrease in both years; Cincinnati, Denver, Kansas City, Mo., Lowell, Omaha, Philadelphia, Portland, Oreg., and Scranton. Twenty cities that showed increase in 1912 showed decrease in 1913, namely, Atlanta, Boston, Brooklyn, Dayton, Hartford, Jersey City, Louisville, Memphis, Milwaukee, Minneapolis, New York, Oakland, Providence, Richmond, Rochester, St. Joseph, St. Louis, San Francisco, Washington, and Worcester. Nine cities that showed decrease in 1912 showed increase in 1913, as follows: Chicago, Fall River, Grand Rapids, Kansas City, Kans., Nashville, New Bedford, New Haven, Pittsburgh, and Syracuse.

New York City (boroughs of the Bronx and Manhattan) is the leading city in the cost of building operations. Notwithstanding its large decrease in 1913, in that year the cost of building operations there exceeded by $17,436,280 that of Chicago, the city of second rank in the cost of building operations. In 1913 the building operations of New York City cost $107,104,707, or 16.24 per cent of the total reported for the 48 cities. In 1912 they constituted 22.13 per cent of the total reported for these cities. The maximum cost of building operations in New York was in 1909, $186,047,477. In 1908, the year of general business depression, the cost of building operations in New York City was $117,819,382, so that in 1913 they cost $10,714,675 less than those of 1908 and $78,942,770 less than those of 1909. The cost of building operations in New York City in 1913 was the lowest since 1903. The reason assigned for this decrease is that that city was overbuilt. In the cost of building operations Chicago, the second city, the maximum was attained in 1911—$103,272,000. In 1912 there was a sharp decline, and in 1913 there was an increase but the cost was less then than in any year since 1908, except 1912. The cost of building operations in Los Angeles rose steadily from $9,931,377 in 1908 to $31,641,921 in 1913, an increase of $21,710,544, or 218.61 per cent. This city rose in rank from seventeenth in 1908 to fifth in 1910, which rank it has since maintained.

The total number of permits or buildings in these 48 cities fell from 202,357 in 1912 to 190,841 in 1913, a decrease of 11,516. The number ranged in 1913 from 527 in Cambridge to 16,442 in Los Angeles. The average cost per permit or building in these 48 cities in 1913 was $3,456, in 1912 it was $3,652, and in 1911 it was $3,407. In New York City the average cost was $11,342 in 1913, $19,742 in 1912, and $20,890 in 1911. In Chicago it was $8,309 in 1913, $7,737 in 1912, and $8,205 in 1911. In Philadelphia, the third city in cost of building operations, this city having regained this position in 1913, the average cost per operation was $4,562 in 1913, $3,252 in 1912, and $2,469 in 1911. In Brooklyn, the fourth city, it was $3,171 in 1913, $3,553 in 1912, and $4,035 in 1911. In Los Angeles, the fifth city, it was $1,924 in 1913, $1,906 in 1912, and $1,841 in 1911.

[a] Includes cost of building at the University of California, permits for which were not issued through the city of Berkeley.

[b] Additions, etc., to all classes of buildings for Binghamton, N. Y., Oakland, Cal., Syracuse, N. Y., and Worcester, Mass., are included with additions, etc., to wooden buildings. New concrete buildings for Binghamton are included with new brick or hollow-tile buildings. All classes of new fire-resisting buildings for Worcester are included with new brick or hollow-tile buildings.

[c] New concrete buildings for Cambridge, Mass., and for Newton, Mass., are included with new brick or hollow-tile buildings. Additions, etc., to concrete buildings for Cambridge, Mass., and Sioux City, Iowa, are included, with additions, etc., to brick or hollow-tile buildings.

[d] The total only was given for fire-resisting buildings for Cincinnati, Ohio, i. e., 589 permits or buildings, costing $4,819,000. The percentage for this value, equivalent to seventy-nine one hundredths of 1 per cent, is included in the percentage for total fire-resisting buildings. Additions, etc., to all classes of buildings for Cincinnati are included with additions, etc., to wooden buildings.

[e] The cost of new concrete and of new steel-skeleton buildings for Cleveland, Ohio, is included with the cost of new brick or hollow-tile buildings, and the cost of additions, etc., to concrete buildings and additions, etc., to steel-skeleton buildings is included with additions, etc., to brick or hollow-tile buildings.

[f] The number of permits or buildings for Covington, Ky., and Fort Wayne, Ind., was not given; nor was it given for additions, etc., to concrete buildings for Pittsburgh, Pa.

[g] With new stone buildings for Duluth, Minn., are included additions, etc., to stone buildings; new concrete buildings and additions, etc., to concrete buildings; new steel skeleton buildings and additions, etc., to steel skeleton buildings; and miscellaneous fire-resisting buildings.

[h] New stone and new concrete buildings for Hartford, Conn., are included with new brick or hollow-tile buildings, and additions, etc., to these two classes of buildings are included with additions, etc., to brick or hollow-tile buildings.

[i] New stone buildings for Jacksonville, Fla., are included with new brick or hollow-tile buildings; and additions, etc., to stone buildings are included with additions, etc., to brick or hollow-tile buildings.

[j] Additions, etc., to brick or hollow-tile buildings for New Britain, Conn., are included with additions, etc., to wooden buildings.

a Includes cost of buildings at the University of California, permits for which were not issued through the city of Berkeley.

b Additions, etc., to all classes of buildings for Binghamton, N. Y., Oakland, Cal., Syracuse, N. Y., and Worcester, Mass., are included with additions, etc., to wooden buildings. New concrete buildings for Binghamton are included with new brick or hollow-tile buildings. All classes of new fire-resisting buildings for Worcester are included with new brick or hollow-tile buildings.

c The total under miscellaneous fire-resisting operations for Buffalo, N. Y., is for municipal work. Under this heading for San Diego, Cal., are included miscellaneous operations" for all classes of buildings.

d New concrete buildings for Cambridge, Mass., and for Newton, Mass., are included with new brick or hollow-tile buildings. Additions, etc., to concrete buildings for Cambridge, Mass., and Sioux City, Iowa, are included, with additions, etc., to brick or hollow-tile buildings.

e The total only was given for fire-resisting buildings for Cincinnati, Ohio, i. e., 589 permits or buildings, costing $4,819,000. The percentage for this value, equivalent to seventy-nine one hundredths of 1 per cent, is included in the percentage for total fire-resisting buildings. Additions, etc., to all classes of buildings for Cincinnati are included with additions, etc., to wooden buildings.

f The cost of new concrete and of new steel-skeleton buildings for Cleveland, Ohio, is included with the cost of new brick or hollow-tile buildings, and the cost of additions, etc., to concrete buildings and additions, etc., to steel-skeleton buildings is included with additions, etc., to brick or hollow-tile buildings.

g The number of permits or buildings for Covington, Ky., and Fort Wayne, Ind., was not given; nor was it given for additions, etc., to concrete buildings for Pittsburgh, Pa.

h With new stone buildings for Duluth, Minn., are included additions, etc., to stone buildings; new concrete buildings and additions, etc., to concrete buildings; new steel-skeleton buildings and additions, etc., to steel-skeleton buildings; and miscellaneous fire-resisting buildings.

i New stone and new concrete buildings for Hartford, Conn., are included with new brick or hollow-tile buildings, and additions, etc., to these two classes of buildings are included with additions, etc., to brick or hollow-tile buildings.

Grand total	......	......	......	......	......	......	......	......	......	......	......	......	285,850	859,657,250	......

This table shows that the 147 cities included reported building operations costing $859,657,250 in 1913. Of these, 108 cities reported sufficient detail to permit the publication of statistics of building operations by classes of structures. These 108 cities reported 203,748 permits or buildings, work on which cost $608,252,502. Of this total, new buildings of every variety as reported cost approximately $516,570,492, or 84.93 per cent of the total; additions, alterations, and repairs cost $78,483,933, or 12.90 per cent; and miscellaneous operations cost $8,379,077, or 1.38 per cent, of the total—$4,819,000, or 0.79 per cent, having been reported as fire-resisting buildings unclassified.

It should be borne in mind, however, these statistics of building operations by kinds, especially in the totals, are only approximate, as many cities were unable to report strictly in accordance with the classification as given in the table. It is believed, however, that the figures as published are accurate enough to give a good idea of the relative importance of the various kinds of operations enumerated.

Taken by classes, the new wooden buildings in 1913 cost $174,197,886, or 28.64 per cent of the total cost, and new brick buildings cost $226,478,584, or 37.23 per cent of the total cost; all other new buildings cost $115,894,022, or 19.05 per cent of the total. Of the total cost of new buildings, those built of wood constituted 33.72 per cent, and those of fire-resisting material cost $342,372,606, or 66.28 per cent. Of the cost of all new fire-resisting buildings, 66.15 per cent was for brick buildings, 2.35 per cent for stone buildings, 11.59 per cent for concrete buildings, and 19.91 per cent for steel-skeleton buildings. Of the cost of all additions, alterations, and repairs—$78,483,933—37.11 per cent was for wooden buildings and 62.89 per cent for fire-resisting buildings. Of the additions to fire-resisting buildings—$49,362,243—86.43 per cent was for brick buildings, 2.55 per cent for stone buildings, 2.85 per cent for concrete buildings, and 8.17 per cent for steel-skeleton buildings.

Operations on brick buildings (new, additions, alterations, and repairs) cost $269,140,047, or 44.25 per cent of the entire cost of all operations in these 108 cities, all other fire-resisting buildings contributing $132,948,047, or 21.86 per cent. In addition to the brick or hollow tile used in the construction of brick buildings large quantities are used in foundations, chimneys to wooden buildings, and in the construction of nearly all fire-resisting buildings.

The average cost of new wooden buildings in the 108 cities shown in this table in 1913 was $2,108; of new brick buildings, $10,537; of new stone buildings, $52,598; of new concrete buildings, $27,616; and of steel-skeleton buildings, $144,410.

Wooden buildings.—Los Angeles reported, as for several years, the largest number of new wooden buildings, 10,377, in 1913, a decrease of 295 buildings from 1912. The average value per building was $1,396 in 1913, compared with $1,541 in 1912, a decrease of $145. Detroit was second in 1913, as for several years, reporting 6,531 new wooden buildings at an average cost of $2,325. This was an increase of 846 in the number of wooden buildings in 1913, and an increase of $248 in the average cost. Seattle was third in 1913, as for 1911 and 1912. The others of the first 10 cities in number of new wooden buildings in the order of their rank were: Minneapolis, Portland (Oreg.), Cleveland, Buffalo, San Francisco, Indianapolis, and Oakland.

Detroit was the leading city in 1913 in the cost of new wooden buildings, displacing Los Angeles (which was second), reporting their cost at $15,182,070, an increase of $3,378,660 over 1912. Los Angeles's new wooden buildings in 1913 cost $14,485,095, a decrease of $1,957,067 from 1912 and $696,975 less than the cost of Detroit's new wooden buildings in 1913. Cleveland, which was sixth in number of permits or buildings of this class in 1913, was third in cost; San Francisco, which was eighth in number of permits or buildings, was fourth in cost; and Boston was fifth in cost. The next cities in the cost of new wooden buildings in the order of their importance were: Buffalo, Rochester, Minneapolis, Seattle, and Portland (Oreg).

Of the leading 10 cities in the cost of all operations on wooden buildings, 5 cities, Boston, Los Angeles, Minneapolis, Rochester, and San Francisco, showed a decrease in the cost of this class of operations; and 4 cities, Buffalo, Cleveland, Detroit, and Seattle, showed increase; in one, Portland, Oreg., comparison can not be made, as the cost of operations on wooden buildings was not given for 1912. The wooden buildings reported from New York City were erected principally in the Borough of The Bronx.

Fire-resisting buildings.—New York City reported the greatest cost of fire-resisting buildings, including additions, alterations, etc., for 1913—$106,097,450, or more than one-fourth of the total cost of this class of buildings in these 108 cities. This was a decrease of $56,096,443, or 34.59 per cent, from 1912. Of the other leading 9 cities in this class of structures, 4 showed decrease compared with 1912—Boston, $3,036,543; Philadelphia, $1,354,800; San Francisco, $1,210,812; and Washington, $6,906,691; and 5 showed increase—Cleveland, $3,934,433; Detroit, $1,259,555; Los Angeles, $2,068,395; Milwaukee, $888,877; and Pittsburgh, $3,508,624.

Brick or hollow-tile buildings.—New York was the leading city in new buildings of this class in 1913, reporting 1,118 at a cost of $52,178,429, or nearly half the cost of all building operations in that city. The average cost of these buildings was $46,671. This was a decrease of 671 in number and of $96,945,607 in cost from 1912. The second city in cost of this class of buildings in 1913, as shown in the table, was Philadelphia, which reported 5,793 permits or buildings costing $25,305,490, or an average cost of $4,368. This was a decrease in number of 79, but an increase of $1,018,205 in cost, compared with 1912. The next 8 cities in cost of brick or hollow-tile buildings, in order of their rank were: Cleveland, Boston, Detroit, Washington, Los Angeles, Pittsburgh, Milwaukee, and Cambridge.

These ranks are probably relative and not actual, as some of the cities that reported no details may have exceeded these cities in the cost of this and other classes of buildings.

Stone buildings.—New stone buildings were reported from 29 of the 108 cities giving figures by classes of buildings. Of these, San Francisco reported the highest cost, $3,500,000, but was second in number of buildings, 18. This was an increase of 4 in number and of $1,203,696 in cost of buildings of this class over 1912.

Concrete buildings.—New concrete buildings were reported by 71 cities. Philadelphia was the leading city in this class of buildings in 1913, reporting them at a cost of $4,634,855, an average of $159,823, a decrease of 1 in number, but an increase of $2,134,655 in cost compared with 1912. San Francisco was the second city in this class of buildings, reporting them at a cost of $3,745,389 in 1913, a decrease of 21 in number and of $438,070 in cost from 1912. The other important cities in the construction of concrete buildings were: Detroit, Minneapolis, and Los Angeles.

Steel skeleton buildings.—New steel-skeleton buildings were reported by 37 cities. New York was the leading city in this class of buildings in 1913, the first year for which figures were procured. It reported 114 new buildings of this class, costing $40,819,800, an average of $358,068. This was more than half of the cost of all new steel-skeleton buildings reported. Los Angeles was the second city in the cost of this class of buildings, $4,367,000, in 1913. Birmingham was third, Boston fourth, and Indianapolis fifth.

SURVEY PUBLICATIONS ON CLAYS, FULLER'S EARTH, ETC.

In addition to the papers named below, certain of the geologic folios also contain references to clays, fuller's earth, etc.

These publications, except those to which a price is affixed or which are out of print, can be obtained free by applying to the Director, United States Geological Survey, Washington, D. C. The priced publications may be purchased from the Superintendent of Documents, Government Printing Office, Washington, D. C.

These reports may be examined in many public libraries.

NOTES ON THE OCCURRENCE AND USE OF FLINT CLAY.

By J. H. Hance.

INTRODUCTION.

Flint clay has been defined as a hard, dense clay, having conchoidal fracture and of high refractory character. Little, if any, plasticity can be developed in it even by fine grinding. It is unique for its hardness, its resemblance to flint, and the peculiar markings which are present in the clay of some localities. These markings may be dark spots producing a mottled effect, or irregular bands resembling contorted laminæ, or closed curves suggesting concretionary action. The color ranges from light gray, grayish-brown, and slate, to black, and all of these shades may appear in a single hand specimen. In many cases it closely resembles limestone both in fracture, hardness, and its peculiar ring under the hammer. Its massive nature and lack of bedding planes are also characteristic. Joint planes are well developed in some places and resemble the cleats in coal beds.

Iron pyrites and marcasite may be present in some specimens as well formed crystals nearly three thirty-seconds of an inch in diameter, in roughly spherical nests up to 2 or 3 inches across. Near the outcrop so-called "ore-pockets" are found, consisting of soft arenaceous clay with a large amount of hematite and limonite. These probably result from oxidation of the pyrite and marcasite by surface waters. Bright-red stains of hematite are also found in some places where surface waters have descended along the joint planes and brecciated faces of a flint clay bed. In such cases the iron stain seems to be confined entirely to the hard clay.

Chemically some of the flint clay appears to resemble kaolinite closely in composition, although in some samples the alumina is too high, whereas in other samples the silica is in marked excess. Following are a few analyses which bring out these relations:

Analyses of flint clay.

	$Al_2O_3.SiO_2.2H_2O$ (kaolinite).	1	2	3	4	5	6
SiO_2	46.3	61.0	41.93	44.55	46.75	44.60	34.76

The clay is low in fluxes and is extremely refractory, but has very high fire shrinkage. This latter feature can be overcome by first calcining the flint and then using it as grog. Preburning, however, is done only when such shrinkage is prohibitive, for it requires an extra burn, and this adds to the cost of the finished product.

USES.

Flint clay is used in a variety of ways, but is in greatest demand where refractory qualities are required. For structural purposes it finds some use in fireproofing materials, but in most cases a less refractory and more plastic clay satisfies the requirements for such products. A minor application of it is in sanitary engineering, but this small use is due to the high cost of the finished product when made with this kind of clay, and a nonrefractory clay serves the purpose just as well. For the manufacture of refractory materials, its most important use, it is generally mixed with a plastic clay, the proportions of flint to plastic clay varying with the use of the product. If toughness and resistance to abrasion are desired, the proportion is about 2 parts of plastic clay to 1 of flint. If heat resisting qualities alone are desired, the ratio is about 1 of plastic to 2 of flint. These ratios, however, depend upon so many factors, such as the properties of individual clays, both of flint and soft, and the exact treatment to be accorded the products, including shipment as well as conditions in use, that the manufacturer has to determine the proportions which best meet the requirements of each case. Its value in the refractory material industries depends chiefly on two properties—resistance to the fluxing action of molten glass and furnace melts and ability to withstand high temperatures. Silica and magnesite brick possess these properties under certain conditions, and hence can be used to some extent instead of ordinary fire brick.

HISTORY.

Flint clay seems to have been discovered in this country about 1836 or 1837, although there is some question as to whether it was first discovered in Pennsylvania or Maryland. In 1839 the Union Mining Co. at Mount Savage, Md., began operations which have been contionued ever since. The Clarion flint clay was worked at this time at Rochester, Pa., and in 1842 James Glover discovered and developed the Bolivar flint clay at Bolivar, Pa. Since that time the fire brick and other refractory material industries have been developed until the present time when next to the iron ore and the fuel they are the most essential to the steel industry.

GEOLOGIC OCCURRENCE.

The term "clay" as applied to this raw material is somewhat of a misnomer. Its specific gravity, hardness, fracture, and lack of plasticity place it in sharp contrast with clay as ordinarily defined, but its occurrence in nature and its place in the ceramic world apparently justify the usage of the term.

Although flint clay occurs in beds between shales, sandstones, coal, and soft clay, it presents some unique features. In most cases it grades above and below into soft clay, a bituminous shale, or an argillaceous shale. The change may be abrupt or it may be a gradual transition. In some mines the flint occupies the upper portion of the clay bed; it may be present exclusively in the middle or lower portion of the bed; it may occur in any or all of these positions. Slips, squeezes, and the like are ordinary features in most clay mines, and are what might be expected when such an incompetent bed lies between more competent ones of sandstone, and deformation has followed deposition. Coal may or may not accompany the clay, but the conditions under which its material was deposited were apparently somewhat similar to those favoring vegetal accumulation. In the cycle of conditions which alternately favor the formation of sands, muds, and swamps are evidently included those furnishing part or all of the material in flint clay. These conditions were rather widespread in Carboniferous time in the area occupied by the eastern extension of the interior sea of North America. The surface of the land was then close to sea level, having but lately emerged; in fact, it underwent more than one resubmergence. The general consensus of opinion is that at that time the climate was more uniform and genial than at present, and was oceanic. Under these conditions laterization was favored, and deposits rich in alumina were probably formed, both of precipitated and of transported material. In some places this material may have been accumulated under specially favorable conditions. Coastal swamps greatly restricting water currents and, at the same time, furnishing abundant organic material for reduction processes and complete rock disintegration would satisfy the requirements; also a slight oscillation of sea level would readily change the balance so as to favor successively vegetal, sand, or mud accumulation. Such an order of progression apparently did exist in Carboniferous time in this region.

Conditions of accumulation postulate a very finely comminuted particle or a precipitate, and where alumina and silica were present in about equal quantities (or the right proportions to form a compound in this case), in a physical state approaching that of a colloid, intimately mixed, and subjected to the leaching action of reducing solutions, a combination of the two radicles and that of water is most reasonable. Some hydrated aluminum silicate was undoubtedly present in the original sediment, and this probably aided in bringing about further combination. Later, under indurating conditions, part of this hydrated aluminum silicate recrystallized, forming the flint clays. The Pittsburgh coal bed was continuous at one time over most of this eastern area, and indicates a minimum thickness of sediment which overlay the clays now flint. Of the flint clays, the Bolivar and the Mount Savage appear most widely distributed, and of these two the latter seems to consist more largely of flint. This latter bed underlies the Homewood sandstone, which is uniform and persistent over wide areas. This is also the basal flint clay of importance and was subjected to the greatest load of overlying sediments; hence, induration and recrystallization would be most favored.

The so-called Cheltenham flint clays in Missouri and Illinois are regarded by Wheeler as having probably been precipitated, at least in part. The theory is plausible.

The flint clays of Missouri occur in pockets or lenses in the base of the Pennsylvanian. The flint clays of Pennsylvania, Maryland, Connecticut, and Ohio occur in beds, the more important ones underlying massive sandstones. This latter feature is important in prospecting for the clay, as the sandstone outcrops in bold ridges or strews the ground with huge bowlders and makes a good key horizon. Although flint clay is less resistant than sandstone, the nodular variety does form permanent ledges, as near Stronach, Pa. Ordinarily, however, the clay, like the coal, weathers faster and forms reentrant outcrops, which can be examined best in road or railroad cuts and stream beds. Trenches, pits, drifts, and drill holes are frequently resorted to, and assist, not only in demonstrating the presence of the clay, but also in determining its thickness, lateral extent, and character.

SAMPLING AND TESTING.

Sampling and testing constitute a feature which is extremely important and should not be neglected. At the present time there are ceramic schools and a Government bureau where such samples are handled at cost and the results are trustworthy, but a sample must be properly taken or else these analytical results mean little, or worse than nothing. The sample should be as carefully taken as that of a coal bed. It should represent the working face and not merely a thin layer. If there are portions of the bed which can be kept separate in the mining, these should be sampled separately, especially if their thicknesses are considerable, their continuity established, and their values of special note.

If the sample is taken at the outcrop, the face should be cleaned of weathered material as nearly as practicable, so as not to introduce surface contamination. One method is to take a uniform strip a foot or so wide and 2 or 3 inches deep clear across the workable portion of the bed. This workable portion should be sufficiently great to include entry and room height. The fragments of clay should then be reduced to about walnut size and be quartered to a final sample of about 60 pounds. This much is desirable if complete tests are to be made, as there is enough to replace possible losses in kiln tests. A chemical analysis is of course desirable, but the kiln and machine tests of the clay are of far more importance. Without them the chemical analysis is of little value except as an indicator.

DEVELOPMENT.

After finding and testing the clay, it is extremely important to know something of its continuity or lateral extent. This can be accomplished most cheaply by drilling and should be resorted to before any large development policy is adopted. In some districts it has been deemed sufficient merely to locate the bed, such as the Bolivar or the Mount Savage, and then start development openings; but this has resulted in some places in greater expense than a careful drilling program would have entailed. Flint clay is extremely variable in thickness and quality within very short horizontal and vertical intervals. The Mount Savage and Bolivar clays, both of unusually wide distribution, are of very low grade in most of the area involved. One company found, after a very detailed drilling program, in an area of approximately 70 square miles considered unusually productive in high-grade flint clay, that less than 5 per cent of the drill cores showed flint clay of sufficient value to mine profitably.

In this connection it is interesting to note a statement common among the producers of this kind of clay that the best flint clay is usually found near the outcrop. As greater depth of cover is attained, the clay is said to contain more silica and fluxes, and a smaller proportion of the clay itself is high-grade flint. The exact reasons for this are not clear to the writer, but they may prove to throw some light on the relations of nonplastic to plastic fire clay. The leaching action of the ground and surface waters undoubtedly plays an important part, but just what chemical actions are involved is not understood.

Another good reason for adopting a drilling program where much cover is involved, is the possible presence of good clay and coal at other horizons. This is important not only to the landowner, but also to the producer, for it may render possible a combined development which is more efficient and economical.

Raw clay is a cheap article and mining economics should be carefully attended to. The plant should be on a railroad with good shipping facilities. It is desirable to have the mine mouth near the plant, if possible. Steam, rope and gravity trams, inclines, and wagon haulage, are used to bring the mine product to the plant. Cost of installment and subsequent maintenance of a long tram line add very materially to the cost of production, and, in most cases, such a system is not used to its maximum capacity, but rather to a small percentage of it. In too many cases, therefore, this addition to the cost of production is unduly large.

The longwall retreating system of mining or a combination of this with the room and pillar system seems to the writer the most efficient for the following reasons: (1) It insures a maximum production; (2) it permits of most rapid development after the entries and headings are driven; (3) production can be maintained at a uniform rate; (4) trackage and entry maintenance are reduced to a minimum and less timber is needed underground.

The more rapidly the clay is mined the greater the efficiency effected and the longer can the clay be weathered or seasoned, features which seem to be overlooked by many producers. Storage space is required for large dumps, but surface rights are usually obtainable at small cost in such territory; for in many localities the land is valuable for its clay content only. It is true that for such mining more capital is needed at the start, and that, if the clay is mined on a royalty basis, the interest charges are greater; but this should be more than offset by the lowered cost of production. The royalty charge is the most serious and may prohibit rapid production of the raw material or practically limit it to the rate of disposal or manufacture. Seasoning the clay and increasing its uniformity would lower the cost of manufacture and thus generally improve the quality of the products.

Mule haulage is probable the cheapest method of underground transportation for this material, but track and entry conditions in many of the old clay mines are such that the mule works against too great odds and by no means attains his real capacity. It is because of the low value of raw clay that its cost laid down at the plant should be a matter of engineering science and not of the mining methods of yesterday. The miner is paid from 30 to 45 cents per ton of clay loaded on the cars underground. To this outlay must be added the cost of development, royalties, mine management and maintenance, including dead work, and transportation to the plant. A ton of flint clay laid down at the factory usually costs the company

$1 or more, a figure which seems unduly large and which might be reduced 20 or 25 per cent by adopting modern mining methods.

In regard to the care used in sorting clay much might be written. Suffice it to say that those manufacturers who are most scrupulous in permitting only the best to enter into the high-grade refractory material are those who are most successful and whose product is more in demand each year. Such producers are usually working at full capacity, even in slack times.

FUTURE DEVELOPMENT.

Flint clay resources can be roughly approximated only, except possibly by some of the larger companies interested. Much drilling and prospecting have been done, but the results are retained in private reports. The quantity available in central and western Pennsylvania is probably much greater than that which has been mined. Improved methods and combined systems of mining will, however, be necessary to obtain part of this clay at a profitable figure. There is enough already developed to last, at the present rate of consumption, for many years, but the increase in consumption is proceeding more rapidly than development. In 1913 the increase of production of fire clay over that in 1912 was 7.38 per cent. The same general relations probably hold for flint clay, so that allowing for a normal increase of production, the clay developed or in sight should last for years. In addition there is much territory which is known to be underlain by these horizons and which is as yet relatively unprospected. This, with the flint clay now known which is not worked because by itself it can not be mined at a profit but which with the accompanying soft clays and shales should yield good returns, constitutes a reserve supply for many years.

Maryland has been a steady producer of flint clay and, except for an occasional year, has increased annually in its production of the raw flint clay at the rate of about 10 per cent. (Estimated from its total fire clay production.) The clay developed or in sight will probably last for at least 25 or 30 years, allowing for a normal rate of increased production. The amount of territory unprospected but which is underlain by these beds is considerable in proportion to the area now developed, so that this State should remain an important producer for the remainder of this century at least.

Kentucky has a supply of flint clay which has scarcely been touched. Five counties in the northeastern part of the State are known to contain valuable deposits, but it is doubtful if any approximate estimate is possible. Some ground is developed along the Chesapeake & Ohio Railway, but this area is only a small part of what is still more or less inaccessible to the producer, a large part of which should contain valuable clay.

Missouri still has a large quantity of flint clay, but its deposits are probably not as extensive as those in the Eastern States.

Ohio includes the northern extension of the northeastern Kentucky field and is known to have flint-clay beds at those same horizons, but developed at few places. Its main clay resources, however, are in the plastic varieties.

BIBLIOGRAPHY OF OCCURRENCES OF FLINT CLAY.

The following bibliography contains references to most of the important articles on flint-clay occurrences in this country, but is scarcely complete. Many brief comments exist scattered through various geological reports, especially those of the State surveys, but most of these merely mention certain occurrences and do not go into any detail as to the character of the clay developed, the geological relations, or the quantity available. Aside from its technology, the clay is none too well understood. The most detailed discussions and those throwing most light on the origin of the clay are by H. A. Wheeler, T. C. Hopkins, G. H. Ashley, and S. Galpin. Other writers have contributed many details of occurrences and properties which are of value to the producer, the manufacturer, and the geologist. It is to be hoped that future study may enable us to determine the exact relations between the flint and the soft fire clay, as these will prove of considerable value to the industry, both the producing and the manufacturing ends.

Stevenson, J. J., Second Pennsylvania Geol. Survey, Ligonier Valley, KKK, 1878.

Cites a few known outcrops of the Bolivar flint clay in this valley and notes its erratic characteristics. Locates outcrops of it in Fairfield, Ligonier, Stewart, Springfield, and Wharton townships. Two analyses are given on page 249.

Kentucky Geological Survey, Analyses A, 1885–1888.

Contains analyses of a number of samples of flint clay from northeastern Kentucky and a brief comparison of this flint with some German clay as adapted to glass pot manufacture.

Cook, R. A., Am. Inst. Min. Eng. Trans., vol. 14, p. 698, 1885.

A short article on the mining and manufacture of fire brick at Mount Savage, Md. Mentions some of the peculiarities of occurrence, such as the presence of soft and hard clay in the same bed. The article is devoted principally to the technical side of the clay industry.

Kinnicutt, L. P., and Rogers, J. F., Jour. Analyt. and Appl. Chemistry, vol. 5, p. 542, 1891.

A short contribution on the fire clay at Mount Savage, Md. Gives a complete analysis, differentiating between free and combined silica. Suggests that the clay might be considered as: free sand or silica, 31.84 per cent; kaolin ($2Al_2O_3.3SiO_2.4H_2O$), 67.07 per cent; iron oxide, 0.89 per cent.

Orton, E., Jr., Ohio Geol. Survey, vol. 7, p. 218, 1893.

Notes the similarity in composition to pure kaolin (kaolinite) but states that some flint clays have a composition like that of common plastic fire clay. Also calls attention to the fact that the flinty structure accompanies clay of impure chemical character and with an absence of any of the refractory qualities. The essential feature is lack of plasticity. Quotes analyses of flint clays from Ohio, Maryland, and Kentucky. Some of these show the presence of considerable free silica with corresponding low alumina content.

Hofman, H. O., Am. Inst. Min. Eng. Trans., vol. 25, p. 14, 1895.

Gives some analyses and the results of some tests on some standard American fire clays.

Blatchley, W. S., Indiana Dept. Geology and Nat. Res., Twentieth Ann. Rept., p. 27, 1896.

Discusses the properties of refractory clays, such as insolubility, infusibility, etc. Emphasizes the importance of a low content of fluxes. Contains a general discussion of clays, with special reference to their occurrence in Indiana.

Wheeler, H. A., Missouri Geol. Survey, vol. 11, p. 201, 1896.

An excellent discussion of the mode of occurrence, chemical composition, and physical and chemical properties of nonplastic fire clays, including details of various occurrences in Missouri. Its similarity in composition to kaolinite and pholerite, its high specific gravity, hardness, compact nature, lack of plasticity, and association with deposits of hematite, all suggest the chemical precipitate theory, whereas the lenticular phases, as in Maryland, Ohio, and elsewhere, indicate secondary crystalization subsequent to deposition. Several analyses are given and the illustrations of flint clay working faces are typical.

HOPKINS, T. C., Clays and clay industries of Pensylvania, pt. I, p. 50, 1897.
Mentions details in occurrence and properties of the Bolivar flint clay. Calls attention to the concentric weathering phase, in which respect the Bolivar clay somewhat resembles basalt. Considers that this peculiarity is independent of, although in some places accompanied by, iron. Near the surface this iron is an oxide, but in the interior of the bed it is in the form of a carbonate. Contrasts the Pennsylvania occurrences with those in Missouri. Discusses the varieties of fire clay and the unique characteristics of flint clay. Suggests that the induration is due to pressure, chemical deposit, recrystallization, or a combination of these agencies. Many analyses are quoted and short descriptions of various workings of the Bolivar clay are given, accompanied by instructive photographs. Gives many interesting facts, both historical and technical, relating to the fire-brick industry, which is largely concerned with flint clay.

——— Mines and Minerals, vol. 19, p. 53, September, 1898.
A short description of plastic and flint fire clays based on their occurrence in Pennsylvania, Ohio, and West Virginia. The Bolivar and Brookville clay beds are said to produce the best flint clay in these States. The article includes a short summary of the methods of testing, mining, preparation, and manufacture, and of the uses of the clays, with a paragraph as to possible future development in the direction of working coal and clay together.

CLARK, W. B., Maryland Geol. Survey, Allegany County, p. 181, 1900.
Contains a brief description of the flint clays in this county, all of which are said to underlie the Homewood sandstone. A paragraph on mining and manufacture is included. Conditions of sedimentation in this region during Carboniferous time are sketched.

——— Maryland Geol. Survey, Garrett County, p. 213, 1902.
Gives a short description of the Mount Savage and Bolivar flint clays as known in this county, with several sections showing the stratigraphic position of each, and includes three analyses.

RIES, HEINRICH, Report on the clays of Maryland: Maryland Geol. Survey, vol. 4, p. 351, 1902.
Defines the flint clay. Speaks of the nonplasticity of flint clays and their irergular occurrence; in some places mixed with the plastic fire clay in the bed. Also notes the presence of concretionary masses of iron in the flint. Quotes some at Olive Hill. Gives analyses of the flint and high alumina clays. Other fire clays in the Pottsville and Allegheny formations near Ashland and Willard are mentioned, and a few measured sections are given. The association of some of this clay with limestone is pointed out. Except for a small band of flint, most of the clay is plastic. Brief mention is made of the uses to which these fire clays are put.

GREAVES-WALKER, A. F., Flint fire clay deposits in northeastern Kentucky: Am. Cer. Soc. Trans., vol. 9, p. 461, 1907.
Contains some notes on the flint clays in this region which the writer considers bear out the theory that flint fire clays were laid down in ponds. The occurrences in each of the five counties (Greenup, Carter, Elliott, Lewis, and Rowan) are taken up and treated in a brief manner. A number of analyses are included. Mention is made of the "aluminite" or "high alumina" flint which is present in one mine in Carter County. The writer considers that railroad extension in this region will open flint clay resources of great importance.

ASHLEY, G. H., Pennsylvania Top. and Geol. Survey Comm. Rept., 1906–8, p. 313.
Mentions the dependence of the great furnace industries of Pennsylvania upon flint clays and the resulting high value placed upon suitable refrectory material. Notes the similarity between analyses of flint clays, indianaite, and pure kaolinite. Indianaite, which is pure white, occurs at the base of the coal measures in Indiana, and may have an origin similar to that of flint clay. The Olive Hill, Ky., clay and that at Sciotoville, Ohio, occur at the base of the coal measures and are both overlain by massive sandstone or conglomerate. It is much nearer the composition of kaolinite than is shale or ordinary clay. Speaks of its smooth, fine grain, conchoidal fracture, sharp edges, and resemblance to limestone. Peculiar occurrence as an original deposit in a regular sequence of layers; in others, deposits as a secondary alteration. Cites the fact that in Clearfield, Cambria, Jefferson, and other counties, the shale between the Upper Freeport and the Mahoning coals grades in places imperceptibly into flinty shale and in other places into typical flint clay.
The widespread occurrence of a thin bed of nearly black flint clay a few inches thick within a lighter Lower Kittanning or Clarion clay in northeastern Kentucky is described. Here the gradation is rather abrupt. Attention is called to peculiar

occurrences near Sligo, and between Curwensville and Clearfield, where irregular bodies of flint clay occur in plastic clay beds, which are difficult to understand on the bases of differences of character in the original deposit. The flint clays usually occur in association with coal from which they are generally separated by some plastic clay. In such cases the flint clay may lie between, above, or below plastic clay and may occupy the entire thickness.

A peculiar mode of occurrence is described in which flint clay occurs as irregular fragments, from pellet size up to lumps 6 to 8 inches through, scattered throughout a sandstone. In other places the clay is in large masses, which grade into sandstone within short distances. It is suggested that peculiar sedimentary differences may have resulted in some of the flint clay beds. The irregular deposits are not understood, however. It has been suggested that these may be subaerial deposits.

Attention is called to the fact that these flint clays occur at a limited number of horizons only, and, although not persistent, yet over very wide areas. This vertical range is from a short distance below the Lower Kittanning coal up to 130 feet above the Upper Freeport coal. Flint clays of known or probable commercial importance are described and a few analyses are given.

Ries, Heinrich, Clays, occurrences, properties, and uses, 1908.

Discusses the various theories regarding plasticity such as (1) the water of hydration; (2) texture; (3) plate; (4) interlocking grain; (5) ball; (6) colloid; (7) molecular attraction; (8) effect of bacteria; and (9) weathering. Outlines in detail various methods of mechanical analyses and tests. The relation of chemical composition to properties and the effect of free silica and titanium are also discussed. Some of the more important physical properties are taken up. Quotes analyses of several high-grade flint clays. A brief note as to the occurrence and distribution of the fire clays, including the flint variety, and some of the various uses to which it is put. A general discussion of the methods of mining and manufacture is supplemented by illustrations of American practice. It includes also a brief statement of the known clay occurrences in each State.

Ries, Heinrich, and Leighton, H., History of the clay-working industry in the United States, 1909.

Makes brief mention of the discoveries of flint clay and subsequent development in Ohio, Missouri, Pennsylvania, Kentucky, and Maryland.

Galpin, S. L., Studies of flint clays and their associates: Am. Cer. Soc. Trans., vol. 14, p. 301, 1912.

A detailed study undertaken to determine the nature of the differences between plastic and nonplastic fire clays. The following summary is based upon geologic occurrences, dehydration tests, and microscopic examination: (1) Flint clays have been formed by the setting and recrystallization of fine-grained, largely colloidal sediments, which have been purified mainly through the agency of carbon dioxide in the waters transporting and depositing them and by the leaching action of plant roots. The products of recrystallization are mainly kaolinite with minor amounts of hydrated micas; (2) the "semiflint" or "soft clays" have been derived from the flint clays through metamorphism by pressure and heat, resulting in a conversion of much kaolinite into hydromicas and the development of a completely microcrystalline structure of coarser texture than that of the original flint clay; (3) the plastic fire clays associated with flint clays have resulted from long weathering of the "semiflint" or "soft clays" and are structurally more crystalline than the fire clays which have never been "set." They also differ from those clays in containing a higher percentage of hydromica, kaolinite in all probability forming the basis of other plastic fire clays; (4) the change from muscovite through hydrated or hydromicas to kaolinite may take place without the destruction of the original structure, indicating the possibility of an isomorphous series embracing all of these minerals; (5) knowledge of the micro structure and composition of a clay may be used to explain and predict peculiarities in its physical and chemical behavior.

Hoeing, J. B., Kentucky Geol. Survey, ser. 4, vol. 1, pt. 2, 1913.

Contains a short historical sketch of the Olive Hill and Ashland districts of eastern Kentucky. The two districts are considered separately because of the difference in origin, quality, and geologic age of the fire clays which are associated with the Mississippian limestone. The Olive Hill district includes approximately the western half of Greenup and Carter counties, the eastern and southeastern parts of Rowan County, and the northwestern part of Elliott County. The Ashland district includes the higher fire clays found in the coal measures in Carter, Greenup, and Boyd counties, the most prominent beds occurring near the horizon of the "Ferriferous" limestone.

The author considers that part of the coal at least "has been formed from decomposition and solution of the Mississippian limestone in place, the other deposits have been formed as a redeposition product from the breaking up of limestone and flint clays." A distinction is drawn between "residual flint clay" and "transported or sedimentary flint clays," the deposits in and below the conglomerate being referred to the latter class. The evidence indicating the sedimentary origin of some of the fire-clay deposits of the Olive Hill district and of the residual origin of a large per cent of the bowlder flint clays is summarized. Mention is made of the flint clays of Missouri, Kentucky, Pennsylvania, Ohio, and Maryland, and the author concludes that the flint of the Olive Hill district is lower stratigraphically than that of the last three States named. Tables showing the results of fire shrinkage, porosity, and melting-point tests on various flint and plastic clays and on special brick are quoted.

The geologic occurrence of the clays is briefly discussed and the various deposits are considered, many analyses being quoted. Short descriptions are given of the various plants in each district. One chapter is devoted to the origin and nature of clay, its classification as to origin and use, minerals present, and chemical and physical properties of clays.

A report on the technology of Kentucky clays, including chemical and mechanical analyses and burning tests, by H. D. Easton, is included in this volume.

GEMS AND PRECIOUS STONES.

By Douglas B. Sterrett

INTRODUCTION.

The precious and semiprecious stone mining industry of the United States in 1913 was marked by a fairly large output of sapphire, a real advance in the work of testing the Arkansas diamond field, a greater activity in the Nevada opal field, and by a decrease in the output of the majority of the other gem minerals mined. The sapphire came chiefly from Montana and consisted of both blue and varicolored gems and culls for mechanical purposes. In Arkansas one diamond-washing plant was in operation about three months and recovered several hundred diamonds, and the construction of another plant was pratically completed. Many new claims were located in the Nevada opal field, development of which, along with those previously opened, resulted in a fairly large output of beautiful gems.

Prospecting work at the emerald mine near Shelby, N. C., was continued during the first part of 1913, but the last find of emeralds was made in August, 1912. Prospect work was renewed at the Ruby mine in Cowee Valley, Macon County, N. C., and is being continued into 1914. The output of the gem minerals tourmaline, spodumene, etc., in southern California was small, but some good gem material was obtained. The exploitation of the less valuable native semiprecious stones has continued with fair success, but the increasing use of cheap, artificial products is making big inroads on this industry.

ACKNOWLEDGMENTS.

The writer wishes here to express his appreciation of the assistance given by a large number of people in the preparation of this report. It is not possible to name individually all of those who have supplied information, such as statistics of production and names of new producers, but such help is greatly appreciated. Other persons have assisted either by supplying detailed information, loaning specimens, or rendering personal assistance in the examination of mines and prospects, and acknowledgment is here made of the kindness of F. M. Myrick, of Johannesburg, Cal.; Joseph Ward, of Barstow, Cal.; Scott Lewis, of Los Angeles, Cal.; Don Maguire, of Ogden, Utah; A. L. Delkin, of Seattle, Wash.; J. H. Mosher, of Glendive, Mont.; Paul E. Hanson, of Billings, Mont., George Howe, Robert Bickford, and C. B. Hamilton, of Norway, Me.; Perien Dudley, of Buckfield, Me.; F. H. C. Reynolds, of Boston, Mass.; Leon Allen, of Keene, N. H.; F. M. Lynch, of Birmingham, Ala.; A. Q. and H. L.

Millar, of Murfresboro, Ark., and St. Louis, Mo.; the late H. E. Bemis, of Prescott, Ark.; Mr. Warren, Superintendent of the Ozark Diamond Mining Corporation; J. D. Endicott, of Canon City, Colo.; George H. Weed, of Florissant, Colo.; George H. Marcher, of the Pacific Gem Co., of Los Angeles, Cal.; J. J. Kinrade, of San Francisco, Cal.; Gordon Surr, of San Bernardino Cal.; James Shea and Dr. Burt Ogburn, of Phoenix, Ariz.; Maynard Bixby, of Salt Lake City, Utah; George D. Mathewson and Deb Roop, of Denio, Oreg., J. B. Kiernan, of Beatty Nev.; A. A. Turner, of Boston Mass.; A. D. Hudson, of El Paso, Tex.; Frances Holstein, of De Roche, Ark.; N. E. Isbell, of Cincinnati, Ohio; Reginald Fenton, of Coronado, Cal.; L. M. Richard, of Stamford, Tex.; Sam Awalt and Lee McGehee, of Katemcy, Tex.; C. J. Worlie and J. W. Bishop, of Streeter, Tex.; J. W. Ware, of San Diego, Cal.; G. W. Morgan and F. B. Horne, of Crescent, Nev.; Gus Hamstadt, of Niton, Cal.; Allen Culver, and George A. Camphuis, of Brice, N. Mex.; W. C. Hart, of Manitou Springs, Colo.; and Prof. J. P. Rowe, of Missoula, Mont.

AGATE.

CALIFORNIA.

A deposit of fine blue chalcedony or agate was prospected during 1913, by F. M. Myrick, about 37 miles east of Johannesburg and about 2 miles northeast of Lead Pipe Spring, in the Death Valley region, California. The deposit was discovered by Joe L. Foisie and located in January, 1911, as the Sard claim. The title was allowed to lapse and new locations were made by Mr. Myrick, with the approval of Mr. Foisie, in May, 1913, under the names Blue Moonstone and Moonstone claims. The region is desert with rough lava capped hills and washfilled valleys, which drain northward. The chalcedony deposits are about 3,000 feet above sea level.

White to gray ash and conglomeratic tuff beds occupy the lower ground, with a heavy flow of dark-red rhyolite overlying and capping the hills. This rhyolite is vesicular in places and has been badly fractured and crushed. Other lava flows occupy higher hills and mountains to the south. In places a layer of gray perlite is exposed at the base of the rhyolite, but the contact between the rhyolite and the underlying ash beds is generally concealed by loose débris and talus. Blue chalcedony has been found over parts of three claims in the lower portion of the rhyolite or loose in the talus below. The best deposit is on the Blue Moonstone claim on the north side of a small knob. The lower contact of the rhyolite capping this knob is concealed by talus, and, so far, the blue chalcedony from this claim has been picked up from the talus where it occurs in lumps of less than an ounce to several pounds weight associated with the red rhyolite matrix. It is probable that prospecting above the talus bearing the chalcedony would uncover the matrix in place. The occurrence on the other claims is similar, but a little of the chalcedony was found in place in the vesicular rhyolite.

The blue chalcedony occurs as fillings in joints, fractures, and vesicular cavities in the rhyolite forming veins and irregular masses. Much of it is very delicately banded, showing straight, curved, or angularly bent layers as in fortification agate. In some specimens the agate passes into crystal quartz, lining or filling geode cavities. In others, the cavities are lined with rounded mammillary deposits of chalcedony. Small fragments of red rhyolite are inclosed in some of the deposits of chalcedony.

Various grades of chalcedony are found ranging from dull semi-translucent to highly translucent. The range of colors noted are dull bluish-gray, bluish-gray with a tint of green, blue tinted with lavender, and lavender. The brighter colors are not so common as the dull ones, and a quantity of the chalcedony which appears strongly colored in the hand specimens proves dull and uninteresting when cut. The apparent depth of color of the rough material is due, in many cases, to the bulk of the chalcedony or the shading caused by the inclosing shells of rhyolite.

The cut stones show the various colors mentioned above with or without banding. The dull-colored stones have no special beauty, but the stronger colored gems are very pretty and can be used in various forms of jewelry, such as cuff buttons, scarf pins, brooches, pendants, and bead necklaces. Very pretty bead necklaces have been made up with beads of the lavender-blue chalcedony alternating with rose quartz. The color of the blue chalcedony is not so pleasing under artificial light, but the better gems are not devoid of beauty even there. Some gems have been cut inclosing patches of the red rhyolite matrix with odd effects. Cut gems sold at the California beaches have been hailed as "blue moonstone," the people recognizing the similarity of this chalcedony and the white or gray varieties wrongly sold as "moonstone" along the California coast.

A deposit of cloudy amethyst-colored chalcedony associated with a peculiar leathery-white asbestos-like mineral was opened by Mr. Myrick near his bloodstone deposit described later under jasper. The chalcedony occurs in lenses in a gash vein cutting altered basalt. The vein filling consists chiefly of the chalcedony and a mashed asbestos-like material. The latter is hydrous silicate of magnesium of leathery claylike consistency when moist. It may be an impure hornblendic mineral or possibly allied to meerschaum. This chalcedony has not been tested as a possible ornamental stone, though the color is rather attractive. Lumps of the chalcedony left exposed to the desert sun for several months bleached to a dull gray to a depth of about one-fourth of an inch.

Agate or chalcedony, containing bright-red inclusions, found in the Death Valley region of San Bernardino County, Cal., was mentioned in this report for 1911. It was discovered by F. M. Myrick, after whom it was locally called "myrickite." The deposit is about 45 miles north of east of Johannesburg and about 15 miles northeast of Lead Pipe Spring. According to Mr. Myrick the mineral is obtained from a shallow shaft in a rough lava-capped hill. The chalcedony occurs in bunches and small masses scattered through the lava. The mineral consists of translucent gray chalcedony and a little white chalcedony through which bright red spots and patches of color are irregularly distributed. The majority of the color occurs in irregular mosslike patterns and is exceptionally bright vermilion-red. Robert Masterson, of Johannesburg, suggested that the coloring was due to cinnabar (mercury sulphide) and that was found to be the case on making blowpipe tests on the mineral. The cut gems show striking contrasts between gray, white, and vermilion-red and should satisfy the desire of the wearer for bright colors.

Mr. Myrick has hesitated placing too much of the "myrickite" on the market since he has discovered that the rich color darkens after long exposure to light. Material left on the dump exposed to the desert sun for a year was discolored, showing a dull purplish red. To what extent the color will deteriorate under conditions of wear in jewelry is not known, but it is not believed the discoloration will be sufficiently rapid to cause the material to be discarded for gem use. The deposit will be tested for its value as a possible source of quicksilver as well as for gem material.

Specimens of chalcedony from the Mohave desert region of California were received from Mr. Scott Lewis, of Los Angeles, Cal. Some of this material was translucent, dimly banded pale lilac or amethystine agate. Specimens cut approximately parallel with the banding show a mottled, cloudlike effect, which is best seen in transmitted light. This lilac-tinted chalcedony has been sold under local name of "Mohave moonstone." Another variety is translucent gray chalcedony with pure white patches or tufts, like snowflakes, scattered through it. The white may be opal occupying pore space in the chalcedony. This variety has been sold as "frost stone" in California. The "Mohave moonstone" and "frost stone" are found on a malpais-capped hill, about 10 miles from Muroc station, on the Santa Fe Railway. Another variety consists of translucent chalcedony mottled with white and dark leek-green streaks, possibly due to inclusions of chloritic material. This comes from near Rosamond, Kern County.

Various types of chalcedony were sent to the Survey by Mr. Joseph Ward, of Barstow, Cal., from deposits he had discovered in the Death Valley region. Among these were gray, blue, red, yellow, and yellowish-green chalcedony. Some of this material was banded like agate, with or without colored layers. Most of the yellowish-green variety contained inclusions of white tufts or patches resembling opal. Several of these varieties of agate were suitable for cutting for the semiprecious stone trade, and the yellowish-green variety, which Mr. Ward calls "amberine," might meet a good sale in the tourist trade.

COLORADO.

Blue chalcedony has been handled by J. D. Endicott, of Canon City, Colo., for several years. Mr. Endicott obtains his supply from his claims on Thirty-one Mile Mountain, about 7 miles west of Guffy, in Park County.

MONTANA.

The fine quality of the Montana moss agate and mocha stone was mentioned in this report for 1911, with a brief description of a collection loaned to the Geological Survey by Mr. J. H. Mosher, of Glendive, Mont. Mr. Mosher has again kindly loaned the Survey another collection of selected cut gems, some of which are mounted in filigree gold settings. Mr. Paul E. Hanson, of Billings, Mont., also kindly loaned a collection of cut stones and furnished rough specimens of the agate, with notes on their occurrence.

All the moss agates cut for jewelry are obtained from pebbles and cobbles gathered along Yellowstone River and its tributaries and from the mesas and buttes for many miles away from the river. These agates are derived from gravel beds, but their original source is not known. They occur in rounded cobbles, some of which are covered with a chalklike but hard coating of silica. Some of the cobbles are geodes composed of chalcedony or agate containing cavities lined with quartz crystals. Such geodes are found in calcareous formations at some localities. Mr. Hanson states that he has observed many such geodes in place, at the headwaters of Boulder River, in some of which a man could stand upright. Nowhere has he observed in the chalcedony of the geodes in place the mosslike markings which are found in similar goedes and fragments in the gravel beds lower down the rivers. He therefore believes that the dendritic markings have been imparted to the agate after it has been liberated from the original rock matrix in the mountains.

The dendrite stains of the moss agate are due to thin films and deposits of oxides of manganese and iron in the seams and pores of the chalcedony. These stains are introduced into the agate by the solutions which spread by capillary action through every seam from the larger channels into still other channels and finally into the pore spaces of the chalcedony. In this way various markings of black, brown, and red in dendritic shapes are produced. The quality of the gems that a fragment of rough agate will yield depends in a large measure on the skill of the lapidary. The rough agates are broken or sawed into slices and gems are developed from those parts which are favorably marked. The majority of the dendrites are black or dark brown. Red stained agates are less common, but furnish beautiful gems. Much of the agate is of fine quality, with pure translucent light-gray to bluish-gray color. Some of the agate is banded but much of it is not visibly so.

Among the cut stones loaned by Mr. Mosher, of Glendive, are the following:

A flat rectangular stone 7.6 centimeters long and 2 centimeters wide, with beveled edges and corners. This contains about 20 black dendrites ranging from 1 to 8 millimeters high, occupying scattered positions, such as may be seen in a group of wooded isles in a lake or along the coast of a northern country. The agate is slightly banded and shows a hazy effect before distant islands and trees.

An oval stone 2.9 by 2.0 centimeters shows a landscape with or without water, according to the fancy of the viewer, with a group of trees to one side and smaller trees or shrubbery in the middle and to the other side. This agate is delicately banded and of fine, pure translucent gray quality.

Another slightly smaller oval gem portrays a lake with narrows in the distance, wooded shore lines, and islands with perfect reflections of the trees in the water. The dendrites are reddish-brown and there is a slight brownish clouding of the water area.

In two closely matched oval stones about 2 by 1.4 centimeters there are marsh scenes with a dead tree, sedge grass in autumn colors, and water.

A small cabochon gem 1.8 by 1.2 centimeters contains a perfect representation of an Indian tepee under two tall slender trees. Even the poles of the tepee are plainly visible..

Another small cabochon gem 2.0 by 0.9 centimeters shows a perfect grove of small bushy trees with brown foliage and black trunks. The lower part of agate contains a peculiar yellowish stain.

A beautiful pendant, 3.7 centimeters long, 1.5 centimeters wide at the lower end and tapering to 3 millimeters at the top, shows a dendrite-like pine tree in fine translucent gray agate.

A number of gems contain one or more dendrites resembling many varieties of moss, ferns, or seaweeds with delicate spreading branches. Among them is a thin, round cabochon stone 2.3 centimeters in diameter, which shows three branching ferns or seaweeds with extremely delicate structure. In other stones various objects, such as the "Mexican eagle" with spread wings, the Austrian eagle, a battleship with fighting top, etc., are readily recognized.

Among the cut stones loaned by Mr. Hanson, of Billings, are some showing beautiful dendrites resembling trees, patches of moss, or ferns, and a few with good landscapes. Mr. Hanson's collection of rough and cut agates was prepared with a view to showing the mode of occurrence of the moss agate and the method of elaboration.

OREGON.

Mr. Don Maguire, of Ogden, Utah, reports the occurrence of fine brown-stained moss agate on McAllisters Butte, near Ochoco River, in Crook County, Oreg.

WASHINGTON.

Specimens of rough and cut lavender-blue chalcedony were received from Mr. A. L. Delkin, of Seattle, Wash. The rough agate was gathered from the sage-brush country around Ellenburg and is reported to be rare. The material is very similar in appearance to that from Myrick's prospect in California, described above. Mr. Delkin reports a good sale for the cut gems.

AMETHYST.

MAINE.

Of the several localities where amethyst has been found in Maine one was examined in June, 1913. This is on Deer Hill in the town of Stow, 1¾ miles N. 30° E. of North Chatham, N. H. Deer Hill was also visited by E. S. Bastin [1] in 1906, but more prospects have been opened since that time. The deposit is on the land of Chester Eastman in the ridge extending south from Deer Hill. One of the new prospects is 20 feet long and 8 feet deep, and other similar pits have been opened within a distance of 150 feet northeast along the west side of the ridge. The old work consisted of numerous small pits in the gravelly soil of the ridge for a distance of about 100 yards northeast of the later work.

The country rock is chiefly granite gneiss, but pegmatite covers much of the ridge at the amethyst locality and is the rock opened by the prospects. A large ledge of quartz is inclosed in the pegmatite having a strike of N. 40° E. and a dip of 35° SE. Geode-like pockets of quartz crystals were opened in the later work along the contact of

[1] Geology of the pegmatites and associated rocks of Maine: U. S. Geol. Survey Bull. 445, p. 102, 1911.

the quartz ledge with the feldspathic part of the pegmatite. No amethysts were left around the new openings, if any were found there, but abundant opaque white and transparent colorless quartz crystals are scattered over the dumps. Numerous pale amethyst-colored quartz crystals were observed around the earlier pits to the northeast. Some of these are quite clear.

An amethyst crystal measuring 2½ by 3 inches was plowed up in a field on the land of Ezra Healds, 1 mile north of North Chatham and about half a mile southwest of the Deer Hill locality. This crystal is irregular in shape and consists of both amethyst and smoky quartz. The colors are not evenly distributed, but are streaked together in parts of the crystal. A portion of the crystal has a rich amethyst color.

Specimens of fine amethyst were seen in the possession of George Howe, of Norway, Me., obtained from a prospect on Pleasant Mountain, in the town of Denmark. These amethysts were rich dark purple and showed a strong garnet-red under artificial light, like the better Siberian amethysts.

NORTH CAROLINA.

A few amethystine quartz crystals and one amethyst of good quality have been found on the R. C. McConnell place, about 3 miles southwest of Mount Ulla, in Iredell County, N. C. The good specimen was found some 20 years ago by the late N. H. Marsh. This was a partly water-worn crystal about 2 inches long and 1¾ inches thick. A large part of it was flawless, with pleasing medium dark purple color. The value of this crystal was not large, but the possibility of a deposit being found should not be overlooked.

SOUTH CAROLINA.

Earle Sloan [1] has mentioned the occurrence of amethyst at several places in the Piedmont counties of South Carolina, especially in Abbeville and Anderson counties. Two localities were visited in 1913 in Greenwood County where amethyst had been reported found. These were on the land of R. M. Haddon, of Abbeville, 1½ miles southeast of Shoals Junction, and of R. W. Dunn, 1 mile southwest of Shoals Junction, both about 3 miles southeast of Donalds.

Amethystine quartz is found at several places on the Haddon plantation, but the best indications are in an area of about 100 feet wide and 250 feet long, north and south, in a field near the road leading to Donalds. The soil in this field is light, sandy, and gravelly, formed by the disintegration of mica gneiss and granite. Numerous crystals of amethystine to nearly colorless quartz were found in the field. Some of these were clear, but none were of sufficient depth of color to warrant cutting for gems. No prospect work has been done at this place and only surface specimens were seen. A trench should easily locate the vein or veins and a little digging would show whether amethysts of value could be expected.

On the R. W. Dunn place amethystine and colorless quartz crystals have been found in the cultivated fields at several places. No regular

[1] Catalogue of the mineral localities of South Carolina: South Carolina Geol. Survey Bull. 2, ser. 4, p. 157, 1908.

prospecting has been done for them and accordingly only surface specimens have been found. The fields have light sandy soil with scattered blocks of hornblende gneiss through it, such as might be derived from the disintegration of granite with hornblende gneiss inclusions.

Amethyst is also reported on the place of J. T. Algary, about 4 miles south of east of Donalds. A good specimen consisting of a cluster of clear pale amethyst crystals from the Algary place was seen at the home of T. F. Drake, of Shoals Junction. This cluster measured 8 inches across and 3 inches thick, and contained some crystals 2 inches thick.

BERYL.

NEW ENGLAND.

Beryl suitable for specimens and gems have been found at many localities in New England. Some of these have been mined for that mineral alone and others have been worked for feldspar and the beryl has been saved as a valuable accessory mineral. In Connecticut fine golden beryl has been obtained from near New Milford, Litchfield County, and during 1913 good aquamarine was found near East Hampton, in Middlesex County. In Maine beryl is widespread in the pegmatites worked for feldspar. Several localities have yielded gem beryl, and among these are prospects in the towns of Buckfield and Stoneham. In Massachusetts Goshen and Royalston have afforded beautiful gem beryl. In New Hampshire beryl is abundant in many of the mica-bearing pegmatites, and some of these have yielded good gems.

A brief examination of several of the New England beryl localities was made in June, 1913. Unfortunately time for this work was so limited that none of the Connecticut localities were visited.

MAINE.

Exceptionally fine beryl gems have been found in the town of Stoneham, Me., at scattered localities. Some of these were visited, but very little local interest was shown in the possibilities of these deposits at that time and only outcrops and old prospects were available for examination. The writer was fortunate in having Mr. Wesley Adams, of North Lovell, guide him to some of the many prospects with which he is familiar. Among these were Sugar Hill, Durgin Mountain, and Chapman Hill or Thousand Acre Hill.

Sugar Hill is about 3 miles northwest of North Lovell. Beryl and associated minerals have been found at several places on the south side of the hill on the land of Edwin McAllister. At one place a prospect pit had been opened in loose talus or drift material a few yards below a rather flat-lying cliff-forming ledge of pegmatite. In this loose drift were found fragments and crystals of beryllonite, a phosphate of beryllium and sodium, beryl, smoky, clear, and transparent gray quartz, mica, and potash feldspar. E. S. Bastin[1] mentions also apatite, cassiterite, columbite, and triplite as having been found here. The pegmatite ledge outcrops about 40 feet higher up on the hillside and, at a distance of about 150 feet northeast of

[1] Geology of the pegmatites and associated rocks of Maine: U. S. Geol. Survey Bull. 445, p. 99, 1911.

the pit, incloses numerous beryl crystals. These crystals are exposed in the bare rock associated with feldspar, opaque and translucent quartz, and a little mica. They range up to 2½ inches in diameter, and one crystal measured about 1½ inches by 10 inches. The pegmatite is exposed for thicknesses of 6 to 12 feet along its outcrop and was followed about 200 feet farther northeast. In places along this outcrop nodules or small masses of translucent quartz are exposed. The pegmatite is in contact with coarse granite above, but the country rock is chiefly mica gneiss intruded by granite and pegmatite in masses of various sizes. About one-third of a mile farther northeast a large pegmatite forms the floor of a bench on the hillside and outcrops as a wall around its lower side. Several prospects have been opened within a distance of 200 feet east and west in the floor of the bench and in these, greenish, yellowish-green, and pale-golden beryl has been found. Most of the crystals are opaque, but some contain translucent and clear portions suitable for gems. The pegmatite is composed of coarse potash feldspar crystals, massive quartz, in part translucent, and muscovite mica. In the wall of the pegmatite below the bench there was an impression in the pegmatite from which a hexagonal crystal, evidently beryl, 3 by 12 inches had been removed. This crystal was larger than those found in the prospects on the bench.

Durgin Mountain is 4 miles N. 30° W. of North Lovell. The prospect visited is on the east side of the mountain on the land of Ernest Bartlett, of East Stoneham. A small prospect had been blasted out of an outcrop of hard pegmatite on the slope of the hill. The pegmatite above the pit is covered with soil and grass. Potash feldspar crystals, 1 to 2 feet thick, are exposed in the pit along with large quartz segregations, some of which are beautifully translucent. Muscovite and biotite mica are both present. Beryl is abundant in crystals ranging up to more than 2 inches thick. They are mostly opaque or only translucent, but some fragments of crystals were seen on the dump having small brilliant transparent portions that were dark golden yellow, yellowish green, bluish green, and nearly colorless. Most of the beryl crystals seen were exposed for a distance of 15 feet in a streak or belt extending north across the pegmatite outcrop.

The beryl locality on Chapman Hill is about 3 miles due north of North Lovell. Two prospects have been opened on the summit of the hill near the east side, one in a field and the other one-fourth mile south in the woods. At both places the openings are small, not over 8 feet deep. The country rock at each place is biotite granite gneiss, but the relations between it and the pegmatite were not exposed. At both prospects rough crystals of orthoclase or microcline, coarse quartz segregations, and crystals of mica, black tourmaline, cleve-landite, and beryl were observed. Small pieces of blue and bluish-green beryl of good color were found on the dumps, and these prospects are reported to have yielded blue beryl of fine color.

Fine golden beryl and aquamarine are reported to have been found on the land of Charles Andrews, on Speckled Mountain, in the town of Stoneham, about 5 miles northwest of North Lovell.

George F. Kunz[1] described two fine beryls picked up in pastures in Stoneham in 1881. One of these was cut into a bluish green brilliant gem weighing 133¾ carats of nearly perfect quality and into

[1] Gems and precious stones of North America, pp. 92–93.

smaller gems weighing altogether over 300 carats. The other crystal was smaller, one half having a transparent faint green and the other a translucent green color.

Beryl has been prospected at several places in the town of Buckfield, Me. Besides the more common aquamarine varieties, golden beryl and colorless to bluish caesium beryl are found. Some of the localities which have yielded chiefly cæsium beryl along with a few other minerals of interest were visited.

The Lewis mine, worked by Perien Dudley, is about 2 miles southwest of Buckfield. It is in the eastern side, near the summit of a low but steep-faced hill. The work consists of two connecting open cuts extending up and down the hillside for a distance of about 120 feet. The lower cut has a direction of N. 20° W. and the upper one N. 80° W. up the hill. They range from 5 to 15 feet in depth and 10 to 20 feet in width. The country rock is quartz-biotite gneiss with layers of typical biotite schist. The gem-bearing rock is pegmatite lying approximately conformable with the gneiss which strikes about N. 30° E. and dips 30° SE. Biotite schist overlies the pegmatite on the south side of the cut, but north of this the pegmatite appears to outcrop as a blanket ledge. It had not been cut through in the open cuts and the thickness is therefore not exposed. The pegmatite is rather coarse, but uneven grained. Orthoclase or microcline occurs in rough crystals several inches across and in graphic intergrowth with quartz. Translucent green and bluish-green tourmaline with occasional pink crystals have been found frozen in the pegmatite along with muscovite, biotite, and clevelandite. Pockets ranging from small size to 2 feet in diameter are reported to occur scattered irregularly through the pegmatite. Colorless cæsium beryl was found frozen in the pegmatite and also in pockets. Arsenopyrite, or the related mineral löllingite, is present in the pegmatite associated with various minerals.

Very fine cæsium beryls have been obtained from the mine of J. H. Fletcher, a little over 2 miles southwest of Buckfield, Me., and about one-fourth mile west of the Lewis mine. The Fletcher mine was also worked by Perien Dudley and was opened by a cut extending north into the hillside. The beryls occur in pegmatite inclosed in quartz-biotite gneiss. The feldspar of the pegmatite is grayish othoclase or microcline which occurs in crystals up to 2 feet thick. Dark greenish-black tourmaline and clear light yellowish-green muscovite are abundant. Many small fragments of brilliant transparent colorless and pale greenish beryl were observed in the workings. Similar beryl in larger pieces would yield gems of exceptional brilliance. The largest beryl crystal found is reported to have been nearly 4 inches in diameter with one end composed of clear gem material.

Beryl with other interesting minerals has been found in several prospects on the north slope of a hill 2½ miles southwest of Buckfield, Me., and about half a mile south of the Fletcher cæsium beryl mine. These different prospects have been opened by Perien Dudley and W. S. Robinson. Much of the beryl found in these prospects is nearly colorless or pale greenish, and contains cæsium. At two or more of the prospects, pollucite, a hydrous silicate of cæsium and magnesium, is found along with beryl. In one opening masses of pollucite 8 to 10 inches across were found. A few crystals of opaque or translucent colored tourmaline have also been found in the pegmatites in this hill, but most of the tourmaline is dark green or nearly black. Among other minerals associated with the beryl are amblygonite, clevelandite, muscovite, arsenopyrite or löllingite, and cassiterite.

MASSACHUSETTS.

Beryl of especially fine quality has been mined at Beryl Hill, 2½ miles N. 68° E. of Royalston, Mass., by F. H. C. Reynolds, of Boston. Beryl Hill is a low, flat topped hill partly cleared for pasture on the summit and west side. Five openings have been made, four on the summit and one a short distance below, on the west side. The openings are on two approximately parallel outcrops of pegmatite about 80 yards apart extending in a northwest direction across the summit of the hill. A small glacier-made depression lies between the two outcrops. Two pits are located on the pegmatite on the southwest, one at the brow of the hill and the other on the slope about 30 yards northwest. This pegmatite outcrops for about 100 yards southeast to the opposite side of the summit. The northeast pegmatite outcrop extends 100 yards from a pit on the east side of the hill across the summit to a trench on the west side with another pit between these. From the trench the outcrop extends more than 100 yards about N. 20° W. along the edge of the hill. None of the openings are large, the deepest being only 12 feet deep and the largest a shallow trench 60 feet long.

The country rock is chiefly mica gneiss cut by biotite granite. The strike of the gneiss varies from northwest to N. 15° E. and the dip is also variable. The relation between the mica gneiss and granite are not well exposed in the workings, but the granite appears to merge into the pegmatite in places. In one of the openings biotite diorite is in contact with the pegmatite and granite. The texture of the pegmatite ranges from that of coarse granite to rock in which the individual minerals are more than a foot across. Most of the feldspar of the pegmatite is the buff-colored to pink potash variety, but some albite is present. Some of the feldspar occurs in rough crystals and other is graphically intergrown with quartz. Much of the quartz occurs in light smoky gray masses or segregations. Among other minerals of the pegmatite besides beryl are muscovite in crystals up to 3 inches across, a little biotite, black tourmaline, and dark-red garnets.

Beryl has been found in hexagonal crystals ranging from small size up to 2 inches in diameter and of varying length. One fine specimen crystal, of good bluish-green color with some gem material in one end, is 11 inches long and 1½ inches thick, This crystal is a nearly perfect hexagon, but has been broken into three sections. With the exception of a small fragment at the lower end the whole has been preserved and cemented together and appears practically perfect. The crystal is attached to a mass of granular gray quartz with a little mica adhering. Another crystal in a quartz matrix has pyramidal terminations. Many perfect crystals of one-half inch to three-fourths inch in diameter have been obtained, most of them in the granular smoky gray quartz. Another fine gem specimen attached to quartz, feldspar, and mica measures seven-eighths inch by 3¾ inches long. Part of this crystal is flawed, but good blue perfect gems of several carats weight could be cut from the clear portions.

The Beryl Hill gems range in color from light to dark aquamarine, fine blue, yellowish green, to golden. Many very fine bluish-green stones have been cut, and among those seen was a table-cut stone of 13¾ carats. The blue beryls of better quality are rarely excelled by those from other localities in brilliance or beauty of color. Among cut gems of this quality a 12½ carat brilliant cut stone was especially beautiful.

NEW HAMPSHIRE.

A deposit has been worked for gem beryl on Melvin Hill, 2¼ miles S. 25° W. of Grafton, N. H., by F. H. C. Reynolds, of Boston. Two openings were made about 150 feet apart at the east side of the hill and about 400 feet higher than the valley below. The principal working is a quarry with a working face over 80 feet long in a N. 60° W. direction along the hillside and 5 to 15 feet high. The country rock is quartz-biotite gneiss which strikes north with a nearly vertical dip and some folding. The pegmatite cuts across the foliation of the gneiss with a north of west strike and a dip of about 20° N. The contact with the gneiss is not regular but rolling, with a few smaller beds of pegmatite extending out into and parallel with the foliation of the gneiss. The bottom of the pegmatite is not exposed in the workings.

The pegmatite is composed of the usual minerals, potash feldspar, quartz, and mica, with other associated minerals. The feldspar occurs in large pure crystal masses or graphically intergrown with quartz. The quartz is mixed through the pegmatite in grains and massive irregular segregations. It is either white or smoky and some of it is quite translucent. Muscovite mica of good quality occurs rather abundantly and would pay part of the mining cost if saved. Much biotite mica was observed on the dumps, and in many specimens biotite was intergrown with muscovite. Among other minerals in the pegmatite are black tourmaline, red garnets, green apatite, and beryl. Beryl was evidently rather plentiful for there were many fragments of broken crystals on the dumps. Some of the crystals measured several inches across, and most of them were opaque or only translucent. In some of the crystals Mr. Reynolds reports clear gem beryl was found, the golden variety of which was especially finely colored. Light golden beryl gems weighing several carats were cut from some of the crystals, but the dark golden beryl crystals yielded only gems of less than 1 carat weight. The colors observed in the beryl fragments on the dumps were light yellow to rich golden yellow, yellowish-green, and light to dark aquamarine green and greenish-blue.

The other opening of the Reynolds Beryl mine is south of the main working. A pit was made in pegmatite cutting biotite granite and quartz-biotite gneiss. The pit and dump were overgrown with brush and little could be seen.

Another beryl deposit was worked about one-third of a mile west of the Reynolds mine, near the summit of Melvin Hill, by the Columbian Gem Mining Co. The gem beryl found was mostly the aquamarine variety. Another beryl prospect has been worked about 2 miles west of the Reynolds mine and about 1 mile south of Prescott Hill, by Franklin Playter, of Boston.

None of these mines was in operation during 1913.

A new beryl prospect was opened in 1913 on the old Porter K. Filbert farm, 1½ miles S. 75° W. of South Danbury, in the town of Wilmot, N. H. The work was done by J. E. Lovering, of Grafton, N. H., for Charles Murphy, of Detroit, Mich., the present owner. The deposit is on the west end of an elongated rounded hill about 200 feet higher than the road on the west. At the time of examination the pegmatite had been stripped of soil covering for about 200 feet and small prospects had been blasted out. The country rock is chiefly coarse porphyritic biotite gneiss which strikes northeast with a variable but high southeast dip. This gneiss is cut by a medium-grained granite, and the gem-bearing pegmatite cuts both rocks near their contact. The pegmatite strikes about N. 75° E. and has a nearly vertical dip. Through most of the exposed parts the pegmatite varies from 6 inches to 2 feet in thickness, but in one place it bulges to nearly 8 feet in thickness. The texture is fairly coarse, potash feldspar crystals up to 8 inches thick being observed. Much of the quartz is smoky gray, and some occurs crystallized along with small albite crystals in pockets. Black tourmaline and muscovite are other minerals associated with the beryls. The beryl crystals occur unevenly distributed through the pegmatite. They range from small size up to more than 2 inches in diameter. Most of the crystals are opaque or translucent yellowish green, pale green, or good aquamarine in color, but some clear gem crystals are found. Mr. Lovering reported finding a crystal nearly 2 inches in diameter and containing some aquamarine of gem quality.

A small prospect has been opened for feldspar and beryl on Stuart Hill, 3 miles southeast of Grafton, in the town of Wilmot. This hill is called Severance Hill on Hitchcock's Atlas of New Hampshire. The hill is composed chiefly of course porphyritic biotite gneiss which strikes about north with an east dip. A large pegmatite cuts across the north end of the hill forming a small cliff or break in the hill slope. The south contact of the pegmatite with the gneiss approximates east and west, with many minor irregularities. The pegmatite is of very uneven grain which ranges from coarse, with potash feldspar crystals 4 feet thick, down to a texture resembling coarse granite. A dike of medium-grained granite cuts the porphyritic gneiss and the pegmatite into which it appears to merge. Among the minerals observed in the pegmatite, besides feldspar and quartz, were black tourmaline, muscovite and biotite mica, and beryl. The beryl was rather plentiful in crystals ranging up to 4 inches in diameter. They were aquamarine-colored, yellowish-green, and yellow, but mostly opaque or translucent. A few pieces nearly clear enough for cutting into small faceted gems were observed and some of the translucent aquamarine-colored would serve for cabochon gems.

Gem beryl has been found at the Island mica mine, 2 miles N. 20° E. of Gilsum, N. H. During the course of mica mining a large number of beryl crystals and fragments, some of which contained gem material, were thrown on the dumps. The dumps have since been picked over by collectors and the best beryl removed. The mine was worked by three open cuts and a short tunnel. Two of the open cuts were at the east foot of a small knoll (glacial "roche moutonée") standing about 25 feet above the surrounding swampy ground. These open cuts were 20 and 25 feet deep, respectively, but are now filled with water. The third cut was made back into the knoll at a level a few feet above the lower cuts, but still 18 or 20 feet lower than the summit of the knoll. The country rock is biotite gneiss carrying much black tourmaline near the pegmatite. The gneiss has been strongly folded and crinkled near the pegmatite and accordingly has a variable strike and dip. The pegmatite is very irregular in shape, having a westerly trend across the knoll. It incloses streaks of biotite gneiss, and the surrounding gneiss has been injected by many small lenses and streaks of pegmatite. The pegmatite contains large segregations of gray and smoky quartz, some graphic granite, orthoclase and albite feldspar, pockets or bunches of mica (both muscovite and biotite), black tourmaline, green apatite, a few red garnets, and numerous beryl crystals. A quantity of mica of good quality was obtained during mining. The beryl crystals range up to a foot in diameter and are vari-colored; some are bluish, bluish green, yellowish green, and light and dark golden yellow. Much of the beryl is translucent, and parts of some of the crystals are transparent and flawless so that perfect gems can be cut from them. Small dark golden beryl of exceptional beauty has been cut from clear portions of large crystals. Much of the translucent beryl could be used to advantage for cabochon gems and beads.

Beryl Mountain, in the town of Acworth, N. H., has long been famous for the size and abundance of its beryl crystals. According to Mr. Eugene Crossett [1] owner of the prospect, an attempt was made in 1884 to quarry a large beryl crystal here for use as a tombstone over the grave of Emerson at Concord, Mass. Difficulty was experienced in removing a crystal without fracturing and the attempt was abandoned. Later a bowlder of rose quartz was adopted for this purpose. Mr. Crossett states that some specimen beryl was removed at this time and a quantity of feldspar and quartz were shipped for the manufacture of pottery, glass, and sand paper.

Beryl Mountain is a steep-faced hill or ridge rising about 200 feet above the road around its base. It has a north-northeast trend and is narrow near the summit. Prospects have been opened on the east side of the northern end about 25 feet below the summit and on the summit above. The work on the summit consists of several pits now badly overgrown by vegetation. The principal work is an open cut or small quarry about 25 feet long, 15 feet wide, and 10 to 12 feet high in the hillside. This cut has a cavern-like face 8 to 10 feet high with an overhanging ledge above.

The beryl occurs in a pegmatite mass cutting the mica gneiss country rock. The pegmatite and the inclosing formations appear to strike with the trend of the hill, but no minerals of interest were observed in the outcrop to the south of the prospects. The open cut has been made in a deposit of mixed oligoclase feldspar and quartz through which are scattered numerous beryl crystals and a little muscovite mica. This deposit is capped by a massive bed of granular sugar quartz mostly pure white or tinted with pink. In places this quartz is glassy and translucent, and some has a pale rose color. The contact between the massive quartz and the beryl matrix is not distinct, but the massive quartz grades into that associated with the feldspar and beryl. Several feet below the massive quartz, feldspar is more plentiful than near the quartz. In an exposure of the quarry face measuring about 16 feet long and 8 feet high 35 large beryls

[1] Personal communication, dated South Acworth, N. H., Mar. 2, 1914.

were counted. These ranged from 3 inches to 16 inches in diameter, and sections over 3 feet long were exposed. Each beryl is surrounded by a layer of oligoclase feldspar one-half inch to 3 inches thick. The beryl crystals are variously colored pale bluish green and yellowish green, and light and dark golden yellow. Most of them are opaque, but some contain translucent portions. Many crystals have been broken, either in mining or by collectors looking for gem material, and hundreds of fragments of beryl are scattered over the dump. No transparent gem beryl was observed, but the impression gained by a study of the deposit was that gem beryl might be found by further excavation.

SOUTH CAROLINA.

A prospect opened on the place of J. N. S. McConnell, 3¼ miles east of north of Anderson, is reported to have yielded specimens of green beryl crystals of good color, almost emeralds. When examined in October, 1913, the prospect consisted of a trench 45 feet long in a N. 70° E. direction, 15 feet wide, and 5 feet deep, with a crosscut trench entering at the west end. The country rock is weathered to a dark reddish-brown sandy soil and no outcrops were seen near the prospect. The soil has probably formed by the weathering of a biotite or hornblende granite, and carries small blocks of diorite. The pegmatite is not now exposed, but the dump contains kaolinized feldspar, blocks of massive white quartz, smoky and colorless quartz in rough crystals, weathered plates of mica 8 inches across, large dark red garnets, black tourmaline, limonite pseudomorphs after pyrite, and black manganese oxide stains. No beryl was seen on the dumps.

DIAMOND.

ALABAMA.

A beautiful diamond crystal was sent to the Survey by Mr. F. M. Lynch, of Birmingham, Ala., along with notes on its history, and further information regarding its discovery was furnished by Mr. J. H. Watkins, geologist for the Southern Railway. This diamond is reported to have been found by J. W. Kerr on the property of J. S. Isbell, at Prescott siding, St. Clair County, 1¼ miles east of Brompton on the Southern Railway, about eight years ago. The nature of the stone was not recognized until it came into the hands of Mr. Lynch, who sent it to George F. Kunz,[1] of New York, for identification. This diamond measures a little over 8 millimeters high and 5.5 millimeters in smallest diameter. It weighs 2.41 metric carats and is clear and flawless, with a slight greenish cast. The crystal is so rounded that its form can not be definitely determined. It is slightly flattened parallel with one of the possible octahedral planes.

ARKANSAS.

The Arkansas diamond field received more active development in 1913 than in any previous year. The nature of the work was not such as to definitely prove or disprove the value of the deposits, but

[1] Jewelers' Circular-Weekly, Jan. 7, 1914.

it served to show in what ways improvements could be made in the mills and machinery so far used to treat the peridotite. The companies making the tests have not seen fit to announce the results of their work, but they kindly allowed examination of their mines and mills at the time of the writer's visit in July, 1913. Two washing plants were built, one by the Ozark Diamond Mining Corporation on their holdings at the northeast side of the original peridotite area, and the other by the Kimberlite Diamond Mining & Washing Co., on the west side of Prairie Creek.

The Ozark Co. operated its washing plant about three months during 1913. Mr. Warren, the superintendent, estimated that about 5,000 loads of 16 cubic feet of decomposed peridotite from the original area and about 1,000 loads of gumbo and wash gravel from the west foot of Twin Knobs were washed. The last of this gumbo and gravel were being washed at the time of the writer's visit, but no diamonds had been found in it. Several hundred diamonds were recovered in washing the peridotite from the original area. This peridotite was obtained from an open cut 300 feet long, 15 to 35 feet across, and 8 to 20 feet deep, with tracks leading to the mill. A quantity of surface material was washed in sluice boxes with riffles and yielded a larger per cent of diamonds than the underlying peridotite. Most of the peridotite, even from the bottom of the open cut, was found to be so decomposed as to be ready for washing as mined.

The mill is equipped with a stationary boiler and engine, a trommel separator feeding an elevator to a large storage bin, sizing screens, jigs, and a stationary grease plate table. The oversize is passed through a jaw crusher and then to the storage bin. After necessary changes have been made in the mill further experiments are to be made in washing the peridotite.

The Kimberlite Diamond Mining & Washing Co.'s plant is nearly a mile from its lease holdings on the original peridotite area. A tram has been built from the mine at this place to the mill and another tram will be built to the company's holdings, 3 miles east of Murfreesboro, if success is met with in prospecting and preliminary washing. The mill is substantially constructed with a large storage floor. The earth to be treated will be fed through a revolving screen and into a 10-foot diamond concentrating pan of South African pattern. It is estimated that this pan will treat from 100 to 150 loads of 16 cubic feet per day, reducing 100 tons of earth down to about 1 ton of concentrates. The concentrates will be further screened and then treated on jigs, and the final concentrates examined on metal covered tables in a well-lighted room. Oversize from first screening will be subjected to further weathering. Tailings will be conveyed by flume to Prairie Creek. Final equipment of the mill with automatic handling machinery, grease table, and other improvements will be carried out after the value of the property is proved.

The Arkansas Diamond Co. was idle during 1913, but since the writer last visited the property in 1908 several changes have been made. The peridotite hills have been stripped of timber and a dozen or more new pits and shafts have been made, some of which were of value in showing the depth of decomposition over various parts of the peridotite area. Weathered peridotite has been scraped off of a small area and washed in improvised machinery which proved wasteful in operation. A large area of ground sloping south toward Little

Missouri River could be readily washed by hydraulic methods for which power pumps would be required. Between the peridotite outcrop and Little Missouri River is a large area of bottom land which may prove to be workable placer ground.

Only a small amount of prospecting was done on the property of the American Diamond Mining Co., but Mr. Fuller states that the company reports the finding of one stone.

The best information on the diamond-bearing peridotites of Pike County has been given by Hugh D. Miser.[1] This report contains a carefully prepared map of the known peridotite exposures, with sections and detailed information concerning them. A good résumé of the developments in the diamond field during 1913 has been given by John T. Fuller.[2]

CALIFORNIA.

Mr. M. J. Cooney, of Oroville, Cal., reports the finding of a first quality white diamond by John McGregor on the old placer grounds of the U. S. Diamond Mining Co., at Cherokee, in December, 1913, and of several other smaller stones of inferior quality in the same area. Mr. McGregor states that the stone weighed 1¼ carats and is valued at $75 in the rough state.

Press reports [3] mention a diamond found by Ed. Bryan, a miner at Sawpit Flat, in Plumas County, Cal. In a personal communication Mr. Bryan states that the stone was very similar to a diamond found at the same locality several years ago and known to be authentic. Both stones were found in old hydraulic mining ground similar to the old placers of Butte County, where a number of diamonds have been obtained. Through misplaced confidence the stone was lost to Mr. Bryan before he could be positive of its determination.

IDAHO.

Mr. Frank E. Johnesse, of Boise, Idaho, reports the discovery of three small fragments of diamond in the Rock Flat mine in Adams County, Idaho. The largest of these fragments weighed a little less than one-eighth of a carat. The diamonds were found during placer mining for gold. Other possible gem minerals in the form of sapphire, garnets, and zircon are also found in the clean ups. Robert N. Bell, State mine inspector of Idaho, states that the rock formation of this area is chiefly gneiss with a dike rock of basic composition which has weathered to a soft yellowish earth in places. Mr. Johnesse is installing a hydroelectric plant to treat the concentrates from placer mining for the various minerals of value they may contain, such as monazite, zircon, etc.

INDIANA.

Messrs. Perry Bradford and R. L. Royse, of Centerton, Ind., have furnished information concerning the finding of five diamonds during 1913 on Gold Creek and Highland Creek, in Morgan County. Two of these were found by Hugh Marshall, two by Fred Doyle, and

[1] New areas of diamond-bearing peridotite in Arkansas: U. S. Geol. Survey Bull. 540, pp. 534–546, 1914.
[2] Eng. and Min. Jour., Jan. 10, 1914.
[3] Sacramento Union, Cal., Aug. 17, 1913.

one by R. L. Royse. Mr. Royse describes the one he found as a small green diamond with fine luster, weighing 0.20 metric carat. One of the stones found by Hugh Marshall is described as colorless or white and weighing 0.73 metric carat. Mr. Bradford kindly sent one of the stones found by Fred Doyle to the Survey for examination. It is a yellowish stone, only partly transparent, and weighed 0.69 metric carat. The crystal form is that of a distorted trisoctahedron truncated by the octahedron. A point projecting from one side of the stone indicates that it is probably a twinned crystal.

NEW YORK.

Specimens from two peridotite outcrops in Syracuse, N. Y., were received from Mr. Edwin C. Dinturff, of that city. Some of these were from Green Street and James Street, on the "south crater," and the others from Griffith Street and Highland Street, on the "north crater." Mr. Dinturff states that at the "south crater" exposure peridotite has been found over an area of about 800 feet by 1,200 feet and that at the "north crater" peridotite has been found for about 300 feet in sewer excavations with another exposure, possibly part of the same mass, about 400 yards farther north. The two localities are about three-fourths of a mile apart. In a small hill on Green Street in the "south crater" the peridotite is seen in contact with shale. This is in the peridotite area which has been known for a number of years.

The peridotites of Syracuse bear a marked resemblance to those of South Africa, Arkansas, and Kentucky in composition, texture, inclusions, and weathering. The material from Highland Street was hard when first excavated, but much of it has disintegrated on exposure to the atmosphere. No careful search for diamonds has been made in the peridotite of Syracuse, though the nature of the material would seem to justify such attempts as much as the peridotite of Kentucky, on which considerable work has been expended. Concentrates from panning the altered rock contained garnet, zircon, olivine, diopside, and other minerals. The zircon occurs in minute crystals, which are best separated by treating the peridotite with hydrofluoric acid. In this separation fine particles of ilmenite or rutile are also obtained.

VIRGINIA.

Information on the reported finding of a diamond in Tazewell County, Va., was kindly supplied by Messrs. Charles H. Reynolds, of North Tazewell; H. W. Pobst, a jeweler, of Tazewell; and J. Sanders Gillespie, of Cliffield. This diamond is reported to have been found by Frank Brewster on the farm of Mr. Gillespie, near Pounding Mill, while plowing in a cornfield. The stone was sold to Mr. Pobst, who had it cut by J. R. Wood & Sons, of New York. The cut stone weighs 0.83 metric carat and is considered to be of very fine color and quality by Mr. Pobst. Little has been done toward prospecting for other diamonds.

AFRICA.

UNION OF SOUTH AFRICA.

The production of diamonds during the fiscal year 1913 by the De Beers Consolidated Mines [1] amounted to 2,293,468 carats, as compared with 2,087,392 carats in 1912. Actual sales of diamonds, plus the increase of stocks taken at the cost of production, amounted to £6,297,782. In round numbers, 2,034,000 carats of diamonds were sold. The total production of blue ground in 1913 amounted to 7,382,216 loads, as compared with 7,950,442 loads in 1912. The total quantity of blue ground and tailings washed during 1913 was 8,702,289 loads, as compared with 7,995,953 loads in 1912. The yield in carats of diamonds per load of blue ground washed decreased from 0.31 to 0.29 in the De Beers and Kimberly mines and from 0.29 to 0.27 in the Wesselton mine, and increased from 0.41 to 0.42 in the Bultfontein mine. In the Dutoitspan mine the yield remained the same, at 0.23 carat per load. The De Beers mine remained closed during the year, with the exception of a small amount of development work.

The Premier Diamond Mining Co. (Ltd.) had a successful year during 1913.[2] The company's report for the year closing October 31, 1913, shows 10,434,680 loads of earth washed, yielding 2,107,983 carats of diamonds. The average value per carat was $5.32 and the value of the total production amounted to $11,216,000, as compared with $9,620,000 in 1912.

The output of diamonds from alluvial diggings has increased greatly, and during the first six months of 1913 the value of the diamonds produced amounted to $1,354,882.[3] Some valuable stones have been found in the alluvial workings, and among those registered were a 64½ carat diamond, valued at $2,092, a 32½ carat diamond, valued at $1,897, and a 16 carat stone, valued at $1,094.

A diamond weighing 229 carats [4] was found in the Pniel diggings by F. J. Van Zyl in the latter part of 1913. This stone is a fine octahedron crystal with a slight tinge of yellow. It brought £2,300.

GERMAN SOUTHWEST AFRICA.

According to Consul General Henry W. Diederich,[5] of Antwerp, Belgium, the output of diamonds in German Southwest Africa amounted to about 1,440,000 carats. During the first half of the year the Antwerp Syndicate purchased about 760,000 carats, for which it paid about $8,330,000, or approximately $10.94 per carat. The German imperial chancellor ordered that the output or sales should be limited to less than 1,000,000 carats in 1914 in order not to overstock the market with diamonds of small size and break prices. During the spring of 1914 the output of the German Southwest Africa diamonds for the year was purchased by the London Diamond Syndicate,[6] which therefore practically controls the market of small as well as large diamonds.

KONGO.

Consul General Henry W. Diederich [1] of Antwerp, Belgium, reports that in January, 1914, 6,795 carats of rough diamonds from Kongo River were sold at auction for $39,372. These diamonds come from the country along Kasai River, a tributary of Kongo River.

FELDSPAR GEMS.

AMAZON STONE.

COLORADO.

The amazon stone and associated minerals of the Pikes Peak region, Colorado, have been a source of interest to mineral collectors and gem dealers for many years. George F. Kunz [2] states that an exhibit of Colorado amazon stone at the World's Fair in Philadelphia, in 1876, occasioned much surprise because of its beauty. There are two general localities where the amazon stone is found, one to the east of Pikes Peak, in the Crystal Park region near Manitou Springs, and the other about 18 miles northwest of Pikes Peak around Crystal Peak, about 4 miles north of Florissant.

In the Crystal Peak region prospects have been opened over an area more than 2 miles square by various prospectors and collectors. The Crystal Peak region is mountainous and timbered, with occasional rocky knobs or domes standing above the ridges and valleys. The prospects examined are situated at elevations ranging from about 9,000 to 9,400 feet above sea level, Crystal Peak having an altitude of 9,668 feet. Crystal Peak is the highest of a range of small knobs along a divide. Other lower knobs are Little Crystal Peak, one-fifth of a mile west of north; Deer Mountain, about one-half of a mile northwest; and Sheeps Head, about two-thirds of a mile northwest of Crystal Peak. Wide ridges and rather gentle slopes extend from the foot of these knobs, but most of these are cut into by valleys within a half mile of the knobs.

The prospects are in both the gentle slopes and in the steeper walled valleys. Among the numerous people who have worked in the Crystal Peak region George Copelen, of Gillette, Colo., was one of the pioneers. Mr. Copelen commenced prospecting here over 35 years ago, but has now abandoned that work. Numerous claims have been filed and some of these are still in force, but others have lapsed. Among the prospects visited in August, 1913, some were on the claims of J. D. Endicott, of Canon City; The Crystal Peak Gem Co., of Cripple Creek; A. Fries, George H. Weed, and Whitmore & Sanders. The claims of J. D. Endicott lie chiefly north of Crystal Peak. One claim is in the gap between Little Crystal Peak and Deer Mountain. A. Fries owns patented ground about one-half of a mile northeast of Crystal Peak and claims other prospects between this and Little Crystal Peak. The claims of the Crystal Peak Gem Co. are scattered, most of them lying north and northwest of Little Crystal Peak with one, the "Pinacoid claim," nearly a mile to the north of Crystal Peak. A claim covering the topaz workings, about 1¼ miles southwest of

[1] Daily Cons. and Trade Repts., Mar. 28, 1914, p. 1170.
[2] Gems and precious stones: Scientific Publishing Co., p. 165, 1890, New York.

Crystal Peak, is held by Whitmore & Sanders, both members of the Crystal Peak Gem Co. G. H. Weed, of the same company, holds a homestead claim at the foot of Crystal Peak on the southeast side, on which some promising amazon stone was found in digging for water.

The best amazon stone was seen in place on the claim of J. D. Endicott, on the northeast side of the gap between Little Crystal Peak and Deer Mountain. In one prospect trench, about 40 feet long on this claim, amazon stone is exposed along the footwall of a pegmatite vein striking N. 20° E. with a dip 30° E. The crystals in this wall range from small size to 4 or 5 inches thick, and the exteriors of some are exceptionally bright bluish green. Good amazon stone has been found on many other claims in the Crystal Peak region, but the exposures were not sufficiently good to determine what prospects are the most promising.

The various workings for amazon stone and other minerals cover considerable ground, but none of them are deep. On some of the claims there are pits every few feet over an area of an acre or more. Practically all of the work has consisted of pits, small open cuts, and occasional tunnels. Most of the workings are less than 12 feet deep, and many have become partly filled with rubbish. In all probably 200 pits were seen, and there are many more in the region that were not visited.

The country rock of the Crystal Peak region is chiefly coarse reddish biotite granite, more or less porphyritic in places. A finer-grained aplitic granite was closely connected with the mineral deposits noted in some of the prospects. Over most of the country the coarse granite has been partly disintegrated and broken down to coarse angular gravelly soil. An accumulation of leaf mold with this has furnished a soil covering for part of the area, so that good outcrops are not abundant. In places the granite outcrops in hard ledges, large bowlders, or gravelly soil without much vegetation, so that that prospecting is easier. Many of the deposits can be mined without blasting because of the disintegrated nature of the granite and the gem-bearing rock, but some of them have to be blasted almost from the outcrop down.

The amazon stone and associated minerals occur in pocket-like deposits more or less irregularly distributed through certain parts of the massive coarse granite of the region. The pockets are miarolitic cavities lined with coarse and often nearly perfectly crystallized microcline and albite feldspar, smoky and colorless quartz, and biotite mica, with occasional crystals of topaz, phenacite, fluorite, columbite, and göthite. Deposits and stains of limonite are abundant. The layer of coarsely crystallized minerals lining the pockets varies from a fraction of an inch to more than a foot in thickness in some places. These pocket linings are typical pegmatite aggregations, which may grade into the surrounding granite or have rather sharp contacts with it. Some of the contacts are plainly banded and the gradation from the pegmatite to the granite is so gradual that it is difficult to determine the actual contact. This is especially true where the pockets are associated with aplitic granite. Some of the gem pockets occur in streaks as in pegmatite veins, but others appear to bear no definite relation to one another.

Amazon stone is widely distributed in the Crystal Peak region, but most of the deposits yield but little material suitable for gem purposes. This is due to inferior color of the crystals, excessive fracturing, or discoloration by iron rust. The amazon stone and other microline occurs in stout crystals with the characteristic prominent cleavage of that mineral. The crystals range from small size to several inches in diameter and project from the walls of the cavities with crystals of smoky quartz, biotite, and the other minerals of the pockets. In some cases clusters of fine amazon stone crystals, with or without other minerals, can be removed from the prospects for cabinet specimens. Most of the pockets contain grayish microcline crystals as well as those of green color.

The amazon stone occurs in various shades of bluish green, some of which are very bright. Occasional specimens of nearly pure pale blue are found. Most of the crystals show color variations, the best color commonly lying near the outside of the crystals. Such crystals may have bright bluish-green exteriors with successively paler colors toward the middle, either in layers or by gradual change. The middle of these crystals is generally gray or only pale bluish green. The outside shell of good color may range from a small fraction of an inch to an inch in thickness in large crystals. This color variation must be taken into consideration in the choice of cutting material, as it occasions large waste.

The amazon stone can be cut in a variety of shapes for gem purposes, such as stones for brooches, scarfpins, pendants, and beads for necklaces. The bright colors are pleasing and blend well with gold mountings. Some of the cut stones exhibit a silvery sheen in certain lights from partly developed cleavage planes. In considering the class of semiprecious and imitation stones sold to the tourists in Colorado each year, it seems that the possibilities of beautiful amazon stone from the Pikes Peak region are almost neglected. A quantity of amazon stone is sold in the rough in the form of crystals and bright-colored specimens to the tourist trade and many fine crystals are sold by mineral dealers for cabinet specimens elsewhere; but the sale of cut gems could be increased by displaying tastefully cut stones of good color.

SUNSTONE.

CALIFORNIA.

Specimens of sunstone were received from the Pacific Gem Co., of Los Angeles, Cal. The rough material is reported to have come from Modoc County and a quantity has been cut for gem purposes. It consists of labradorite feldspar, rather high in calcium, with many minute inclusions that reflect a bright coppery red light. The inclusions are too minute to be readily recognized. Their arrangement is only partly governed by crystal structure. The body of the feldspar is colorless and clear; in some specimens the particles are almost submicroscopic but sufficiently abundant to impart a red color to the labradorite. The cut gems are very pretty and have been sold under the name of both goldstone and sunstone. Owing to the quantity of artificial goldstone, falsely sold as a natural mineral, it seems better to call this beautiful natural product sunstone.

JADE.

ALASKA.

P. S. Smith [1] has given a few notes on the occurrence of nephrite in Alaska. Bowlders of a hard, green, slightly translucent rock are plentiful in nearly all of the streams of the Shungnak region north of the Kobuk. These are commonly called jade, but the majority are probably serpentine and green quartzite and some may be nephrite. None of the nephrite seen was of gem quality, since it contained many imperfections in the way of cleavage and inclusions, of which magnetite is so abundant as to give the mineral a spotted appearance. Several unsuccessful attempts have been made to work the jade in the Jade Mountains, west of Ambler River; but the inferior quality of the mineral, combined with its inaccessible location, will probably prove too great obstacles for its exploitation for some time to come.

JASPER.

ARKANSAS.

Mr. Francis Holstein reports an occurrence of jasper on sec. 23, Hot Springs County, Ark., near Morrison Springs. This jasper is stated to be beautifully colored and susceptible of receiving a high polish, but the deposit has so far received no development.

CALIFORNIA.

The variously marked and colored jaspers of the San Francisco region, especially the "kinradite" variety, are meeting with increasing appreciation in that city and among tourists. Some of the best of these jaspers have been found on the beaches along the southern part of Marin peninsula, between Point Bonita and Lime Point. Most of the southern end of Marin peninsula terminates abruptly in cliffs at the water's edge, but narrow beaches have formed in a few places below the cliffs and on these the jasper can best be found. Some of the beaches are exposed only at low tide and are difficult to reach.

The rocks along this part of the peninsula belong to the Franciscan group and consist of sandstone and radiolarian chert with intrusive basalt and diabase. The formations strike generally north or northwest chiefly with high dips. The radiolarian chert is a rather thin bedded jaspery rock. The diabase and basalt may have a common origin presenting only variations in texture. Near the water's edge they outcrop in fresh dark greenish-black cliffs which show a large amount of jointing. Fifteen feet above the water and higher up on the hills they have reddish-brown weathered surfaces. These rocks contain jaspery inclusions, some of which may be altered masses of radiolarian chert. Veins and deposits of quartz have formed in joints and fissures in the diabase and basalt. Some of this quartz grades into jaspery material and other is greenish through chloritic or actinolite-like inclusions. It should be possible to find good jasper in the rock, but the greater part is obtained from the beaches where the jasper inclusions have fallen from the cliffs. The force of the waves has ground off much of the adhering matrix and rounded

[1] The Noatak-Kobuk region, Alaska: U. S. Geol. Survey Bull. 536, pp. 154–155, 1913.

the jasper into pebbles and bowlders, which display their color and markings very well when wet.

The jaspers show a wide range of colors, with both dark and light red, yellow, brown, and green. Some of the red and yellow jaspers are very bright colored. A variety of markings or patterns are met with, of which the most interesting is that called "kinradite," after J. J. Kinrade, of San Francisco, who discovered and first used it for gems. This variety shows spherulites, generally of one color, scattered through jasper of another color. The spherulites are composed of radiated aggregates of quartz, with concentric color bands in some specimens. The spherulites resemble chalcedony, but under the microscope, between crossed nicols they have the positive elongation characteristic of quartz. The spherulites range in diameter from microscopic dimensions to over an inch. In cutting kinradite the gem may contain only one large spherulite or there may be several spherulites of various sizes. Some gems may contain 25 or more smaller spherulites. The colors, the variations in texture, and the interesting structure of the spherulites in kinradite render it an attractive gem and ornamental stone.

Some of the other jasper found with kinradite is of good gem quality. Among specimens seen were some showing very bright crimson red in small streaks and patches through yellow and dark dull green. This would yield gems showing the three colors in strong contrast. Almost innumerable other color patterns can be cut from these associated jaspers.

A deposit of bloodstone and jasper was discovered by F. M. Myrick, of Johannesburg, Cal., in the Death Valley region of San Bernardino County, in February, 1908. Considerable prospecting since that time has resulted in promising finds of gem minerals. Many cut gems have been sold in several towns of southern California where they have been favorably received.

The deposit is about 45 miles northeast of Johannesburg and 4 miles S. 20° E. of Brown Mountain in the rough mountains about 12 miles west of Death Valley. Prospects have been opened over an area about 300 yards across among the gulches at the head of three valleys draining west and northwest. The prospects are at elevations of about 3,300 feet above sea level, or 200 feet higher than the camp in the draw to the west. The principal work consists of a cut, 15 feet across and 12 feet deep, and a prospect tunnel in the side of a draw. Over a dozen other pits have been made on outcroppings of bloodstone or associated jasper.

The geology around the bloodstone deposits is complex. Basaltic lava and andesitic rock predominate, but some sedimentary rocks are exposed close to the prospects. The basalt is dark reddish brown, through the oxidation of ferruginous constituents and quite vesicular in places. The andesitic rocks are fine grained and in places they are greenish from the presence of epidote and chloritic alteration products. The sediments consist of gray to white shaly calcareous rock with interbedded sandy and sintery layers. These rocks contain fossil mud cracks, ripple marks, raindrop marks, and a few markings resembling worm tracks. A portion of the sediments contain pebbles and angular inclusions, like a tuff or volcanic ash formation, and such is their general appearance. It is probable that these rocks were formed as ash beds in shallow pools of water. The carbonate of lime may have been deposited either at the same time from lime-saturated water of the pools or later by solutions penetrating somewhat porous rock. Later action, possibly by hot springs, has apparently leached portions of the tuffaceous rock to porous vesicular masses.

The sedimentary rocks contain a bed of vesicular basalt near their top, and in this basalt the bloodstone occurs. The strata have been tilted and broken by block faulting and contacts are covered with talus slopes in many places, so that it is difficult to trace any horizon far.

The jasper and bloodstone occur in irregular nodular and kidney-shaped masses unevenly distributed through altered phases of the vesicular basalt. The nodules range from about an inch across up to nearly 1 foot in thickness, and most of them are surrounded by shells of dark-green impure opal or soft yellowish-green, rather porous material, which is probably a clayey aggregate. In the largest pit some of the nodular masses occur irregularly distributed in a warped layer having a northwest strike and a northeast dip. The various openings in which bloodstone and jasper have been found, however, do not indicate any definite occurrence in veins or belts of separate deposits.

Red, yellow, and green jasper are the most common, but in places the red and the green are so blended as to yield bloodstone. The bloodstone shows hard, dense, dark-green plasma or jasper with blood-red spots, patches, and streaks. The heliotrope variety of bloodstone, in which the red occurs in small round spots in the green, is rare in the Myrick prospects, but a quantity of bloodstone showing irregular patches and streaks of red in green is found. Jasper of various shades of red, brown, and yellow occurs in nodules several inches across, with or without the green. In some specimens yellow or brownish spots and streaks are scattered through the green, similar to the red in the bloodstone. Some of the larger lumps of jasper show mottlings in various shades of red with or without brown and yellow. Some of the patches of color in the bloodstone are formed by a crushing of the larger pieces and later a cementing by chalcedony or jasper fillings. Such bloodstone shows an abundance of small faults with straight contacts between the red and the green. Occasional seams and veinlets of gray chalcedony cut the jasper and bloodstone, filling fracture lines and joints.

The jasper and bloodstone from this locality take a high polish, and the cut gems show a wide range of patterns and color variations. Stones may be cut showing dark, bright, or dull red, brown, yellow, or green, or pleasing combinations of these colors. The gems are suitable for various forms of jewelry, especially for persons not desiring flashy gems. In cutting, the lapidary should exclude all of the dark-green opal shell surrounding the jasper and bloodstone, for this is brittle and will crack after cutting.

Numerous specimens of jasper with more or less associated chalcedony have been received from Mr. Joseph Ward, of Barstow, Cal. Mr. Ward has collected these from several claims which he has located in the Death Valley region of San Bernardino County, and some of the specimens may have come from Nevada. The jasper shows a wide range of color and markings and would furnish very attractive gems. Some of the jasper shows mosslike patterns of red, brown, or yellow, with patches of gray or blue chalcedony. In other specimens these markings are in nearly pure chalcedony. There were a few pieces of greenish jasper, both with and without red markings. Some of the bluish chalcedony with bright-red jasper inclusions was particularly attractive. Of the several pounds of specimens received, the colors were bright enough for gem purposes in only a small part.

OREGON.

Mr. Don Maguire, of Ogden, Utah, reports the occurrence of a deposit of bloodstone discovered by him in Harvey County, Oreg., about 15 miles east of the town of Burns. The bloodstone occurs in a ledge over 3 feet thick cutting a trap dike. Some of the rough material was shipped for cutting during 1913.

UTAH.

Richly colored jasper, showing various shades of red in laminations or other structures, is reported by Mr Don Maguire, of Ogden, Utah, from the Wasatch Mountains in that State. Some of this jasper has been cut with very pleasing results in Salt Lake City.

JET.

TEXAS.

Prof. J. A. Udden, of Austin, Tex., reports the occurrence of jet in Presidio County, Tex. The jet occurs as compressed and flattened trunks of trees in a thin layer of coal from 100 to 200 feet below the San Carlos coal bed.

LAPIS LAZULI.

CALIFORNIA.

An occurrence of lapis lazuli in California has been described by Gordon Surr,[1] and the following notes are taken from his description. Mr. Surr also kindly sent a specimen to the Survey for examination. The locality is on the north slope of the south fork of Cascade Canyon, 1½ miles south of east of the "Hogback," a well-known landmark in San Antonio Canyon, to which Cascade Canyon is tributary. The deposit is about 12 miles from Upland, a town on the Santa Fe Railway, about 20 miles west of San Bernardino. The "blue rock" was long thought by prospectors to carry silver, and the deposit was opened with this idea. A pit 15 feet deep apparently went through the "blue rock," and work was abandoned.

The mineral was identified by John T. Reed, an assayer in San Bernardino, whose son made an attempt to open the deposit further. The locality was visited by several persons subsequently, and in 1913 by Mr. Surr and his associates. No lapis lazuli was found in place, but probably 150 pounds of loose rock with some of the blue intermixed were found in the talus on the slope and in the drift in the stream bed.

The country rock consists chiefly of quartzites and limestones, which strike east with a high northerly dip near the old workings. At

[1] Lapis-lazuli in southern California: Min. and Eng. World, Dec. 27, 1913.

the latter place there is a layer of light-gray quartzite carrying pyrite and iron oxide stains. Above this is dark quartzite with pyrite, then a few inches of soft shaly rock with limestone overlying. The lapis lazuli was apparently found in the layer of dark quartzite. It is not of good quality, being mixed with a number of other minerals difficult of determination. Under the microscope in thin section two varieties of pyroxene, fine sericite, calcite, pyrite, clinozoisite, and other minerals not identified, were observed besides bright-blue lazurite. The matrix consists of a granular mass of these minerals with blue lazurite as a filling in interstices. The specimen furnished by Mr. Surr is about 2 inches thick, showing alternating bands of dark grayish black, lighter gray, pale to dark bright blue, and yellowish streaks of pyrite crystals. It is probable that the bands containing the most blue could be cut into rather pretty matrix gems.

LAZULITE.

ARIZONA.

Specimens of lazulite (false lapis lazuli) were received from Mr. James Shea and Dr. Burt Ogburn, of Phoenix, Ariz., along with a few notes on its occurrence. The deposit is about 12 miles north of Phoenix, in a small hill near the edge of Paradise Valley. A good wagon road passes near the locality. The lazulite is inclosed in quartzite, in which rock it occurs disseminated in small grains and clusters and in larger crudely shaped crystals. The matrix is white, gray, pinkish, brownish, and greenish from staining. Fine mica or sericite has developed through the quartzitic country rock, and some is associated with the lazulite. Of the specimens seen, only a few could be cut into pure blue gems, but a quantity would yield matrix stones showing dark ultramarine-blue patches of various sizes. The presence of a little pyrite in small crystals heightens the resemblance of this material to lapis lazuli.

OBSIDIAN.

UTAH.

A small specimen of obsidian from Millard County, Utah, was received from Mr. Maynard Bixby, of Salt Lake. This is glassy reddish brown with jet-black streaks and patches through it. The black appear as rounded spots in one position and as streaks in a position at right angles showing the direction of flow of the molten volcanic glass. The mottled effects of the brown and black are very pretty, and Mr. Bixby states that this obsidian takes a high polish.

OPAL.

CALIFORNIA.

Two deposits of opal have been prospected by F. M. Myrick, about 35 miles east of Johannesburg, Cal. One of these is in the side of the same knob as Lead Pipe Spring and about 100 yards northwest of the spring; and the other is about a mile and a half to the northeast on the north side of a steep hill slope. Only small prospects have been opened at each locality.

Opal from the Lead Pipe Spring locality has been called "sobrisky" opal. It occurs in nodular masses at the contact of a red rhyolite flow with underlying white tuffaceous beds. The rhyolite is perlitic near the contact and has been partly decomposed. It contains an abundance of nodules and clusters of siliceous balls varying in size to over 2 inches in diameter. When these are broken open they are found to contain cores of red rhyolite, chalcedony, common or white opal, and occasionally precious opal. Mr. Myrick states that it is sometimes necessary to break open hundreds of these nodules to find a few inclosed precious opals. The cores of precious opal are rarely over three-fourths of an inch thick, but some of the specimens seen had very good color showing flashes of red, blue, and green in gray or milky white background. Many of these cores included fragments of chalcedony or rhyolite, so that pure gems could not be cut from them. If larger pieces of the precious opal can be found and in greater abundance than up to the present time, the prospect would prove of value.

The other locality has so far not yielded any precious opal, and the claim has been called the "white opal" claim after the variety first found. The deposit occupies the same relative position with the rock formations as at Lead Pipe Spring; that is, in partly decomposed perlitic rhyolite forming the contact between a rhyolite flow and underlying tuffaceous beds. The decomposed perlitic layer is about 10 feet thick, and in this are numerous nodules or balls of common opal from 1 to 5 inches in diameter. White opal was found first and later greenish, yellow, and red opal without fire. A small spring has been opened by Mr. Myrick, on the "white opal" claim.

These opal deposits are in the same region as the blue chalcedony already described, and are associated with the same reddish rhyolite flow as the chalcedony. The White Opal claim is about two-thirds of a mile southwest of the Blue Moonstone claim.

Very pretty clusters of clear colorless glassy hyalite opal have also been found by F. M. Myrick in the rhyolite flows east of Granite Springs and about 30 miles east of Johannesburg, Cal. These are not only very pretty specimens, but a few have been mounted in their natural state as gems. Many of the specimens consist of cup-shaped aggregates of small globules of clear limpid hyalite.

Mr. Joseph Ward, of Barstow, Cal., furnished specimens of opal he has found in the desert region of San Bernardino County. Among these were white and cherry red common opal, botryoidal incrustations of clear glassy hyalite, and thin layers of precious opal in rhyolite matrix. The hyolite was very pretty as specimens, forming clusters of bright globules in cavities in spherulitic rhyolite. The other specimens consisted of dark reddish-brown flow-banded rhyolite cut by seams of precious opal mostly less than 1 millimeter thick, both parallel with the banding and at angles to it. Some of the seams showed bright green and red fire. Other specimens of the rhyolite contained common bluish opal and translucent chalcedony. If precious opal can not be obtained in larger pieces from this locality, opal matrix showing seams of gem opal in the red rhyolite might prove of sufficient beauty to cut for gems.

NEVADA.

Considerable prospecting and development work was done in 1913 in the opal field in the valley of Virgin Creek, Humboldt County, Nev., about 25 miles southwest of Denio, Oreg. A number of new claims were located, which extended the known opal-bearing area. Precious opal was discovered in this region in 1908, in which year several claims were located. Other claims have been located successively each year since, and some of them have been worked on a small scale. The yield of precious opal from some of the prospects has been very encouraging in regard to both quality and quantity. Other claims are still of doubtful value.

This opal field was visited in August, 1913, but only three days were available for examination of the deposits. Under favorable conditions the region can best be reached from Jungo, Nev., a station on the Western Pacific Railway, by automobile stage to Denio, Oreg. From Denio the trip can be completed by automobile or other conveyance.

Virgin Creek drains northward, joining Beet Creek at the head of a narrow canyon below which place it is called Thousand Creek. The valleys above the canyon form an irregular-shaped basin with outlet into Thousand Creek. The opal deposits are in certain formations exposed in the sides of the valley of Virgin Creek.

The opal claims examined lie at elevations ranging from 5,100 feet to 5,400 above sea level. Some of them are in rather gently sloping ground in the foothills along the sides of the valley and others are in the steep valley walls. The plateau country in which Virgin Valley has been carved has an elevation of over 6,000 feet above sea level. The region is desert, but water supplied by several large springs, some of which are hot springs, flows into Virgin Creek and Beet Creek. The creek waters are used for irrigation and supply several large meadows for the different ranches.

Four groups of claims were visited, the location of which will be given with respect to McGee's ranch, about a mile south of the junction of the creeks. The principal group is that in which the claims of Ivan Dow, George D. Mathewson, Alfred Thompson, and others are located, about 3 miles southwest of McGee's ranch in the west side of the valley. Among these claims are the Cracker Jack, Bonanza, Opal Queen, and Opal Queen Fraction. Most of the opal from this group of claims has been handled by the International Gem Co., of New York. Another group of claims belonging to D. Roop, E. McGee, and George T. Hill is situated about 5 miles south of McGee's ranch. W. B. Seitz and C. A. Howard hold claims to a third group about 5 miles southwest of McGee's ranch. In the fourth group is the Stone Tree claim, owned by several parties, about a mile and a half north of west of McGee's ranch.

Bateman & Boyd have the Big Horn claim nearly half a mile east of the Stone Tree claim. George W. Brown has located a claim about 2¼ miles west of W. K. Ebeling's ranch, or 3½ miles north of west of McGee's ranch. A large number of other claims have been located in the opal field, some of which may prove of value.

Developments have not been large, and most of the work is limited to pits, small open cuts, and trenches. Some of the deposits are so situated that practically all of the mining can be done by open cuts, but in other places continued work would require the driving of tunnels and the sinking of shafts. As a general rule all excavations can be made without the aid of dynamite, but in some places the work of loosening the claylike earth could be facilitated by blasting. Much of the work could be done by pick and shovel aided by horse scrapers to remove overburden.

The general geology of the Virgin Valley region has been described by Prof. J. C. Merriam [1] and the following notes have been abstracted from his description and supplemented by a few personal observations. The rocks of Virgin Valley are in a synclinal basin of older formations consisting largely of tuffs, ashes, and rhyolitic lavas. The "Virgin Valley beds," as Prof. Merriam tentatively calls them, consist chiefly of ash and tuff of variable induration which weather into characteristic badland topography. They may be rather arbitrarily divided into upper, middle, and lower beds. The lower beds are the hardest, and the badland sculpture developed in them is characterized by steep-walled gulches. The strata are white, greenish, and bright red. The middle beds are brownish and gray and weather into rounded hills and knolls. The upper beds are softer cream-colored ash. A dark-gray vesicular lava flow caps the upper beds along the rims of the valley. Various fossil mammals have been found in the upper beds, including a mastodon, a horse, camels, and a cat. The middle beds contain many plant remains and petrified wood is abundant. Fossil evidence points to the Miocene age of the beds.

The formations have been broken by extensive block faulting, some of the blocks having dropped several hundred feet. Tilting of the strata has also produced differences in elevation of parts of the same horizons.

The opal occurs in ash or fine tuff beds associated with petrified wood. The ash beds are grayish and greenish-gray with a hard claylike consistency. The surface material is dry and crumbling, but some of the same material below the surface if moist resembles hard sticky gumbo. The ash contains variable quantities of sand, pebbles, and cobbles. Among these inclusions quartz, a little obsidian, and rhyolite were observed. On the Cracker Jack claim two horizons about 75 feet apart, vertically, have been worked for opal. These were separated by harder ash beds. At most of the horizons carrying opal considerable petrified wood is found in which common opal and silica are the petrifying agents. The ash beds have been somewhat altered by solutions, probably those which were active in depositing the opal.

The opal occurs in a variety of shapes most of which are associated with petrified wood. Petrified wood is abundant in the form of logs, limbs, twigs, bark, and roots, in which the petrifying material is opal and other forms of silica. This wood is in various stages of petrification ranging from partly silicified lignite to material completely replaced by silica or opal. A quantity of wood has been petrified with common opal by a replacement process retaining minutely the texture and grain of the wood. This variety occurs in petrified wood, bark, roots, and other structures, among which Mr. Roop has found spruce or pine cones.

---

[1] Science, new ser., vol. 26, pp. 380-382, 1907.

The precious opal occurs chiefly as casts of different parts of trees and as coatings and fillings in cracks in ordinary petrified wood. The precious opal casts rarely retain the texture or grain of the wood, but may show such structure as bark and inclosed wood by slight color variations or other lines of demarcation. Mr. Roop has found two very interesting specimens of opalized cones, one measuring about 1 inch long that has been perfectly cast by milky opal and the other, a slightly larger cone of milky color, completely inclosed in a mass of translucent precious opal 2½ inches thick. Twigs and limbs of trees 2 and 3 inches thick have been reproduced in precious opal of beautiful colors. Logs several inches in diameter have been cast with common jet-black or dark-brown opal, parts of which show fire. The black opal gives off water and tarry matter smelling of pyroligneous acid when heated in a closed tube. A quantity of other variously colored common opal occurs with gem variety, as translucent purplish, reddish-brown, gray, and white. Some precious opal has been found as fillings in cavities in the volcanic ash. Among such specimens are small patches of gray or white opal with a beautiful play of green, yellow, blue, and red fire, but exceedingly brittle so that the small pieces can be crushed between the fingers into powder. The minute grains still display their fine color and fire after the opal has been crushed. Opal, both in casts and in veinlets filling cracks in petrified wood, is used for gem purposes, and some of the petrified wood containing seams and veinlets of precious opal would yield very good matrix opal.

The best gem opal from Virgin Valley is unexcelled in variety and brilliance of fire and color by that from other localities. The cut gems exhibit superb flashes of green, blue, yellow, and red of various shades with milky white, gray, bluish, or brownish background which may be opaque, translucent, or nearly transparent. In some the color is uniform over the whole stone or over large areas, changing, as the gem is turned, from green to red, or from red to blue, and so on. Some of the gems show a rich ultramarine blue in one position, and green or red in another. Many gems display various bright colors arranged in patches, and each patch changes color as the stone is turned. The brilliant flashes of peacock-feather colors exhibited by the opal of dark color yield a gem which might be called black opal, but most of it is not like the Australian gem of that name, since it occurs in thick pieces and the colors are less localized. Most of the dark-colored gems, no matter how beautiful in reflected light, become a rich reddish-brown in transmitted light. The more opaque bluish-gray and milky opal with good fire also yields especially beautiful gems.

A quantity of brittle opal which checks and cracks considerably after removal from the mines has been found. Some of this opal has magnificent color and fire, but close inspection shows that it contains fine cracks, some of which are sufficiently pronounced to allow the stone to fall apart. In many cases this tendency to check could be partly overcome by a careful handling of the rough material, that is, by a rather slow seasoning process in which the opal is not immediately exposed to the dry atmosphere and considerable temperature changes of the desert, but is kept in a moderately cool place or in moist wrapping.

At the suggestion of H. D. McCaskey, of the United States Geological Survey, specimens of opal containing cinnabar were cut with a view to determining their suitability for gem purposes. This material came from a quicksilver mine operated by J. B. Kiernan, of Beatty, Nev. Specimens of the rough mineral were kindly supplied by Mr. Kiernan and general information on the deposit was given by A. A. Turner, a mining engineer of Boston, Mass.

The mine is in Bare Mountain in southwestern Nevada, the nearest point being about 10 miles from the California State line. The Amargosa Desert lies west of the mountain and Crater Flat to the east, the highest point being approximately 6,235 feet above sea level, or 3,300 feet above the surrounding plains. The formations around the cinnabar deposit are limestone, quartzite, schist, and a volcanic rock, probably dacite. The deposit lies between two dacite dikes and is apparently a replacement deposit. Opal impregnated with cinnabar was found within a few feet of the surface and extended to a depth of 61 feet, the depth of the workings at the time last examined by Mr. Turner. The opal is an associated mineral but much of it contains sufficient mercury to smelt with the regular ore. The opal bodies are surrounded by a fine white sand resulting from the decomposition of impure opal. The nature of the deposits and the presence of small vent holes in the sand near the ore bodies indicate that they have resulted from past hot spring activity.

Most of the material that can be cut as a semiprecious stone consists of milk-white to slightly translucent gray opal impregnated with bright vermilion-red cinnabar. The cinnabar occurs in minute particles disseminated or grouped in irregular tufts, patches, and streaks through the opal. Specimens were seen in which the cinnabar was in a duller chalcedonic material, probably altered quartzite. The contrast between the red and the white or gray, with the variations of markings displayed by the cut stones, make this an attractive semiprecious stone which could be readily used in the western tourist trade. The possibility of the cinnabar losing some of the brightness of its color, as in the "myrickite" described under agate, will have to be taken into consideration.

OREGON.

Mr. Don Maguire, of Ogden, Utah, reports the occurrence of semiprecious opal along Deschutes River, Crook County, Oreg. This opal is reported to be abundant and very pretty. A limited quantity was shipped to Portland, Oreg., for gem purposes during 1913.

TEXAS.

Specimens of opal found near Alpine, Tex., were received from Mr. A. D. Hudson, of El Paso. They consisted of small patches of white and bluish opal in a dark red rhyolite-like matrix. Some of the opal showed flashes of rich green and bluish fire. The reddish matrix might be cut showing patches of precious opal, if pure gem can not be obtained in larger pieces.

QUARTZ.

ARKANSAS.

Mr. Francis Holstein, of De Roche, Ark., states that a quantity of the quartz crystals from near that place are still sold to visitors and jewelers at Hot Springs. These quartz crystals range in size from small specimens up to fine cabinet specimens. They vary from colorless and limpid to light and very dark smoky brown. Inclosures of phantom crystals and bubbles are present in some specimens. Bright lustrous faces are characteristic of these Hot Spring County quartzes, and occasional crystals show an unusual development of planes. Others are variously etched. Mr. Holstein states that the quartz crystals are obtained chiefly from pockets where they are imbedded in red clay.

MAINE.

Minerals of interest because of their semigem nature are found at the J. A. Hibbs feldspar and mica quarry, a little over a mile northeast of Hebron, in Oxford County, Me. These minerals are translucent quartz and beryl. The quartz varies from colorless to pale rose, light and dark smoky brown, and yellowish. Specimens were seen in which there were rounded patches of dark smoky brown in quartz of lighter color. The beryl is mostly opaque grayish-green. Other associated minerals are potash feldspar, mica, and black tourmaline.

RHODONITE.

COLORADO.

Mr. J. D. Endicott, of Canon City, Colo., reports the discovery of a deposit of rhodonite about 10 miles southeast of that place. He states that the deposit will yield a quantity of mineral with good pink color and of fine texture.

RUBY.

NORTH CAROLINA.
